that are modifiable by the CSF1R inhibition treatment. We could also construct gene networks in TAMs that are modified by the treatment. Furthermore, we could construct correlation gene networks for the treated mice by contrasting the drug-resistant (Reb) and drug-sensitive (Ep) groups in TAMs and in TCs, as discussed in subsequent sections.

Human glioma cohorts

To translate the identified differentially expressed genes (DEGs) and candidate markers of the drug resistance in mice to human glioma patients, two independent human glioma cohorts, The Cancer Genome Atlas (TCGA) database (<https://cancergenome.nih.gov/>) and Chinese Glioma Genome Atlas (CGGA) database (<http://www.cgga.org.cn/>), were prepared for the subsequent gene network construction, gene cluster detection, and survival modeling. After matching the clinical information with the gene expression data (RNA-seq data) for each patient, a set of 690 samples (GBM: $n = 165$; LGG: $n = 525$) from TCGA and a set of 310 samples from CGGA (GBM: $n = 138$; LGG: $n = 172$) were collected. Since the mice were initiated with tumors from the proneural subtype of GBM, the subsequent analyses including network construction and signature identification were mainly performed in GBM proneural patients ($n = 38$ in TCGA; $n = 30$ in CGGA). In general, the TCGA dataset was used as the training dataset for the identification of the prognostic signature, and the CGGA dataset was used as an independent testing set to validate the predictive power of the polygenic signature.

Differential gene expression analysis in mice and translation to human homolog

Differential gene expression analyses were conducted to compare the average gene expression level between drug-sensitive (Ep) and drug-resistant mice (Reb) for TCs and TAMs, respectively. The RNA-seq read counts data were normalized by the trimmed mean of M -values method. For each gene, the expression level was modeled by the generalized linear model with a negative binomial link, and the quasi-likelihood (QL) F -test was used to compare the gene expression level between the Ep and Reb subgroups. The logarithm of fold-change ($\log_{2}FC$; to base 2) and nominal P -value were calculated using the R/Bioconductor software package

edgeR^[13–15]. The Benjamini-Hochberg false discovery rate (FDR) was used as an adjustment for multiple testing. Genes with $|\log FC| > 1.5$ and $FDR < 0.05$ were considered as differentially expressed genes (DEGs) for TCs and TAMs, respectively. Due to the fact that human gene expressions are derived from the RNA-seq data of bulk tumor tissues, we only focused on DEGs that had the same signs of logFC in both TCs and TAMs in mice. This facilitated the interpretations of concordance of up- or downregulations of candidate DEGs in humans and mice. We then translated the selected DEGs identified in mice to human homolog using the NCBI database (<https://www.ncbi.nlm.nih.gov/gene>), which resulted in 818 DEGs in TAMs and 1730 DEGs in TCs.

A network-based and translational research strategy to select candidate genes from important gene clusters

Our goal is to identify a set of key genes that has the potential as novel treatment targets to overcome drug resistance as well as is predictive of patient survival. The differential expression analyses typically discover a large number of DEGs, which makes it difficult in practice to design effective interventions for all of them in lab-based biological studies. Hence, we needed to refine the set of candidate DEGs to get a relatively smaller set of candidate genes that are indicative of drug resistance and predictive of survival. Depending on the co-expression network, DEGs can be clustered according to their intrinsic correlations. Clusters of genes may pertain to specific biological functions and have a greater impact on the outcome than single genes. In general, given a set of gene expression data, it is straightforward to construct correlation gene networks or weighted correlation gene networks, e.g., as done by Sun *et al.*^[16] or He *et al.*^[17]. In the following sections, we discuss how to identify key genes from important clusters detected through weighted gene correlation networks (WGCNA)^[18].

Detection of gene clusters (modules) by weighted correlation network analyses for TC and TAM in mice and human

First, we constructed the weighted correlation network using weighted correlation network analyses (WGCNA) for TAMs and TCs, in mice and humans, respectively, which resulted in four networks. For each of the networks, denote the gene expression matrix as $X = [x_{ij}]_{n \times p}$, where n is the sample size, $i = 1, \dots, n$, p is the number of genes, and $j = 1, \dots, p$. Let $\mathbf{x}^{(j)} = (x_{1j}, \dots, x_{nj})^T$ denote the expression of the j^{th} gene and $\mathbf{x}_i = (x_{i1}, \dots, x_{ip})$ denote the gene expression of the i^{th} subject. A correlation network is fully specified by its adjacency matrix $A = [a_{ij}]_{p \times p}$, which is a symmetric $p \times p$ matrix with entries in $[0, 1]$ representing the connection strength of the i^{th} and j^{th} gene. The weighted adjacency a_{ij} is modeled by the power adjacency function, that is,

$$a_{ij} = s_{ij}^{\beta}, \quad (1)$$

where s_{ij} is the co-expression similarity that defined by the Pearson correlation, i.e.,

$$s_{ij} = |\text{cor}(\mathbf{x}^{(i)}, \mathbf{x}^{(j)})| = \left| \frac{\sum_{k=1}^n (x_{ik} - \bar{x}^{(i)}) (x_{jk} - \bar{x}^{(j)})}{\sqrt{\sum_{k=1}^n (x_{ik} - \bar{x}^{(i)})^2 \sum_{k=1}^n (x_{jk} - \bar{x}^{(j)})^2}} \right|, \quad (2)$$

where $\bar{x}^{(i)}, \bar{x}^{(j)}$ are the mean expression level of the i^{th} and j^{th} genes. The power parameter $\beta (\beta \geq 1)$ was chosen by applying the approximate scale-free topology criterion. Details can be found in the work of Zhang and Horvath (2005)^[19].

The network was constructed once β was specified. Next, we detected clusters of genes that were tightly interconnected. Such clusters of genes in the WGCNA method are called modules. To group the highly correlated genes into modules, we needed to introduce a distance measure that quantified the dissimilarity between each pair of genes within a weighted correlation network. We adopted the topological overlap matrix (TOM)-based dissimilarity, which is commonly used in many applications. The TOM-based dissimilarity is defined as

$$d_{ij} = 1 - \frac{l_{ij} + a_{ij}}{\min\{k_i, k_j\} + 1 - a_{ij}}, \quad (3)$$

where a_{ij} is the weighted adjacency defined in the weighted correlation network, $l_{ij} = \sum_u a_{iu}a_{uj}$, $k_i = \sum_u a_{iu}$. The hierarchical clustering dendrogram (tree) can be built with $\{d_{ij}\}_{i \neq j}^p$. Dynamic branch cut method was applied to identify gene modules from the hierarchical clustering dendrogram [20]. Parameters involved in the network construction and module detection were selected for each of the four networks individually (TAM network in humans, TC network in humans, TAM network in mice, and TC network in mice). The network construction and module detections were performed using the R/Bioconductor package WGCNA [18].

Identification of important gene clusters through concordance analysis between mouse and human modules

We identified four sets of modules from the weighted gene correlation network: modules for TAM in mice, modules for TC in mice, modules for TAM in humans, and modules for TC in humans. These modules can be viewed as “sub-networks” as they represent gene clusters in which genes are closely correlated. They may perform certain biological functions, since biological functions are rarely determined by a single gene, but rather by a set of tightly interconnected genes. In addition, the correlation networks and subsequently identified modules are based on DEGs that are differentially expressed between Reb mice and Ep mice. Thus, modules and their underlying biological functions identified in mice TAM and TC are likely to be associated with drug resistance. In each cell type, given that mouse modules and human modules share the same set of DEGs, and mice and humans are evolutionarily conserved, it would be of interest to know whether mouse modules and human modules perform similar biological functions or if the sub-networks and biological functions in mice are preserved in humans. If a mouse module and a human module do share a “sub-network”, its underlying drug resistance-related biological functions should be more likely to be translated to humans. Therefore, in the same cell type, the concordance between each pair of mouse-human modules was assessed by calculating the number of genes that overlapped for each pair of mouse-human modules. Whether such overlap was due to chance alone was assessed by the Fisher’s exact test. Contingency tables are reported for TC and TAM, respectively. Specifically, gene clusters from the top significantly associated mouse-human modules were selected by setting a threshold for P -values. In addition to the translation of drug-resistant DEGs from mice to humans at “gene-level”, the concordance analysis between mouse modules and human modules can be viewed as a “network-level” translation, which is more relevant to reflect biological functions, since biological functions are normally activated by a set of genes instead of a single gene. Thus, adding “network-level” translation could help avoid false positives while enhancing the likelihood of success of the translational approach.

Enrichment analysis of important gene clusters

The biological functions of the gene clusters identified by the overlaps were investigated by the gene set enrichment analyses (GSEA) using Metascape [21] (<http://metascape.org>), which is a widely used online tool for gene annotation and enrichment analysis integrating multiple well-known ontology sources, including the KEGG Pathway, GO Biological Processes, etc. Gene clusters that are enriched in biologically relevant pathways were selected for the subsequent analyses. Gene set enrichment analysis leverages existing biological knowledge drawn from independent, published studies and databases, which helps to find biologically important gene clusters that are more relevant to the clinical outcome and reduce the likelihood of false-positive findings. Key genes can be further selected from the biologically important gene clusters. In short, using GSEA produces results that are more likely to be biologically meaningful and reproducible because it integrates biological and statistical information from other existing databases.

Selection of a small set of candidate genes from biologically important gene clusters

While several gene clusters that are biologically important for disease progression were selected by the enrichment analysis, these gene clusters still contained too many genes chosen as biomarkers of drug resistance and targets for possible interventions. Thus, we sought an even smaller set of candidate genes that are not only functionally important and representative for each of the selected gene clusters, but also possess good predictive accuracy for the survival of human glioma patients. Accordingly, two criteria were adopted to select such candidate genes. The first criterion was about the importance of the gene within each selected cluster. The first

principal component (PC) is a good summary metric for a given cluster, which is denoted as “eigengene”^[18]. Assuming the eigengene is a good representative for a given cluster, for each gene, its correlation with the eigengene can be used to quantify its importance within a cluster. Higher correlations indicate stronger biological importance. Thus, the eigengene of the q^{th} selected cluster, denoted as $E(q)$, was calculated by the PCA. Similar to the concept of module membership, we defined the cluster membership as the Pearson correlation between the i^{th} gene and $E(q)$, that is,

$$CM_i^{(q)} = |\text{cor}(\mathbf{x}^{(i)}, E(q))|. \quad (4)$$

Important candidate genes would be highly correlated to $E(q)$ and can be selected by choosing an appropriate cut-off for $CM_i^{(q)}$.

The second criterion was about the predictive accuracy of survival. K-index is a commonly used metric that measures the overall concordance of a risk score and the survival, i.e., $P(T_1 > T_2 | R_2 > R_1)$, where T_j is the survival time and R_j is the risk score^[22]. It does not depend on the censoring distribution, which makes it more general to assess the predictive power^[23]. Higher K-index implies better predictive accuracy. Then, the K-index of the i^{th} gene was calculated by

$$K_i = \frac{2}{n(n-1)} \sum_{s \neq t} \frac{I(R_{i,t} > R_{i,s})}{1 + \exp(R_{i,t} - R_{i,s})}, \quad (5)$$

where $R_{i,j}$ is the linear combination of the covariates obtained from the univariate Cox regression model for the i^{th} gene and j^{th} subject, and $I(\cdot)$ is the indicator function. Genes that are predictive of survival would be selected by choosing an appropriate cut-off for K_i . In our study, candidate genes were selected by setting $CM_i^{(q)} > 0.7$ and $K_i > 0.55$ for each of the selected biologically important clusters.

Identification of the genetic biomarkers via regularized Cox regression model

As discussed in the previous section, we selected candidate genes from biologically important clusters according to cluster membership and K-index. However, the number of candidate genes heavily depends on the threshold chosen. A large number of genes can be selected when a low threshold is chosen. In addition, cluster membership and K-index are univariate methods, which do not take into account the correlation between genes within each cluster. Thus, the sparse-group lasso Cox regression model^[24] was adopted to further shrink the number of candidate genes as biomarkers of drug resistance. It is a multivariate model that can account for sparsity and the correlation within clusters. Suppose p candidate genes belonging to m clusters were selected in previous steps, and their expressions for the i^{th} sample are denoted as $\mathbf{x}_i = (x_{i1}, \dots, x_{ip})$. Let $\mathbf{x}_{i(l)}$ denote the gene expression of p_l genes in the l^{th} group and $\beta_{(l)}$ denote the regression coefficient of $\mathbf{x}_{i(l)}$. Then, the coefficient β for \mathbf{x}_i is estimated by

$$\hat{\beta} = \arg \max_{\beta} \left\{ l_n(\beta) - (1 - \alpha)\lambda \sum_{l=1}^m \sqrt{p_l} \|\beta_{(l)}\|_2 - \alpha\lambda \|\beta\|_1 \right\}, \quad (6)$$

where $\alpha \in [0, 1]$ is the weighting parameter for the combination of lasso and group-lasso penalties, λ is the tuning parameter, $l_n(\beta) = \frac{1}{n} L_n(\beta)$, and $L_n(\beta)$ is the log-partial likelihood function:

$$L_n(\beta) = \sum_{i=1}^n \delta_i \left\{ \mathbf{x}_i^T \beta - \log \left[\sum_{j \in R(t_i)} \exp(\mathbf{x}_j^T \beta) \right] \right\}, \quad (7)$$

where (t_i, δ_i) is the observed survival time and censor indicator ($\delta_i = 1$ if the survival time is observed, $\delta_i = 0$ if the survival time is censored). The sparse group-lasso Cox regression was performed by the R package SGL^[24].

According to Quail *et al.* [1], resistance to CSF1R inhibition was reflected by the elevated expression level of M2-like genes in TAMs and the activation of PI3K pathways in TCs. DEGs involved in M2-type activation and PI3K pathways are very likely to be associated with glioma survival. Therefore, we performed a sparse group-lasso (SGL) analysis to select genetic biomarkers from the combination of biologically important clusters and two additional groups of candidate genes: M2-like and PI3K pathway genes. α was set as 0.98 for more sparsity within the cluster. The tuning parameter λ was determined by 10-fold cross-validation.

Moreover, to obtain a parsimonious model, we further reduced the number of biomarkers using the L_1 -Cox regression. The coefficients were estimated by

$$\hat{\beta} = \arg \max_{\beta} \{l_n(\beta) - \lambda \|\beta\|_1\}, \quad (8)$$

where the tuning parameter λ is determined by cross-validation. The candidate genes with non-zero coefficients were selected as the prognostic signature for glioma.

Evaluation for the predictive performance of the constructed drug-resistant signature

The predictive accuracy of the signature identified in the previous section was evaluated in different subgroups using time-dependent receiver operating characteristic (ROC) analyses. In each subgroup, a Cox regression model was fitted using all genes in the final signature to obtain the regression coefficient $\tilde{\beta}$ in the training set (TCGA). Risk scores were calculated by $x_i^T \tilde{\beta}$ in both the training set and the testing set (CGGA). Given a cut-off $c \in R$, the sensitivity and specificity at a specific time t is

$$\begin{aligned} Se(c, t) &= P(x_i^T \tilde{\beta} > c | \delta_i(t) = 1), \\ Sp(c, t) &= P(x_i^T \tilde{\beta} \leq c | \delta_i(t) = 0), \end{aligned} \quad (9)$$

where $\delta_i(t)$ is the censor indicator at time t . The time-dependent ROC curve [25] could be plotted by connecting all the coordinates $(1 - Sp(c, t), Se(c, t))$ at time t , and the time-dependent AUC at time t is

$$AUC(t) = \int_{-\infty}^{+\infty} Se(c, t) d[1 - Sp(c, t)]. \quad (10)$$

In our study, one-, two-, and three-year time-dependent AUCs in training set and testing set were calculated by R package timeROC [26].

In addition, patients could be further divided into a high risk of death group and a low risk of death group by taking the median of risk scores as a cut-off. KM curves were generated for the high-risk and low-risk groups of patients, and the log-rank test was employed to examine the significance of the difference in the overall survival between the high/low-risk groups.

RESULTS

Module detection from correlation networks constructed in mouse and human

Based on the translation of DEGs of drug resistance from mouse to human homolog, 818 DEGs were used to construct a correlation network for macrophages (TAMs), and 1730 DEGs were used for tumor cells (TCs), in both mice and humans. On the one hand, for the mouse TAM network, the soft threshold power parameter β was chosen to be 9 by applying the approximate scale-free topology criterion. Using the dynamic branch cutting method, setting the “deepSplit” parameter to be 3, “minClusterSize” parameter to be 30, and merging the highly correlated modules together, four modules were identified, as demonstrated in Figure 2A. Each branch referred to a gene and was marked by different colors, which represented different modules. Genes not assigned to any module were marked in grey. For the mouse TC network, the soft threshold power parameter β was chosen to be 16. Using the dynamic branch cutting method, setting the “deepSplit” parameter to be 3,

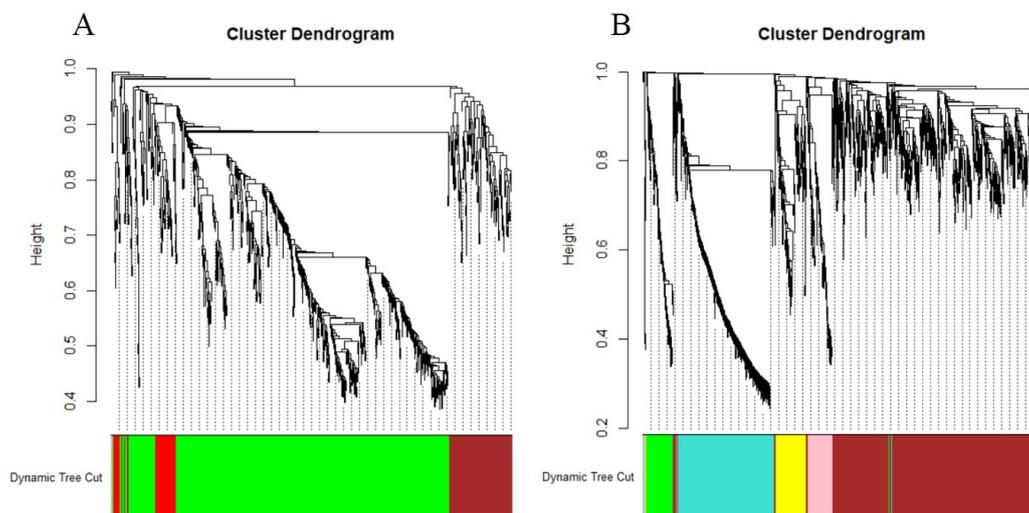

Figure 2. Hierarchical clustering dendrograms and modules identified in mice. (A) Dendrogram for TAM in mice. Four modules were identified (including the grey cluster, which represents genes that were not assigned to any cluster). (B) Dendrogram for TC in mice. Six modules were identified (including the grey module). Each branch refers to a gene and is marked by different colors, which represent different modules. The “height” axis refers to the value of the TOM-based dissimilarity.

“minClusterSize” parameter to be 50, and merging the highly correlated modules together, six modules were identified, including the grey module, demonstrated in Figure 2B.

On the other hand, the human TAM network was constructed using the WGCNA method on patients classified as the proneural subtype GBM using 818 DEGs translated from the candidate genes in TAMs of mice differentially expressed between drug-resistance and drug-sensitive subgroups of mice. The soft threshold power parameter β was chosen to be 6 by applying the approximate scale-free topology criterion. Using the dynamic branch cutting method (by means of dissimilarity matrix of mice), setting the “deepSplit” parameter to be 3, “minClusterSize” parameter to be 30, and merging the highly correlated modules together, seven modules were identified (including the grey module), as demonstrated in Figure 3A. The human TC network was constructed on patients classified as GBM proneural using 1730 DEGs. The soft threshold power parameter β was chosen to be 6. Using the dynamic branch cutting method, setting the “deepSplit” parameter to be 3, and “minClusterSize” parameter to be 70, eight modules were identified (including the grey module), as demonstrated in Figure 3B.

Selection of biologically important gene clusters from top-related human-mouse modules

Four modules were identified in the mouse TAM network, six modules in the mouse TC network, seven modules in the human TAM network, and eight modules in the human TC network. Since the mouse and human networks were constructed based on the same set of genes, we examined the similarities between them within the same type of cell. Thus, the contingency tables were generated to show the overlaps of each pair of mouse-human modules for TAM and TC, respectively, as shown in Figure 4A and B. The human modules with their sizes were spread as columns, and the mouse modules with their sizes included were spread as rows. In each cell, the number of overlapped genes for a given pair of mouse-human modules was calculated. Fisher’s exact test was applied to test whether the overlap was statistically significant versus due to chance alone, and the P -value is shown in the parentheses (in $-\log_{10}$ scale). The color scale represents the P -value of the Fisher’s exact test: the darker the color, the lower the p -value and the stronger significance of the overlap.

By setting a threshold for p -value $< 10^{-4}$, in Figure 4A, the top three most significant gene clusters overlapped between mice and humans for TAM are mouse brown-human green (MH-TAM1), mouse green-human turquoise

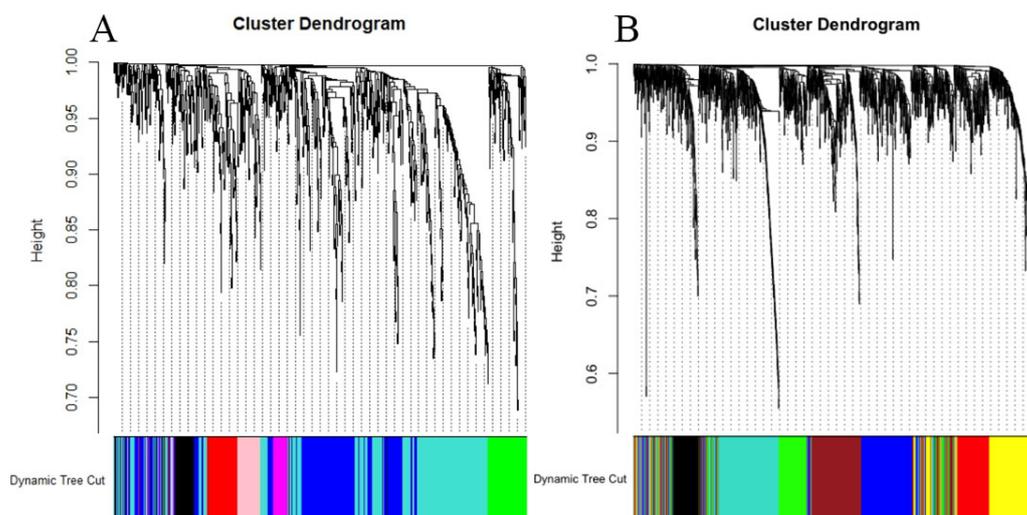

Figure 3. Hierarchical clustering dendrograms and modules identified in humans. (A) Dendrogram for TAM in humans. Seven modules were identified (including the grey cluster, which represents genes that were not assigned to any cluster). (B) Dendrogram for TC in humans. Eight modules were identified (including the grey module). Each branch refers to a gene and is marked by different colors, which represent different modules. The “height” axis shows the value of the TOM-based dissimilarity.

(MH-TAM2), and mouse brown–human black (MH-TAM3). In Figure 4B, the top four most significant gene clusters overlapped between mice and humans for TC are mouse green–human yellow (MH-TC1), mouse pink–human black (MH-TC2), mouse brown–human blue (MH-TC3), and mouse brown–human turquoise (MH-TC4). Genes in each of the seven clusters are highly correlated in both mice and humans, which makes the drug resistance more likely to be translated to humans from mice.

To see what biological impacts these overlaps might have, functional gene set enrichment analyses (GSEA) were performed on each of the seven clusters with significant overlaps. The results are shown in Figure 5A–G. Figure 5A–C shows that, in TAM, MH-TAM1 was enriched in GABA receptor signaling and cell cycle; MH-TAM2 was enriched in inflammatory response, lymphocyte activation, *etc.*; and MH-TAM3 was enriched in cellular responses to external stimuli. Figure 5D–G suggests that, in TC, MH-TC1 was enriched in microglia pathogen phagocytosis pathways, *etc.*; MH-TC2 was enriched in extracellular matrix organization *etc.*; MH-TC3 was enriched in mitotic cell cycle process, chromosome segregation, *etc.*; and MH-TC4 was enriched in synapse organization, neural system, *etc.* The inflammatory response, microglia pathogen phagocytosis pathways, extracellular matrix organization (ECM), mitotic cell cycle process, *etc.*, are the most significantly enriched pathways and are believed to play an important role in cancer metabolism and progression. Specifically, inflammation increases susceptibility to cancer development and facilitates all stages of tumorigenesis^[27]. Microglia is crucial in phagocytosing tumor cells^[28]. In tumor tissues, the growth and malignancy of tumors as well as the response to therapy are affected by the ECM^[29]. Thus, we mainly focused on the MH-TAM2, MH-TC1, MH-TC2, and MH-TC3 clusters for the subsequent identification of candidate genes and drug-resistant signatures.

Identification of the drug-resistant biomarkers and predictive signature of survival in the proneural subtype of GBM

We wanted to effectively link expression levels of candidate biomarkers of drug resistance to the population survival rate of human glioma patients. To obtain a relatively smaller but most important candidate set of genes for the identification of drug-resistant biomarkers, cluster membership (CM) and K-index were first calculated for each gene within each of the four biologically important gene clusters among proneural GBM patients. By setting the thresholds $CM > 0.7$ and $K > 0.55$, 105 genes were selected as functionally important

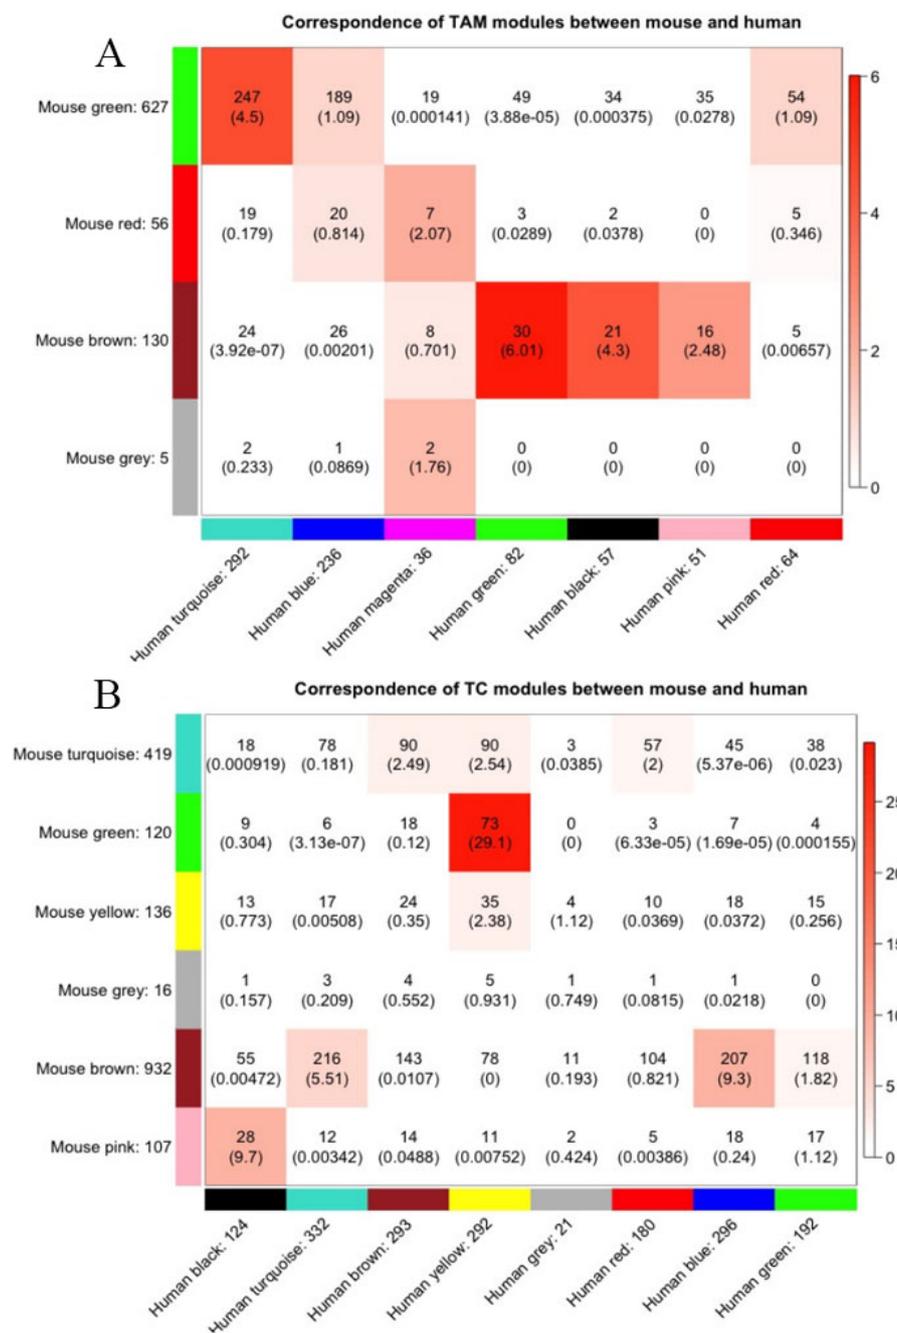

Figure 4. Correspondence between mouse and human modules: (A) correspondence of TAM modules between mouse and human; and (B) correspondence of TC modules between mouse and human. The human modules with their sizes were spread as columns, and the mouse modules with their sizes included were spread as rows. In each cell, the number of overlapped genes for a given pair of mouse-human modules was calculated, and the statistical significance of the overlap was tested by the Fisher's exact test. The P -value is shown in the parathesis (in $-\log_{10}$ scale). The color scale also represents the P -value of the Fisher's exact test: the darker the color, the lower the P -value and the stronger significance of the overlap. TAM: Tumor-associated macrophages. TC: Tumor cells.

and predictive of survival from the four selected biologically important clusters. In addition to the 105 genes, since M2-like genes and IGF/PI3K pathways were considered important for drug resistance in immunotherapy in animal models^[1], 15 M2-like and 5 PI3K pathway genes that were also differentially expressed between Ep and Reb mice were added as two additional groups of genes. As a result, 125 candidate genes were prepared for the construction of prognostic signatures.

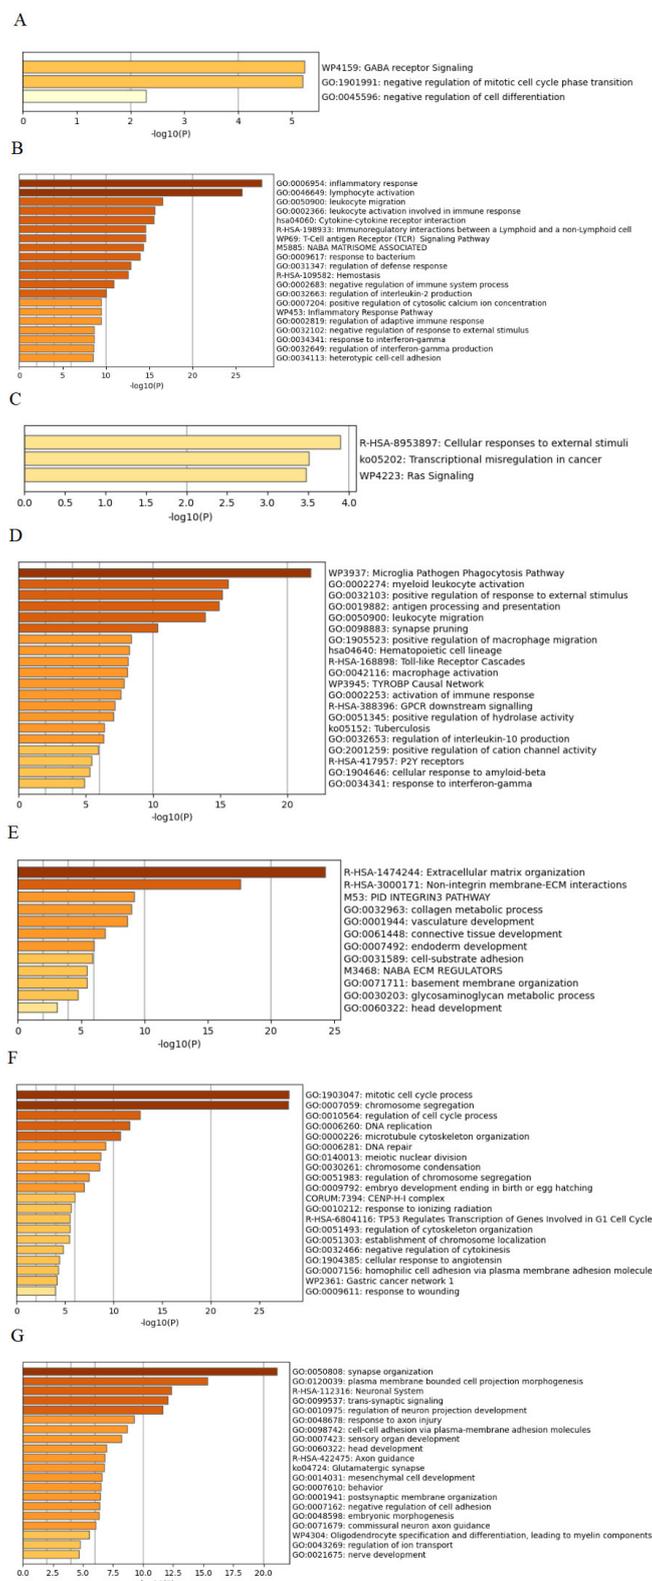

Figure 5. Functional enrichment analyses for the seven gene clusters overlapped between mouse and human: (A) mouse brown-human green in TAM (MH-TAM1); (B) mouse green-human turquoise in TAM (MH-TAM2); (C) mouse brown-human black in TAM (MH-TAM3); (D) mouse green-human yellow in TC (MH-TC1); (E) mouse pink-human black in TC (MH-TC2); (F) mouse brown-human blue in TC (MH-TC3); and (G) mouse brown-human turquoise in TC (MH-TC4).

Table 1. Summary for the 14 identified genetic biomarkers

Gene symbol	Gene name	Cell type	Gene clusters	Pathways
<i>CCL22</i>	C-C motif chemokine ligand 22	TAM	M2-like gene	Inflammatory response; response to cytokine
<i>ADCY2</i>	Adenylate cyclase 2	TC	PI3K pathway-related genes	PI3K pathways
<i>PDK1</i>	Pyruvate dehydrogenase kinase 1	TC	PI3K pathway-related genes	PI3K pathways
<i>CP</i>	Ceruloplasmin	TAM	MH-TAM2	Positive regulation of cytosolic calcium ion concentration
<i>ZFP36</i>	ZFP36 ring finger protein	TAM	MH-TAM2	Response to cytokine; leukocyte activation
<i>CD2</i>	CD2 molecule	TAM	MH-TAM2	Lymphocyte activation; positive regulation of cytokine production
<i>PLAUR</i>	Plasminogen activator, urokinase receptor	TAM	MH-TAM2	Regulation of leukocyte activation
<i>ACAP1</i>	ArfGAP with coiled-coil, ankyrin repeat and PH domains 1	TAM	MH-TAM2	-
<i>COL5A1</i>	Collagen type V alpha 1 chain	TC	MH-TC2	ECM organization; PI3K pathways
<i>FAM83D</i>	Family with sequence similarity 83 member D	TC	MH-TC3	mitotic cell cycle, etc.
<i>PBK</i>	PDZ binding kinase	TC	MH-TC3	mitotic cell cycle, etc.
<i>FANCA</i>	FA complementation group A	TC	MH-TC3	mitotic cell cycle, etc.
<i>ANXA7</i>	Annexin A7	TC	MH-TC3	-
<i>TACC3</i>	Transforming acidic coiled-coil containing protein 3	TC	MH-TC3	mitotic cell cycle, etc.

Cell type (TAM or TC) refers to the cell from which the gene was selected. Gene clusters list the gene clusters to which the gene belonged. Pathways indicate the pathways that the gene was associated with (if any). TC: Tumor cells. TAM: Tumor-associated macrophages.

Next, considering both the correlation and the sparsity within each cluster, a sparse group-lasso was performed on the 125 candidate genes from six groups: MH-TAM2, MH-TC1, MH-TC2, MH-TC3, M2-like genes, and PI3K-related pathways. If modules (gene clusters) were detected via a dissimilarity matrix from human data, a similar set of candidate genes would be selected. Given the tuning parameters $\alpha = 0.98$ and $\lambda_{SGL} = 0.0254$, 14 genes were selected as drug-resistant biomarkers: *CCL22*, *ADCY2*, *PDK1*, *CP*, *ZFP36*, *CD2*, *PLAUR*, *ACAP1*, *COL5A1*, *FAM83D*, *PBK*, *FANCA*, *ANXA7*, and *TACC3*. Twelve of them were also selected when modules were detected using the dissimilarity matrix from mouse data. The gene names, cell types, and related pathways/gene clusters of the selected 14 genes are summarized in Table 1. Their biological functions related to gliomas are further illustrated in the discussion.

For the purpose of building a parsimonious model including a small set of genes that are most likely to serve as the potential targets for developing novel treatments, the biomarkers were further reduced by fitting L_1 -penalized Cox regression model. Given the $\lambda_{Lasso} = 0.1450$, five genes were finally selected for the polygenic signature: *CCL22*, *ADCY2*, *PDK1*, *CD2*, and *COL5A1*. Fitting a Cox regression model on the five genes (gene expression was standardized by median and IQR) with adjustment of age, the risk score (RS) can be calculated as the linear combination of the covariates by the following formula:

$$RS = 0.04203 \times \text{Age} - 0.65889 \times \text{CCL22} - 0.65991 \times \text{ADCY2} + 0.40717 \times \text{PDK1} + 1.14938 \times \text{CD2} + 0.25144 \times \text{COL5A1}. \quad (11)$$

Here, *CCL22* is an M2-like gene. *ADCY2*, *PDK1*, and *COL5A1* are all involved in PI3K-related pathways. *COL5A1* was chosen from the *MH-TC2* gene clusters and is involved in an extracellular matrix organization. *CD2* was chosen from the *MH-TAM2* gene cluster associated with inflammatory response. All five of the signature genes have been demonstrated in the literature to be associated with the progression and metabolism of multiple malignant tumors, including GBM. Details are further illustrated below.

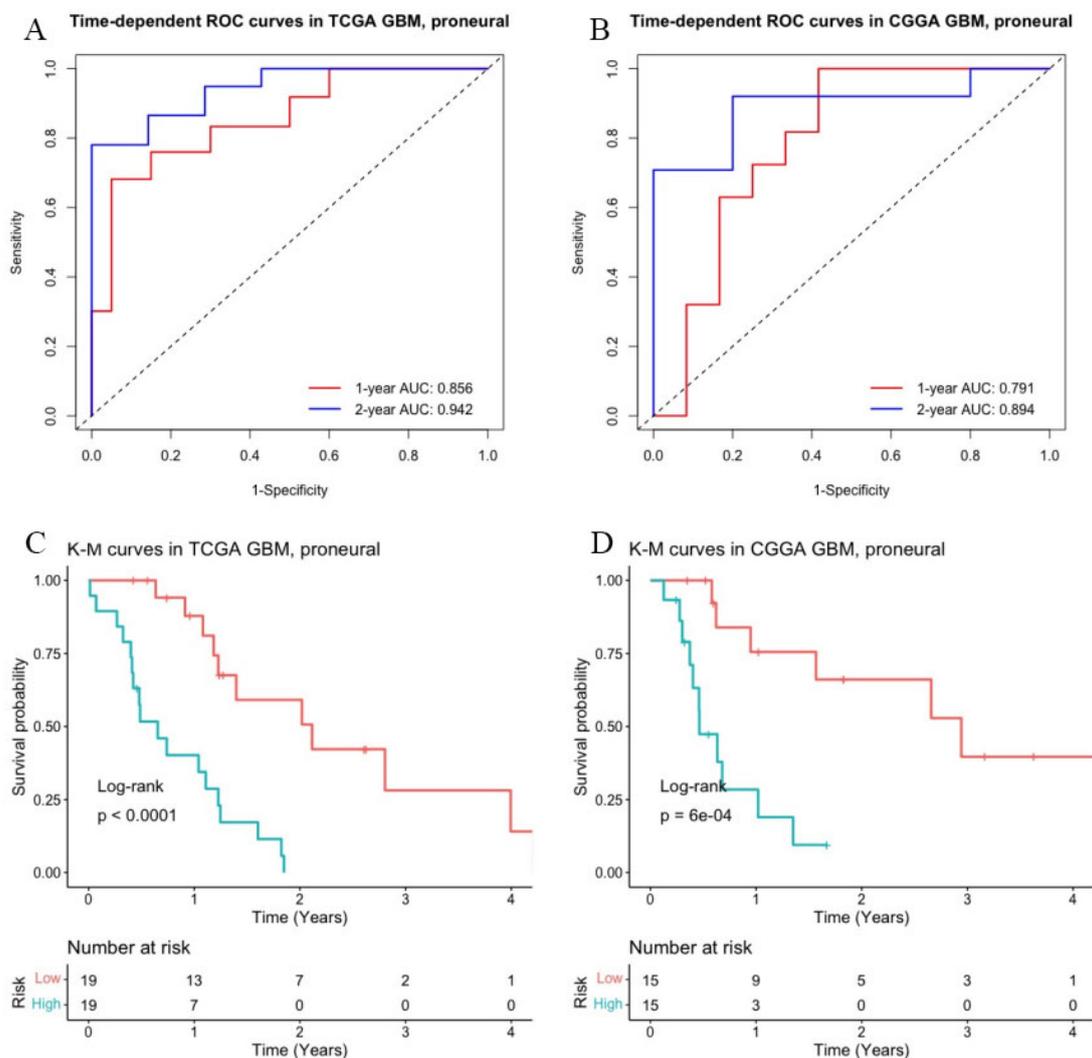

Figure 6. Evaluation of the predictive performance of the identified signature in the proneural subtype of GBM: (A) time-dependent ROC curves with corresponding AUCs at one and two years in training set (TCGA, $n = 38$); (B) time-dependent ROC curves with corresponding AUCs at one and two years in testing set (CGGA, $n = 30$); (C) KM curves for high-risk and low-risk patients in training set; and (D) KM curves for high-risk and low-risk patients in testing set. P -values were calculated from the log-rank test. TCGA: The Cancer Genome Atlas. CGGA: Chinese Glioma Genome Atlas. ROC: receiver operating characteristic. GBM: glioblastoma multiforme. KM: Kaplan-Meier.

Evaluation of the predictive accuracy of the drug-resistant signature in different subgroups

We first assessed the predictive performance of the identified signature in the proneural type GBM patients. Risk scores were calculated in both training set (TCGA) and testing set (CGGA) by Equation (12) with gene expressions standardized by median and IQR. Figure 6A shows the time-dependent ROC curves in the training set (TCGA). The corresponding 1- and 2-year AUCs were 0.856 and 0.942, respectively. Figure 6B shows the time-dependent ROC curves in testing set (CGGA). The corresponding one- and two-year AUCs in the independent testing set were 0.791 and 0.894, respectively, which demonstrated that the identified signature possessed a high predictive accuracy of survival in the proneural subtype of GBM patients. Moreover, K-M curves were generated for high-risk and low-risk patients classified by the median of the risk scores, as shown in Figure 6C and D. The overall survivals were significantly different between the high-risk group and low-risk group in both training and testing sets (Log-rank test: $P < 0.0001$ in training set and $P = 6 \times 10^{-4}$ in testing sets).

Furthermore, since many LGG will eventually progress to high-grade gliomas, with the majority of them being

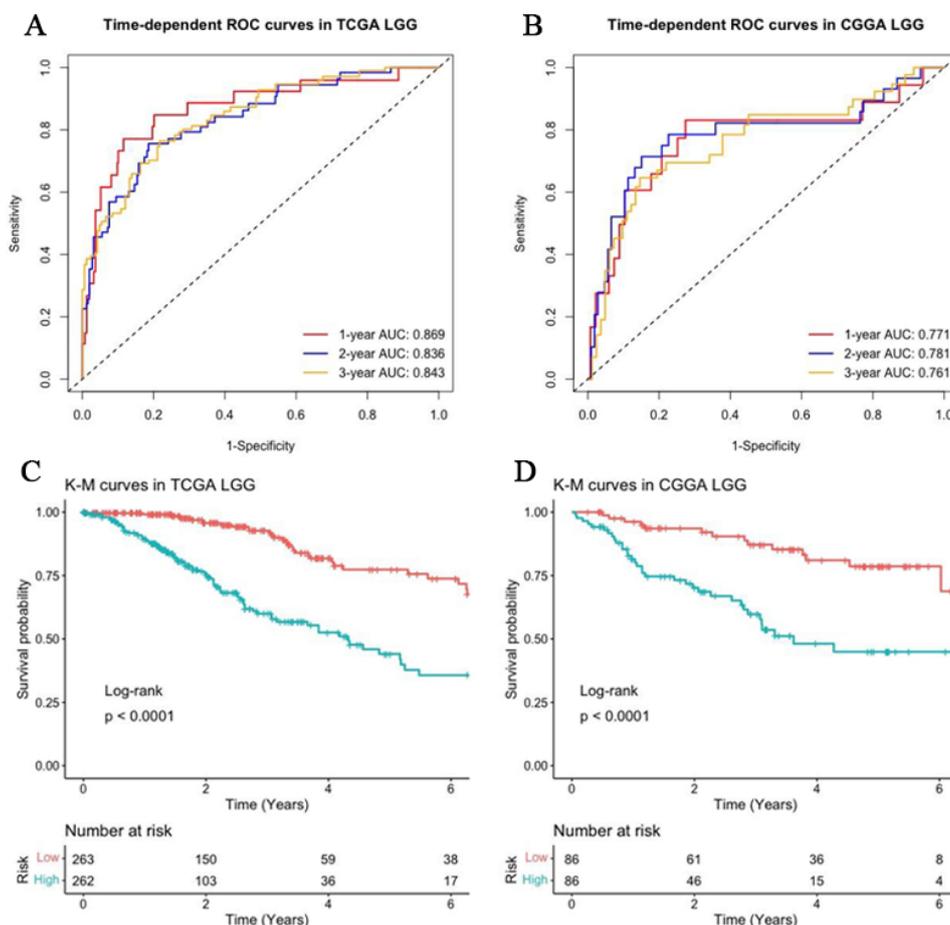

Figure 7. Evaluation of the predictive performance of the identified signature in LGG: (A) time-dependent ROC curves with corresponding AUCs at one, two, and three years in training set (TCGA, $n = 525$); (B) time-dependent ROC curves with corresponding AUCs at one, two, and three years in testing set (CGGA, $n = 172$); (C) KM curves for high-risk and low-risk patients in training set; and (D) KM curves for high-risk and low-risk patients in testing set. P -values were calculated from the log-rank test. TCGA: The Cancer Genome Atlas. CGGA: Chinese Glioma Genome Atlas. ROC: receiver operating characteristic. LGG: lower-grade gliomas. KM: Kaplan-Meier.

the proneural subtype of GBM^[30,31], it would be interesting to investigate the prognostic and predictive properties of the drug-resistant signature within LGG. We therefore refitted the Cox model using the five signature genes and age in a training set of 525 LGG patients from TCGA. We validated it using an independent testing set of 172 LGG patients from CGGA. Risk scores were calculated based on the standardized expression levels. Figure 7A and B shows that the time-dependent AUC of this signature at one, two, and three years were 0.896, 0.836, 0.843 in training set and 0.771, 0.781, 0.761 in testing set. Figure 7C and D indicates that the overall survivals were significantly different between the high-risk group and low-risk group classified by the median of risk scores, as P -value < 0.0001 in both training and testing sets. These results suggest that the drug-resistant signature identified in GBM proneural subtype also has good prognostic power in LGG.

The mouse study reported by Quail *et al.*^[1] was conducted on the proneural subtype of mice; thus, one may doubt whether the findings and biomarkers would be generalizable to non-proneural type of GBM patients. Indeed, in contrast to GBM proneural subtype and LGG, the identified candidate genes had very poor prognostic power in non-proneural types of GBM patients. To be specific, 127 non-proneural GBM patients collected from TCGA were used as the training set and 108 non-proneural GBM patients from CGGA were used as the testing set. We retrained the Cox model using the five candidate genes and age in the training set and calculated risk scores in both sets based on standardized expression levels. In the training set, the time-dependent

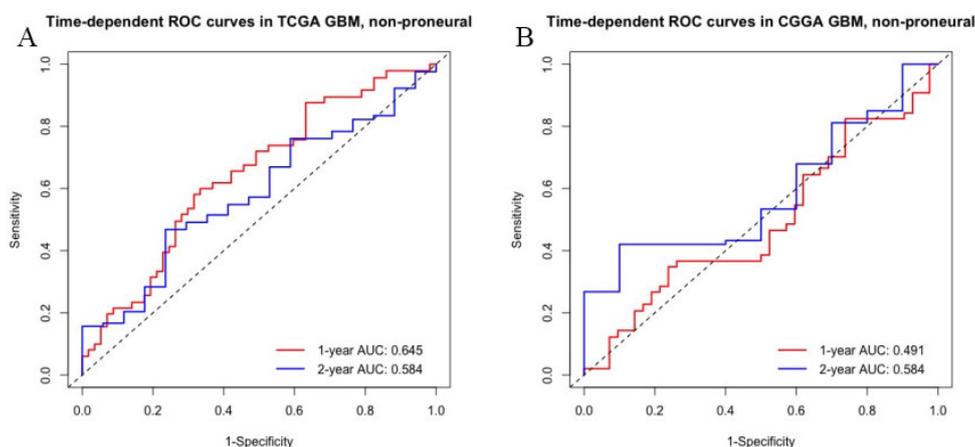

Figure 8. Evaluation of the predictive performance of the identified signature in non-proneural type of GBM: (A) time-dependent ROC curves with corresponding AUCs at one and two years in training set (TCGA, $n = 127$); and (B) time-dependent ROC curves with corresponding AUCs at one and two years in testing set (CGGA, $n = 108$). GBM: glioblastoma multiforme. TCGA: The Cancer Genome Atlas. ROC: receiver operating characteristic.

AUCs at one and two years were only 0.645 and 0.584, respectively; in the testing set, they were 0.491 and 0.584, respectively [Figure 8]. Thus, the findings from the mouse study are not generalizable to non-proneural type GBMs, which is not surprising due to different genomic profiles for the different subtypes of GBMs.

DISCUSSION

Glioma is the most malignant and invasive tumor that has a poor prognosis, with a median survival of GBM of only 12 months [12,31]. Despite the advances in cancer immunotherapy, patients still have limited sensitivity to current therapies, which implies a high prevalence of drug resistance. In fact, CSF1R inhibition as a treatment of glioma is being evaluated in some early-phase human clinical trials. However, some trials have been stopped or failed due to no evidence of survival improvement. The reported early-stage trials did not focus on subtypes of GBM, thus did not have adequate power to detect treatment effect in a subtype of GBMs given the small sample size. Even the likely responsive subgroups of GBM patients may have drug resistance [32,33]. Quail *et al.* [1] identified the drug resistance mechanism that the long-term inhibition of CSF1R in macrophage cells could activate IGF1/PI3K pathway in tumor cells and lead to drug resistance in mice. Therefore, it is of particular interest in identifying evidence to indicate whether the drug resistance mechanism in mice might also exist in human glioma patients, and whether some subgroups of GBM patients might have better survival using such therapies, in order to potentially improve the response and feasibility of this therapy in humans. In this study, we carried out a network-based, translational research strategy to identify potential targets for therapies with gene signatures that are predictive of survival and indicative of drug resistance to CSF1R inhibition treatment. Specifically, borrowing strength from the mouse study, we identified candidate genes that were differentially expressed between the drug-sensitive and drug-resistant mice, and translated those genes to human homologs. Then, those DEGs were used to construct weighted gene correlation networks in TAMs and TCs, for mice and the proneural subtype of GBM patients, respectively. Clusters of genes (modules) were detected from each of the networks, and biologically important gene clusters were identified as DEGs with top significant overlaps between human and mouse modules, incorporating results of gene-set enrichment analyses. The construction of weighted gene networks and detection of gene clusters in humans borrow information from the dissimilarity matrix from the mouse data to improve stability, given the lack of cell-specific gene expression data in humans. To obtain a smaller candidate gene set, functionally important and predictive genes were selected via cluster membership and the K-index from those gene clusters as well as M2-like and PI3K-related pathway DEGs. The regularized Cox regression models were then applied to further shrink the candidate gene set to obtain

genetic biomarkers that are more likely to be actionable, which resulted in 14 genes (*CCL22*, *ADCY2*, *PDK1*, *ZFP36*, *CP*, *CD2*, *PLAUR*, *ACAP1*, *COL5A1*, *FAM83D*, *PBK*, *FANCA*, *ANXA7*, and *TACC3*).

Knowing the selection process, it is not a surprise that all the candidate genes selected are known to play important functional roles in cancer progression, as reported in the literature. In particular, *CCL22* is an M2-like gene, while *ADCY2*, *PDK1*, and *COL5A1* belong to PI3K pathway. According to Quail *et al.* [1], resistance to CSF1R inhibition was reflected by elevated expression of M2-like genes in TAM and activation of PI3K pathway in TC. *ZFP36*, *CP*, *CD2*, *PLAUR*, and *ACAP1* were selected from the gene cluster that was enriched in inflammatory, immune response, and regulation of cytokine pathways (MH-TAM2). Inflammation and immune responses are associated with increased susceptibility to cancer development and facilitate all stages of tumorigenesis [27,34]. Cytokines are potent but complex immune mediators and have drawn great attention to the development of cancer immunotherapies [35]. *COL5A1* also came from the gene clusters that were enriched in ECM organization (MH-TC2). In tumor tissues, the growth and malignancy of the tumor as well as the response to therapy are affected by the ECM [29]. *FAM83D*, *PBK*, *FANCA*, *ANXA7*, and *TACC3* were selected from the gene cluster that was enriched in mitotic cell process pathway (MH-TC3). Aberrant activities of various cell cycle proteins can lead to uncontrolled proliferation in cancer. Targeting mitotic cell cycle has been studied as a novel cancer treatment strategy [36–38]. Since these gene clusters were identified from DEGs that were differentially expressed between the drug-resistant mice and the drug-sensitive mice, these pathways are likely to be associated with drug resistance.

In the literature, the 14 identified genes have been suggested as essential for the development and progression of many cancers including gliomas. Particularly, *CCL22* (C-C motif chemokine ligand 22) is found in many types of human cancers and has lower expression levels in gliomas cases than in controls [39,40]. As a T cell trafficking chemokine, *CCL22* attracts regulatory T cells (Treg), which could promote tumorigenesis. Inhibiting Treg trafficking in GBM may be a novel strategy to develop therapeutic interventions, which has been shown to be effective in other cancer models [41]. *ADCY2* (adenylate cyclase 2), which is involved in the calcium signaling pathway, may play a crucial role in the development and progression of gliomas [42]. Aberrant methylation of *ADCY2* is observed in many other cancers [43]. *PDK1* (pyruvate dehydrogenase kinase 1) is a hypoxia-inducing factor (HIF)-1 regulated gene which may promote EGFR activation that can subsequently sustain malignant progression [44,45]. By inactivating *PDK1*, glioma cell colony and sphere formation could be greatly inhibited, and glioma spheres would become more sensitized to temozolomide (TMZ) toxicity [46–49]. *CD2* (CD2 molecule) is a transmembrane molecule expressed on T, natural killer (NK), and dendritic cells and is essential for immunology [50,51]. It was found to be involved in tumor invasion and is highly expressed in breast cancer [50,52]. *COL5A1* (collagen type V alpha 1 chain) was found to be related to the occurrence and progression of multiple types of malignant tumors, including breast cancer and gliomas. Recent studies found *COL5A1* was positively correlated with the increasing malignancy of glioblastoma through the PPRC1-ESM1 axis activation and extracellular matrix remodeling, and it may be a potential therapeutic target for glioma [53–56]. *FAM83D* (family with sequence similarity 83 member D) is a member of *FAM83* family (including *FAM83A*, *FAM83B*, and *FAM83D*), which has been shown to have oncogenic potential recently. *FAM83D* was found to be consistently upregulated across human tumor types, including gliomas [57,58]. *PBK* (PDZ binding kinase) expression, which is associated with cell growth and apoptosis, DNA damage repair, immune responses, *etc.*, plays an essential role in tumorigenesis and metastasis. It was found to be upregulated in GBM patients [59,60]. An *in vivo* study reported that inhibition of *PBK* could almost completely abolish tumor growth, which made *PBK* serve as a potentially promising therapeutic target for GBM treatment [61,62]. *FANCA* (FA complementation group A) is associated with tissue proliferation and was found to be overexpressed in many types of cancers [16,63,64]. *FANCA* is essential for the function of Fanconi anemia (FA) pathway. Targeting the FA pathway may provide a novel strategy for the sensitization of solid tumors and investigation of chemoresistance in different tumor types [65]. *ANXA7* (annexin A7) is a ubiquitinated tumor suppressor gene [66]. Loss of *ANXA7* function stabilizes the EGFR protein, augments EGFR transforming signaling in glioblastoma cells,

and promotes tumorigenesis^[67,68]. TACC3 (transforming acidic coiled-coil containing protein 3) is often mentioned with FGFR3-TACC3 fusion, which is an oncogenic driver. FGFR3-TACC3 fusions generate powerful oncogenes that combine growth-promoting effects with aneuploidy through the activation of as yet unclear intracellular signaling mechanisms^[69,70]. FGFR inhibition has shown encouraging outcomes in mouse studies^[70]. Targeting FGFR3-TACC3 fusion is evaluated by many ongoing early phase human clinical trials^[70-72]. ZFP36 (ZFP36 ring finger protein) is a well-known mRNA binding protein. In the tumor microenvironment, ZFP36 might reduce the growth and invasion of glioma cells by targeting IL-13 mRNA to inhibit the role of PI3K/Akt/mTOR pathways^[73-75]. CP (ceruloplasmin) serves as a prognostic biomarker in many cancers, including bile duct cancer, bladder cancer, breast cancer, *etc.*^[76-78]. The expression of ACAP1 (ArfGAP with coiled-coil, ankyrin repeat and PH domains 1) is correlated with immune infiltration levels in many types of cancers^[79-81]. PLAUR encodes the urokinase receptor (uPAR). The overexpression of PLAUR has been shown to be associated with poor prognosis in many types of gliomas, particularly in mesenchymal subtype GBM and LGG^[82-84]. Indeed, the 14 identified genes are more likely to reflect drug resistance and serve as potential targets since they are differentially expressed between drug-resistant and drug-sensitive mice. They might be modified in patients just as they can be modified in mice, as studied by Quail *et al.*^[1].

In addition, among the 14 genetic biomarkers, five genes (*CCL22*, *ADCY2*, *PDK1*, *CD2*, and *COL5A1*) were chosen to form a prognostic signature using the L_1 -Cox regression model. The established signature has good prognostic power in the proneural subtype of GBM and LGG patients. We set TCGA as the training set for modeling and used CGGA, an independent cohort, as the testing set to validate the performance. In proneural subtype of GBM patients, the two-year AUC of this signature attained 0.89 in the testing set, which reveals the potential to build treatment targets for improved patient survival. Furthermore, as Quail *et al.*^[1] also identified interventions to overcome the drug resistance in mice, any genetic biomarkers we identified here would likely to be modifiable targets for therapeutic intervention in humans. Thus, new clinical trials targeting proneural type GBMs might be developed. This drug-resistant signature also shows moderate time-dependent AUCs in LGG patients. Since many LGG will eventually progress to high-grade gliomas, with the majority of them being the proneural subtype of GBM^[30,31], it would be interesting to investigate which LGG might progress to the proneural type of GBM, and it would be of clinical importance to find out whether a novel therapy based on our candidate target genes might prevent LGG from progression to advanced stage and prolong patient survival. Consequently, using a translational network-based multicellular analysis, we linked the drug-resistance mechanism identified in mice to population-level survival rates of both the proneural type GBM and a large number of LGG patients. Importantly, the biomarkers identified from the mouse study of proneural type have a poor predictive power of survival in non-proneural GBM patients, which implies that new biological mechanisms need to be identified for the non-proneural type of GBM patients. The 14 identified biomarkers and the signature are promising targets for therapies in glioma precision medicine, or individualized treatment, because they are potentially feasible only in some subgroups of glioma patients instead of all glioma patients.

One limitation of our human study is that we only have gene expression data from bulk tissue, not knowing expression levels in TCs and in TAMs, respectively. As the cell-specific RNA-seq gene expression data will become increasingly available in the future, one might be able to construct gene networks and models using human cell-specific RNA-seq data, which would further improve the efficiency and precision of the methods we developed here to identify candidate biomarkers. In addition, with cell-specific human gene expression data on TAMs and on TCs, we would be able to model and investigate the interactions between TAMs and TCs, which is clearly important in directly investigating the mechanisms of drug resistance in humans and the identification of novel treatment targets to overcome drug resistance and prolong survival of patients.

DECLARATIONS

Acknowledgments

The authors would like to thank Dr. Xiaoqiang Sun and Dr. Xinwei He of Sun Yat-sen University for helpful discussions.

Abstract

Lung cancer remains the malignant tumor with the highest morbidity and mortality in China, with non-small cell lung cancer (NSCLC) accounting for 80%-85% of cases. Nowadays, the treatment pattern of NSCLC has evolved toward precision management with the development of molecular targeted therapy and immunotherapy. However, the median overall survival for patients with metastatic NSCLC, unfortunately, remains less than three years. Drug resistance is the bottleneck to preventing drugs from playing a further role, and the mechanistic study of drug resistance is the prerequisite for new regimen development. This Special Issue pays special attention to drug resistance in the treatment of NSCLC. We received and published several excellent articles regarding this topic. We hope that, through this Special Issue, we can have a deep understanding of the existing problems, the underlying mechanism, and the future solutions and that the publication of this Special Issue can bring some inspiration to readers.

Keywords: Non-small cell lung cancer, drug resistance, targeted therapy, immunotherapy

INTRODUCTION

According to the most recent statistics from the National Cancer Center of China^[1], lung cancer remains the most common malignant tumor as well as the first leading cause of cancer-related deaths in China, with an estimated 0.828 million new cases and 0.657 million deaths per year, placing a heavy burden to public health

and economy development. Approximately 80%-85% of lung cancers are classified pathologically as non-small cell lung cancer (NSCLC)^[2]. With substantial improvements in understanding of tumor biology, genomic mutational landscapes, cancer immunology, and tumor microenvironment, the treatment pattern of NSCLC has evolved toward precision management^[3]. Molecular targeted therapy based on different driver oncogenes and immune checkpoint inhibitors (ICIs) based on programmed cell death ligand 1 (PD-L1) expression are the 2 major branches of personalized treatment paradigm, which have brought great survival benefits to patients with oncogene-addicted and non-oncogene-addicted cancers, respectively^[4]. However, the median overall survival for those presenting with metastatic NSCLC, unfortunately, remains less than 3 years^[4]. Drug resistance is always the bottleneck to preventing drugs or new regimens from playing a further role. This Special Issue pays special attention to drug resistance in the treatment of NSCLC. We hope that, through this issue, we can have a deep understanding of the existing problems, the underlying mechanism, and the future solutions and that the publication of this Special Issue can bring some inspiration to readers.

MAIN TEXT

Resistance mechanism for targeted therapy

EGFR

The activating mutation of epidermal growth factor receptor (EGFR) is highly common in Asian patients with NSCLC, accounting for 40%-50% of cases^[5]. Despite the significant benefits of EGFR-tyrosine kinase inhibitors (EGFR-TKIs), patients with EGFR activating mutation inevitably develop drug resistance within a certain treatment period. Nowadays, many studies focus on resistance mechanisms to third-generation EGFR-TKIs, as they have been recommended as the preferred first-line treatment for advanced NSCLC patients with EGFR activating mutation. Numerous resistance mechanisms have been identified^[6-8], which can be broadly classified into two groups: (1) The first includes EGFR-dependent mechanisms, mainly referring to secondary or tertiary mutations, such as C797S, G724, L792, L718, and G719; (2) the second includes EGFR-independent mechanisms, including activation of downstream signaling pathways such as human epidermal growth factor receptor 3 (HER3), anaxelekto (AXL), fibroblast growth factor receptor (FGFR) signaling pathways, *etc.*; acquisition of other potentially targetable oncogenic drivers such as mutations in phosphatidylinositol-3-kinase catalytic α (PIK3CA), Kirsten rat sarcoma (KRAS), BRAF V600E, anaplastic lymphoma kinase (ALK) fusions, MET amplification, *etc.*; and histological transformation to small-cell or squamous carcinoma.

Recently, some new mechanisms have been revealed. For example, Kashima *et al.* identified CD74 upregulation as a novel mechanism of resistance to osimertinib by applying single-cell analyses to cell models^[9]. Nilsson *et al.* found that the activation of yes-associated protein (YAP) and forkhead box protein M1 (FOXM1) could mediate epithelial-to-mesenchymal transition (EMT)-associated EGFR-TKIs resistance^[10]. These mechanistic studies have promoted some potential strategies to overcome EGFR-TKIs resistance. The allosteric inhibitor of src homology 2 domain-containing phosphatases (SHP2), a blockade to receptor tyrosine kinases (RTK) signaling, was recently shown to be a therapeutic strategy in acquired EGFR-TKIs-resistant NSCLC at the preclinical stage^[11]. The combination of osimertinib and a novel AXL inhibitor ONO-7475 showed remarkable activity on osimertinib-resistant tumor cells *in vitro* and *in vivo*^[12]. Zhu *et al.* identified a novel connection between osimertinib and c-Myc and further demonstrated targeting c-Myc as a potential strategy to overcome osimertinib acquired resistance in cell lines^[13]. However, these therapeutic strategies need to be further validated in clinical trials and more research is welcomed.

KRAS

The KRAS gene is the most frequently mutated oncogene in human cancer, accounting for approximately 30% of NSCLC^[14]. However, because RAS protein has a picomolar affinity for GTP and lacks known allosteric regulatory sites, KRAS had long been considered “undruggable” despite 40 years of sustained efforts. In 2013, the breakthrough by Ostrem *et al.* of small molecules that covalently bind to the acquired cysteine residue within the switch II region in KRAS^{G12C} opened the door to therapy targeting KRAS^{G12C}^[15]. In recent years, a series of clinical trials have evidenced the remarkable antitumor activity of KRAS^{G12C} inhibitors such as AMG510 and MRTX849, with a response rate of 30%-40%^[16,17]. However, drug resistance also has limited survival benefits for most patients, with a median progression-free survival of 6.3 months. Similarly, the resistance mechanisms of KRAS^{G12C} inhibitors are divided into the KRAS-dependent and -independent ways. The reported acquired KRAS alterations^[18,19] include G12D/R/V/W, G13D, Q61H, R68S, H95D/Q/R, Y96C, Y96D, Y96S, and high-level amplification of the KRAS^{G12C} allele, whereas KRAS-independent mechanisms^[20,21] also involve bypass signaling activation, such as upstream RTK regulators (EGFR, HER2, FGFR, and SHP2), direct mediators of KRAS activation (AURKA), and/or effectors of mitogen-activated protein kinase (MAPK) and PI3K pathways (MYC and mTOR); acquired alterations of other oncogenes, such as NRAS, BRAF, MAP2K1, RET, ALK, FGFR3, CDKN2A, PTEN, *etc.*; and histological transformation to squamous cell carcinoma. In addition, impaired antitumor immunity could confer resistance to KRAS^{G12C} inhibition independent of the above mechanisms, which might be attributed to the partial antitumor efficacy of KRAS^{G12C} inhibitors derived from the activation of an immune response, as KRAS^{G12C} inhibition could induce a pro-inflammatory tumor microenvironment (TME) and prime antigen-presenting cells and cytotoxic T cells^[22]. Therefore, the feasibility and efficacy of the combination of KRAS^{G12C} inhibitor with immunotherapy are worthy of further studies.

Together, although drugs targeting KRAS were first developed less than 10 years ago and only two kinds of targeted drugs have entered the clinic and are both under phase III clinical trials now, the mechanisms of drug resistance have been studied to develop effective therapeutic strategies better. However, more relevant clinical data are needed in the near future when the drugs are widely used in clinical practice.

Resistance mechanism for ICIs-based therapy

Immune checkpoint inhibitors (ICIs) targeting programmed cell death 1 (PD-1) and its ligand (PD-L1) have revolutionized the treatment scenario for patients with NSCLC. Albeit with unprecedented improved long-term survival in selected patients, ICIs failed to achieve a high response rate for the whole population. Because of the specific kinetics and patterns of response to ICIs, their resistance mechanisms are much different from those of chemotherapy or targeted therapy. In 2020, the Society for Immunotherapy of Cancer published an expert consensus on clinical definitions for resistance to ICIs in three distinct scenarios: primary resistance, secondary resistance, and progression after treatment discontinuation^[23].

Primary resistance is defined as evidence of disease progression after receiving at least 6 weeks (2 cycles) of exposure to ICIs but no more than 6 months. This type of resistance is related to the inability of the immune system to activate an appropriate immune response to malignant neoplasm, which can be due to any impaired functions in the cancer-immunity cycle^[24], including cancer antigen release and presentation; T-cell priming, activation, trafficking, migration, and infiltration; or recognition and killing of cancer cells by T cells. Factors contributing to this resistance involve tumor-intrinsic and tumor-extrinsic mechanisms. Tumor-intrinsic mechanisms refer to the cancer cells enabling the suppression of the immune response by modulating their genome, transcriptome, and proteome. Some gene alterations^[25,26] [loss of phosphatase and tensin homolog (PTEN), the mutation in Liver kinase B1 (LKB1), TP53, EGFR, ALK, *etc.*], and oncogenic signaling pathways^[27] (WNT/ β -catenin, MYC, MAPK, JAK/STAT3, *etc.*) decrease T-cell infiltration. LKB1-mutation also results in the recruitment of suppressive myeloid cells, and the inhibition of granulocytic

myeloid-derived suppressor cells (G-MDSCs) via all-trans-retinoic acid could overcome the resistance of PD-1 blockade in LKB1-deficient murine NSCLC^[28]. Yang *et al.* discovered that USP12 downregulation fostered an immunosuppressive microenvironment with increased macrophage recruitment and reduced T-cell activation via NF- κ B hyperactivation in tumor cells^[29]. Recently, Wennerberg *et al.* described the expression of mono-adenosine 5'-diphosphate-ribosyltransferase 1 (ART1) on tumor cell-mediated cell death of P2X7R+ CD8 T cells as a novel mechanism of immune resistance in NSCLC and provided preclinical evidence that antibody-mediated targeting of ART1 could improve tumor control^[30]. Tumor-extrinsic factors are those components beyond cancer cells that contribute to suppressive TME. For example, the overexpression of vascular endothelial growth factor (VEGF) on endothelial cells promotes MDSC infiltration and decreases T-cell infiltration^[31]. Cancer-associated fibroblasts (CAF), one of the most abundant components of TME, could also create an immune-suppressive TME by increasing the infiltration of MDSCs and tumor-associated macrophages, promoting the polarization of macrophages and reducing proliferation and antitumor activity of CD8⁺ T cells and natural killer cells^[32]. Recently, Horton *et al.* reported that abnormal differentiation of CD8⁺ T cell during priming mediated ICIs resistance in T cell-infiltrated NSCLC^[33].

Acquired resistance is defined as evidence of disease progression after experiencing clinical benefit (either objective response or stable disease lasting 6 months or greater). As the name implies, this type of resistance is “acquired” through the adaption of tumor cells to the host immune system, reflecting the evolution of the tumor as a malignant organism under selection pressure from therapeutic drugs. Early research^[34] suggested that tumor cell-autonomous defects in interferon (IFN) signaling through JAK1/2 inactivating mutations or HLA class I antigen processing through mutation or loss of beta-2-microglobulin (B2M) mediated acquired resistance to ICIs. Neoantigen depletion was also identified to lead to subsequent immune evasion in NSCLC^[35]. The upregulation of additional coinhibitory receptors^[36], such as LAG-3, TIM-3, TIGIT, VISTA, *etc.*, could also abrogate the effect of PD-1/PD-L1 blockade. In addition, acquired resistance to ICIs could also arise upon selection for new oncogenic variants that mediate T-cell exclusion, including loss of PTEN and WNT/ β -catenin activation^[34]. Recently, the upregulation of CD38 induced by ATRA and IFN- β was found to mediate acquired resistance by suppressing cytotoxic T-cell proliferation, antitumor cytokine secretion, and killing capability via adenosine receptor signaling^[37].

Considering the special context that disease progression occurs after discontinuation for adjuvant/neoadjuvant immunotherapy with a fixed duration, or for the metastatic setting either secondary to toxicity or after achieving maximal benefits, the conception of “progression after treatment discontinuation” was proposed. In terms of mechanism, this type of resistance can be mediated by the elements from either “primary resistance” or “acquired resistance”. The early recurrence after discontinuation of adjuvant therapy may resemble primary resistance, whereas late recurrence after adjuvant therapy discontinuation and initial disease control may resemble acquired resistance. However, up to now, studies focused on resistance mechanisms specifically in these settings are lacking.

Taken together, resistance mechanisms to ICIs are much different from those to chemotherapy or targeted therapy, in which tumor-intrinsic and tumor-extrinsic factors both need to be considered. Although there are many barriers to investigating resistance mechanisms to immunotherapy, including difficulty acquiring optimal tumor samples for analyses and the absence of routine and effective tools to comprehensively interrogate alterations in the tumor, host, and/or microenvironment, more in-depth studies are needed to better clarify the underlying molecular mechanism and develop corresponding rational therapeutic strategies to overcome resistance. Of note, there is a lack of studies on resistance mechanisms to combinations of ICIs and chemotherapy, since the synergistic antitumor activity leaves it difficult to

distinguish which component is the driver of response.

In this Special Issue, some new factors are reported to contribute to ICI resistance. Wu *et al.* found that circRNA hsa_circ_0020714 was related to a poor prognosis of anti-PD-1 immunotherapy in NSCLC, and a mechanistic study suggested that hsa_circ_0020714 functioned as an endogenous miR-30a-5p sponge to enhance SOX4 expression, thereby promoting immune evasion and anti-PD-1 resistance in NSCLC patients^[38]. Their study raised the important role of circRNA in immune resistance and provided a potential targeted pathway “hsa_circ_0020714/miR-30a-5p/SOX4” to overcome resistance to anti-PD-1 therapy. The role of tumor-derived exosomes in tumor response to immunotherapy was recapitulated by Wu *et al.*, and they pointed out that tumor-derived exosomes should be studied and manipulated to provide clinical benefits and improve the clinical management of lung cancer^[39]. Li *et al.* reviewed the resistance mechanism to ICIs, especially in KRAS-mutant NSCLC, with a critical focus on metabolism remodeling mediated by the oncogenic KRAS pathway, and they argued that these alternated metabolic pathways could be promising approaches to overcome immunotherapy resistance^[40]. From the present clinical practice, Yu *et al.* discovered that the use of ICIs plus chemotherapy and/or anti-angiogenesis therapy correlated with better survival after resistance to previous ICI treatment, which provides a therapeutic option for patients with resistance to ICIs before more reliable strategies enter the clinic^[41]. More research on lung cancer drug resistance is needed to improve patient survival in the future.

Abstract

Liquid biopsies are a powerful tool to non-invasively analyze tumor phenotype and progression as well as drug resistance. In the bone oncology field, liquid biopsies would be particularly important to develop, since standard biopsies can be very painful, dangerous (e.g., when found in proximity to the spinal cord), and hard to collect. In this review, we explore the recent advances in liquid biopsies in both primary (osteosarcoma and Ewing sarcoma) and secondary bone cancers (breast, prostate, and lung cancer-induced bone metastases), presenting their current role and highlighting their unexpressed potential, as well as the barriers limiting their possible adoption, including costs, scalability, reproducibility, and isolation methods. We discuss the use of circulating tumor cells, cell-free circulating tumor DNA, and extracellular vesicles for the purpose of improving diagnosis, prognosis, evaluation of therapy resistance, and driving therapy decisions in both primary and secondary bone malignancies.

Keywords: Liquid biopsy, bone metastasis, osteosarcoma, Ewing sarcoma, extracellular vesicles, minimal residual disease, drug resistance

INTRODUCTION

Normal bone physiology: cellular players and the “virtuous cycle”

Bone is a connective tissue composed of a mineralized matrix and a cellular component. The former is

made up of an inorganic part (mainly calcium phosphate) and an organic one, composed of type I collagen fibers as well as a plethora of proteins such as osteonectin, osteopontin, osteocalcin and proteoglycans. This bone matrix is also a storage for several growth factors belonging to the transforming growth factor (TGF)/insulin-like growth factor (IGF) superfamilies^[1,2]. The two matrix components make bone a composite material with outstanding mechanical properties, but this comes with a caveat: bone needs to be modeled and remodeled during growth and adult life, respectively, otherwise its mechanical properties degrade over time, as is the case for elderly individuals of both genders and for some bone genetic diseases^[3,4]. Proper bone modeling/remodeling is guaranteed by a finely tuned balance among the three main bone cells: osteoblasts, the bone-forming cells; osteoclasts, the bone-resorbing cells; and osteocytes, key controllers of bone matrix homeostasis^[5,6]. During bone modeling, all bone sections change shape following both mechanical cues and microenvironmental factors and expand to accommodate the growing organism in physiological conditions. In adults, bone switches to remodeling, where osteoblasts and osteoclasts act on the same surfaces and constantly resorb and depose new bone, resulting in a net bone mass balance, following physiological mechanical stimuli as well as the organismal needs for calcium and phosphate^[7]. Although this might appear to be a waste of energy, it is crucial to maintain proper mechanical features and guarantee the repair of microfractures that are detected by osteocytes, which subsequently drive the remodeling of the damaged surfaces. Osteocytes are also able to sense mechanical loading, which acts as an anabolic stimulus that promotes osteoblast activity^[8,9]. Since the process of bone resorption-deposition in homeostatic conditions keeps bone at its best, and it is cyclic, bone researchers often use the term “virtuous cycle” to describe it.

Primary bone tumors

Osteosarcoma is the most common primary bone tumor. It has two separate incidence peaks, the highest one between 10 and 20 years of age and a secondary one in people aged ≥ 65 years^[10]. Although the overall incidence of this cancer is low (3.1 cases per million per year in the US)^[11], it represents 2% of all cancers in 0-14-year-old and 3% in 14-19-year-old^[12], and its consequences can be devastating, ranging from limb amputation (20% of operable osteosarcomas) to death because of lung metastases^[11]. Osteosarcoma derives from a malignant transformation of the mesenchymal cells that can present different cellular features, but they all have in common the deposition of osteoid-like matrix and mineralized or demineralized lesions that are clearly visible upon X-ray examination^[13]. When the gold standard treatment, i.e., neo-adjuvant chemotherapy-surgery-adjuvant chemotherapy, is not possible, the only available treatment course is chemotherapy alone, since radiotherapy does not provide significant benefits and increases the risk of infection^[14]. However, despite advances in the field, chemoresistance is a serious problem in this type of neoplasia, and the survival benefits of chemotherapy are limited due to the onset of drug resistance^[14-16], which eventually leads to lung metastasis development, inevitably ending with the death of the patient. Chemotherapy is therefore a limited tool in osteosarcoma management, but having a reliable way to monitor the onset of drug resistance would make it much more effective.

There is still no consensus on the cell from which Ewing sarcoma originates, but what is certain is that it most often localizes in bone (80%-85%) or the soft tissue surrounding it (15%-20%)^[17]. Ewing sarcoma also has quite a high incidence of 2.93 per million in newborns to adolescents^[18]. Moreover, 85% of Ewing sarcomas harbor a specific chromosomal translocation [t(11:22)(q24:q12)] leading to the fusion of the N-terminal portion of Ewing sarcoma gene (EWS) with the C-terminal portion of Friend leukemia integration 1 transcription factor (FLI1), which encodes for a chimeric protein that behaves as a transcription factor and modulates a plethora of cellular processes, eventually leading to malignant transformation^[17]. While most other bone cancers have specific morphological features that make tracking their lineage relatively easy, Ewing sarcoma cells are round, small basophils and defined as “uniformly undifferentiated”^[17]. Despite advances in the field of Ewing sarcoma treatment, 70% of metastatic patients, in whom lungs are most

frequently affected as a secondary site, will eventually perish^[19]. Treatment of this tumor is multimodal and comprises surgery, radiotherapy, and chemotherapy^[20]. However, drug resistance is a very concrete issue, which sadly tends to increase after more aggressive rounds of chemotherapy that, in fact, do not seem to provide significant survival benefits and is especially marked in relapsing Ewing sarcoma^[21,22]. Hence, monitoring the onset of drug resistance with a non-invasive technique such as liquid biopsy could be a valuable tool in the fight against this family of tumors as well.

Bone metastases and the “vicious cycle”

The bone milieu is a particularly attractive microenvironment for metastasis development by many primary tumors, such as breast, prostate, lung, and kidney cancers^[23-25]. There could be several reasons for this “preference”, such as the richness in growth factors of the bone matrix^[26], the presence of higher levels of calcium, which acts as a growth-promoting factor^[27,28] especially following bone resorption, and the particular structure of bone/bone marrow blood vessels, which are fenestrated, hence quite permissive for tumor cells extravasation. In fact, metastasis is a stepwise process, in which first cancer cells have to invade locally in the primary site, after gaining the expression of specific sets of molecules such as matrix metalloproteinases^[29,30], migrate into the bloodstream or lymphatic system, escape immune killing while circulating, extravasate in the secondary site, engraft, and finally survive in the secondary organ. The final parts of the process, spanning from the extravasation to the survival in the new microenvironment, are often termed “homing” and require cancer cells to “trick” the resident cells into believing that they actually belong there, expressing bone-specific factors (osteomimicry)^[31] or hematopoietic stem cell-specific factors (HSC-mimicry)^[32].

Depending on the type of cancer, osteoblasts, osteoclasts, and osteocytes are affected in specific ways. In the case of breast cancer, metastatic dissemination usually causes the local degradation of the bone matrix, which is evident on X-ray analysis as void areas where bone should be. These types of metastases are termed “osteolytic”, and while both osteoblasts and osteoclasts are involved in their establishment, the main culprit for their radiographic appearance and fueling are osteoclasts, which become overactivated following their interaction with cancer cells^[33,34]. On the other hand, prostate cancer preferentially causes a net activation of osteoblasts in the bone metastatic microenvironment, leading to abnormally high bone deposition and the onset of radio-dense spots identifiable by X-ray examination. These metastases are termed “osteosclerotic” or “osteoblastic”^[24]. Both cancers can present osteolytic and osteosclerotic features in the same anatomical site, and in this case, bone metastases are defined as “mixed”^[23]. The process leading to osteolytic or osteosclerotic lesions relies on a pathological cross-communication between cancer cells and bone cells, where the former tilt the balance towards bone resorption or bone deposition, hijacking the virtuous cycle of cross-regulation between osteoblasts and osteoclasts into an osteolytic or osteosclerotic “vicious cycle”.

In the former, cancer cells that reached the bone/bone marrow microenvironment secrete factors that induce a net increase in osteoclast differentiation and activity. These factors can act directly [e.g., tumor necrosis factor- α , interleukin (IL)-6, and IL-1 β], and/or indirectly [like parathyroid hormone-related protein (PTHrP)], through the promotion of osteoblastic expression of pro-osteoclastogenic factors such as receptor activator of nuclear factor κ B (RANKL) and macrophage colony-stimulating factor (M-CSF)^[26,33-35]. The increase in osteoclast activity and differentiation leads to the degradation of bone matrix and the release of IGF-1, TGF- β , platelet-derived growth factor (PDGF), and bone morphogenetic proteins (BMPs) from it, which in turn stimulate tumor growth, thus creating a feed-forward loop, with bone cells, i.e., the osteolytic vicious cycle. In the osteosclerotic vicious cycle, cancer cells secrete a different set of proteins, including IGF-1, wingless-related integration site-1 (WNT-1) and WNT-3A, BMPs, and endothelin (ET)-1. These promote osteoblast differentiation and activity, leading to deposition of primary bone and production of growth factors^[24,36,37]. Tumor growth is therefore fomented by osteoblasts, thus

closing the osteosclerotic vicious cycle. Osteoblast differentiation also stimulates osteoclast differentiation, which further exacerbates the release of matrix-bound growth factors, with dangerous and painful consequences^[23,37].

LIQUID BIOPSY IN BONE ONCOLOGY

Liquid biopsies: what, how and why

Liquid biopsies are obtained in body fluids that are in direct contact with cancerous tissue and can provide important insights into the tumor without having to remove a part of it directly^[38,39]. This is especially important for those tumors that are not easily accessible and for which even drawing a simple biopsy core may be dangerous and/or extremely painful. Furthermore, classical biopsies may be taken from a relatively small area of the tumor and may not be representative of it as a whole^[40]. Although depending on the neoplasia might be useful to use urine, cerebrospinal fluid, and even saliva as a liquid biopsy, the body fluid that is most useful for this application is blood^[39]. An additional advantage of using liquid biopsies from blood is that they can be multiplexed and implemented with classical as well as next-generation cancer profiling analyses, including circulating bone turnover biomarkers such as carboxy-terminal telopeptide cross-linked type 1 collagen, pro-peptide of type 1 collagen, bone sialoprotein, tartrate-resistant acid phosphatase 5B (TRAcP5B), and osteoprotegerin^[41,42]; metabolites such as pyridinoline and deoxypyridinoline^[43]; and protein markers correlating with poor outcome in bone cancers, including vascular endothelial growth factor (VEGF)^[44], metallothionein^[45], IL-4, and IL-8^[46,47]. There are three main types of actionable biological materials that can be obtained from a blood liquid biopsy: (i) circulating tumor cells (CTCs); (ii) cell-free circulating tumor DNA (ctDNA); and (iii) extracellular vesicles (EVs, also referred to as exosomes)^[48].

CTCs

As the name suggests, CTCs are tumor cells that extravasate into the blood flow. They were first identified by Ashworth more than 150 years ago and are now commonly used in clinical practice^[49]. Although isolating CTCs has historically been a challenge because of their low number in the general circulation, newly developed microfluidic platforms (e.g., the FDA-approved CellSearch platform) are making this task easier, and next-generation sequencing approaches made it possible to deeply phenotype every single circulating tumor cell isolated^[50]. These important advances mean that a simple liquid biopsy can provide information about the genetic mosaicism of the primary tumor, their mutational landscape, epigenetics, and even their gene and protein expression.

Circulating tumor (ct)DNA

Cell-free ctDNA arises from apoptotic and necrotic primary tumor cells, which release their cellular content into the general circulation, as demonstrated by the fact that most of the ctDNA detected is 180-200 bp in length, which is consistent with what is observed in apoptotic cells^[48]. Circulating tumor DNA can provide important information about tumor mutations and copy number variation and suggests whether to proceed with a specific-target therapy or not. For example, the V600E mutation in v-raf murine sarcoma viral oncogene homolog B1 (BRAF) is found in several tumors, including metastatic colorectal cancer^[51], melanoma^[52,53], papillary thyroid cancer^[54], etc. The V600E variant of BRAF is targetable with drugs such as vemurafenib, dabrafenib, and trametinib, and its presence can drive the choice of therapy^[55].

Extracellular vesicles

The third class of biological material that is usable as liquid biopsy includes extracellular vesicles. These are lipid bilayer particles ranging from 30 to 1000 nm in diameter, which, according to their size, can be classified into three main types: apoptotic bodies, large extracellular vesicles (also known as microvesicles), and small EVs (also known as exosomes). These also differ in biogenesis and biological function^[56,57].

Importantly, EVs secreted by cells often mimic the molecular composition of the cell of origin, and they contain DNA, miRNAs, mRNAs, proteins, and other biological molecules that are interesting for theranostic and prognostic purposes^[56,58]. It has been thoroughly demonstrated that EVs have an important role in cancer^[59,60], including bone metastases^[60-63], osteosarcoma^[64-66], and Ewing sarcoma^[67,68], and cancer cells secrete more EVs than their normal counterparts^[69]. Moreover, hypoxia, higher intracellular calcium or lower pH, oxidative stress, ionizing radiation, and ultrasounds have all been shown to increase EV production in both normal and cancer cells^[70].

EVs are especially interesting for studying RNAs because these molecules are prone to be degraded in the circulation; however, when they are encapsulated into EVs, they become more stable and can be analyzed to gain insights into the transcriptional profile of the cells of origin, as well as regarding miRNAs and long non-coding RNAs^[71]. A summary of the primary and secondary tumors and the potential information that can be gained by liquid biopsies is schematized in [Figure 1](#).

Adopting different approaches to acquire all this biological information from a patient's blood could be possible to perform accurate diagnosis, estimate prognosis, and even monitor the onset of drug-resistant clones to make informed therapeutic choices and change therapy during treatment^[72].

Despite the advances in the field at the preclinical level, clinical adoption of bone liquid biopsies remains poor due to costs, scalability, reproducibility, and isolation methods. In the following sections, we focus on the recent developments, as well as preclinical and clinical applications of liquid biopsies in bone oncology, focusing on both secondary [[Table 1](#)] and primary [[Table 2](#)] tumors.

Liquid biopsy in bone metastasis

All the key components in liquid biopsies, i.e., ctDNA, CTCs, and EVs, have been exploited to monitor bone metastases secondary to breast, prostate, and lung cancers at the preclinical level.

ctDNA for bone metastasis detection

Circulating tumor DNA analysis may provide a complete genetic profile of the mutational landscape of metastatic disease, and is also correlated with patients' relapse or changes in response to surgical or pharmacological treatment^[73]. In this regard, a retrospective study of patients with primary breast cancer showed that the detection of metastatic disease, also spread in the bone, was possible by serial measurements of selected tumor-specific chromosomal rearrangements in ctDNA using droplet-based digital PCR technologies from plasma samples, with an average of almost one year before clinical recurrence detection during the follow-up of the disease, and the ctDNA amount was directly proportional to poor survival^[74]. This highlights the possibility of using ctDNA detection as a diagnostic tool for earlier prediction of metastasis. Liquid biopsies also hold the potential to detect minimal residual disease (MRD), thus providing indications for therapy and prognosis. Detection and analysis of plasma tumor-associated ctDNA were found to be a good indicator of MRD identification and monitoring in breast cancer patients with a high risk of recurrence^[75,76]. In particular, the detection of ctDNA at baseline was associated with a higher incidence of bone metastasis and subsequent poor prognosis in newly diagnosed patients with advanced non-small cell lung cancer (NSCLC)^[77]. Consistently, quantification and analysis of ctDNA in late-stage NSCLC patients revealed that higher ctDNA levels were detected in the group of patients with bone metastasis^[78]. It should be noted that using liquid biopsies as a means of detecting MRD is still a developing field, and the risk of false positives and false negatives is a concrete one that needs to be addressed in larger-scale longitudinal studies. Regarding the use of ctDNA, to the best of our knowledge, there are no studies focusing specifically on prostate cancer bone metastases. However, Vandekerkhove *et al.* showed that

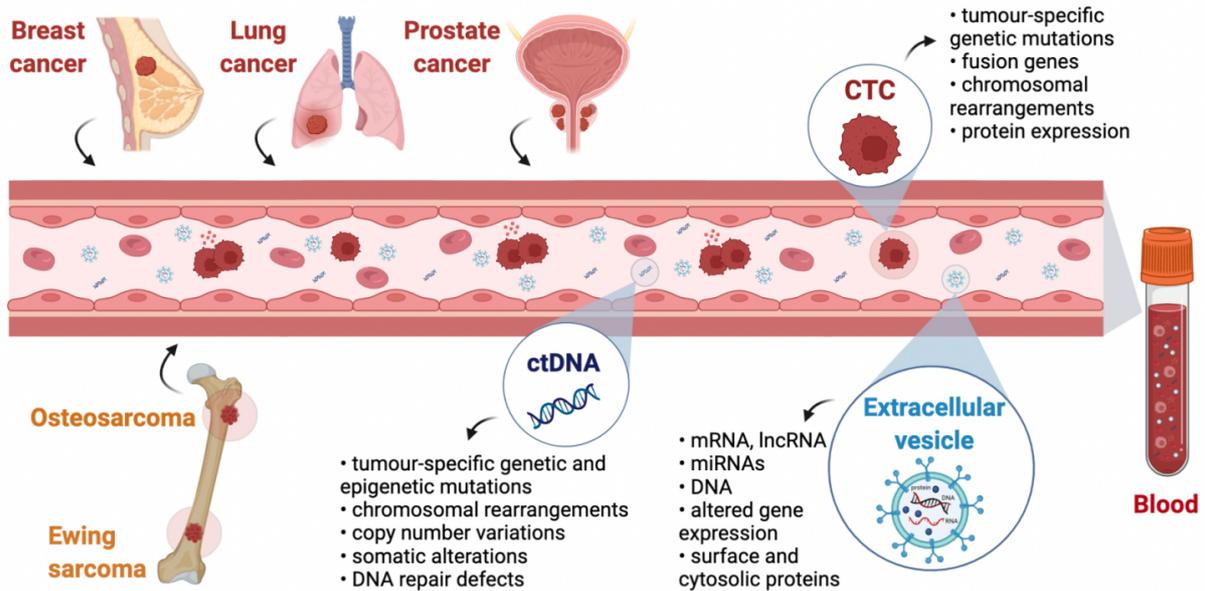

Figure 1. Liquid biopsies in primary and secondary bone cancers. Cell-free ctDNA, CTCs, and EVs are released into the general circulation by both primary (osteosarcoma and Ewing sarcoma) and secondary (breast, lung, and prostate) cancers and can be collected with a simple blood draw. Studying these three cancer-derived components by molecular or cellular analysis is termed liquid biopsy. Much information about the tumor can be achieved by analyzing CTCs, ctDNA, and EVs, making liquid biopsies a minimally invasive alternative to classical biopsies. Created with BioRender.com. ctDNA: Circulating tumor DNA; CTCs: circulating tumor cells; EVs: extracellular vesicles.

prostate cancer patients with visceral metastases had higher levels of ctDNA than bone metastatic patients^[79].

CTCs for bone metastasis detection

As for CTCs, they have also been proven useful for diagnosis, prognosis, and monitoring treatment efficacy in metastatic breast cancer. Indeed, CTC quantification and characterization in patients with metastatic breast cancer have been associated with the presence of bone and liver metastases^[80].

Remarkably, higher CTC counts correlated with multiple metastatic sites, while a lower CTC count was found in bone-only metastatic breast cancer patients, who also presented with a better prognosis^[81,82], indicating that patients with less advanced disease had fewer CTCs. Moreover, patients with only one or two bone metastases had sharply fewer CTCs compared to patients with more bone metastases^[82]. CTCs seem to have a subpopulation of metastasis-initiating cells that express epithelial cellular adhesion molecule, CD44, CD47, and c-MET. Once these cells were sorted and transplanted from a patient to immunocompromised mice, they induced bone, lung, and liver metastases^[83].

CTC detection and quantification have shown prognostic potential in lung cancer patients, especially in advanced NSCLC, the most common histological subtype, highly metastasizing to bone. In the last decade, some studies showed that a high number of CTCs is a predictive and prognostic indicator of bone metastasis^[84,85] in advanced lung cancer patients. The prognostic utility of CTCs in monitoring prostate cancer bone metastases was validated by multiple prospective studies performed on peripheral blood of metastatic castration-resistant prostate cancer patients after treatment. It was found that CTC counts ≥ 5 per 7.5 mL of blood are associated with lower overall survival and are predictive of bone metastases^[86-88].

Some studies suggested a liquid biopsy approach involving simultaneous detection and quantification of both CTCs and ctDNA. A valid example to report is the COMET (NCT01745757) prospective study, conducted on peripheral blood samples collected before and after chemotherapy from a homogeneous group of HER2-negative breast cancer patients. In patients with bone, liver, and brain metastasis, CTCs were greater in number and ctDNA analyses revealed at least one mutation in tumor protein 53, phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit alpha, and estrogen receptor 1 (*ESR1*) genes compared to non-metastatic patients^[89]. These tumor-specific mutations in ctDNA analysis from plasma of patients with visceral and non-visceral metastasis, including bone, were confirmed in other studies^[90-93], making this CTC-ctDNA signature potentially useful for diagnosis and prognosis of metastatic breast cancer.

Extracellular vesicles cargo and miRNAs for bone metastasis detection

As for EVs, starting from a meta-analysis conducted on publicly available microarray datasets derived from multiple-cancer type patients with and without bone metastasis, Bhadresha and colleagues identified 15 genes that were consistently upregulated in bone metastatic patients, and then validated their expression in patient serum-derived EVs. Among these, five were confirmed upregulated by qPCR in EVs isolated from the serum of breast and lung cancer patients harboring bone metastasis, namely, heat shock protein 90 alpha family class A member 1 (*HSP90AA1*), secreted phosphoprotein 1 (also referred to as osteopontin), IL-3, VEGFA, and protein tyrosine kinase 2. The authors concluded that this EV-derived mRNA gene signature could be a useful predictive tool for the early detection of bone metastases in breast and lung cancers^[94]. Few studies focused their attention on EV-derived miRNAs released from lung cancer cells. A retrospective study was conducted on plasma-derived EV miRNAs from NSCLC patients, focusing on their potential as biomarkers of early detection and monitoring of bone metastasis. In particular, hsa-miR-574-5p, hsa-miR-328-3p, and hsa-miR-423-3p have been suggested as potential biomarkers for bone metastasis^[95]. As for prostate cancer, EV-derived miR-181a-5p- was recently found upregulated in bone-metastatic prostate patients by Wang *et al.* and proposed as a biomarker for its diagnosis; similar findings were shown by Bryant *et al.* for miR-141 and miR-375^[96,97]. Additionally, prostate microparticles, a type of prostate-specific EVs, were found to be more numerous in metastatic prostate cancer compared to non-metastatic cancer and showed better predictive ability than CTCs detected with the FDA-approved CellSearch system^[98]. It is worth mentioning that a platform based on urine exosomal gene expression, termed ExoDX, was recently developed and tested in a utility trial on more than 500 patients. ExoDX-based scoring could predict high-grade prostate cancer in patients with uncertain prostate-specific antigen scores better than the gold standard (ROC AUC 0.7 vs. 0.62) and, conversely, it managed to predict which patients only had benign prostate hyperplasia, thus avoiding unnecessary biopsies^[99].

Liquid biopsy in primary bone malignancies

ctDNA detection

Few studies have been performed on plasma-derived ctDNAs analysis from osteosarcoma patients^[100,101]. One study focused on somatic mutations associated with tumor burden and disease outcome. Here, the researchers, using the targeted next-generation sequencing (NGS) approach, identified tumor-specific somatic alterations by comparing tumor and germline DNA extracted from peripheral mononuclear blood cells with tissue biopsies and demonstrated that patient-specific somatic alterations can be detected in ctDNA collected from the plasma samples at various stages of treatment, which allows the monitoring of disease burden^[100]. In another study, Shulman and colleagues showed that ctDNA levels detected by NGS hybrid capture assay in peripheral blood samples of patients with newly diagnosed localized osteosarcoma and Ewing sarcoma may be associated with tumor burden, relapse, and negative disease outcomes. Interestingly, ctDNA analysis led to the identification of novel genomic features of osteosarcoma, including chromosome arm 8q copy number gains^[101]. Specific and well-characterized genetic mutations, such as

stromal antigen 2 (STAG2) and TP53 loss-of-function mutations, translocation events, and fusion genes [Most commonly, EWSR1-FLI1 and EWSR1-erythroblast transformation specific-related gene (ERG)], have been found expressed in Ewing sarcoma patients, leading to the opportunity to monitor this bone malignancy through ctDNA^[102]. The above-described retrospective study conducted by Shulman and colleagues showed an association between ctDNA detection in plasma samples and a poor clinical outcome in patients with newly diagnosed Ewing sarcoma and identified from ctDNA analysis additional genomic information, such as EWSR1 fusion and STAG2 loss-of-function mutations^[101]. Another promising application for liquid biopsy in Ewing sarcoma was provided by Hayashi *et al.*, who found that tumor burden and response to therapy were related to increased levels of circulating *EWSR1-FLI1* fusion gene in plasma of patients. Moreover, they observed that *EWS-FLI1* levels in the circulation decreased after chemotherapy or surgery and then started to rise again during tumor recurrence^[103].

CTCs analysis

CTCs have been proposed as potential predictive and prognostic markers for osteosarcoma metastasis^[104]. A prospective study undertaken by Li *et al.* revealed a higher number of CTCs detected at baseline in peripheral blood of metastatic osteosarcoma patients compared to ones with localized disease. Moreover, they observed that CTC count was inversely correlated with the patient response after neoadjuvant chemotherapy^[105]. Consistently, other preclinical studies have shown that CTC count variations after therapy or surgical resection can reflect the tumor's sensitivity to the treatment and may be a good indicator of metastasis^[106,107], highlighting the clinical interest in dynamic monitoring of CTC changes for understanding treatment efficacy and detecting disease recurrence or metastasis in time. In particular, the presence of an increased percentage of CTCs with mesenchymal phenotype (identified by the epithelial-to-mesenchymal transition markers) in peripheral blood of a small group of osteosarcoma patients after chemotherapy treatment was associated with reduced disease-free survival, leading to the possibility to predict disease relapse and lung metastasis occurrence^[106,107].

A few studies have reported the use of tumor-specific makers for CTC isolation and characterization in Ewing sarcoma patients, including CD99 expression and presence of chromosomal translocations, such as amplification of EWSR1-FLI1 transcript fusion gene, by using different methods^[108,109]. Others have suggested that detection of CTCs at diagnosis in Ewing sarcoma patients may be associated with worse clinical outcomes and increased risk of recurrent disease or development of overt metastasis^[109,110].

Extracellular vesicles cargo and miRNAs

EVs have recently been studied as diagnostic or prognostic serum biomarkers via a liquid biopsy approach in osteosarcoma. Circulating EVs RNA profiling of metastatic vs. primary osteosarcoma samples allowed the detection of multiple transcriptomic alterations in the former, providing a new clinically relevant approach to track metastatic osteosarcoma^[111].

Several miRNAs, which are known to at least partially circulate inside EVs, with oncogenic or antitumor-suppressor roles in osteosarcoma, have been detected in the peripheral blood of patients. Some of them are emerging as important diagnostic and prognostic biomarkers, such as miR-148a^[112], miR-574-3p, miR-214 and miR-335-5p^[113], miR-49^[114], miR-221^[115], miR-191^[116], and miR-421^[117]. Conversely, miR-124^[118], miR-101^[119], and miR-195^[120] were shown to be downregulated in the serum of osteosarcoma patients, compared to healthy individuals. A potential application for these findings could be to establish a predictive strategy for osteosarcoma prognosis using a combination of these miRNAs. Circulating miRNAs have also recently become the subject of study in Ewing sarcoma. As an example, a widely studied circulating miRNA related to Ewing sarcoma progression is miR-125b, which was found decreased in patients serum after surgical

resection when compared to healthy controls^[121]. In the same study, its downregulation in the group of patients analyzed was also correlated with poor response to chemotherapy^[121]. Recently, the research focus is shifting towards Ewing sarcoma-derived EV cargo as a prognostic biomarker source, particularly to their protein content. Samuel *et al.* identified and used CD99, histidine triad nucleotide-binding protein 1 (HINT1), and nerve growth factor receptor (NGFR) membrane proteins as potential biomarkers of Ewing sarcoma-derived small EVs. They developed an approach of immuno-enrichment of Ewing sarcoma-associated small EVs based on these EV surface proteins, for the subsequent detection of EWS-FLI1 and EWS-ERG fusion transcripts in EVs isolated from plasma of both localized and metastatic patients^[122].

CLINICAL IMPLICATION OF LIQUID BIOPSY IN MONITORING DRUG RESISTANCE

Liquid biopsies in chemoresistance of primary and secondary bone cancers: an overview

A growing body of evidence suggests that the tumor secretome, including circulating-free DNA fragments from drug-resistant cells containing tumor-specific genetic and epigenetic mutations, is highly abundant in plasma; thus, the role of blood-based liquid biopsy is fundamental for this field of research^[123]. Although several studies have been conducted on plasma samples of relatively small cohorts of patients, trying to identify resistance mutations that occur during treatment, the data obtained thus far are clinically informative about therapy response, but still not completely validated in clinical practice. According to the different types of tumors, quantification and analysis of ctDNA were found to be usable as a viable tool for this purpose^[124].

A good example suggesting that ctDNA is a valuable strategy to monitor treatment efficacy was provided by Schiavon *et al.*, who showed that ESR1 mutations found in ctDNA from plasma of metastatic breast cancer patients previously treated with aromatase inhibitors are associated with resistance to endocrine therapy and shorter progression-free survival^[125]. Additionally, liquid biopsy has also proved to be useful for the identification of biomarkers associated with cyclin-dependent kinase inhibitors (CDKi) resistance and for predicting the subsequent development of metastatic disease, in hormone receptor-positive/human epidermal growth factor receptor 2 negative (HR+/HER2-) advanced breast cancer patients. Patients treated with CDKi in combination with endocrine therapy presented with specific therapy-induced mutations in the ctDNA analyzed, including retinoblastoma, ESR1, fibroblast growth factor receptor 1, or phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit alpha alterations^[126-128], which could be useful for predicting disease outcomes and drive therapeutic decisions. It is also important to mention the detection and quantification of CTC acquired resistance, which may also act as a prognostic marker able to predict treatment outcomes^[129]. Similarly, in castration-resistant prostate cancer patients treated with docetaxel, CTC count in blood was found to be an effective indicator of treatment sensitivity and patient survival^[130].

Due to its high genetic instability, osteosarcoma treatment is often hampered by the acquisition of chemoresistance following therapy-induced selective pressure. Some studies observed that low serum levels of miR-375 in osteosarcoma patients were related to poor tumor response to preoperative chemotherapy^[131]. Recently, other tumor-associated miRNAs have been linked with osteosarcoma chemoresistance, such as miR-491, which was found to be decreased in serum from osteosarcoma patients compared with healthy control subjects, and this decreased serum miR-491 level is correlated with increased metastasis, poor chemoresponse, and lower survival rate^[114]. In contrast, the serum levels of miR-21 were found to be significantly higher in patients with osteosarcoma than in control subjects and correlated with advanced Enneking stage and chemotherapeutic resistance^[132].

As for the development of chemoresistance in Ewing sarcoma, a recent study showed that circulating miR-125b levels were decreased in patient serum, and this was associated with poor response to chemotherapy^[121].

Implication of extracellular vesicles in chemoresistance

Extracellular vesicles are emerging as key players in the transfer of drug resistance^[133]; hence, they could be useful for monitoring the onset of this phenomenon during treatment.

Among the most studied constituents of tumor-derived EVs cargo, miRNAs have been identified as potential biomarkers for monitoring chemoresistance. EVs from doxorubicin-resistant osteosarcoma MG63 cells express high levels of the membrane transporter pump P-glycoprotein, transferring resistance to doxorubicin treatment to sensitive cancer cells horizontally^[134]. In another report, miR-25-3p upregulation in the blood of osteosarcoma patients correlated with increased tumor growth and drug resistance^[135].

Wei and colleagues demonstrated the role of EV-derived miR-222-3p detected in the serum of NSCLC patients for predicting gemcitabine sensitivity and identifying patients with the aggressive advanced and resistant disease^[136]. In addition, higher levels of EV-derived miR-425-3p were found in the serum of NSCLC platinum-resistant patients compared with platinum-sensitive patients^[137].

In breast cancer, it was found that EV-shuttled miR-222 released by doxorubicin-resistant breast cancer cells was locally transferred to M2 macrophages, thus activating their polarization. In these cells, overexpression of miR-222 suppressed phosphatase and tensin homolog gene, resulting in phosphorylation of Akt and activation of Akt signaling, which in turn supports cancer cells proliferation, migration, and invasion in a positive feedback loop. Accordingly, increased levels of miR-222 were found in EVs from plasma of patients presenting with chemoresistant breast cancer^[138]. In another study, it has been demonstrated that the human osteotropic breast cancer cell line MDA-MB-231 treated with paclitaxel was able to release EVs enriched in the cell survival protein Survivin^[139].

Interestingly, EVs can also act directly against anti-neoplastic agents. In fact, a recent study showed that HER2-positive breast cancer-derived EVs interfere with the activity of trastuzumab, acting as decoy receptors for it^[140]. In fact, EVs secreted by those cancer cells were found to have HER2 on their surface, and trastuzumab administered systemically binds it, hence making the amount of antibody available to bind cells lower. Furthermore, higher levels of glutathione S-transferase P1 (GSTP1) mRNA were found by Yang *et al.* in EVs from the serum of non-responding breast cancer patients treated with neoadjuvant chemotherapy compared to the responders. Intriguingly, they also demonstrated that GSTP1-containing EVs transferred drug resistance horizontally, and hence proposed their use as negative predictive factors of chemoresistance and clinical outcomes in breast cancer patients treated with anthracycline/taxane-based therapy^[141]. Similar results were observed for EV-bound transient receptor potential channel 5 mRNA found in peripheral blood of metastatic breast cancer patients, which could be a potential predictive marker of chemoresistance^[142].

Kharaziha *et al.* conducted proteomic analysis on EVs derived from prostate cancer cells sensitive *vs.* resistant to docetaxel, identifying multidrug resistance protein 1 (MDR-1), MDR-3, endophilin-A2, and poly(A) binding protein 4 as proteins enriched in the latter as well as present in EVs from the serum of castration-resistant prostate cancer patients, suggesting that EVs may be used as biomarker candidates for predicting therapeutic response or resistance^[143].

Larger longitudinal studies will be crucial to validate the biomarkers identified thus far, but the field holds great promise.

Factors hindering the clinical application of liquid biopsies

Although liquid biopsies are extremely promising tools, there are issues that need to be addressed before widespread clinical adoption can occur. First, since the techniques used are extremely sensitive, even small differences at the sample collection or processing level can cause significant differences in the final outcome. The use of serum instead of plasma, for example, can increase the amount of cell-free DNA released from other sources such as leukocytes, thus reducing the diagnostic ability of NGS-based assays, especially when trying to detect rare variants^[144]. Moreover, lifestyle-related factors can affect the release of cell-free DNA in the general circulation, thus constituting an array of possible confounding factors that are hard to identify and characterize systematically^[145]. As for CTCs, they are usually extremely rare and hard to capture, and although the CellSearch method has provided the field with a standardized method, CTCs captured this way are not viable. This means they can only be used for DNA and FACS/Immunofluorescence studies, but not for RNA-based assays or functional assays, including patient-derived xenografts or *in vitro* drug sensitivity tests^[146,147]. Moreover, CTC analysis has some of the drawbacks as classical biopsies, since they are not necessarily representative of the entire tumor, but only a subpopulation of cells that were able to migrate and survive in the circulation. A possible solution under investigation to at least partially solve this issue is choosing different sites for the blood collection. It has been reported that arterial blood and blood withdrawn from a closer site to the primary tumor may provide a higher number of CTCs^[148,149]. Significant efforts have been made by societies in both the United States and Europe to draw standard guidelines for preanalytical sample treatment, but while the consensus is widely accepted, liquid biopsies remain technically challenging for both the clinician and the analytical lab staff, which need specific training and facilities that are not always available locally, as well as training to interpret the results correctly^[150]. In addition to the general problems outlined above, EVs carry their own challenges at the preanalytical level. They are the most recently recognized source of biological information, and therefore their development as liquid biopsy tool is still at an early stage. A key example is the issue of EV isolation. There are several methods that are currently available to isolate EVs, namely differential ultracentrifugation, isopycnic ultracentrifugation, size-exclusion chromatography, polymer-based precipitation, immune-capture, asymmetric field flow fractionation, ultrafiltration, and the countless possible combinations among them^[151]. Unfortunately, no technique is absolutely superior to another, and, depending on the one investigator's use for EV isolation, the results obtained may vary^[151]. Moreover, as stated above, EV secretion is stimulated by several factors that may relate to one's lifestyle, which may make the detection of tumor-specific exosomes challenging^[70]. Finally, while these considerations are valid for oncology in general, the field of bone oncology is currently lacking specific clinical trials, although we are confident that it is just a matter of time before this gap is filled.

DISCUSSION AND CONCLUSIONS

Liquid biopsies have the potential to become one of the most powerful instruments in the clinical oncologist's toolkit, making diagnosis and prognosis increasingly accurate and therapy more personalized. In fact, the technique is rapidly gaining popularity, albeit still with somewhat limited success, as happens with most new implementations at early stages^[39]. This is particularly important in bone oncology, where minimally invasive techniques to evaluate clinical response to therapy and prognosis are limited. Despite this, the field is currently lagging behind, and there is a significant gap that needs to be filled before concretely applying liquid biopsies in clinical practice. The potential benefits of liquid biopsies not only are related to the life quality and expectancy of cancer patients but also extend to the cost-effectiveness of treatments. In this regard, a cost-consequence analysis was recently conducted comparing the use of tissue biopsy alone vs. tissue biopsy-liquid biopsy combined diagnostic strategy, in NSCLC^[152], where the

application of the latter implied lower overall medical expenses for the healthcare system compared to tissue biopsy alone. Additionally, liquid biopsies not only are a potential means of diagnosis but also can be used as risk-profiling tools, which could be able to identify subjects that are at risk for bone metastases, so that preventive therapies can be initiated. Of course, CTCs have been the most widely used in preclinical and clinical practice thus far, gaining FDA approval for use in some metastatic tumor prognosis (i.e., colorectal, breast, and prostate cancer), mainly due to the development of well-standardized isolation and analytical techniques. Nevertheless, ctDNA and tumor-derived EVs may become even more important than CTCs in the future, especially for personalized medicine. Indeed, they are easier to detect and characterize and can genetically reflect the tumor as a whole, providing the potential for real-time monitoring of tumor progression and development of chemoresistance, as has also been proposed or demonstrated in other neoplasias^[153-155]. Liquid biopsies could also be useful in tracking metastases before they become overt and therapy resistance by implementing them in standard follow-up protocols and analyzing the emergence of mutations that are important for therapy resistance and metastasis, as the pioneering work by the Bardelli group already demonstrated in colorectal carcinoma, although timelines may need to be readapted^[153,154]. Moreover, EVs also play an active role in malignancy and chemoresistance, and targeting them could be a valuable tool in the oncologist's toolkit, especially considering that some of the most commonly used EV secretion inhibitors are clinically approved for other conditions (manumycin A, D-pantethine, imipramine, tipifarnib, neticonazole, climbazole, ketoconazole, and triademenol)^[156] and could be repurposed to reduce EV-induced chemoresistance. We believe this research area is largely underexplored and will see an increase of interest in the next few years, also considering the advances in next-generation sequencing that could eventually lead to a "single-EV sequencing", which would really open a new avenue for the field^[157].

DECLARATIONS

Authors' contributions

Drafted the manuscript: Ucci A, Ponzetti M

Reviewed the manuscript: Ucci A, Rucci N, Ponzetti M

Availability of data and materials

Abstract

Triple-negative breast cancer (TNBC) is characterized as an aggressive form of breast cancer (BC) associated with poor patient outcomes. For the majority of patients, there is a lack of approved targeted therapies. Therefore, chemotherapy remains a key treatment option for these patients, but significant issues around acquired resistance limit its efficacy. Thus, TNBC has an unmet need for new targeted personalized medicine approaches. Calcium (Ca²⁺) is a ubiquitous second messenger that is known to control a range of key cellular processes by mediating signalling transduction and gene transcription. Changes in Ca²⁺ through altered calcium channel expression or activity are known to promote tumorigenesis and treatment resistance in a range of cancers including BC. Emerging evidence shows that this is mediated by Ca²⁺ modulation, supporting the function of tumour suppressor genes (TSGs) and oncogenes. This review provides insight into the underlying alterations in calcium signalling and how it plays a key role in promoting disease progression and therapy resistance in TNBC which harbours mutations in tumour protein p53 (TP53) and the PI3K/AKT pathway.

INTRODUCTION

Triple-negative breast cancer is associated with a worse disease outcome

Breast cancer (BC) is the most common female-specific cancer in the world^[1]. Triple-negative BC (TNBC) accounts for ~15% of all BC cases and is characterized by a clinically more aggressive disease, which is linked with higher recurrence rates, increased metastatic potential and poorer overall survival^[2-4]. Unlike oestrogen receptor-positive (ER+) BC and human epidermal growth factor receptor 2 (HER2)-positive BC, TNBC lacks the expression of oestrogen, progesterone and HER2 receptors^[5,6]. In both ER+ and HER2-positive BC, the expression at the protein and/or gene level of these receptors has been successfully targeted as a cancer treatment with either small molecule inhibitors or monoclonal antibodies^[7]. The results of these interventions in ER+ and HER2-positive BC have resulted in both improved response rates and overall survival of those BC patients^[8,9]. In TNBC, the development of targeted approaches to treat the disease lags behind other BC subtypes meaning that TNBC has one of the poorest survival rates of all breast cancer subtypes^[10,11].

In TNBC, chemotherapy remains one of the main treatment options for patients, but acquired resistance to chemotherapy remains a significant clinical problem^[12]. In recent years, advances in treating TNBC patients with novel targeted agents have shown benefits. For example, for patients who have a germline breast cancer gene (BRCA) 1/2 mutation, poly(ADP-Ribose) polymerase (PARP) inhibitors are used to treat TNBC patients in both the adjuvant and metastatic settings^[13-15]. However, patients with BRCA mutations account for only a small percentage of TNBC cases. Immunotherapy offers new hope for TNBC patients: results from the recent IMPASSION study demonstrate that immunotherapy combined with chemotherapy offers benefit to a subset of patients who have elevated programmed death ligand (PDL) 1 expression^[16]. Lastly, tumour-associated calcium signal transducer 2 (TROP2), encoded by the (*TACSTD2*) gene, is a transmembrane glycoprotein expressed in approximately 80% of TNBC. The antibody-drug conjugate (ADC) sacituzumab govitecan, a TROP2-directed antibody and topoisomerase inhibitor drug conjugate, has been approved for the treatment of TNBC by the FDA^[17]. However, there remains a significant proportion of TNBC patients for whom these therapies offer little benefit.

Calcium (Ca^{2+}) is an essential component required for normal cellular function and is involved in the regulation of processes such as metabolism, muscle contraction and phagocytosis as well as cell growth, proliferation and apoptosis^[18,19]. Local Ca^{2+} concentrations oscillate with varying frequency and amplitude, enabling the induction or modulation of signal transduction and gene transcription^[20-22]. In line with this, it has become evident that Ca^{2+} supports the functions of key tumour suppressor genes (TSGs) and oncogenes commonly altered in BC, such as tumour protein p53 (TP53), phosphatase and tensin homolog (PTEN) and Phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit alpha (PIK3CA), as well as a number of others reviewed elsewhere^[23]. Generally, oncogenes promote cellular survival by dampening Ca^{2+} signalling, whereas TSGs induce apoptosis through Ca^{2+} influx^[23]. Owing to this key role, it is unsurprising that Ca^{2+} is altered downstream of key driver genes, enabling cancer progression and treatment resistance^[18,24,25]. Consequently, Ca^{2+} represents an area of interest for the development of new drug therapies targeted to specific genomic alternations^[26-28]. This review outlines in detail the mechanisms of Ca^{2+} modulation and how these mechanisms are altered in specific TNBC cohorts who harbour mutations in TSGs such as TP53 and PTEN and oncogenes such as PIK3CA.

The role of calcium in cancer

Ca^{2+} plays a key role in cell growth, proliferation and apoptosis through rapid local fluctuations in intracellular calcium (Ca_i^{2+}), as well as long-term genomic changes by regulating signal transduction and gene transcription. In non-excitabile cells such as epithelial cells in BC, Ca_i^{2+} is predominately modulated through store-operated calcium (SOC). Here, store-operated calcium channels (SOCCs) allow the influx of Ca^{2+} into the cytosol due to differential Ca^{2+} concentrations which are established and tightly regulated through the continual action of various pumps and calcium channels^[18,24,29]. Extracellular Ca^{2+} is maintained at a concentration of 2 mM and cytosolic Ca^{2+} at a concentration of 100 nM^[30]. In addition, the ER and mitochondria act as Ca^{2+} stores, holding Ca^{2+} concentrations of ~1 mM and ~200 nM, respectively^[31]. These differential calcium gradients allow for localised changes in Ca^{2+} through the action of calcium channels, which in turn promotes various functions such as signal transduction and gene transcription as well as cellular processes such as proliferation and apoptosis.

SOC is initiated by Ca^{2+} release from the endoplasmic reticulum (ER) through associated calcium channels such as inositol trisphosphate (IP₃) receptors (IP₃Rs) or ryanodine receptors (RyRs). IP₃R activation is initiated by upstream activation of plasma membrane G protein-coupled receptors (GPCRs) and receptor tyrosine kinase (RTK)^[32]. Following activation of these receptors by their associated ligands, phospholipase C (PLC) enzyme is produced, hydrolysing phosphatidylinositol 4,5-bisphosphate (PIP₂) and resulting in the production of diacylglycerol (DAG) and IP₃, the latter of which activates IP₃R inducing ER Ca^{2+} release^[33]. In addition, the channel can also be activated by common cellular stresses found in the tumour microenvironment (TME), such as reactive oxygen species (ROS), ER stress, altered cellular energetics, hypoxia and drug treatment^[23]. Alternatively, RyR releases Ca^{2+} from the ER upon sensing changes in intracellular Ca^{2+} ^[34]. Subsequently, the decrease in store Ca^{2+} is detected by a family of stromal interaction molecule (STIM) channels^[35], which mediate store-operated calcium entry (SOCE) primarily through calcium release-activated calcium modulator (ORAI) and occasionally transient receptor potential (TRP) channels at the plasma membrane^[36-38]. Normal Ca^{2+} concentrations are subsequently restored through Ca^{2+} efflux via the plasma membrane calcium pump (PMCA) and $\text{Na}^+/\text{Ca}^{2+}$ exchanger (NCX) along with reabsorption into the ER through the sarco/endoplasmic reticulum Ca^{2+} ATPase (SERCA). In addition, it has been increasingly found that the membrane potential of cancer cells has become more depolarised, and as such voltage-gated calcium channels (VGCC) have also been shown to contribute to calcium entry^[39,40]. Furthermore, these channels have also been shown to contribute to SOCE in cancer cells^[41].

Research has continued to demonstrate that aberrant Ca_i^{2+} is a common feature in cancer that is able to promote neoplastic transformation and drug resistance^[20,42,43]. This is mediated through altered calcium channel expression or activity, enabling cancer hallmarks such as migration/invasion, proliferation, survival and apoptotic resistance^[25,27,28,44]. Typically, increased Ca_i^{2+} enhances proliferation, while a reduction and faster recovery are linked to apoptotic resistance and decreased sensitivity to chemotherapeutic agents^[45]. To date, several studies have shown various calcium channel families are altered in BC and linked to tumorigenesis^[31]. Importantly, this work has also uncovered specific differences in channel expression between BC subtypes^[46]. For example, IP₃R2 and IP₃R3 have been found to be upregulated in TNBC tissue compared to luminal subtypes. SOCE is also altered in TNBC through increased ORAI1 and STIM1 expression, which promotes invasion and migration, while in patient samples, it was linked to poorer prognosis^[47,48]. In contrast, ORAI3 was found upregulated in luminal and HER2 BC^[49]. SOCE inhibitors in early preclinical studies have demonstrated an ability to inhibit proliferation and migration in MDA-MB-231 TNBC cell lines and reduce tumour growth in TNBC mouse models^[50]. In addition, Azimi *et al.* (2017) observed that TRPC1 is significantly increased in TNBC compared to all other BC subtypes, resulting in an enhanced epithelial-mesenchymal transition (EMT) phenotype^[51]. Going forward, this review focuses on the role of Ca^{2+} in supporting TSGs and oncogenes commonly altered in TNBC; however, altered calcium

channel expression in BC subtypes has been extensively reviewed elsewhere^[24,46,52].

The role that calcium plays on the impact of TP53 mutations in TNBC

TNBC is a heterogeneous disease, which includes distinct molecular subtypes^[6,53-55]. This heterogeneity partly explains the limited impact that targeted therapeutic approaches have made in treating the majority of TNBC patients. Part of this heterogeneity is associated with the mutational background of TNBC, which could impact a patient's response to therapeutic intervention. However, this could provide opportunities for scientists and clinicians to design novel approaches to treat TNBC.

Somatic mutations in the TSG TP53 (located at 17p13.1) occur in ~80% of TNBC cases^[56,57]. Normally, TP53 is activated due to various stress signals such as DNA damage, hypoxia, ROS, oncogenic activation and cancer treatment^[23]. In this way, TP53 helps prevent tumorigenesis by regulating biological processes such as apoptosis, cell cycle, DNA repair and senescence^[58]. Mutations that result in loss of TP53 activity and impair its normal cellular functions have been linked to chemoresistance as well as reduced overall survival^[59-64]. Most (90%) functionally relevant TP53 mutations produce missense products that have both loss- and gain-of-function features^[65,66] and are more resilient to degradation^[57]. Most known cancer-associated TP53 coding DNA sequence (CDS) changes are within the DNA-binding domain corresponding to exons 5-8 and amino acids 102-292, with > 28% of these nonsynonymous SNPs occurring at eight key sites^[67]. Many of these originate from aberrant CpG methylation^[67]. Notably, recurrent TP53 aberrations during cancer growth result in selective sweeps of new clones with independent mutant TP53 proteins^[68].

In relation to Ca²⁺, TP53 is known to have a non-transcriptional role in the cytosol, inducing apoptosis in cells by regulating Ca²⁺ release from the ER^[69,70]. Recent research has shown that wild-type TP53 localises to ER and mitochondria-associated membranes (MAMs), where it interacts with SERCA increasing Ca²⁺ loading in the ER by enhancing its activity^[71,72] [Figure 1A]. In addition, TP53 also promotes ER Ca²⁺ transfer to the mitochondria inducing pro-apoptotic mitochondrial overload, leading to the release of pro-apoptotic factors^[72].

Mutant TP53 disrupts these processes, leading to apoptotic resistance and reduced sensitivity to chemotherapy^[69,72,73]. Here, TP53 fails to induce SERCA activity, reducing mitochondrial Ca²⁺ response, which also reduces caspase 3 and PARP cleavage, thus promoting an anti-apoptotic phenotype^[72] [Figure 1B]. In addition, Giorgi *et al.* (2015) demonstrated that wild-type TP53 cells were sensitive to doxorubicin (Adriamycin) treatment, as TP53 mediated an increase in cleavage of PARP and caspase 3, which resulted in reduced cell survival^[72]. However, in TNBC TP53 mutant MDA-MB 468 cell lines, doxorubicin failed to increase both SERCA activity and Ca²⁺ levels, thus conferring chemotherapy resistance^[72]. This critical role of TP53 in promoting pro-apoptotic Ca²⁺ in treatment sensitivity was further confirmed by Giorgi *et al.*, who demonstrated that overexpression of SERCA or mitochondrial calcium uniporter (MCU) restored treatment sensitivity^[74]. This effect was lost when Ca²⁺ levels were reduced by chelation, highlighting how Ca²⁺ is integral to the function of TP53^[74]. In addition, mouse xenograft tumours established using mouse embryo fibroblast (MEF) H-ras induced cells were observed to double in size with TP53 loss compared to wild-type controls, corresponding with an observed decrease in Ca_i²⁺ Activity^[74].

Other calcium channels such as TRP have also been linked to TP53 pro-apoptotic Ca_i²⁺ changes in BC. TRP channels promote calcium entry at the plasma membrane following activation by PLC, DAG or store release from IP₃R channels^[75]. These channels support store refilling via SOCE through the interaction with ORAI and STIM^[76]. A novel anti-neoplastic organic derivative GaQ3 (which has undergone phase 1 clinical trials in patients with solid tumours) was demonstrated to induce apoptosis by promoting TP53 expression

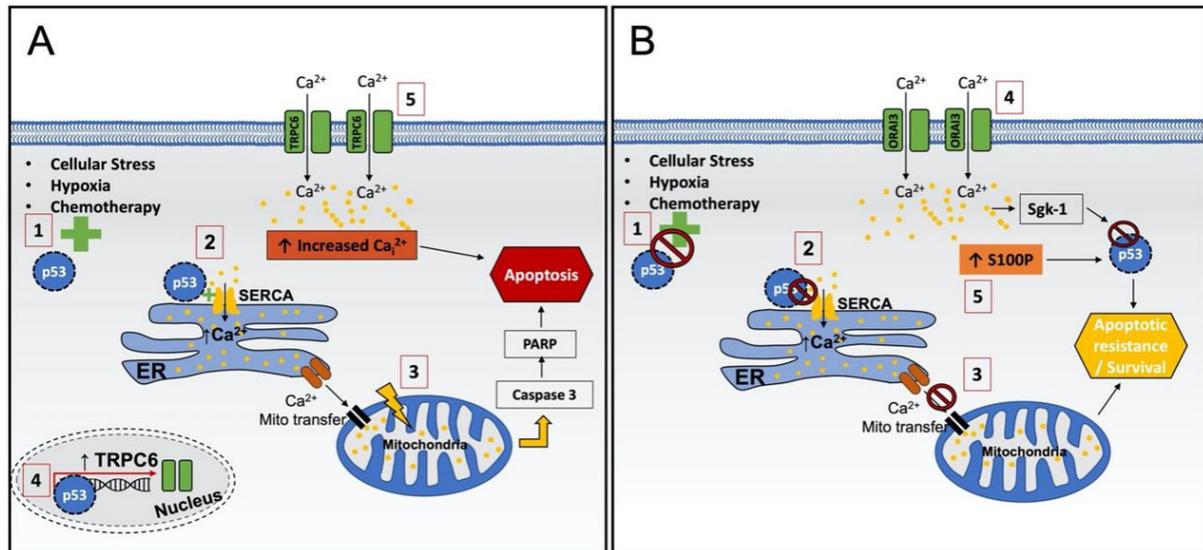

Figure 1. Summary of wild-type and mutant p53 calcium mediated cell death processes. (A) Wild-type p53: (1) induces apoptosis by different cellular stresses such as hypoxia and chemotherapy; (2) mediates an increase in ER Ca²⁺ through SERCA; (3) promotes ER Ca²⁺ transfer to the mitochondria resulting in a Ca²⁺ overloading activated caspase 3 and thus PARP; and (4) mediates apoptosis through an induction in TRPC6 expression and (5) associated Ca²⁺ influx. (B) (1) Mutations in TP53 result in a loss of function; (2) TP53 fails to induce SERCA; (3) this leads to reduced mitochondrial Ca²⁺ promoting apoptotic resistance; (4) Orai3 is increased in TNBC, promoting Ca²⁺-mediated increase in serum and glucocorticoid-induced protein kinase-1 (SGK-1) inducing TP53 degradation and (5) increased S100 calcium-binding protein P (S100P) also induces TP53 degradation. Both enhance cell survival. ER: Endoplasmic reticulum; PARP: poly(ADP-Ribose) polymerase; SERCA: sarco/endoplasmic reticulum Ca²⁺ ATPase.

through elevated Ca_i²⁺ concentrations^[77,78]. The key role of Ca²⁺ in this mechanism was confirmed using the Ca²⁺ quencher TMB-8, which prevented an increase in Ca_i²⁺, leading to an inhibition of TP53-mediated apoptosis. Further work found that this increase in Ca_i²⁺ was mediated by the binding of TP53 to the *TRPC6* promoter, resulting in the overexpression of TRPC6, enhancing Ca²⁺-dependent apoptosis in MCF-7 BC cells^[78]. A putative TP53 binding site on the *TRPC6* promoter was also identified by bioinformatic analysis using the Mat Inspector module of the genomatrix database, suggesting TP53 is a potential regulator of TRPC6^[78]. Thus, it was identified that the Ca_i²⁺ released through TRPC6 is mediated by TP53 and plays a major role in promoting apoptosis in a range of cancer cell line models including MCF-7^[77,78].

Research in a range of BC subtypes including TNBC has also observed that altered SOC channel expression is linked to apoptotic and chemotherapy resistance through the TP53 pathways^[23,79]. A recent study demonstrated through bioinformatic analysis that Orai3 was elevated in patients with poor response or residual disease following chemotherapy treatment, which was also predictive of poor patient outcomes^[80]. Increases in Orai3 expression induced resistance to the chemotherapeutic drugs cisplatin, 5-FU and paclitaxel by reducing apoptosis and increasing survival of T47D and MCF7 BC cell lines^[80]. These effects were found to be mediated by Orai3, promoting a decrease in TP53 and cyclin-dependent kinase inhibitor 1A (p21). This was confirmed by the removal of extracellular Ca²⁺ and/or Orai3 functionality, which resulted in an increase in TP53 expression and reduced chemoresistance. Interestingly, Hasna *et al.* (2018) also discovered that the Phosphoinositide 3-Kinase (PI3K)-Protein Kinase B (AKT) pathway was also induced by the observed increase of Orai3 expression in chemoresistant cells^[80]. PI3K inhibitors partially inhibited resistance induced by TP53 expression. This chemoresistant effect was mediated by PI3K induction of the SGK-1, leading to TP53 degradation via MDM2 proto-oncogene (Mdm2) and Nedd4-like E3 ubiquitin-protein ligase (Nedd4-2). Prior to this work, Brickley *et al.* (2013) highlighted a link between SOCE and SGK-1 in TNBC cell lines^[81]. SOCE activation induced the expression of SGK-1 following

exposure to cellular stress. This mechanism appeared cytoprotective, as siRNA targeting SGK-1 under the same conditions increased apoptosis.

Proteins such as S100P are also linked to TP53, where their expression was found to be altered in BC, enabling drug resistance^[82]. Specifically, the expression of S100P is elevated in TNBC and linked to chemotherapy resistance and poor survival^[83-86]. Gibadulinova *et al.* identified reduced phosphorylation and activity of TP53 in response to DNA damage following S100P binding in a range of cancer cell lines including BC cell lines MCF7 and T47D^[87]. When bound to TP53 protein, S100P promotes cell survival and resistance towards anticancer drugs such as paclitaxel and cisplatin, evading senescence and thus promoting cancer progression^[87].

Until recently, it has been challenging to develop drugs that can target TP53 for cancer treatment^[88]. This is primarily because TP53 expression is lost in ~10% of cases, and in the other cases, the function of the mutant protein is changed. However, advances in drug design have enabled both scientists and clinicians to develop drugs such as Eprenetapopt (APR-246) and COTI-2, which aim to reactivate TP53. These TP53 reactivators have been tested in preclinical studies in TNBC^[89] but also in clinical trials of TP53-mutant myelodysplastic syndromes (MDS)^[90] and solid tumours (NCT02433626). Further investigation is warranted to ascertain if these drugs impact any of the calcium signalling mechanisms mentioned previously.

Taken together, there is compelling evidence that Ca²⁺-dependent TP53 apoptosis and associated mechanisms contribute to poor outcomes in TNBC and resistance to chemotherapy. Consequently, it highlights calcium channels as a therapeutic target to modulate Ca²⁺ concentrations in mutant TP53 TNBC, which, through TP53 restoration or calcium channel activation drugs, could lead to improved responses to existing treatments and better overall patient survival.

Calcium signalling in PI3K/AKT and PTEN pathways in TNBC

PI3K/AKT oncogenic signalling through pathway activation is linked to cell survival, growth and apoptosis^[91]. Alterations in this pathway are common in TNBC and are associated with poorer outcomes and treatment resistance^[92]. Up to 30% of TNBC tumours harbour aberrations in the oncogenic PI3K/AKT pathway through mutation of either AKT serine/threonine kinase 1 (AKT1) or PIK3CA^[93,94]. The loss of wild-type TP53 regulation of AKT (located at 14q32.33), PIK3CA (at 3q26.32) and PTEN (at 10q23.31) has consequences for the PI3K-AKT pathway. PIK3CA encodes an alpha subunit of Phosphatidylinositol 3-Kinase (PI3K). PTEN is another TSG whose mutation can mimic the effects of mutant TP53^[95]. PTEN is a negative regulator of the PI3K/AKT pathway through downregulation of phosphorylated AKT, and it is also commonly altered in TNBC^[94,96].

TP53, AKT, PIK3CA and PTEN changes together constitute the genetic basis of the majority of TNBC cases and initiate the initial stages of tumour development^[97]. Mutations at these four genes may be oncogenic on their own, or may occur in tandem with other TSG mutations: PIK3CA, PIK3R1 (encoding regulatory protein p85 α) and PTEN commonly co-occur in BC^[98]. Changes at AKT, PIK3CA and PTEN are much less common than those at TP53^[61]. PIK3CA mutations are typically missense and constitute ~10%-18% of cases, and in ~4% of cases, PIK3R1 may be mutated^[99,100] - often, PIK3CA and PIK3R1 co-occur independently^[101]. PTEN is mutated in ~6%-7% of cases and AKT1 is rarer at ~3%^[100]. Although all 4 genes may have cancer-related SNPs, TP53 tends not to have other mutation types, in contrast to AKT and PIK3CA that can be amplified or possess CNVs; additionally, PTEN tends to be inactivated, often by deletion.

There is an established link between the PI3K/AKT pathway and TP53 [Figure 2]. RTKs are usually activated and phosphorylated by growth factors and hormones. PI3K, consisting of p110 ($\alpha, \beta, \gamma, \delta$) and p85, is recruited to the RTK leading to phosphorylation of PtdIns (4,5) P₂ to PtdIns (3,4,5) and subsequent recruitment of PDK1 to AKT at the PH domain. PDK1 is reliant on activation by PI3K. Activation of the AKT signalling pathway results in regulation of the cell cycle, promoting cell growth, survival and migration and inhibiting apoptosis^[102]. mTORC₂ activates AKT, thus leading to cell proliferation and survival. mTORC₁ is activated by phosphorylated AKT and promotes protein translation and cell growth^[103,104]. TP53 has three primary domains - transactivation domain, DNA-binding domain and tetramerization domain^[105]. TP53 is regulated by the MDM2 proto-oncogene (Hdm2) protein via binding and physical separation from target genes, resulting in low levels of TP53 in normal cells. TP53 regulates PI3K via binding and inhibition of PIK3CA, which encodes p110 α , and reduces AKT activation. Mutations in TP53 may lead to hyperactivation of PIK3CA and the PI3K signalling pathway^[99]. Studies have demonstrated the regulatory effects of TP53 on PTEN via the functional TP53 binding site present within the PTEN promoter region, resulting in inhibition of PtdIns(4,5)phosphorylation and subsequent AKT activation. AKT can enhance the function of Hdm2 via phosphorylation, and evidence suggests that PTEN may prevent the degradation of TP53 through suppression of AKT activation^[106]. PTEN has also been identified as a stabiliser of TP53 by way of physical association between the two, conferring protection from degradation to TP53. Despite these stabilising functions, deletion of PTEN and subsequent activation of the PI3K pathway have been shown to activate TP53, with significantly increased TP53 expression present in PTEN^{-/-} cells^[106].

PTEN has also been identified as a stabiliser of TP53 by way of physical association between the two, conferring protection from degradation to TP53. Despite these stabilising functions, deletion of PTEN and subsequent activation of the PI3K pathway has been shown to activate TP53, with significantly increased TP53 expression present in PTEN^{-/-} cells^[106].

TP53 can regulate cell survival via inhibition of the PIK3CA as well as the PI3K/AKT pathway, independent of PTEN. This transcriptional downregulation of PIK3CA via TP53 has been demonstrated in head and neck cancer cell lines, where the PTEN protein was not detected and induction of TP53 resulted in decreased PIK3CA expression and reduced AKT phosphorylation, indicating the transcriptional regulatory effects of TP53 on PIK3CA^[107]. A study investigating the mechanisms involved in the regulation of PIK3CA transcription via TP53 in ovarian cancer described two promoters present on the *PIK3CA* gene that have been shown to directly bind TP53 resulting in transcriptional inhibition. It was found that suppression of TP53 resulted in increased levels of p110 α transcripts, proteins and PI3K signalling pathway activity, while overexpression of TP53 resulted in decreased levels of p110 α protein^[108]. Loss-of-function mutations in TP53 correlate with hyperactivation of PIK3CA and the PI3K pathway, resulting in worse prognoses for head and neck squamous cell carcinoma patients^[99].

Research has demonstrated that the PI3K/AKT pathway can modulate Ca²⁺ release from ER stores via interaction with IP3R^[23] [Figure 3A]. This calcium channel is found on the ER membrane, where it controls the frequency and amplitude of Ca²⁺ oscillations to either promote cell survival or induce apoptosis^[109]. Under hypoxia conditions or chemotherapy treatment, IP3R promotes Ca²⁺ transfer to the mitochondria, inducing the release of pro-apoptotic factors^[23]. However, the anti-apoptotic protein AKT has been shown to phosphorylate IP3R, preventing ER Ca²⁺ transfer to the mitochondria and inhibiting apoptosis^[110,111] [Figure 3B]. This, in turn, enables resistance to chemotherapy and promotes survival during hypoxia^[110,111]. The PI3K/AKT pathway is also negatively regulated by the TSG PTEN^[112], which is commonly lost or mutated in TNBC and associated with poorer prognosis as well as treatment resistance^[113,114]. PTEN is known to localise at the ER and reduce AKT-induced phosphorylation of IP3R, thus promoting ER Ca²⁺

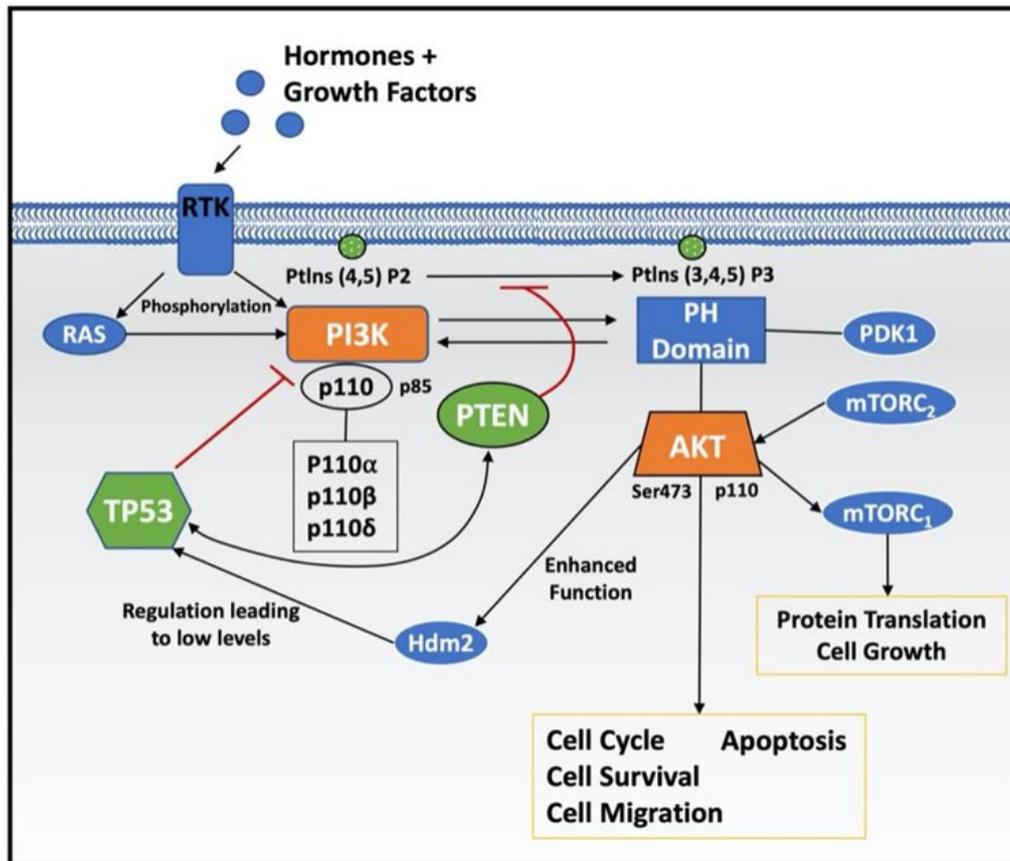

Figure 2. The role of TP53 in the PI3K/AKT signalling pathway. RTKs are activated by hormones and growth factors, leading to the recruitment and phosphorylation of PI3K. PDK1 is then recruited to AKT at the PH domain. Cell cycle, survival, migration and apoptosis regulation occur as a result of AKT signalling pathway activation. AKT is also activated by mTORC₂ and mTORC₁ is activated by phosphorylated AKT, promoting protein translation and cell growth. Hdm2 regulates P53 in normal healthy cells, resulting in low levels. P53 regulates PTEN, inhibiting PI3K phosphorylation and AKT activation. AKT may enhance the function of Hdm2 and PTEN may prevent P53 degradation via AKT pathway inhibition. P53 binds to PI3K to inhibit PIK3CA and mutations in TP53 may result in PIK3CA hyperactivation and subsequent PI3K signalling pathway activation. AKT: Protein kinase B; PTEN: phosphatase and tensin homolog.

release. In addition, it also associates with MAM and regulates the transfer of Ca²⁺ to the mitochondria, enabling Ca²⁺-mediated apoptosis^[115]. In PTEN mutant BC, IP3R becomes phosphorylated and inactivated by AKT, decreasing Ca²⁺ release from the ER and associated transients to the mitochondria, reducing the sensitivity to Ca²⁺-mediated apoptosis^[115]. This work highlights a potential link between PTEN loss and AKT activation, supporting treatment resistance and disease progression via deactivated IP3R mediated apoptotic resistance.

In relation to IP3R, its ability to mediate Ca²⁺ release from ER can be finetuned through interaction with calcium binding proteins such as neuronal calcium sensor-1 (NCS-1)^[116]. Recent studies in TNBC cells have shown that overexpression of NCS-1 increases Ca²⁺, promoting survival^[117]. Furthermore, this mechanism was linked to paclitaxel resistance, where NCS-1 binding to IP3R promotes drug resistance^[116,118] [Figure 3B]. Interestingly, researchers found IP3R2 and IP3R3 expression was elevated in breast tumours compared to adjacent normal cells^[119]. Furthermore, Singh *et al.* (2017), analysing MCF-7 cells, demonstrated that IP3R inhibition is able to induce autophagy and subsequent cell death, an effect not observed in non-tumorigenic cells^[119]. In addition, IP3Rs are also associated with the nuclear envelope and nucleoplasmic reticulum, where IP3Rs can also regulate Ca²⁺ levels within the nucleus to promote cell

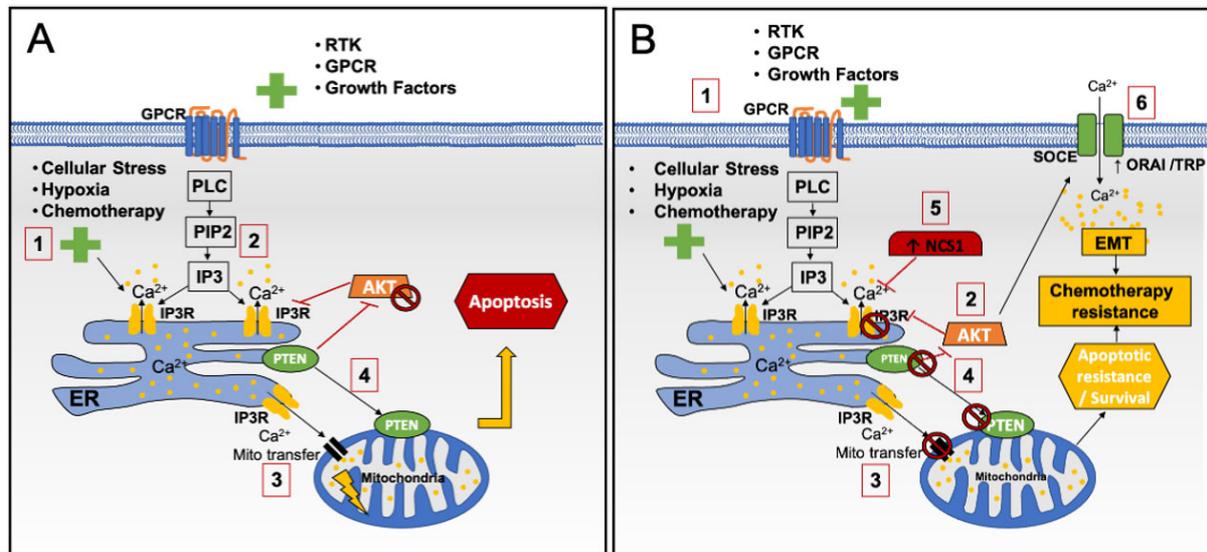

Figure 3. Role of calcium store release via IP3R in mediating apoptosis and its regulation via PI3K/AKT pathways. (A) (1) G protein-coupled receptors (GPCR), Receptor tyrosine kinase (RTK) and others, along with cellular stress, can induce PLC, PIP2 and IP3, leading to activation of IP3R channels on the ER, promoting Ca^{2+} store release. (3) This mediates Ca^{2+} transfer to the mitochondria inducing apoptosis. (4) PTEN also plays a role in mediating this pathway in part by blocking anti-apoptotic oncogene AKT. (B) (1) Activation of oncogenes such as AKT inhibits IP3R Ca^{2+} release from ER stores under chemotherapy and GPCR activation. (2) This is achieved by phosphorylating IP3R and (3) reducing Ca^{2+} transfer to the mitochondria, enabling apoptotic resistance. (4) PTEN loss is common in TNBC, enabling AKT signalling. (5) NCS-1 is increased in TNBC, promoting IP3R inactivation as well. (6) SOCE is mediated after store release via IP3R; channels such as ORAI and TRP that are activated have increased expression in TNBC and are linked to promoting EMT and thus chemotherapy resistance. RTK: Receptor tyrosine kinase; Orai: calcium release-activated calcium channel protein; PLC: phospholipase C; GPCR: G protein-coupled receptors.

proliferation^[120,121]. In TNBC, reducing nuclear IP3R Ca^{2+} by chelation decreased cell proliferation and induced tumour necrosis^[122]. Overall, this research identified that IP3R can impact both PI3K/AKT dependant and independent pathways.

Ca^{2+} store release via IP3R, which is modulated by PI3K-AKT/PTEN pathways, has an indirect contribution to drug-resistant mechanisms by association with Ca^{2+} binding proteins. For example, Ca^{2+} /calmodulin-dependent kinase (CAMKK) is essential for AMP-activated protein kinase (AMPK) induction following activation by epidermal growth factor (EGF) in TNBC cell lines^[123]. AMPK is an essential regulator of AKT activation under cellular stress such as drug treatment and hypoxia^[123]. Ca^{2+} is a requirement for this mechanism as its chelation using BAPTA-2AM completely inhibits AMPK-induced phosphorylated AKT. Specifically, AMPK phosphorylates s-phase kinase-associated protein 2 (Skp2) at S256, triggering the formation of an E3 ligase complex that promotes activation of AKT^[123]. This outlined mechanism was shown to promote cell survival and apoptotic resistance. In BC patient samples, Skp2 activation correlates with increased AKT and AMPK expression and is associated with poor survival outcomes. In addition, Han *et al.* (2018) found that targeting AMPK-Skp2 in TNBC MDA-MB-231 cell lines increased their sensitivity to anti-EGF receptor-targeted therapy^[123]. Furthermore, this study also showed in the same TNBC cell lines that this mechanism is not only induced by EGF but also hypoxia, promoting survival under such conditions. Hypoxia is a common characteristic in the tumour microenvironment (TME), which is also linked to chemotherapeutic resistance^[73].

SOCE mediated through ORAI and STIM as well as TRP enables the refilling of ER stores following PI3K-IP3R induced release, which supports signal transduction. Both ORAI and STIM have been shown to be

upregulated in TNBC, enabling disease progression and promoting treatment resistance^[124]. Using TNBC MDA-MB-231 cell lines, Bhattacharya *et al.* further demonstrated that (in the presence of phosphorylated AKT) ORAI3- and STIM1-mediated Ca^{2+} promotes the induction of Snail family transcriptional repressor (SNAIL)^[125]. Induction of SNAIL expression is known to mediate EMT, a cellular phenotype linked to drug resistance^[126,127]. In addition, TRPC1 has also been shown to play a role in EMT of TNBC via regulation of hypoxia-inducible factor 1 alpha (HIF-1 α) and AKT signalling in PTEN-deficient BC cells^[51]. Azimi *et al.* also noted that TRPC1 has a prognostic value in basal BC a molecular subtype associated with TNBC^[51]. Specifically, high TRPC1 expression was associated with significantly poorer patient relapse-free survival^[51]. Furthermore, it was noted that TRPC1 can induce EMT and promote chemotherapy resistance in MDA-MB-468 TNBC cell lines through the upregulated ATP-binding cassette, subfamily C, member 3 (ABCC3), a multidrug resistance ATP-binding cassette (ABC) transporter^[128]. In addition, this channel, alongside ORAI1 and IP3R2, has been found to be upregulated following doxorubicin treatment in MDA-MB-231 TNBC cells^[129].

TRPC5 is another family member whose overexpression is linked to chemotherapy resistance by induction of a protective autophagy mechanism which promotes cancer cell survival^[130]. Adriamycin (ADM/doxorubicin) was found to induce an increase in Ca^{2+} which was reduced with siRNA targeting of TRPC5. Exploration of the underlying pathway discovered that Ca^{2+} mediated through TRPC5 could activate CaMKK β , AMPK α and mammalian target of rapamycin (mTOR), which resulted in the induction of autophagy^[130]. As noted above, AMPK modulates AKT activation, which can regulate ER store release, and this can then facilitate chemotherapy resistance. In the study by Zhang *et al.* (2017), targeting the TRPC5-mediated CaMKK β /AMPK α /mTOR pathway increased sensitivity to ADM^[130]. Furthermore, analysis of patient samples via a tissue microarray (TMA) found that TRPC5 was significantly increased in patient samples post chemotherapy treatment when compared to pre-treated samples. Supporting the role of TRPC5 in chemotherapy resistance, studies have linked TRPC5 expression to the induction of expression of the multidrug resistance protein 1 (MDR1) in TNBC cells^[18].

Because of the large number of TNBCs that have an activated PI3K/AKT pathway, it is unsurprising that early phase clinical trials of both PI3K inhibitors such as buparlisib^[131,132] and AKT inhibitors such as capivasertib^[133] and ipatasertib^[134] have been conducted in this setting. Interestingly, these trials have reported clinical activity and benefits to patients. The identification of key biomarkers of response to these treatments and their study in combination with chemotherapy or other targeted therapies warrants further investigation.

Furthermore, as discussed above, there is a strong link between Ca^{2+} signalling and those TNBC cancers that have a TP53 mutation and/or activation of the PI3K/AKT pathway. Activation of the PI3K/AKT pathway can be achieved through either mutation of PIK3CA/AKT1 or loss of expression of PTEN. Our review highlights that several calcium channels associated with Ca^{2+} release from ER and subsequent SOCE are linked to the activation of the PI3K/AKT pathway. Aberrations in the PI3K/AKT pathway disturb Ca^{2+} handling and enable escape mechanisms such as cell survival and apoptotic resistance, thus promoting chemotherapy resistance.

Current approaches to target calcium channel signalling in cancer

The role of calcium channels in mediating therapy resistance through interplay with genomic alternations in TNBC highlights calcium channels as potential targets for personalized medicine approaches. The study of calcium channel blockers (CCBs) is an area of intense research^[26-28,135]. Several calcium blocking drugs have been developed which can modulate calcium channels and be exploited as cancer treatments^[27,43,135,136].

Calcium channels provide a plethora of targets to modulate Ca_i^{2+} , and ion channel targeting drugs are currently the second largest group of FDA-approved drugs, therefore providing a bank of new drugs which can be repurposed for the treatment of cancer^[137].

Several studies have identified existing FDA-approved drugs that can modulate store-operated release and entry through key channels such as ORAI, STIM, TRP and IP₃R, as outlined herein, thus representing potential future therapeutics for the tackling disease progression and chemotherapy resistance in the TNBC cohorts outlined. For example, an extensive screen of 1118 unique FDA-approved drugs discovered 11, mainly cardiac glycosides, which have the ability to modify Ca^{2+} signalling, promote Ca^{2+} -calmodulin kinase (CamK) activity and reverse the suppression of TSGs such as secreted frizzled related protein 1 (SFRP1), tissue inhibitor of metalloproteinase-3 (TIMP-3) and WNT inhibitory factor 1 (WIF-1), leading to cell death of colorectal cells^[26]. Other similar studies identified the ability of the immunosuppressant drugs to regulate SOCE, namely, leflunomide used to treat arthritis and teriflunomide used for multiple sclerosis^[138]. In addition, the drug eflornithine, also known as DFMO, has been found to reduce SOCE and promote a decrease in cell proliferation and cell death resistance in colorectal cancer^[139]. Eflornithine has been found to inhibit TRPC1 expression, which, as outlined above, plays a role in AKT signalling in PTEN deficient TNBC.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are commonly prescribed anti-inflammatory, anti-pyretic drugs that have demonstrated anti-cancer activity^[140]. The metabolite of aspirin, salicylate, has been found to inhibit SOCE and mediate mitochondrial uncoupling, reducing mitochondrial Ca^{2+} uptake and leading to a decrease in the proliferation of colon cancer cells^[141]. Furthermore, other NSAIDs such as ibuprofen and indomethacin have also been shown to modulate SOCE through STIM1, which decreased colorectal cancer growth^[142]. The CCB mibefradil, previously used to treat hypertension, can also inhibit SOCE by blocking ORAI channels, promoting cell apoptosis and cell cycle arrest^[143]. In addition, a potent synthetic oestrogen used in the treatment of prostate and breast cancer, diethylstilbesterol, can inhibit SOCE via TRPM7 channels^[144,145]. The potential to target SOCE modulation for disease benefit has led to the development of a number of drugs, such as CM2489, which has entered into phase 1 clinical trial for psoriasis; if successful, it could prove useful for TNBC treatment^[146]. CM2489 is a first-in-class calcium release-activated calcium (CRAC) channel inhibitor that targets ORAI channels. Lastly, IP₃R channels appear to be a key target in PI3K/AKT pathways mediating chemoresistance; both caffeine and heparin have been shown to inhibit these channels and could hold future potential as novel treatments in combination with existing anti-cancer agents^[147,148].

CONCLUSION

Targeting calcium channel signalling and key oncogenic pathways is a novel therapeutic approach to treating TNBC

TNBC is characterized as an aggressive form of BC associated with poor patient outcomes. For the majority of patients, there is a lack of approved targeted therapies. TNBC has frequent genomic alternations in TP53 and the PI3K/AKT pathway. This review provides insight into the underlying alterations in Ca_i^{2+} mediated through calcium channels and how this plays an important role in promoting disease progression and therapy resistance in TNBC harbouring mutations in key TSG and oncogenes. Specifically, TNBC with mutant TP53 is associated with a loss of Ca^{2+} store release via SECRA, leading to reduced mitochondrial Ca^{2+} loading; this, in turn, promotes cell survival and apoptotic resistance, thus enabling treatment resistance. In addition, I₃PR-mediated ER store release and SOCE modulation are altered by PI3K/AKT activation, promoting apoptotic resistance. Consequently, the outlined evidence highlights calcium channels as therapeutic targets to modulate altered Ca_i^{2+} downstream of common genomic alterations in TNBC.

This promise is supported by the fact that a growing number of calcium targeting drugs are under development, as well as a number of existing FDA-approved drugs. However, owing to the complexity of calcium signalling, its ubiquitous nature and differential expression between cell types and genomic alterations, care needs to be exercised when targeting Ca^{2+} signalling. It may be that targeting Ca^{2+} signalling, whilst beneficial for one cancer, could be detrimental for another. Overall, this review highlights Ca^{2+} electroporation as an emerging area in TNBC that could hold significant potential as disease biomarkers as well as future therapeutics when combined with treatments that can inhibit the PI3K-AKT pathway or reactivate TP53 expression.

Abstract

Hypoxia is a common phenomenon in solid tumors as the poorly organized tumor vasculature cannot fulfill the increasing oxygen demand of rapidly expanding tumors. Under hypoxia, tumor cells reshape their microenvironment to sustain survival, promote metastasis, and develop resistance to therapy. Exosomes are extracellular vesicles secreted by most eukaryotic cells, including tumor cells. They are enriched with a selective collection of nucleic acids and proteins from the originating cells to mediate cell-to-cell communication. Accumulating evidence suggests that exosomes derived from tumor cells play critical roles in modulating the tumor microenvironment (TME). Hypoxia is known to stimulate the secretion of exosomes from tumor cells, thereby promoting intercellular communication of hypoxic tumors with the surrounding stromal tissues. Exosome-mediated signaling pathways under hypoxic conditions have been reported to cause angiogenesis, invasion, metastasis, drug resistance, and immune escape. Recently, the programmed cell death ligand-1 (PD-L1) has been reported to reside as a transmembrane protein in tumor exosomes. Exosomal PD-L1 was shown to suppress T cell effector function in the TME and cause drug resistance to immune checkpoint therapy. This review provides an update about the pivotal role of tumor-derived exosomes in drug resistance to chemotherapy and immunotherapy, particularly under hypoxic conditions. Emerging strategies that target the exosomes in the hypoxic TME to enhance the antitumor efficacy are discussed.

INTRODUCTION

Hypoxia is a well-known hallmark of solid tumors when the tumor vasculature cannot provide adequate oxygen to support the aggressive growth of rapidly expanding tumors. Preclinical studies demonstrated that hypoxia mediates resistance to various modalities of cancer therapy, including chemotherapy, radiotherapy, and immunotherapy^[1,2]. Tumor hypoxia may also promote invasion and metastasis. Extensive evidence is also available from clinical investigations to suggest that highly hypoxic tumors are associated with treatment failure, increased incidence of distant metastases, and dismal disease-free and overall survival^[3].

Exosomes are a unique form of extracellular vesicles with endosomal origin and sizes ranging from 30 to 100 nm. They are secreted from diverse cell types upon the fusion of multivesicular bodies with the plasma membranes^[4]. Exosomes mediate intercellular crosstalk by transferring mRNAs, microRNAs (miRNAs), and proteins from donor to recipient cells^[5,6]. Cargoes loaded in exosomes are biologically active when taken up by the recipient cell, and they lead to various downstream functions^[7]. Tumor-derived exosomes have been shown to facilitate the intercellular transfer of pro-tumorigenic factors in the tumor microenvironment (TME)^[8,9]. They promote angiogenesis, invasion, and proliferation in recipient cells to support tumor growth and a pro-metastatic phenotype. In a recent proteome profiling study of exosomes derived from human primary and metastatic colorectal cancer cells, selective enrichment of metastatic factors and signaling pathway components was observed^[10]. In glioma, exosomes have been reported to convey signals between the tumor and TME to facilitate bidirectional communication^[11]. Hypoxia is known to stimulate the secretion of exosomes from tumor cells, thereby promoting cell-to-cell communication between the hypoxic tumors and the surrounding stromal tissues. Exosomal cargoes are also altered under hypoxic conditions to stimulate angiogenesis, invasion, metastasis, therapeutic resistance, and immune escape^[12].

In this article, we summarize the critical role played by hypoxic tumor-derived exosomes in tumor progression and resistance to cancer therapy. Novel approaches to target the exosomes in the hypoxic TME to potentiate the anticancer efficacy are discussed.

HYPOXIC TME

TME is a dynamic and complex system around a tumor, which is composed of blood vessels, fibroblasts, extracellular matrix fibers, immune cells, and signaling molecules, supporting proliferation, metastasis, and therapy resistance of tumor cells^[13]. The rapid proliferation of cancer cells and aberrant blood vessel formation create hypoxic conditions in malignant tumors. Hypoxia is considered a hallmark of TME, which is generally defined by a low oxygen tension of below 10 mmHg^[14]. It is also known to orchestrate the various malignant phenotypes of cancer cells by activating multiple oncogenic signaling pathways. At the molecular level, the hypoxic TME is largely regulated by the hypoxia-inducible factor (HIF) family of transcriptional factors^[15]. Accumulating evidence suggests that tumor-derived exosomes play a critical role in invigorating the interaction between cancerous and non-cancerous cells in the hypoxic TME to propel cancer progression^[16].

EFFECT OF HYPOXIA ON TUMOR-DERIVED EXOSOME

Induction of exosome release

TME-associated cells have been shown to secrete more exosomes than normal cells to promote intercellular communication and nutrient exchange^[17]. In the clinical setting, the number of circulating exosomes

collected from the blood of cancer patients was estimated to be more than two-fold higher than that of healthy subjects^[18]. Granulocytic myeloid-derived suppressor cells (G-MDSCs) in tumors were reported to produce more exosomes than those found in the spleen^[19]. Indeed, more secretion of exosomes from cancer cells has been reported in breast cancer^[20], colorectal cancer^[21], gastric cancer^[22], glioma^[23], hepatocellular carcinoma^[24], and pancreatic cancer^[25]. Interestingly and in contrast, hyperoxia (excessive oxygen tension) has been reported to reduce the number of exosomes released from colorectal cancer cells^[19]. It is noteworthy that the induction of exosome secretion in hypoxia may be universal because more exosomes were also released from non-cancerous cells (including bone, cardiac, and kidney cells) under hypoxic conditions^[26-28]. To date, the detailed mechanism leading to increased exosome release in hypoxia is still not clear. Nevertheless, two Rab GTPases (Rab27a and Rab27b) were shown to promote exosome secretion by facilitating the docking of the multivesicular bodies at the plasma membrane^[29], whereas Rab7 was reported to direct exosomes to lysosomes for degradation^[30]. In ovarian cancer cells, hypoxia was shown to upregulate Rab27a but downregulate Rab7 to promote exosome release^[31].

Increase in exosomal heterogeneity

Exosomes secreted from different cells contain different cargoes and markers. On the other hand, exosomes released from the same cell line can carry different constituents^[18]. While this heterogeneity is advantageous for exosome applications, it poses obstacles to a thorough understanding of exosome biology^[32,33]. Depending on the cell state, exosomes of different sizes and carrying different cargoes are secreted^[34]. To this end, exosomes secreted from glioma cells were shown to reflect the hypoxic status, and they mediate hypoxia-dependent activation of neovascularization during tumor development^[34]. The heterogeneous exosome population could have a different functional effect on the recipient cells^[35,36].

Production of smaller exosome

The size of exosomes released from mammalian cells is known to vary considerably in individual cells because of their unique exosome biogenesis process^[36]. Interestingly, it has been reported that exosome size is associated with different disease states. In non-small cell lung cancer (NSCLC) patients, a smaller exosome detected in the pulmonary vein is associated with a shorter time to relapse and shorter overall survival after curative surgery^[37]. It is generally believed that hypoxia tends to release smaller exosomes. Relatively smaller exosomes have been reported in different cancer cell lines, including colon^[21], pancreatic^[25], and prostate^[38] cancer cells. Under hypoxic conditions, it is believed that the supply of cellular materials for membrane synthesis may not meet the demand for exosome production, thus leading to the secretion of smaller exosomes^[12]. It is also hypothesized that smaller exosomes could be transmitted more easily via the blood circulation to metastatic sites to form the pre-metastatic niches because hypoxia changes the hemodynamics in the tumor vasculature^[12]. Moreover, smaller exosomes could be internalized faster and more efficiently than larger exosomes in the recipient cells^[39]. An ongoing prospective clinical trial (NCT02310451) is underway, which examines exosome size and various other parameters as potential biomarkers in melanoma patients.

Influence on exosomal cargo sorting

It is known that exosome content is not simply reflecting the cellular content of its origin. Some sorting mechanisms are in place to facilitate specific cargo sorting processes. Hypoxia has been shown to affect the sorting of the following three major cargoes (i.e., nucleic acids, proteins, and lipids) into exosomes.

Nucleic acids

The effect of hypoxia on the nucleic acid content in tumor-derived exosomes has recently been summarized in a few excellent reviews^[40,41]. It is noteworthy that only limited studies have reported the effect of hypoxia on cancer-derived exosomal DNA. On the other hand, the alteration and biological effects of non-coding

RNAs (ncRNAs) in tumor-secreted exosomes under hypoxia have been extensively studied. Representative examples are summarized in [Table 1](#). Various mechanisms have been proposed to regulate the expression of ncRNAs in hypoxia. For the HIF-dependent mechanism, the binding of HIF-1 α and/or HIF-2 α to the hypoxic response element (HRE) of the gene promoter of miR-155 has been reported^[42,43]. Moreover, miRNAs are differentially sorted into exosomes according to their specific sequence or motif^[44]. A few RNA binding proteins, such as SYNCRIP, were shown to direct specific miRNAs sharing a common extra-seed sequence hEXO motif for enrichment in the exosomes^[45]. Moreover, hypoxia also affects RNA alternative splicing^[46,47] and RNA editing^[48], which could make specific miRNAs more suitable for loading into tumor-derived exosomes. On the other hand, hypoxia was also reported to regulate a few facilitators which load nucleic acids into exosomes. The RNA binding proteins YBX1 and hnRNPA1 were reported to mediate the selective loading of miR-133 and miR-1246, respectively, into tumor-derived exosomes under hypoxia^[49,50].

Hypoxia has been shown to regulate the expression of several ncRNAs, which affect the expression of HIF-1 α and subsequently form positive or negative feedback loops to modulate the hypoxic TME^[51,52]. In hypoxic gastric cancer cells, such a positive feedback loop involving miR-301a-3p, PHD3, and HIF-1 α has been reported^[53]. miR-301a-3p was upregulated in hypoxic gastric cancer cells and the tumor-secreted exosomes^[53]. miR-301a-3p was subsequently shown to suppress the hydroxylase PHD3 and thus promote the protein stability of HIF-1 α to maintain the hypoxic response. In pancreatic cancer, the hypoxic induction of a HIF-1 α -stabilizing circular RNA (circZNF91) in cancer-secreted exosomes was reported to promote chemoresistance in normoxic cancer cells^[54]. Upon transmission to normoxic cells, circZNF91 was found to bind competitively to miR-23b-3p, subsequently abolishing the inhibition of miR-23b-3p on its target Sirtuin1 (SIRT1). The upregulated SIRT1 was shown to increase the deacetylation-dependent stability of HIF-1 α protein, thus promoting glycolysis and chemoresistance in the recipient normoxic cancer cells^[54].

Proteins

Similar to nucleic acids, proteins loaded into tumor-derived exosomes are not necessarily proportional to the cellular protein composition^[55]. However, the precise mechanism contributing to specific exosomal protein sorting remains obscure. It has been postulated that hypoxia could influence the protein loading process of tumor-derived exosomes by regulating ubiquitination. Ubiquitinated proteins are recognized by ubiquitin-binding domains within multivesicular endosomes for degradation, thus limiting the amount of membrane available for exosome formation^[56]. To this end, hypoxia is commonly known to control protein ubiquitination and ubiquitination-associated enzymes^[57].

Cell membrane glycoproteins are also known to participate in cell-to-cell and cell-environment communication^[58]. Interestingly, the expression profile of glycoproteins in tumor-derived exosomes is different from that of healthy cells^[59]. Moreover, glycoprotein expression could be affected by hypoxia^[60]. As glycans are known to regulate protein sorting and uptake into exosomes, hypoxic cells have been shown to take up more exosomes in a proteoglycan-dependent manner^[61].

Proteins secreted in tumor exosomes are also known to participate in hypoxia-associated responses. In breast cancer, metastasis-associated protein 1-loaded exosomes were reported to transfer in between cancer cells to regulate the response to hypoxia and estrogen signaling^[62]. Taken together, hypoxia promotes numerous malignant phenotypes of cancer cells by altering the exosome protein heterogeneity, whereas proteins in tumor-derived exosomes could contribute to the hypoxic response. [Table 2](#) summarizes the representative exosomal protein cargoes and other constituents that are preferentially secreted from hypoxic tumors to modulate the TME.

Table 1. Representative non-coding RNA cargoes secreted in hypoxic cancer cell-derived exosomes to modulate the tumor microenvironment

Non-coding RNA	Donor cell	Recipient cell	Biological function (mechanism)	Reference
let7a	Melanoma	Macrophage	Induce M2 polarization of TAM and promote oxidative phosphorylation to support cancer growth (downregulation of insulin-AKT-mTOR signaling)	[121]
linc-RoR	Hepatocellular carcinoma	Hepatocellular carcinoma	Promote cancer cell proliferation; mediate chemoresistance (induction of PDK1 and HIF-1 α protein expression by suppressing miR-145)	[78]
lncRNA UCA1	Bladder cancer	Bladder cancer	Promote cancer growth; stimulate migration and invasion (induction of EMT)	[95]
miR-10a	Glioma	MDSC	Activate MDSC (regulation of RORA/I κ B α /NF- κ B signaling)	[113]
miR-21	Glioma	MDSC	Activate MDSC (regulation of PTEN/PI3K/AKT signaling)	[113]
miR-23a	Lung cancer	Endothelial cells	Promote angiogenesis; increase vascular permeability (inhibition of the propyl hydroxylases PHD1 and PHD2, thereby stabilizing HIF-1 α protein; inhibition of the tight junction protein ZO-1)	[92]
miR-24-3p	Nasopharyngeal carcinoma	T cell	Inhibit T cell proliferation and differentiation (inhibition of FGF11; upregulation of p-ERK, p-STAT1, and p-STAT3)	[103]
miR-25-3p	Breast cancer	Breast cancer and macrophage	Promote cell proliferation and migration (stimulation of IL-6 secretion from macrophage via NF- κ B signaling)	[94]
miR-125b-5p	Ovarian cancer	Macrophage	Induce M2 polarization (regulation of SOCS4/5-STAT3 pathway)	[120]
miR-210	BMSC	Lung cancer	Promote metastasis (induction of STAT3 to mediate EMT)	[73]
miR-301a-3p	Pancreatic cancer	Macrophage	Induce M2 polarization (downregulation of PTEN and activation of PI3K/Akt signaling)	[118]
miR-5100	BMSC	Lung cancer	Promote metastasis (induction of STAT3 to mediate EMT)	[97]

BMSC: Bone marrow-derived stem cell; EMT: epithelial-mesenchymal transition; linc-RoR: long intergenic non-protein coding; RNA: regulation of reprogramming; lncRNA: long non-coding RNA; MDSC: myeloid-derived suppressor cells; TAM: tumor-associated macrophage.

Table 2. Exosomal protein cargoes and other constituents are preferentially secreted from hypoxic tumors to modulate the tumor microenvironment

Cancer type	Type of cargo	Biological function and mechanism	Reference
Colorectal cancer	Wnt4 protein	<ul style="list-style-type: none"> • Intercellular communication with normoxic cancer cells • Exosomal Wnt4 promoted the translocation of β-catenin to the nucleus in normoxic cells • Activation of β-catenin signaling enhanced cancer cell motility and invasion 	[137]

IL-8; Interleukin-8; LOX: protein lysine 6-oxidase; MMP: matrix metalloproteinase; PDGF: platelet-derived growth factor; TSP1: thrombospondin-1; VEGF: vascular epithelial growth factor.

Lipids

Various lipid components are important building blocks for exosome membranes. They include phosphatidylcholine, phosphatidylethanolamine, phosphatidylinositol, phosphatidylserine, phosphatidic acid, cholesterol, ceramide, sphingomyelin, and glycosphingolipids^[59]. They play critical roles in the biogenesis of exosomes. Sphingomyelin is hydrolyzed to ceramide, which promotes the budding of multivesicular bodies from the endosomes^[63]. On the other hand, ceramide is metabolized to sphingosine 1-phosphate, which interacts with the inhibitory G protein-coupled receptors to induce exosome biogenesis^[64]. Interestingly, knockdown of a key cholesterol lipid efflux transporter ABCG1 was found to inhibit cancer growth, concomitantly with the intracellular accumulation of exosomes and the exosomal cargo^[65]. Phosphatidylserine has been reported to play a critical role in facilitating the uptake of exosomes secreted from hypoxia-induced stem cells by human umbilical cord endothelial cells^[66]. Under hypoxic conditions, triglyceride was found to accumulate in prostate cancer cells and the secreted exosomes. Importantly, these exosomes were shown to promote cancer proliferation and invasion following reoxygenation^[67]. Hypoxia is known to upregulate ceramide expression, which is proposed to promote the exosome release^[68].

Effect on exosome uptake by recipient cells

Little is known about the effect of hypoxia on the intercellular transfer and uptake of tumor-derived exosomes from other components within the TME. A hypoxic environment is known to promote glycolysis and lactic acid production. Excess production of lactic acid results in acidic pH in the hypoxic TME. Given that an acidic environment is more suitable for the stability and isolation of exosomes^[69], the intracellular transport of exosomes may benefit from a hypoxic and acidic TME. It has also been proposed that the uptake of cancer-secreted exosomes by the recipient cells was found to be more efficient under hypoxia^[70]. The smaller exosomes secreted from hypoxic tumors, as described above, may facilitate the more efficient intercellular transfer. However, this hypothesis has not been verified by a detailed experimental investigation. On the other hand, hypoxic tumor cells are also known to take up more exosomes from the surroundings^[61]. Upon the recognition and binding of exosomes to recipient cells, the former is internalized by various processes, including endocytosis via clathrin, caveolae, or lipid raft-dependent manner. Under hypoxic conditions and the closely associated acidic cellular environment, exosome uptake could be promoted by lipid raft-dependent endocytosis^[61], caveolin-dependent endocytosis^[71], and phagocytosis^[72].

REGULATION OF TME BY HYPOXIC TUMOR-DERIVED EXOSOMES

As described in the previous section, hypoxia significantly alters the properties of exosomes secreted from cancer cells. Accumulating evidence indicates that the altered tumor exosomes are responsible for the reshaping of TME, thereby promoting cancer cell proliferation, chemoresistance, metastasis, and angiogenesis [Figure 1].

Promotion of cancer proliferation and chemoresistance by hypoxic tumor-derived exosomes

Within the hypoxic TME, cancer cells are known to secrete pro-tumorigenic molecules in the exosomes to promote cancer survival and proliferation. miR-210 is one of the most extensively studied hypoxia-induced miRNAs driving cancer progression^[73]. In breast cancer, the abundance of miR-210 was reported to be remarkably higher in the exosomes derived from hypoxic cancer cells than those from normoxic ones, which allows the cells to sustain survival under hypoxia^[74]. A set of differentially expressed exosomal miRNAs has been identified in the exosomes secreted from patient-derived melanoma cells under hypoxic culture conditions^[75]. Hypoxia was found to upregulate miR-494-5p, miR-4497, miR-513a-5p, and miR-6087 but downregulate miR-125b-5p, miR-21-5p, and miR-3934-5p in the exosome^[75]. Interestingly, the alteration of miRNAs was closely associated with cancer survival according to bioinformatics pathway analysis^[75]. Exosomes secreted by human glioma were also shown to promote the differentiation of neural stem cells into astrocytes^[76]. Transcripts related to cell proliferation and astrocyte differentiation were found

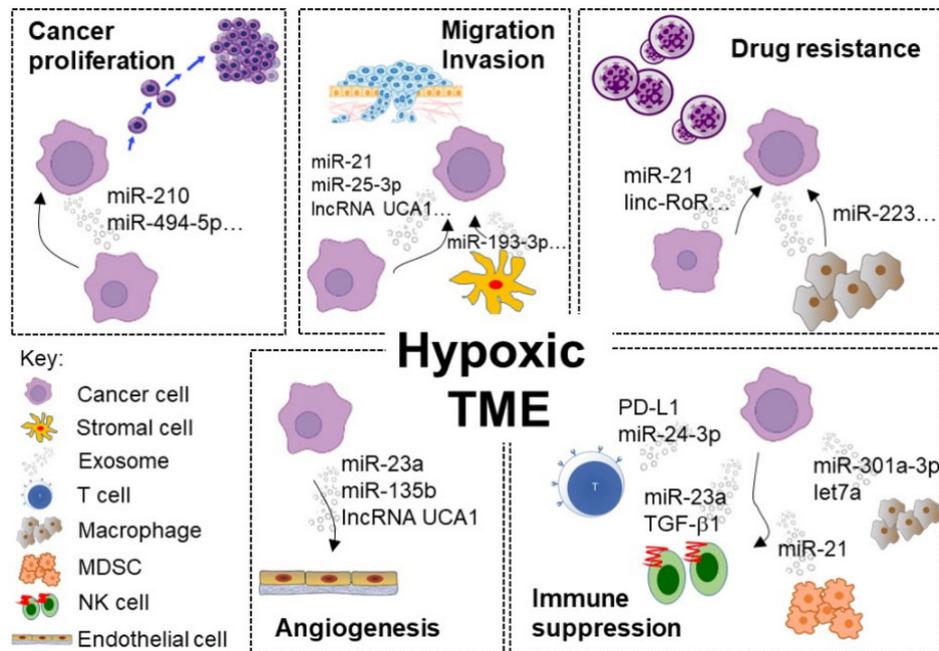

Figure 1. Representative examples of exosome-mediated intercellular communication within the hypoxic TME driving cancer progression, chemoresistance, and immune suppression. (1) Cancer proliferation: Hypoxic cancer-secreted exosomes were enriched with miRNAs supporting cell survival (e.g., miR-210) in the neighboring cancer cells. (2) Drug resistance: Numerous ncRNAs (e.g., linc-RoR and miR-21) were transferred via exosomes from hypoxic and resistant cancer cells to sensitive cells and induced drug resistance. (3) Migration and invasion: exosomes containing various ncRNAs (including lincRNA UCA1 and miR-193-3p) facilitate cancer-cancer or cancer-stromal intercellular communication to stimulate migration and invasion by modulating EMT. (4) Angiogenesis: ncRNAs (including miR-23a and lincRNA UCA1) were enriched in the exosomes secreted from hypoxic tumor cells to promote tumor vascular endothelial cell proliferation and angiogenesis in HIF-1 α -dependent or -independent pathway. (5) Immune suppression: Exosomes enriched with miRNAs (e.g., miR-23a and let-7a) and other immunosuppressive molecules (e.g., PD-L1 and TGF- β 1) were secreted from hypoxic tumors to promote an immunosuppressive TME. TME: Tumor microenvironment.

to be remarkably upregulated in human mesenchymal stem cells when co-cultured with glioma-secreted exosomes^[76]. Hypoxic tumor-secreted exosomes may represent an important therapeutic target that mediates the aggressiveness of glioma.

Hypoxia is known to mediate chemoresistance by regulating the cell cycle, autophagy, cell senescence, and drug efflux transporters. In recent years, the emerging role of hypoxic cancer cell-derived exosomes in reshaping the TME and causing chemoresistance is also revealed. In NSCLC, hypoxic cancer-derived exosomes have been shown to induce cisplatin resistance in normoxic cancer cells through the transmission of miR-21^[77]. The transfer of miR-21 from hypoxic cell-derived exosome to normoxic cancer cells was demonstrated to downregulate PTEN and the PI3K/Akt pathway, which subsequently induced cisplatin resistance^[77]. In hepatocellular carcinoma, the abundance of a stress-responsive lincRNA (linc-RoR) was significantly increased in hypoxic cancer-derived exosomes than in their normoxic counterpart^[78], which is associated with resistance to sorafenib and doxorubicin. Linc-RoR was shown to induce TGF- β , thereby suppressing chemotherapy-induced cell death but promoting tumor-initiating cell proliferation^[78]. Stromal cells, such as cancer-associated fibroblasts (CAFs) in the TME, could also mediate chemoresistance in cancer cells. miR-223 was upregulated in TAMs and TAM-derived exosomes under hypoxia^[79]. miR-223 loaded in hypoxic exosomes was shown to reduce apoptosis and induce drug resistance in ovarian cancer by downregulating PTEN and thus activating PI3K/Akt signaling^[79].

Moreover, exosomes have also been shown to mediate the transfer of the drug-resistant phenotype. Drug-sensitive cancer cells have been shown to become drug-resistant following the incorporation of exosomes shed from drug-resistant cancer cells^[80-84]. Moreover, exosomes were shown to be involved in the intercellular transfer of functional ABCB1 (P-gp) from multidrug-resistant donor cells to drug-sensitive recipient cells^[81,85-87]. Furthermore, exosomes have also been reported to mediate drug resistance by exporting specific drugs via the exosome pathway^[88] and neutralizing antibody-based chemotherapy^[89].

Induction of cancer angiogenesis by hypoxic tumor-derived exosomes

The induction of angiogenesis by hypoxia has been extensively studied^[90]. More recently, accumulating evidence demonstrates that hypoxic tumor-derived exosomes played a significant role in angiogenesis. In malignant glioblastoma multiforme, exosomes derived from cancer cells under hypoxia were shown to induce angiogenesis by stimulating cytokine and growth factor secretion from endothelial cells, subsequently promoting pericyte migration^[34]. In pancreatic cancer, the exosomal lncRNA UCA1 secreted from cancer cells under hypoxic conditions was shown to promote angiogenesis via a miR-96-5p/AMOTL2/ERK1/2 pathway^[91]. In lung cancer, miR-23a secreted in tumor-derived exosomes in hypoxia was reported to target the key HIF-1 α regulators (propyl hydroxylases PHD1 and PHD2), thereby sustaining the overexpression of HIF-1 α and promoting angiogenesis^[92]. Moreover, hypoxia-induced exosomal miR-23a was also shown to inhibit the tight junction protein ZO-1 and increase vascular permeability^[92]. It is noteworthy that most studies in this research area were conducted under acute hypoxic conditions. Umezu *et al.* were the first to report intercellular communication via exosome under chronic hypoxia^[93]. A few hypoxia-resistant multiple myeloma (MM) cell lines were developed after incubation in hypoxic conditions for more than six months to mimic the hypoxic bone marrow environment *in vivo*^[93]. Increased exosomal level of miR-135b was detected in these hypoxia-resistant MM cells, and it was shown to promote endothelial tube formation under hypoxia via the HIF-FIH signaling pathway^[93].

Promotion of cancer cell invasion and metastasis by hypoxic tumor-derived exosomes

Exosomal ncRNAs within the hypoxic TME are known to regulate tumor invasion and metastasis by modulating EMT. In breast cancer, higher expression of miR-25-3p in hypoxic cancer-derived exosomes was found to stimulate cancer proliferation and migration by inducing IL-6 secretion and activating NF- κ B signaling in macrophages^[94]. In bladder cancer, the lncRNA (UCA1) preferentially secreted by hypoxic cancer cells was shown to promote cancer growth by stimulating EMT both *in vitro* and *in vivo*^[95]. In oral squamous cell carcinoma, a higher level of miR-21 was detected in the exosomes from hypoxic cancer than those from normoxic cancer to promote migration and invasion by inducing EMT^[96]. The interaction between stromal and cancer cells via exosome within the TME plays a critical role in the initiation of metastasis. Lung cancer cells have been shown to take up exosomes secreted from hypoxic bone marrow-derived mesenchymal stem cells (BMSCs) and acquire a greater tendency for invasion^[97]. Three miRNAs (miR-193-3p, miR-210-3p, and miR-5100) showing a high abundance in hypoxic BMSC-derived exosomes were transferred to cancer cells and subsequently activated STAT3 signaling to induce EMT in the lung cancer cells^[97]. Interestingly, these three miRNAs were also found to be upregulated in plasma-derived exosomes from lung cancer patients with metastatic disease than in non-metastatic patients^[97].

Modulation of cancer immune system by hypoxic tumor-derived exosomes

Reduced immune surveillance is the major reason allowing primary tumors to develop metastasis in distant secondary organs^[98,99]. Tumor-secreted exosomes have been reported to induce T-cell apoptosis, inhibit interferon gamma-dependent expression of macrophages, suppress natural killer (NK) cell activity, and increase myeloid-derived suppressor cell (MSDCs) population, which collectively suppress immune surveillance and allow tumor growth^[100,101]. **Figure 2** illustrates the major mechanisms by which hypoxic tumor-derived exosomes promote an immunosuppressive TME.

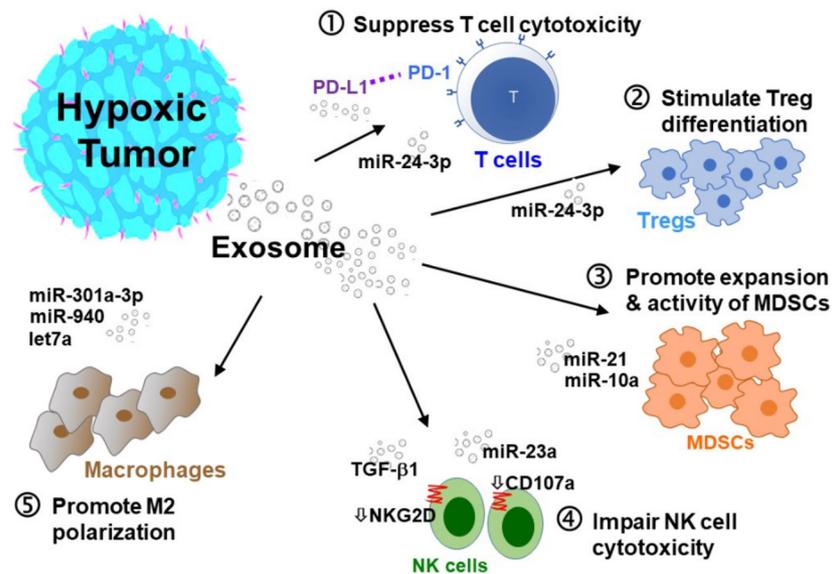

Figure 2. Hypoxic tumor-secreted exosomes promote an immunosuppressive TME. Hypoxic tumor-secreted exosomes promote an immunosuppressive TME by interfering with several intracellular pathways and modulating immune accessory cells, including cytotoxic T cells, T-regulatory cells (Tregs), myeloid-derived suppressor cells (MDSCs), natural killer cells (NK), and tumor-associated macrophages (TAMs). (1) Inhibition of T cell proliferation; (2) stimulation of Treg differentiation; (3) induction of MDSCs; (4) impairment of NK cells; and (5) stimulation of M2 polarization of TAMs.

Inhibition of T cell proliferation

Tumoral exosomes loaded with biologically active cargoes have been proposed to mediate the intercellular transmission of signals within the TME to promote immune escape and tumor progression. Ye *et al.* were the first to report a differential miRNA signature from nasopharyngeal carcinoma-derived exosomes to mediate T cell dysfunction^[102]. The induction of exosomal miR-24-3p in nasopharyngeal carcinoma-derived exosomes under hypoxia was found to inhibit T cell proliferation but promote differentiation of T-regulatory cells (Tregs) by targeting FGF11 via the upregulation of p-ERK, p-STAT1, and p-STAT3 and downregulation of p-STAT5^[103].

Immune checkpoint inhibitors including anti-programmed cell death receptor (PD-1) (nivolumab and pembrolizumab) or anti-PD-ligand (PD-L1) (duralumab, atezolizumab, and avelumab) monoclonal antibodies are revolutionizing cancer therapy. They lead to durable anticancer responses and overall survival benefits in a wide range of cancer types^[104]. PD-1 is an inhibitory receptor expressed on activated T cells, B cells, and natural killer cells, which blunt the immune response under physiological conditions. The T cell-mediated cancer-killing effect will be suppressed when PD-1 is occupied by its major ligand PD-L1 (expressed in tumor cells and infiltrating immune cells). Anti-PD-1/PD-L1 antibodies work by binding to the inhibitory PD-1 receptors on tumor-reactive T cells and PD-L1 on tumor cells, respectively, to disrupt the PD-1/PD-L1 interaction and reactivate the cytotoxic T cell activity.

Despite the breakthrough of anti-PD-1/PD-L1 immunotherapy, the response rate is low. Moreover, most patients who initially respond to immunotherapy will eventually relapse because of adaptive resistance. To maximize the full potential of anti-PD-1/PD-L1 immunotherapy, the mechanisms underlying these *de novo* and adaptive resistance mechanisms is a research area of intensive investigation. When T cells recognize the tumor antigen on the cancer surface, they release interferons to induce PD-L1 expression in cancer cells^[105]. The increased PD-L1 expression in cancer cells will then lead to specific inhibition of T cell recognition of cancer, subsequently resulting in a phenomenon known as adaptive immune resistance and inhibiting the

antitumor immune response. To this end, PD-L1 loaded in exosomes was shown to interact directly with T cells to suppress anticancer efficacy of chemotherapy in various cancer types, including breast^[106], gastric^[107] head and neck^[108], melanoma^[109], pancreatic^[110], and prostate^[111] cancer. It will be useful to elucidate whether hypoxia regulates the loading of PD-L1 into tumor-derived exosomes.

Induction of MDSCs

MDSCs are a heterogeneous population of immune cells from the myeloid lineage which migrate to tumor sites to create an immunosuppressive TME^[112]. MDSCs suppress adaptive and innate immunity by inhibiting T cell activation, promoting macrophage M2 polarization, inducing CAF differentiation, and inhibiting NK cell cytotoxicity. The abundance of MDSCs at tumor sites is known to correlate closely with poor clinical prognosis and reduce the efficacy of immunotherapy in cancer patients. In glioma, miR-21 and miR-10a secreted in tumor-derived exosomes under hypoxia have been reported to promote the expansion and activity of MDSCs *in vitro* and *in vivo* via the miR-21/PTEN/PI3K/AKT and miR-10a/RORA/IkBa/NF- κ B pathways, respectively^[113]. Therefore, novel strategies to modulate hypoxic tumor-secreted exosomes may be developed to regulate MDSCs and potentiate immunotherapy^[114]. To this end, miR-21 loaded in $\gamma\delta$ T cell-secreted exosomes has been shown to abate the function of MDSCs by targeting PTEN in a PD-L1-dependent manner^[115].

Impairment of natural killer cells

Hypoxia is also known to promote an immunosuppressive TME by attenuating cytotoxic T cell and Impairment of natural killer (NK) cell-mediated tumor cell lysis. Berchem *et al.* were the first to report the secretion of non-coding RNAs in exosomes from hypoxic lung cancer cells to impair NK cell cytotoxicity^[116]. Under hypoxic conditions, higher miR-23a expression was observed in lung cancer cell-derived exosomes, which impaired NK cell cytotoxicity by targeting CD107a^[116]. Moreover, the hypoxic tumor-derived exosomes were also shown to transfer TGF- β 1 to NK cells, thereby reducing the cell surface expression of the activating receptor NKG2D and inhibiting NK cell cytotoxicity^[116].

Stimulation of M2 polarization of tumor-associated macrophages

TAMs refer to the major tumor-infiltrating immune cells, which interact with the tumors and tumor-associated macrophages (TME) to regulate tumor immunity^[117]. Macrophage polarization is the process by which macrophages adopt distinct functional phenotypes in response to environmental stimuli and signals. M1 macrophages are functionally pro-inflammatory and antimicrobial, whereas M2 macrophages are anti-inflammatory. M1 and M2 macrophages exhibit a high degree of plasticity and are converted into each other upon changes within the TME or anticancer therapies. Under hypoxic pressure, tumor-derived exosomes have been shown to induce M2 polarization in various cancer types. In pancreatic cancer, miR-301a-3p was highly expressed in hypoxic cancer cell-derived exosomes, and it was shown to promote macrophage M2 polarization by activating PTEN/PI3K γ signaling pathway^[118]. Coculture of pancreatic cancer cells with the hypoxic cancer-derived exosomes or miR-301a-3p-upregulated macrophages was shown to facilitate the epithelial-mesenchymal transition and lung metastasis^[118]. In epithelial ovarian cancer (EOC), hypoxic tumor-derived exosomes were shown to express a high level of miR-940, and they stimulated M2 polarization of macrophages and promoted cancer proliferation and migration^[119]. A differential miRNA expression signature was also identified in the EOC-derived exosome under hypoxia to promote M2 polarization. miR-21-3p, miR-125b-5p, and miR-181d-5p were induced by HIF-1 α and HIF-2 α in the exosomes under hypoxic conditions, which regulate SOCS4/5-STAT3 signaling to stimulate M2 polarization and a malignant TME^[120]. In melanoma, let-7a was shown to be downregulated in hypoxic cancer cells but remarkably increased in the hypoxic cancer-derived exosomes^[121]. The exosomes carrying let-7a were found to promote a metabolic shift towards enhanced mitochondrial oxidative phosphorylation in macrophages by suppressing insulin-Akt-mTOR signaling to enhance cancer progression^[121].

SUMMARY

Rapidly expanding and hypoxic tumors exploit exosomes to communicate with both cancerous and non-cancerous cells in the TME to promote cancer survival and resist immune surveillance. Hypoxia has been shown to directly induce the production of exosomes, modulate the exosome cargo sorting process, and promote exosome uptake by recipient cells. Under low oxygen tension, cancer cells are primed to glycolytic metabolism, thus inducing an acidic TME to indirectly promote intracellular transport of the exosome. Numerous regulatory molecules are involved in the regulation of exosome biology under hypoxia. More studies are warranted to fully unravel the effect of hypoxia on exosome-mediated intercellular communication within the TME.

FUTURE PERSPECTIVES

Advances in precision oncology have led to the increasing application of tissue and liquid biopsy methods in clinical practice to facilitate treatment selection and monitoring of cancer progression. For the traditional method using tissue biopsy, limited tissue specimens are taken from the patients. They are not able to reflect the spatial and temporal heterogeneity of a primary tumor or between multiple potentially discordant metastatic lesions. In comparison with tumor tissue analysis, liquid biopsy is less invasive, and the samples can be obtained throughout disease progression. The liquid biopsy analytes include circulating tumor cells, circulating nucleic acids^[122], extracellular vesicles^[123], and other tumor-derived materials present in blood and other body fluids. Among various liquid biopsy analytes, exosomes are unique in the way that they contain not only DNA but also RNAs, ncRNAs, proteins, glycoconjugates, and lipids, thus making them more versatile biomarkers.

Currently, the exogenous hypoxic marker drug pimonidazole has been used to visualize hypoxic regions in histological sections of tumors in pathological research *in vivo*^[124]. However, the method is invasive and involves the surgical removal of tumors for imaging. Therefore, the application of tumor-derived exosomes from biological fluid to reveal the presence of hypoxic tumors will be beneficial. A few exosome biomarkers have been shown to reflect the hypoxic status of tumors as well as the stage of tumor progression. Exosomes derived from hypoxic glioma cells were enriched with hypoxia-related mRNA and proteins (including caveolin 1, IL-8, MMPs, and PDGF)^[34]. Importantly, patients presenting with high levels of these biomarkers were associated with worse survival^[34]. In rectal cancer patients, low levels of miR-486-5p and miR-181a-5p but high levels of miR-30d-5p in the exosomes harvested from plasma samples are associated with hypoxic tumors and poor prognosis^[125]. Indeed, exosomes have been used as diagnostic or prognostic tools for assessing hypoxic tumors in recent clinical trials [Table 3].

As hypoxic tumors produce exosomes to promote tumorigenesis, the inhibition of exosome formation and secretion may be exploited as a novel strategy to suppress tumor development. In an excellent recent review, He *et al.* summarized the strategies for exosomal targeting and discussed the potential clinical applications^[126]. Experimental reagents such as manumycin A and GW4869 were shown to inhibit exosome biogenesis and secretion from mammalian cells^[127]. On the other hand, the Rab family of GTPases involved in exosome secretion can also be targeted to hinder exosome-mediated intercellular communication. For example, Rab5a is involved in the early step of exosome biogenesis, whereas Rab11, Rab27a, and Rab35 regulate the fusion of multivesicular bodies with the plasma membrane and exosome secretion^[128]. Downregulation of Rab27a has been shown to inhibit exosome-dependent and -independent tumor cell growth^[128]. Specific inhibition of sphingomyelinase (an enzyme catalyzing the formation of ceramide from sphingomyelin) has also been shown to suppress exosome biogenesis and cargo loading, thereby retarding tumor growth^[63].

Table 3. Representative clinical trials exploiting exosome biomarkers to assess hypoxic tumors

Cancer type	ClinicalTrials.gov Identifier	Aim(s) relevant to exosome biology	Current status
Lung cancer	NCT04629079 (LungExoDETECT)	<ul style="list-style-type: none"> To validate exosomal assays that are based on hypoxia detection as potential biomarkers for early detection Compare exosomal analysis with the standard of care imaging 	Recruiting; Started in October 2020
Lung cancer	NCT04529915	<ul style="list-style-type: none"> Multicenter clinical research for early diagnosis of lung cancer using exosomes derived from blood plasma 	Active; Not recruiting; Started in April 2020
Colorectal cancer	NCT04394572 (EXOSCOL01)	<ul style="list-style-type: none"> To identify new diagnostic protein markers (e.g., integrins and metalloproteases) for colorectal cancer in circulating tumor exosomes 	Recruiting; Started in January 2021
Clear cell renal carcinoma	NCT04053855	<ul style="list-style-type: none"> To analyze urinary exosomes as a liquid biopsy tool for early diagnosis of clear cell renal cell carcinoma 	Recruiting; Started in August 2019
Ovarian cancer	NCT03738319 (EOC-EXOSOME)	<ul style="list-style-type: none"> To analyze the expression of miRNA and lncRNA from exosomes in blood samples by next-generation sequencing in patients with high grade serous ovarian cancer or benign gynecologic diseases 	Recruiting; Started in November 2018
Melanoma	NCT02310451	<ul style="list-style-type: none"> Pilot study to examine exosomes collected from the blood before and after BRAF inhibitor therapy in patients with advanced unresectable or metastatic BRAF mutation-positive melanoma To develop an exosome-based theranostic tool for personalized care in melanoma patients 	Recruiting; Started in 2016

miRNA: MicroRNA; lncRNA: long non-coding RNA.

The removal of oncogenic exosomes has been investigated as a novel therapeutic strategy for cancer therapy^[129]. Mesoporous silica nanoparticles loaded with EGFR-targeting aptamers have been used to mop up circulating cancer-secreted EGFR+ exosomes, thus preventing their entry into the small intestine to suppress metastasis of lung cancer cells^[129]. On the other hand, exosomes from immune cells were shown to exhibit anticancer activity^[17]. Recently, Jiang *et al.* reported the induction of exosome production from NK cells under hypoxia^[130]. More importantly, compared to normoxic conditions, NK cell-derived exosomes were found to express remarkably higher levels of FasL, perforin, and granzyme B in hypoxia to produce a higher NK cell cytotoxic effect^[130]. Therefore, hypoxia-treated NK cells may be used to potentiate cancer immunotherapy.

Exosomes may also be employed as a drug delivery system for cancer therapy. Drugs or therapeutic siRNAs could be loaded into exosomes by various methods such as direct incubation, electroporation, and sonication^[131]. Zhuang *et al.* reported the encapsulation of curcumin or an investigational STAT3 inhibitor (JSI124) in cancer cell-derived exosomes by incubating the exosomes with the drugs^[132]. The drug-loaded exosomes were delivered to the brain for the treatment of inflammation via an intranasal route^[132]. Besides, therapeutic siRNAs could also be loaded into the hydrophilic core of exosomes in the pharmaceutically active form^[133,134]. Recently, Alvarez-Erviti *et al.* reported the successful delivery of siRNAs to the mouse brain using dendritic cell-derived exosomes^[135]. Alternatively, the anticancer drug paclitaxel has been loaded indirectly into exosomes secreted from gingival mesenchymal stromal cells (MSCs) after co-culturing them with the drug^[136]. Importantly, the exosomes derived from MSCs after priming with paclitaxel were shown to exhibit significant anticancer activity against human pancreatic cancer cells *in vitro*^[136]. Interestingly, in a recent study examining anticancer drug delivery by exosomes, exosomes from hypoxic human breast cancer cells loaded with olaparib (a PARP inhibitor) were found to exhibit a superior uptake rate when they were co-cultured with hypoxic cancer cells^[20]. A more detailed investigation of exosome loading and production under hypoxic conditions is advocated to further optimize exosome-mediated drug delivery.

DECLARATIONS

Acknowledgments

We acknowledge the researchers who have contributed to the understanding of tumor microenvironment regulation by cancer-derived exosomes in hypoxia and whose works have not been cited here because of space limitations.

Abstract

Aim: Cutaneous squamous cell carcinoma (cSCC) is a common disease in patients exposed to UV-light and human papillomavirus. Electrochemotherapy, a well-established treatment modality with minimum side effects in human and veterinary medicine, circumvents chemoresistance to bleomycin by the use of electric fields. However, patients are sensitive to the trauma produced by the insertion of the needles that lengthen recovery times, particularly cats with nasal planum cSCC. To address this matter, we developed thin-needles electrodes.

Methods: Thin-needles electrodes developed using computer simulations and plant tissue models were compared to standard electrodes. A prospective non-randomized study recruiting 52 feline patients with nasal planum cSCC was performed. Local response, anorexia, and overall survival were evaluated.

© The Author(s) 2022. **Open Access** This article is licensed under a Creative Commons Attribution 4.0 International License (<https://creativecommons.org/licenses/by/4.0/>), which permits unrestricted use, sharing, adaptation, distribution and reproduction in any medium or format, for any purpose, even commercially, as long as you give appropriate credit to the original author(s) and the source, provide a link to the Creative Commons license, and indicate if changes were made.

Results: Computer simulations and plant model experiments showed satisfactory results with both electrodes. The patients treated with the thin-needle electrode obtained similar local response rates compared to the standard group, OR 97.3% vs. 80%, respectively ($P < 0.067$). Most patients in the thin-needle group resumed eating in less than 48 h, as the anorexia was significantly lower ($P < 0.0001$). Using the standard electrode, most patients took 3 to 5 days to resume normal feeding. The electric current circulating in the standard electrode was 44% higher, contributing to a longer duration of anorexia due to tissue damage. The overall survival in both groups was similar.

Conclusion: Electrochemotherapy using thin-needle electrodes provides equivalent local response rates and overall survival compared with standard electrodes but significantly reduced return to appetite after the treatment. These results may be useful in the development of new electrodes for human patients.

INTRODUCTION

Cutaneous squamous cell carcinoma (cSCC) is a malignant neoplasm of keratinocytes of the skin. It is one of the most common malignancies diagnosed in humans. Older people are at an increased risk, with a ten-fold increase in patients above 70 years. People with light skin color, light-colored eyes, and light hair, who are predisposed to sunburn, are at an increased risk. In this context, UV light exposure acts as a tumor-initiating and tumor-promoting factor by inducing the formation of actinic keratosis, a precursor lesion of cSCC. The mutation of both *p53* genes is an early event in carcinogenesis, and it is the most common mutation found, but not the only one^[1]. An association between human papillomavirus (HPV) and cSCC has been reported^[2].

The similarities between human cSCC and feline cSCC are remarkable. In cats, this tumor mostly occurs in areas exposed to UV light. Particularly, areas without fur, such as the nasal planum, the pinnae, and the eyelids, are at greater risk. As the damage to the skin is cumulative, the cancer mainly affects cats older than 10 years, which according to their lifespan, is equivalent to humans around 70 years of age. Typically, a history of chronic solar exposure is present, where actinic changes lead to carcinoma *in situ* (noninvasive carcinoma confined to the epidermis, similar to the actinic keratosis in human patients), which progresses to invasive carcinoma. White-haired cats have an increased risk of developing cSCC than other hair colors as they lack the protection of melanin. More than half of the cats with nasal planum cSCC have mutations of the tumor-suppressor gene *p53*, indicating that a genetic predisposing factor may have an important role in the development of the disease^[3-5]. Interestingly, HPV has been isolated from cSCC in cats, supporting that it can contribute in the same way to the disease development^[6]. Resistance to chemotherapy and failure of combined treatments (radiotherapy plus chemotherapy) is a concern, which leads to a poor prognosis among affected patients^[7-12]. Due to the similarities between the cSCC of cats and humans, cats provide a very good translational model for improving or developing new treatment approaches^[13,14].

Diagnosis

Physical examination, including evaluation of mandibular lymph nodes, is standard. The definitive diagnosis is made with histopathology. For complete staging, the presence of metastasis in the nodes should be assessed with cytology or biopsy. Full biochemical panels, three-view thoracic radiographs, and complete blood cell counts are advised before treatment^[15].

Treatment options

The preferred treatment for cSCC is surgery when possible and accepted by the owner. Wide surgical resection provides long-term control of the disease in most situations^[16]. Another effective treatment option

is radiotherapy (RT), which provides good results with mild self-limiting side effects for patients at the initial stages of the disease^[17]. RT may also be combined with surgery to improve treatment outcomes, even with incomplete resections^[18]. When the lesion is small, up to 0.5 cm in diameter, cryosurgery is a treatment option that may be used successfully. However, many sessions may be required for adequate control of the disease^[19]. Similarly, photodynamic therapy (PDT) is another emerging treatment option. In one study, 90% of the treated lesions achieved a complete response, but 60% of them relapsed. As with cryotherapy, PDT may require many sessions, and it is most suitable for superficial lesions^[20].

There is limited evidence of the use of chemotherapy for this disease. The use of carboplatin with sterile sesame oil injected into the nasal planum showed modest results, with a complete response rate of 73% and 55% progression-free survival at one year^[21]. The exposure of the medical staff to chemotherapy during treatment is no longer acceptable in the interest of safety, and for that reason, safety measures for handling chemotherapy are mandatory. Among effective chemotherapeutic drugs for treating cSCC, bleomycin is a good choice. Bleomycin, an antibiotic with anticancer properties, was discovered by Umezawa, who published its anticancer effects in 1966. He described its curative effect on skin cancer in dogs. The dog and mouse were the first translational models for this drug^[22]. One of the first uses of bleomycin in human patients was in the treatment of cSCC, where the minimum effective dose was 12 cycles of 6,000 IU/m². Considering the average body surface area for a human patient is around 2 m², a total dose of 144,000 IU was used. The treatment could be continued after the 12th dose if good results were observed^[23]. Other studies report using doses twice as high, achieving good local responses in cSCC, but with significant pulmonary and skin complications^[24]. Bleomycin is non-permeant to the cell membrane, and to be internalized, it has to interact with specific membrane proteins^[25,26]. The sensitivity of tumors to bleomycin depends on the presence of these proteins in the cell membrane, as well as the concentration of an enzyme called bleomycin hydrolase capable of degrading it^[26]. Typically, the skin and lungs have very low concentrations of this enzyme, explaining their sensitivity to it^[27]. The drug was approved by the FDA in 1975 for the treatment of cSCC^[28]; however, its use steadily declined over the years due to its serious side effects when cumulative doses were high. Today, bleomycin is still used in combination with other agents for the palliative treatment of cSCC in human patients, with a cumulative dose capped at 400,000 IU^[29]. In this context, with the discovery of electrochemotherapy by Mir *et al.* in 1997, the resistance mechanisms were overcome and the drug could once again be used with greatly reduced doses, increasing its effectiveness and reducing its side effects^[26,30].

Electrochemotherapy

Electrochemotherapy (ECT) is a well-established treatment modality in veterinary medicine for treating cutaneous, subcutaneous, and mucosal tumors^[31-34]. An aspect of ECT that sometimes is difficult to understand is how a tumor previously resistant to bleomycin can become exquisitely sensitive to it, even to the point of drastically reducing doses and still obtaining very good results.

Electroporation, depending on pulse parameters, can be irreversible, where the cells affected by the electric field die by necrosis, or reversible, where the affected cells are spared. When an electroporation-based treatment is performed, there is always an extent of reversible and irreversible electroporation coexisting^[35].

In reversible electroporation, cell membrane permeabilization is transient, permitting the introduction of certain molecules into the cytosol, such as bleomycin^[35]. The combination of reversible electroporation with bleomycin or cisplatin is termed ECT. Once inside the cell, bleomycin cuts DNA strands and impedes mitosis of cells inducing mitotic cell death. The treatment displays selectivity towards dividing cells, sparing quiescent ones. Then, normal cells have time to proliferate and repair tissue defects, allowing excellent

cosmetic results. For these reasons, ECT provides very good local response rates with minimum side effects^[36].

ECT may be used independently or in combination with surgery, especially when the surgery cannot provide clean margins. ECT may be used as a neoadjuvant, adjuvant, or concomitant therapy^[37-40]. Some authors have reported an objective response rate of 97.3% when treating feline patients with nasal planum cSCC with minimum side effects^[41]. ECT may also be used in combination with chemotherapy, RT, or cryosurgery for selected cases^[40]. In the Discussion Section, we present our recommendations for performing ECT alone or combined with other therapies for treating cSCC in cats.

As mentioned above, it is reported in the literature that ECT has minor and self-limited side effects, along with very good clinical responses^[42]. However, when treating the nasal planum in feline patients, we observed increased sensitivity to the trauma produced by the insertion of the needles. The lesions produced lead to subsequent anorexia that sometimes requires supportive treatment^[43,44]. To evaluate a role for less trauma, our group developed two electrodes: (1) the first, labeled standard, is very similar to commonly used electrodes in standard ECT; and (2) a thin-needle electrode with needles of a reduced diameter. We evaluated electric field distribution and electroporated area to determine if the new design (2) would provide an adequate electric field distribution. A poorly designed electrode can lead to local recurrence since the tumor can be left insufficiently treated^[45]. In the patients, we evaluated response rates, the severity of anorexia, and overall survival times to determine if the new electrode would improve the effectiveness of the treatment and the post-procedure anorexia.

METHODS

Two electrodes were used in this study: (1) the standard electrode, composed of four 20 G needles arranged in two rows, 4 mm apart; and (2) the thin-needle electrode with the same geometry but with four 25 G needles. Both electrodes use disposable needles [Figure 1A]. The configuration of the electroporator was the same for both types of electrodes [Figure 1B].

To assess the electric field distribution, both electrodes were simulated in COMSOL Multiphysics 4.3, applying a voltage-to-distance ratio of 1000 V/cm, according to the updated standard operating procedures for ECT^[46].

Electrical resistance from tumors was measured using the standard electrode and used in the COMSOL model. Afterward, the design of the electrodes was validated in a simple plant model^[47]. With the final design, the two electrodes were fabricated, and the selected patients were treated [Figure 1C and D].

Patient selection and group allocation

Fifty-two feline patients were selected for treatment based on confirmed histopathology and nasal planum location. Cats were randomly assigned to one of the experimental groups [standard needles (1) or thin-needle group (2)] in an alternating pattern. When 15 cats were placed in the standard group (1), we added the remaining cats only to the thin-needle group (2). A full physical examination was performed, along with complete blood work (CBC, chemistry, and UA) to assess the status of the patient and the anesthetic risk. The patients were staged following the WHO criteria^[48] [Table 1]. In addition, feline immunodeficiency virus (FIV) was tested in all the patients and correlated with the results.

Follow-up

Follow-up visits were scheduled every two weeks until the final response was obtained (a complete response

Table 1. Staging system for feline cSCC (WHO criteria)^[48]

Grade	Description
T0	No evidence of tumor
Tis	Tumor <i>in situ</i>
T1	Tumor < 2 cm in diameter
T2	Tumor 2-5 cm diameter or minimally invasive
T3	Tumor > 5 cm diameter or with the invasion of subcutis
T4	Tumor invading other structures such as the fascia, muscle, or bone
N0	Absence of lymph node metastasis
N1	Presence of lymph node metastasis
M0	Absence of distant metastasis
M1	Presence of distant metastasis

As all patients were NOM0, the stages were defined as: Stage I = T1, Stage II = T2, Stage III = T3, and Stage IV = T4.

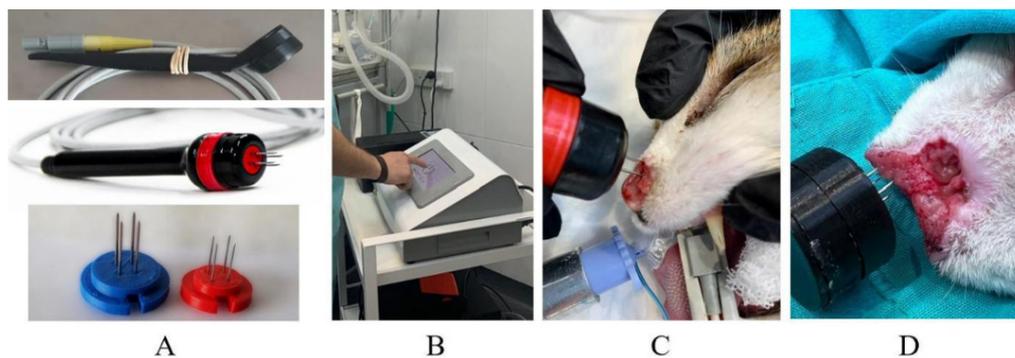

Figure 1. Images showing the electrodes and the electrochemotherapy procedure. (A) (top) the standard electrode; (middle) the thin-needle electrode; and (bottom) the disposables 20 G (left) and 25 G (right). (B) The operator is configuring the electroporator. (C) A patient is treated with the thin-needle electrode. (D) A patient is treated with the standard electrode.

or a lesion stable in size which was not growing back again) and monthly thereafter. We evaluated local response using modified RECIST 1.1 criteria for solid tumors^[49].

Complete response (CR) was defined as complete eradication of the treated tumor with re-epithelialization of skin.

Partial response (PR) was defined as a decrease of > 30% in the sum of the diameters of measurable lesions.

Stable Disease (SD) was defined as a reduction of < 30% or an increase of < 20% of the above-mentioned measurements.

Progressive disease (PD) was defined by an increase of > 20% of the above-mentioned measurements. Responses were confirmed one month after they were achieved.

Anorexia after the procedure was evaluated following the criteria of LeBlanc *et al.*^[50], where anorexia is defined as “a disorder characterized by a loss of appetite/decreased interest in food”. Table 2 presents the classification of anorexia.

Table 2. Grading of anorexia extracted from LeBlanc et al.^[50]

Grade	Description
1	Complete anorexia lasting < 48 h
2	Complete anorexia lasting 2-3 days
3	Anorexia lasting 3-5 days; associated with significant weight loss ($\geq 10\%$) or malnutrition; IV fluids, tube feeding, or force-feeding indicated
4	Life-threatening consequences; total parenteral nutrition indicated; complete anorexia lasting > 5 days
5	Death

The electric current that circulates during each pulse is shown on the screen of the electroporator. This allows us to monitor the treatment and seek a relation to the side effects.

Anesthetic procedure

Patients were treated under general anesthesia using intramuscular administration of xylazine (Xylazine 100[®], Richmond, Buenos Aires, Argentina) 0.5 mg/kg and tramadol (Tramadol[®], John Martin, Buenos Aires, Argentina) 2 mg/kg. Induction was performed with intravenous administration of propofol (Propofol Gemepe[®], Gemepe, Buenos Aires, Argentina) 2-3 mg/kg. For maintenance, isoflurane (Zuflax[®], Richmond, Buenos Aires, Argentina) 2%-3% and intravenous fentanyl (Fentanyl Gemepe[®], Gemepe, Buenos Aires, Argentina) 2 μ g/kg were used. Amoxicillin with clavulanic acid (Clavamox[®] Zoetis, Buenos Aires, Argentina) 15 mg/kg/bid and meloxicam (Meloxivet[®], John Martin, Buenos Aires, Argentina) 0.2 mg/kg/sid were administered orally for prophylaxis and analgesia after the treatment according to the needs of each patient.

Electrochemotherapy procedure

Intravenous bleomycin was administered at 15,000 UI/m² body surface area. After 5-8 min, to allow drug distribution, the electric pulses were delivered^[46] with a monopolar square-wave electroporator (EPV-200, BIOTEX SRL, Buenos Aires, Argentina). The pulse trains applied with both electrodes were eight 100 μ s long pulses of 400 V (1000 V/cm) at a repetition frequency of 5 kHz^[46].

Statistical analysis

Statistical analysis was made using MedCalc 14.8.1. To compare age, sex, and body weight, the independent samples t-test and ANOVA, respectively, were used. To compare the anorexia score, the Mann-Whitney test was used. The comparison of the response rates obtained utilized the Fisher's exact test. For survival comparison, Kaplan-Meier curves of survival were used, and the significance was assessed with the Log-Rank test.

RESULTS

COMSOL simulations showed that the electric field was distributed between the needles in both electrodes, which was above 480 V/cm. This electric field intensity was enough for reversibly permeabilizing the tissues. In addition, the area above 1050 V/cm was studied, which is the threshold for irreversible electroporation^[51]. To obtain the best results, the area of reversible electroporation should be maximized (or at least cover the whole area between needles) and the area of irreversible electroporation should be kept to a minimum. This exploits the benefits of ECT, as irreversible electroporation damages the tissue without selectivity and produces necrosis that should be avoided^[52]. As shown in [Figure 2A](#) and [B](#), the area of reversible electroporation was adequate on both electrodes. However, the area of irreversible electroporation was larger in the standard electrode, thus contributing to the differences in trauma within this treatment group. The plant models correlated with the simulations [[Figure 2C](#) and [D](#)].

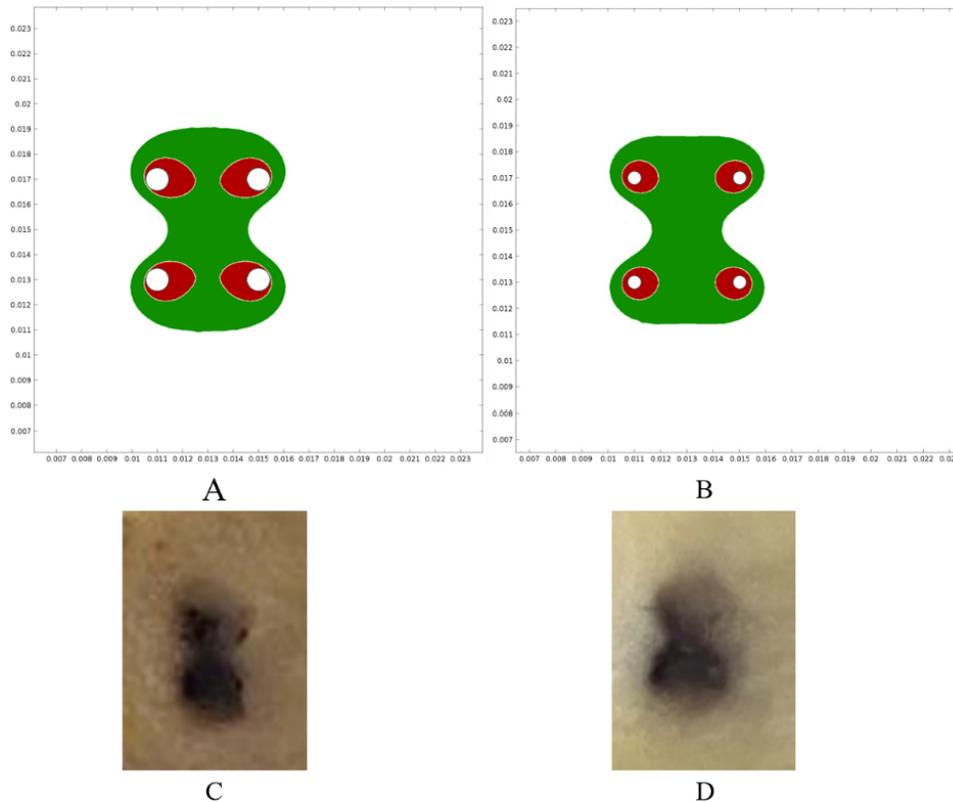

Figure 2. Electric field simulations and vegetable experiments. (A) Reversible and irreversible areas of permeabilization in the standard electrode. (B) The same areas in the thin-needle electrode. Green indicates the electric field was above the reversible electroporation threshold (480 V/cm) and below the irreversible electroporation threshold (1050 V/cm). Red indicates the area where the field was above the irreversible threshold (1050 V/cm). These areas were obtained using COMSOL simulations of the electric field distribution. As can be seen, in both electrodes, the region between needles is covered by reversible electroporation, but the standard electrode presents larger areas of irreversible electroporation. (C,D) The electroporated plant tissue showed an electroporated area very similar to the simulations: (C) the standard electrode (1) was used, and (D) the thin-needle electrode (2) was used.

The composition of the experimental groups is shown in [Table 3](#). There were no statistically significant differences among groups regarding age (ANOVA, $P = 0.601$), sex (independent samples t -test, $P = 0.768$), or body weight (ANOVA, $P = 0.185$).

During follow-up, if a relapse was observed, i.e., the growth of a previously shrinking lesion, the patient was scheduled for a new treatment session. The average number of treatment sessions for the standard group (1) was 1.7 (median 2, range 1-5) and for the thin-needle group (2) was also 1.7 (median 2, range 1-3).

The response rate obtained in the standard group (1) was as follows: 40%CR, 40%PR, 13%SD, and no PD. The OR rate was 80%. For the thin-needle group (2), the results were 70.3%CR, 27%PR, 2.7%SD, and no PD. The OR rate was 97.3% [[Figure 3](#)]. There were no statistically significant differences between the responses obtained in the groups (Fisher's exact test, $P = 0.067$). The cosmetic results were very good. In some cases, small scars developed not because of the treatment but because the tumor had already invaded and damaged the tissues, and thus a second intention healing with a scar is seen after the tumor responded to the treatment [[Figure 4](#)].

Table 3. Composition of the experimental groups. The details of both experimental groups are presented. The differences in sex (independent samples t-test, $P = 0.768$), age (ANOVA, $P = 0.601$), and body weight (ANOVA, $P = 0.185$) were not significant between groups

	Standard	Thin-needle
n	15	37
males/females ($P = 0.768$)	7/8	16/21
FIV+	7	6
Average age [years] ($P = 0.601$)	11.3	11.1
Average body weight [kg] ($P = 0.185$)	4.78	3.92
Stage I	26.7%	43.2%
Stage II	26.7%	40.5%
Stage III	20.0%	13.5%
Stage IV	26.7%	2.7%

Response composition in each group

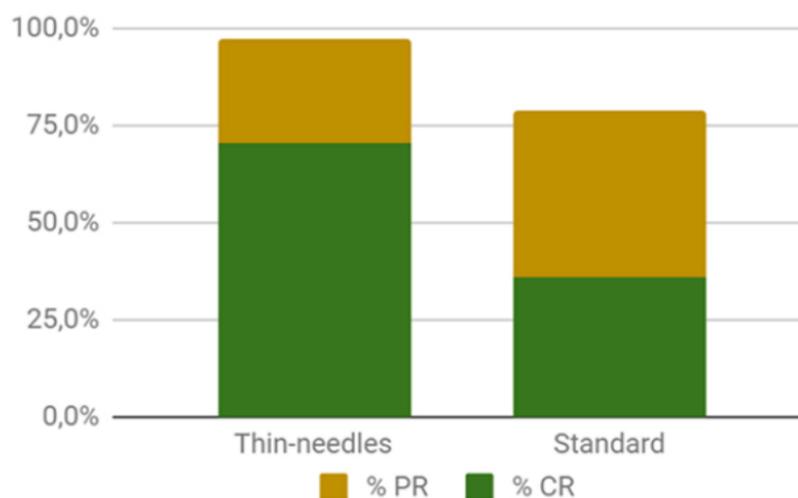

Figure 3. Composition of the objective response rates in each group (97.3% and 80% for the thin-needles and standard group, respectively). The differences between groups are not significant.

The anorexia score of the standard group (1) was, on average, 3.1 (median 3, range 1-5) and for the thin-needle electrode group (2) was 1.3 (median 1, range 1-3), the difference is statistically significant ($P < 0.0001$). These results show that thin needles significantly reduced post-treatment anorexia in the patients. Subjectively, the area treated looked much less inflamed after the treatment using the thin-needle electrode when compared with the standard electrode. No systemic toxicity was observed in either of the groups.

Measurements of the average electric current that circulated during the delivery of the pulses were 2.73 A in the standard group (1) and 1.89 A in the thin-needle group (2). This may be attributed to the larger surface contact with the standard needles. Approximately 44% more electric current circulated with each pulse when the standard electrode was used. The circulating electric current induces electrolysis of water molecules producing extreme pH changes in the region of the electrodes^[53,54]. Even though they are transient, these changes can contribute to tissue damage and inflammation, and they may play a role in

Figure 4. Feline patient with cSCC in the nasal planum treated with ECT using the thin-needle electrode: (left) before the treatment; and (right) 51 days after the treatment. The patient obtained CR. As can be seen, minimum tissue scarring is present where the tumor was located.

worsening anorexia after the treatment.

FIV+ patients showed more PR than CR when compared with the FIV- patients. This makes sense considering that ECT relies mainly on the immune system to produce a clinical response^[31]. However, a specific study is needed to validate this observation.

The median overall survival for the patients in the thin-needle group (2) was 611 days (ranging from 170-1003 days), and for the standard electrode (1) was 520 days (ranging from 23-840 days) [Figure 5]. The differences were not statistically significant, supporting that using thin needles does not reduce the survival probability of the patients (Log-Rank test, $P = 0.019$). At the end of the study, 54% (20/37) of the patients in the thin-needle electrode group (2) remained alive, while 20% (3/15) were alive in the standard electrode group (1).

The Kaplan–Meier curves of survival by stage are shown in Figure 6A, where the differences between stages I and II as well as between III and IV were not statistically significant (Log-Rank test, $P = 0.179$ and $P = 0.113$, respectively). If we group stages I and II as early stages and III and IV as late stages, survival was significantly better at earlier stages (Log-Rank test, $P < 0.0001$), as shown in Figure 6B. This result was expected and is concurrent with the experience of other authors who have used ECT^[42,43].

DISCUSSION

Companion animals are increasingly accepted models of human disease^[55]. In oncology, translation from murine models only leads to approved drugs for human use in 11% of the cases^[56], leading to the expenditure of billions of dollars^[57]. The situation for companion animals as models is very different from murine models because of their unique characteristics. Companion animals work as sentinels for human diseases, due to their exposure to similar environmental hazards as their owners^[58]. For example, the cSCC described in this work has the same risk factors and behavior as its human counterpart^[59], with tumors developing in the context of complex tumor–stroma interactions^[60] and in the presence of an intact immune system^[61]. Both characteristics are very important for tumor resistance to different therapies present in human patients. In addition, the size of the animals allows multiple tissue sampling, and the same

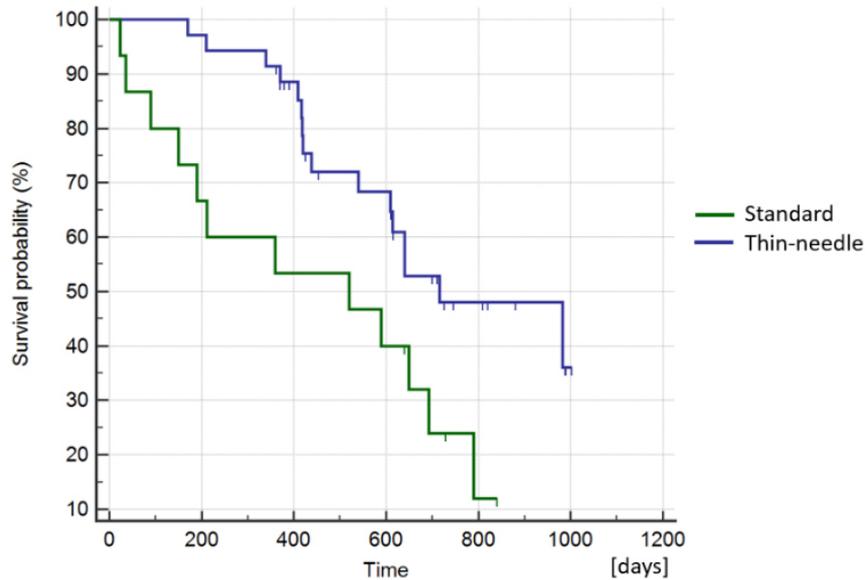

Figure 5. Kaplan-Meier curves of survival comparing the standard group vs. the thin-needle group. The curves show no statistically significant difference, meaning that the use of thin needles does not affect the long-term response (Log-Rank test, $P = 0.019$).

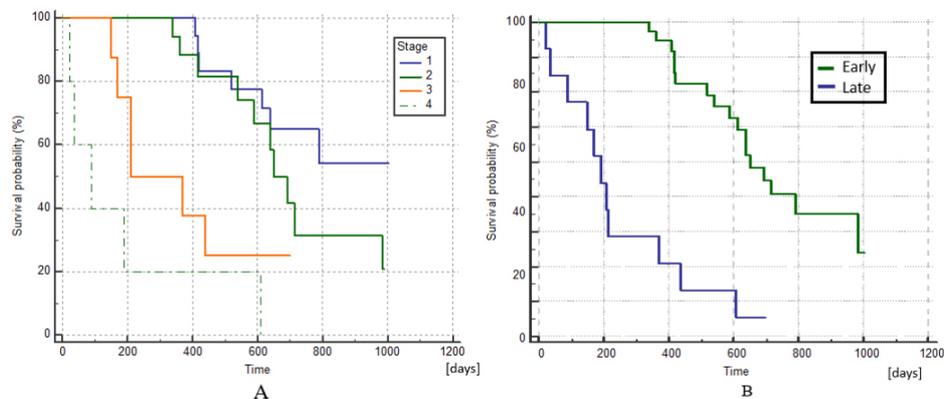

Figure 6. Kaplan-Meier curves of survival comparing patients at different stages of the disease. (A) There are no statistically significant differences in survival between stages I and II or between III and IV (Log-Rank test, $P = 0.179$ and $P = 0.113$, respectively). (B) Kaplan-Meier curves of survival comparing patients at early stages (I + II) with late stages (III + IV), which are significantly different (Log-Rank test, $P < 0.0001$).

procedures for diagnosis and treatment are used, making the translation more efficient. The lifespan of companion animals is short; thus, clinical trials can provide results in a reduced timeframe^[55]. Another interesting point is that owners provide very valuable information regarding their pets because they know them and can perceive changes in appetite, mood, or behavior. Finally, from the ethical viewpoint, the animals used in the studies already have the disease, and if the treatment under investigation works, there is a benefit for the patient and the owner.

ECT is a very valuable therapy in our setting, in both human and veterinary medicine. In the case of tumors of the nasal planum in cats, we use the following approach for ECT. (1) As stand alone therapy is used when the tumor can be completely treated in one treatment session. This means a tumor around 3 cm³, with an invasion depth of less than 2.5 cm (the length of the needles). (2) As cytoreductive therapy is used before

surgery to increase the chances of success of the latter. (3) ECT may also be used during surgery, after the removal of the tumor to clean the tumor bed and reduce the risk of recurrence. In this case, plate electrodes are very useful since the tumor is removed, and the margins do not need to be too deep in the tissue. In addition, ECT may be used for treating relapses after surgery or RT. We reserve RT for very large tumors when the risk of relapse with a single ECT session is high. Very large tumors can be challenging to treat with ECT, as areas may be left untreated unintentionally^[40]. If large tumors are meant to be treated with ECT, a close follow-up is advisable. During the follow-up, if a regrowth inside the treated area is observed, a new treatment session should be scheduled quickly. We do not perform ECT sessions on a fixed-time basis; when repeating the ECT session, a relapse is the reason after a complete remission^[42]. In some cases, where a relapse inside the treated area is small, cryosurgery can be performed. In our experience, this is less costly for the owner than other ECT, and, for small relapses, it can be equally effective.

Human and veterinary practices of ECT share many similarities that allow us to take advantage of the results obtained from both human and veterinary patients. However, there are many differences among them, as in veterinary medicine, the variety of patients is wider, and their characteristics greatly differ. Treating the back of a Doberman, where very sharp and rigid needles are needed, is different from treating the sensitive nose of the cat. Veterinary ECT is more challenging if we consider the variety of species that can be treated, i.e., cats^[37,39,62], dogs^[63,64], horses^[65,66], and even wild animals^[67,68], and, ideally, an equal variety of electrodes should be available. The inconveniences of using the same electrodes for every patient are often accepted, but it may lead to poorer results for the patients. This challenge is not present in human medicine, since the human skin is similar among different subjects.

To address this concern and add options to the available list of electrodes for ECT, we developed a thin-needle electrode. To validate the design and study possible problems with the available electrodes, we performed simulations in COMSOL. These simulations showed that an important area of irreversible electroporation was produced when using the standard needles. This area is not negligible and should be considered in the treatment planning. Irreversible electroporation is used mainly for the treatment of visceral neoplasia, and not used in the skin, as necrosis will impact healing^[69-71]. This delay in the healing process may have contributed to additional days of anorexia in the patients treated in the standard group. In previous work, we demonstrated the presence of extreme pH fronts emerging from the needles during the delivery of the pulses^[53]. Even if they are rapidly neutralized by the tissue buffers, extreme pH conditions surrounding the electrodes add damage to the irreversibly electroporated area. Damaging the tumor with these extreme pH fronts may not be important, but damaging healthy tissue is. Reducing the diameter of the needles will reduce their contact surface and the circulating current (44% less electric current), thus reducing the extension of the pH fronts and thus tissue damage^[53]. Regarding human patients, the use of thin-needle electrodes may reduce inflammation and can improve patient comfort after treatment. It may allow the reduction of medication for pain management and improve patient acceptance to return for additional treatment if needed.

As was expected, there was no statistically significant difference between the local response rate using both electrodes (Fisher's exact test, $P = 0.067$) or in the survival time of the patients (Log-Rank test, $P = 0.019$). This is very important since ECT is an effective treatment, and any modification to the electrodes could negatively affect its performance. Even if it was not significant, a better response rate was seen in the thin-needle group, which may be due to the higher proportion of early-stage (I + II) tumors (53.4% in the standard needle group vs. 83.7% in the thin-needle group).

CRs were obtained only in patients at the early stages of the disease, with the early stage a factor significantly associated with the response (Fisher's exact test, $P < 0.0001$). Both results are in accordance with the results of other studies^[43,72]. The microscopic bone involvement in later stages may act as a sanctuary for tumor cells^[73]. The heterogeneity between soft tissues and bone leads to electric field inhomogeneity in the interface, reducing treatment effectiveness^[42,74]. In addition, the bone may present with a reduced concentration of bleomycin due to its anatomical and physiological characteristics. To address this, a combination of intravenous plus intratumoral bleomycin has been proposed, allowing an optimal concentration of the drug in the poorly vascularized areas^[75,76].

Surgery with clean margins can provide a median survival time of 360-594 days or more^[16,77]. Photodynamic therapy showed a median time to recurrence of 133-392 days^[78]. Cryosurgery can provide a median disease-free time of 270 days; however, only early-stage tumors (T1 or T2) can be successfully treated^[79]. When using ECT as a single therapy, other authors have reported an overall survival time of 210-1260 days, being the survival longer in early-stage tumors^[43,72]. Our results with ECT are in agreement with other ECT users and seem to be comparable to surgery with clean margins. It is very encouraging, as surgery is the treatment of choice because of the unavailability of electroporation worldwide compared to surgical options. Further study is needed to compare survival times of ECT with surgery to assess if ECT can be used as first-line therapy.

Regarding the adverse effects, Spugnini *et al.* used an electrode similar to our standard electrode, with needles of 1 mm in diameter^[44]. They observed electrode-induced burns and scars, and some of the patients also experienced damage to the underlying tissues. These adverse effects were resolved in 2-3 weeks. The authors used a biphasic device, and, for that reason, the contribution of the pH to the damage was lessened. Denner S. Dos Anjos *et al.* identified local side effects; particularly, hyporexia was reported with a duration of seven days, including two cases where a feeding tube had to be placed for 7-14 days after the ECT procedure^[43]. In this case, the authors used bipolar pulses too, but plate or needle electrodes were used depending on the size of the tumor. They reported using both in many cases. However, it is not clear if the hyporexia was worse when using plates, needles, or both at the same time. Again, even if the damage related to the extreme pH changes is reduced by the use of a bipolar device, the damage attributed to the irreversible electroporation cannot be ruled out. Using both electrodes in the same area may also contribute to increasing the area of irreversible electroporation by excessive overlapping of the electric field, i.e., overtreatment. It is also worth mentioning that all the complications were adequately managed, and the patients obtained good results. Tozon *et al.* did not report local or systemic adverse effects after ECT^[72]; in this case, plate electrodes were used, and, thus, no trauma was produced. Using plate electrodes would be an option reserved for tumors with an invasion depth of a few millimeters^[80]. Even though we did not use plate electrodes in this work, we used them for selected cases [Figure 7]. If the tumor invades deeper, then multiple sessions are needed when using plate electrodes. For that reason, invasive tumors may be treated better using needle electrodes.

Another important aspect where human medicine diverges from veterinary medicine is the mandatory use of disposable electrodes. In the latter, only a few manufacturers offer disposable electrodes, which in the authors' point of view, are very important for several reasons. First, new needles are sharp, and the tip is in optimal condition with each treatment. This significantly reduces the insertion trauma. Second, the conduction of the electricity is better, as there is no oxidation (which even occurs in stainless steel electrodes), providing an optimal electric field distribution. We strongly recommend using disposable needles in every case. In this study, their use was fundamental, as we kept the trauma induced by insertion to a minimum. Most patients underwent one or two treatment sessions (median 2). Spugnini *et al.* used

Figure 7. Feline patient with nasal cSCC treated with ECT using plate electrodes: (left) the patient during the treatment, where the plate electrodes were applied over the lesion; and (right) 54 days after the treatment, where a complete response was obtained.

more treatment sessions (median 4) to obtain similar objective response rates using caliper electrodes^[81]. The fact that we needed fewer treatment sessions to achieve similar responses could be attributed to the use of disposable needles, which improve conductivity and produce a more homogeneous electric field distribution. However, in another study, Tozon *et al.*^[72] reported performing mostly one treatment session and an 81.8% CR rate in 11 patients. In this case, the difference is that they used plate electrodes. Denner S. Dos Anjos *et al.* mostly performed one session but used plates and needles^[43]. The combination may overcome the use of reusable needles at the expense of longer hyporexia time due to overtreatment. In any case, further study is needed to confirm that the use of disposable needles may reduce the number of treatment sessions.

In conclusion, cSCC is a common malignancy in feline patients exposed to UV light and HPV, which shares many characteristics with its human counterpart. For that reason, they are excellent models of human disease. The treatment of choice is surgery with clean margins, as other approaches are less effective. Particularly chemotherapy is not a good option because of cSCC's chemoresistance. However, ECT has overcome that barrier, being very effective. In particular, ECT using thin-needle electrodes in the nasal planum, when compared with standard electrodes, reduces anorexia times, improves recovery, and provides equally good results.

DECLARATIONS

Authors' contributions

Conceived the idea of the electrode, treated the patients, made the follow-up of the patients, analyzed the response: Tellado M

Built the prototypes of the electrodes, made experiments in plant tissue, treated the patients: Michinski S

Evaluating the results, writing and proofreading the manuscript: Impellizeri J

Worked in the computer simulations and in the models of the prototypes, analysed Computer simulations and correlated with experiments: Marshall G

General design of the study, analysed results and performed statistics: Signori E

Conceived the design of the electrodes, designed plant tissue experiments, treated the patients, analysed results, wrote the manuscript: Maglietti F

Abstract

Aim: The development of chemotherapy resistance is the major obstacle in the treatment of advanced prostate cancer (PCa). Extracellular vesicles (EVs) secretion plays a significant role among different mechanisms contributing to chemoresistance. Hence, inhibition of EVs release may increase the efficacy of chemotherapeutic drugs against PCa.

Methods: Paclitaxel (PTX) resistant PCa cells (PC3-R and DU145-R) were treated with GW4869, a known exosome biogenesis inhibitor. EVs were isolated from the conditioned media by ExoQuick-based precipitation method and characterized for concentration and size distribution by nanoparticle tracking analysis. The effect of GW4869 treatment on the survival and growth of PCa cells was assessed by MTT, and colony formation assays *in vitro*, and ectopic PC3-R xenografts in male athymic nude mice *in vivo*. The effect of other EV biogenesis inhibitors, imipramine and dimethyl amiloride (DMA), treatment was also analyzed on the survival of PC3-R cells.

Results: GW4869 (10-20 μ M) treatment of PTX resistant PCa cells significantly reduced the release of small EVs (50-100 nm size range) while increasing the release of larger EVs (> 150 nm in size), and inhibited their clonogenicity. Moreover, GW4869 (5-20 μ M) treatment (24-72h) significantly inhibited the survival of PC3-R cells in a dose-dependent manner. We observed a similar growth inhibition with both imipramine (5-20 μ g/mL) and DMA (5-20 μ g/mL) treatment in PC3-R cells. Furthermore, GW4869 treatment (IP) in mice bearing PC3-R

xenografts significantly reduced the tumor weight (65% reduction, $P = 0.017$) compared to the vehicle-treated control mice without causing any noticeable toxicity.

Conclusion: Inhibiting the release of EVs could sensitize the resistant PCa cells to chemotherapy.

Keywords: Prostate cancer, extracellular vesicles, GW4869, chemoresistance, paclitaxel

INTRODUCTION

Prostate cancer (PCa) is one of the most predominant types of cancer in men, accounts for 26% of all cancer cases, and remains one of the leading causes of death^[1]. Most of the PCa cases show an indolent stage with no or less risk of mortality; however, many patients develop intermediate or high-risk locally advanced or metastatic phenotype. It is well established that the growth and progression of the PCa are dependent on androgen; thus, androgen deprivation therapy (ADT) is the most accepted practice as the first-line treatment for metastatic /disseminated PCa in the clinical setting^[2,3]. Despite the initial response to the ADT, most patients develop castration-resistant PCa (CRPC), characterized by increased serum levels of prostate-specific antigen (PSA) and increased growth and metastasis of primary tumor, leading to disease aggressiveness despite castrate serum levels of testosterone^[4,5]. Treatment of patients with CRPC is one of the major challenges for the development of effective treatment therapy for PCa. Many clinical trials have demonstrated the effectiveness of taxol (paclitaxel and its semisynthetic analog docetaxel) for the treatment of CRPC patients due to its effectiveness in prolonging the overall survival^[6-8]. Docetaxel has already been approved by the United States FDA for the treatment of CRPC patients.

Paclitaxel (PTX) was the first member of the taxane family approved for cancer chemotherapy. PTX is used in the treatment of CRPC (in combination with ADT) and possesses anti-neoplastic properties by promoting and stabilizing the polymerization and assembly of tubulin required for microtubule formation during the cell cycle, which ultimately causes cell cycle arrest leading to apoptosis^[9]. After multiple treatment schedules with PTX, cancer cells develop resistance that leads to a poor prognosis. The development of drug resistance by cancer cells is one of the major challenges in cancer therapy. However, the mechanism of drug resistance is largely unknown but often mediated by insufficient availability of the drug to the target cell. Many mechanisms which are adopted by cancer cells to develop drug resistance have been demonstrated, including drug efflux by membrane-bound efflux proteins, increased interstitial fluid pressure that impairs drug uptake, acidic extracellular microenvironment and hypoxia, hyperglycemia, cellular rewiring, altered drug metabolism, and mutation in drug's target^[10-16]. PTX resistant DU145 and PC3 cells have been shown to overexpress multiple drug resistance gene (MDR-1)-encoded P-glycoprotein and enhanced expression of F-actin polymerization^[17] as a mechanism to develop resistance against PTX. The direct expulsion of the anticancer drug through extracellular vesicles (EVs) may contribute crucially to the development of chemoresistance. In an earlier study, Shedden *et al.* demonstrated the efflux of anticancer drug doxorubicin through EVs, hence preventing the drug from reaching its target site and also decreasing the available drug concentration for its anti-neoplastic effect^[18]. Moreover, it has also been reported that the EVs isolated from drug resistant-cancer cells can efficiently transfer proteins involved in drug efflux pumps to the drug-sensitive cells resulting in the acquisition of MDR^[19,20]. Several studies have shown the involvement of EVs released from drug-resistant cells in transmitting resistance to the other cells (reviewed in^[21]).

EVs are membranous vesicles released by all cell types and can contain nucleic acids, lipids, and proteins as cargos, which are representative of the secretory cell and its biological behavior^[22-24]. EVs are classified into exosomes (~30-150 nm), ectosomes/microvesicles (100-1000 nm), apoptotic bodies (1-5 μ M), and large

oncosomes (1-10 μM) on the basis of their size and released pathway^[22,25]. The role of EVs in cell-to-cell communication in modifying tumor microenvironment, preparation of pre-metastatic niche, and helping the formation of metastatic foci at distant sites in cancer is well established. Many studies have also suggested the role of EVs in mediating drug resistance in cancer^[23,26]. Inhibition of the EVs biogenesis or release by cancer cells may be helpful in preventing the metastasis and the spread of drug resistance to the sensitive cells.

Inhibition of EV biogenesis using specific inhibitors can be used to evaluate the involvement of EVs in cancer cell proliferation and metastasis. GW4869, dimethyl amiloride (DMA), and imipramine are known chemical compounds commonly used as inhibitors of the EV biogenesis/secretion^[27]. GW4869 acts as a non-competitive inhibitor of membrane neutral sphingomyelinase (nSMase) enzyme, which is responsible for the generation of lipid ceramide through the hydrolysis of the membrane lipid sphingomyelin and inhibits the release of small EVs/exosomes^[28,29]. Imipramine is a tricyclic antidepressant that also exhibits an inhibitory activity on acid SMase and inhibits the generation of ceramide^[27]. DMA inhibits H^+/Na^+ and $\text{Na}^+/\text{Ca}^{2+}$ exchangers and prevents the calcium gradient establishment which is required for the release of exosomes from the cells^[30,31]. Earlier, we have reported that GW4869 and DMA treatment inhibits the survival and clonogenicity of PCa cells under both normoxic and hypoxic conditions, as well as the survival of enzalutamide-resistant PCa cells^[31,32]. Earlier studies have also suggested that GW4869 reduces the chemoresistance in the cancer cells by inhibiting the EV release^[33,34]. Richards *et al.* reported that treatment of gemcitabine to cancer-associated fibroblasts causes increased exosome secretion, which ultimately increases the rate of proliferation in chemosensitive pancreatic epithelial cancer cells and their survival, subsequent treatment with GW4869 significantly reduced their survival^[34]. In the present study, we reported the inhibitory effects of GW4869 on the survival of PTX-resistant PCa cells, both *in vitro* and *in vivo*. We also found that the concentration and size distribution of EV released by PTX-resistant PCa cells was significantly affected by the GW4869 treatment.

MATERIALS AND METHODS

Cell lines and reagents

In this study, we used the previously developed PTX resistant human PCa PC3 and DU145 cells^[35,36]. PTX resistant PC3 (PC3-R) and DU145 (DU145-R) cells were maintained in RPMI1640 medium supplemented with 10% heat-inactivated FBS, 100 units/mL final concentration of penicillin-streptomycin (Gibco Laboratories, Gaithersburg, MD), and 0.2 μM final concentration of PTX (in DMSO). Cells were incubated at 37 °C in CO_2 incubator at a 5% CO_2 concentration (Heracell VIOS 160i; ThermoFisher, Waltham, MA). GW4869 was purchased from Sigma-Aldrich (St. Louis, MO) and 5-(N,N-Dimethyl) amiloride hydrochloride (DMA) from ThermoFisher (Waltham, MA), while imipramine was purchased from Selleckchem (Pittsburgh, PA).

EVs isolation

Total EVs were isolated from both PC3-R and DU145-R cells after treatment with 10 and 20 μM doses of GW4869. Cell number was counted, and condition media was collected after 24 and 48 h following treatment with GW4869. Next, EVs were isolated from conditioned media using ExoQuick™ (System Biosciences, Palo Alto, CA) precipitation method as described earlier^[37]. Briefly, the cell culture conditioned media was first centrifuged at 500 g for 5 min, 2,000 g for 10 min, 10,000 g for 30 min at 4 °C to remove large-sized vesicles. Finally, EVs were isolated using ExoQuick following the manufacturer's recommendations. EV pellet was dissolved in filtered Dulbecco's phosphate-buffered saline (DPBS).

Nanoparticle tracking analyses

The concentration and size distribution of the EVs were analyzed using Nanosight NS300 (Malvern Instruments, UK) as described earlier^[38].

MTT assay

PC3-R cells (~1,000) were seeded in 96-well plates and, after 24 h, treated with different doses of GW4869 (5, 10, and 20 μ M), DMA (5, 10, and 20 μ g/mL), and imipramine (5, 10, and 20 μ g/mL). The MTT assay was performed 24, 48, and 72 h after treatment. Briefly, 20 μ L MTT (5 mg/mL in PBS) was added to each well and incubated in the dark for 2 h, and then 200 μ L of DMSO was added to dissolve the formazan crystals. Finally, absorbance was measured at 560 and 650 nm.

Clonogenic assay

PC3-R and DU145-R cells (200 cells per well) were seeded in 6-well plates and treated with 10 and 20 μ M doses of GW4869. After 6-7 days of treatment, colonies (\geq 50 cells) were counted under a microscope. Thereafter, cells were fixed in methanol, stained with crystal violet solution, dried, and photographs were captured.

Tumor Xenograft

All mice were housed and all experiments performed in accordance with the protocol approved by the Institutional Animal Care and Use Committee (IACUC) at Wake Forest University Health Sciences (Winston-Salem, NC). Male athymic nude mice (*nu/nu*) were purchased from Envigo (Indianapolis, IN) at 4-6 weeks of age and were given ad libitum food and water on a 12-h light-dark cycle.

PC3-R cells were collected on the day of injection and resuspended in serum-free media. An equal volume of Matrigel matrix (Corning, Bedford, MA) was added to the cells and kept on ice. Mice were anesthetized with Isoflurane at 2%-4%. Using a 1cc syringe with a 27g needle (BD, Franklin Lakes, NJ), $\sim 2.1 \times 10^6$ cells were injected subcutaneously on each flank of all the mice. As soon as the tumors were visible, they were measured twice a week with calipers, and volume was calculated as $\text{Width (mm)}^2 \times \text{Length (mm)} \times 0.52 = \text{Volume (mm)}^3$. At the time when the tumors were approximately 50-100 mm^3 , mice were divided into two groups. Mice were treated with either GW4869 (Sigma, St. Louis, MO) or vehicle [Vehicle control (VC)], 5% DMSO in 0.9% Sodium Chloride (Baxter, Deerfield, IL). Mice were injected intraperitoneal (IP) with 2.5 mg/kg GW4869 or vehicle (200 μ L) 6 days a week for 21 days, and then the dose of GW4869 was increased to 5.0 mg/kg. Throughout the experiment, the body weight of each animal was regularly measured. Any mouse with xenograft volume approaching the size limit or other parameters (e.g., necrosis) defined by IACUC was sacrificed, and tissues were collected. At the end of the experiment, animals were sacrificed using CO₂ asphyxiation, and blood and tumors were harvested. Plasma was isolated from the blood and stored at -80 °C until further use.

Tissue processing and immunohistochemistry

Tumor tissues were processed, and 5 μ m formalin-fixed and paraffin-embedded (FFPE) sections were analyzed for CD63 expression by processing and immunohistochemistry (IHC) as described by us previously^[39]. CD63 primary antibody was purchased from ThermoFisher (Waltham, MA) and detection system (ImmPRESS-AP horse anti-rabbit IgG polymer detection kit) with secondary antibody from Vector laboratories (Burlingame, CA). All the immunostained slides were scanned by NanoZoomer (Hamamatsu, Japan) at 20 \times . The CD63 immunostaining scoring was conducted manually by evaluating the intensity of staining and percentage of stained cells: intensity was given scores of 0-3 (0 = no staining, 1 = weak staining, 2 = moderate staining, 3 = intense staining), and the percentage of immunopositive cells was given scores 0%-100%. The 2 scores were multiplied to obtain the final IHC score (between 0-300).

EVs isolation from plasma

Isolation of total EVs from mice plasma was performed as described by us previously^[38,40]. Briefly, plasma was diluted in PBS and centrifuged at 500 g for 5 min, 2,000 g for 10 min, followed by 10,000 g for 30 min at 4 °C to remove the larger sized vesicles. Finally, EVs were isolated using ExoQuick following the manufacturer's recommendations (System Biosciences, Palo Alto, CA). EV pellet was dissolved in filtered DPBS.

Western blotting

Briefly, 35 µL of EVs isolated from mice plasma were denatured directly in 5× loading buffer and separated using sodium dodecyl sulfate-polyacrylamide gel electrophoresis on a 12% Tris-glycine gel. The separated proteins were transferred onto nitrocellulose membrane, and after blocking with 5% non-fat milk powder (w/v) in Tris-buffered saline with tween (TBS-T, 10 mM Tris-HCl, pH 7.5, 100 mM NaCl, and 0.1% Tween 20), the fresh membrane or stripped membrane was probed with anti-syntenin (Abcam, Waltham, MA) or anti-CD63 (Invitrogen, Waltham, MA) or anti-GOLGA2 (Novus Biologicals, Littleton, CO) primary antibodies for overnight incubation at 4 °C. Further, in each case, the membrane was washed 3 times with TBS-T and incubated with appropriate secondary antibodies before visualization by the ECL detection system. The autoradiograms/ bands were scanned and quantified using Image J (version 1.53e) using corresponding bands in Ponceau stained membrane as the loading control.

Statistical analysis

Student's *t* test (unpaired) was used to examine the statistical significance ($P < 0.05$) of differences between control and treatment groups.

RESULTS

Effect of GW4869 treatment on the EVs secretion by PC3-R cells

PC3-R cells were treated with 2 different doses (10 µM and 20 µM) of GW4869, and conditioned media was collected after 24 and 48 h. A significant shift in the size distribution of EVs was observed at both 24 and 48 h, with a more noticeable difference at 10 µM dose [Figure 1A]. Though no difference in total particle number secreted per million cells was observed at 24 h, a significant increase in the particle number per million cells was observed at the higher dose of GW4869 with 48 h of treatment [Figure 1B, lower panel]. We also noticed a significant increase in the mean size of EVs isolation at 24 and 48 h with both the doses, though the increase was more prominent with the 10 µM dose [Figure 1C]. Analysis of change in EVs in different size ranges showed that the proportion of EVs in size range 50-100 nm was significantly decreased, while the proportion of > 150 nm sized EVs increased significantly with 10 µM dose of GW4869 at both 24 h and 48 h [Figure 1D]. Treatment of PC3-R cells with a 20 µM dose of GW4869 resulted in a 35% reduction (though statistically non-significant) in the proportion of 50-100 nm sized EVs and increased the proportion of 150-200 nm and 200-250 nm sized EVs at 24 h time [Figure 1D, upper panel]. Furthermore, GW4869 at 20 µM dose marginally (statistically not significant) reduced the proportion of 50-100 nm sized EVs and increased 150-200 nm sized EVs at 48 h [Figure 1D, lower panel].

GW4869 reduces the survival and clonogenicity of PC3-R cells

Next, an MTT assay was performed to assess the viability of the PC3-R cells after GW4869 (5-20 µM) treatment for 24-72 h. A significant reduction in cell viability was observed compared to control in treatment with a 20 µM dose at all the time points. We observed a decrease in cell viability with a 10 µM dose at either early (24 h) or late time (72 h); however, with a 5 µM dose, we only observed a statistically significant decrease at 72 h [Figure 2A].

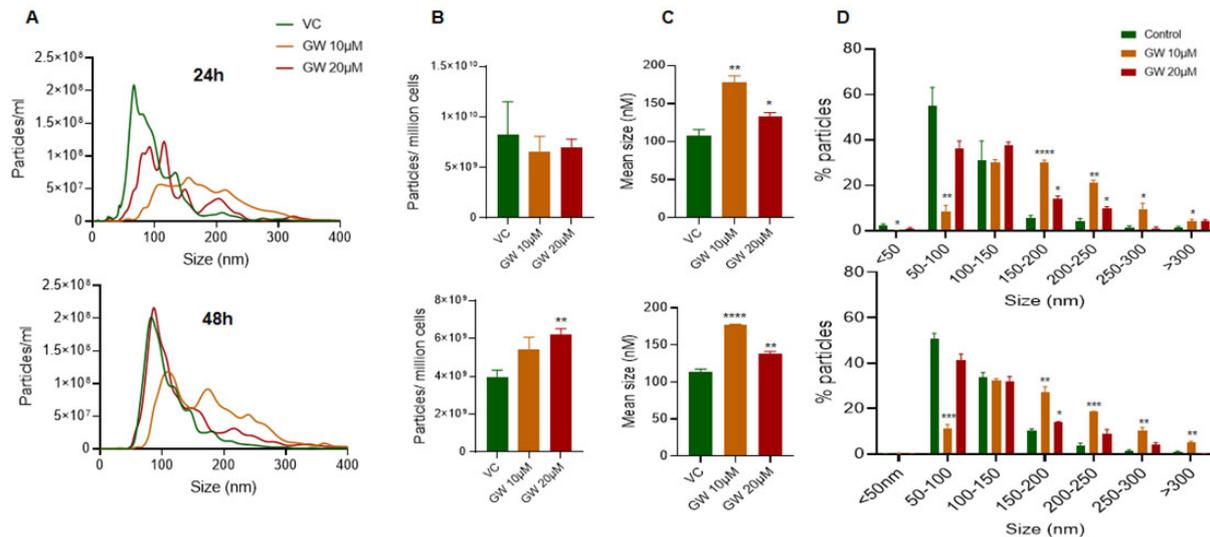

Figure 1. Characterization of EV concentration and size distribution following GW4869 treatment in PC3-R cells. EVs were isolated from the conditioned media of paclitaxel-resistant PC3-R cells following 24 h (upper panel) and 48 h (lower panel) of treatment with GW4869 (10-20 μ M) and characterized for concentration and size distribution by NTA. (A) Concentration and size distribution of EVs isolated from DMSO (VC) or GW4869 (10 and 20 μ M) treated cells are represented with green, orange, and red colors, respectively ($n = 3$). Each line represents the mean of three samples, and an average data of 5 videos of 30 sec each was used for each sample. (B-C) Total EV concentration per million cells and mean size are plotted. (D) Size distribution of EVs is presented as percent particles in the mentioned size range. Each bar represents mean \pm SEM ($n = 3$). VC: Vehicle control; * $P < 0.05$, ** $P < 0.005$, *** $P < 0.0005$, **** $P < 0.0001$.

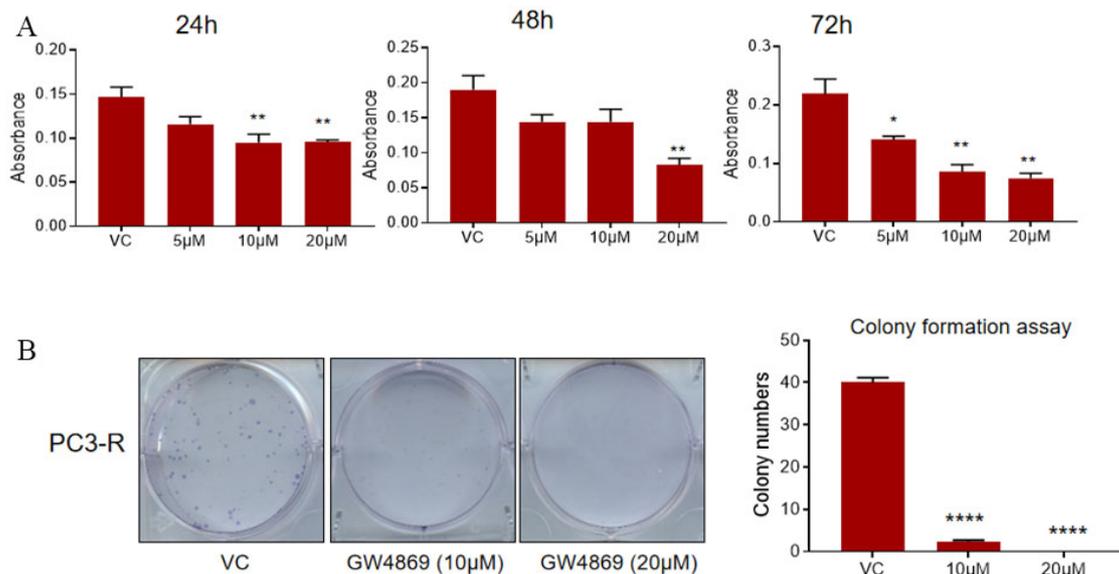

Figure 2. Effect of GW4869 treatment on the survival and clonogenicity of PC3-R cells. (A) Paclitaxel-resistant PC3-R cells were treated with DMSO (VC) or GW4869 (5-20 μ M), and cell viability was measured in MTT assay after 24, 48, and 72 h. Data are presented as mean \pm SEM ($n = 5$ replicates per group). * $P < 0.05$, ** $P < 0.005$. (B) Colony formation was measured in PC3-R cells after GW4869 treatment (10 and 20 μ M) as described in the methods. Representative images are shown (left panel), and the colony number is presented as mean \pm SEM ($n = 3$ replicates per group). **** $P < 0.0001$. VC: Vehicle control.

Since PC3-R cells showed a prominent effect of GW4869 treatment mostly at later time points, a colony formation assay was performed to assess the effect on the clonogenicity of PC3-R cells following GW4869

treatment. In colony formation assay, a significant reduction in the number of colonies was observed in PC3-R cells at both 10 and 20 μ M doses [Figure 2B].

GW4869 administration inhibits the PC3-R xenograft tumor growth in nude mice

The anti-tumorigenic potential of the GW4869 was evaluated in the nude mice by implanting PC3-R cells subcutaneously in two groups (control and GW4869). No significant change in the body weight of control and GW4869 administered mice was observed after 40 days [Figure 3A]. The tumor volume from the mice that survived at each time point was measured, and the animals that survived by the end of the study were sacrificed on the 44th day after PC3-R cells implantation. A statistically significant difference in tumor volume was observed compared to the control group towards the end of the experiment [Figure 3B]. The tumor tissue weight was also reduced significantly (65% reduction, $P = 0.017$) with GW4869 treatment compared to the control group [Figure 3C].

The expression of CD63 (typical small EVs/exosome marker) in tumor tissues was analyzed by IHC to identify the effect of GW4869 on EVs biogenesis in the tumor tissue. However, no significant difference in the CD63 expression was observed between control and GW4869 treated mice [Figure 3D]. Further, total EVs were isolated from the plasma of control and GW4869 treated animals and analyzed by NTA. No significant difference in the concentration and size distribution was observed between the control and GW4869 groups [Figure 3E]. However, Western blot analysis showed a 95% decrease in the expression of syntenin and about a 70% decrease in the expression of CD63 [Figure 3F and G]. GOLGA2 (Golgin A2) was used as a potential negative marker for EV cargo.

DMA & imipramine treatment reduce the survival of PC3-R cell

To confirm that the observed effect of GW4869 on PC3-R cells and tumor growth is mediated by inhibition of EVs secretion, we used two other compounds (DMA and imipramine), known to inhibit EV biogenesis [reviewed in^[27]]. PC3-R cells were treated with different concentrations of DMA and Imipramine to evaluate their effect on cell viability by MTT assay. Treatment with different concentrations (5-20 μ g/mL) of DMA showed a significant reduction in the viability of PC3-R cells at all time intervals [Figure 4A]. Similarly, imipramine treatment (5-20 μ g/mL) also reduced the PC3-R cell's survival at all-time intervals with all concentrations [Figure 4B].

GW4869 treatment inhibits EVs secretion and clonogenicity of DU145-R cells

The effect of GW4869 treatment was also assessed on EVs secretion by PTX resistant DU145-R cells. GW4869 treatment did not significantly affect the particles per million cells at both 24 h and 48 h [Figure 5A and B]. We observed a significant increase in the mean size of the particles with a 10 μ M dose at both 24 and 48 h, while no change was observed with a 20 μ M dose [Figure 5A and B]. Consistent with PC3-R cells, GW4869 treatment reduced the proportion of 50-100 nm sized EVs by more than 50% (though statistically not significant) at 10 μ M dose and increased the proportion of > 150 nm sized EVs at 24 h [Figure 5A]. The treatment with a 20 μ M dose of GW4869 did not show any significant effect on EVs size at 24 h [Figure 5A]. We also observed a significant reduction in the proportion of 50-100 nm sized EVs with 10 μ M dose of GW4869 and a statistically significant increase in 150-200 nm, 200-250 nm, and 250-300 nm sized EVs at 48 h. Further, a higher dose of GW4869 (20 μ M) increased the proportion of 150-200 nm and 250-300 nm sized EVs after 48 h of treatment without significantly affecting the proportion of 50-100 nm sized EVs [Figure 5B].

The colony formation assay showed that GW4869 treatment (10 and 20 μ M) resulted in a significant reduction in the number of colonies formed by DU145-R cells [Figure 5C].

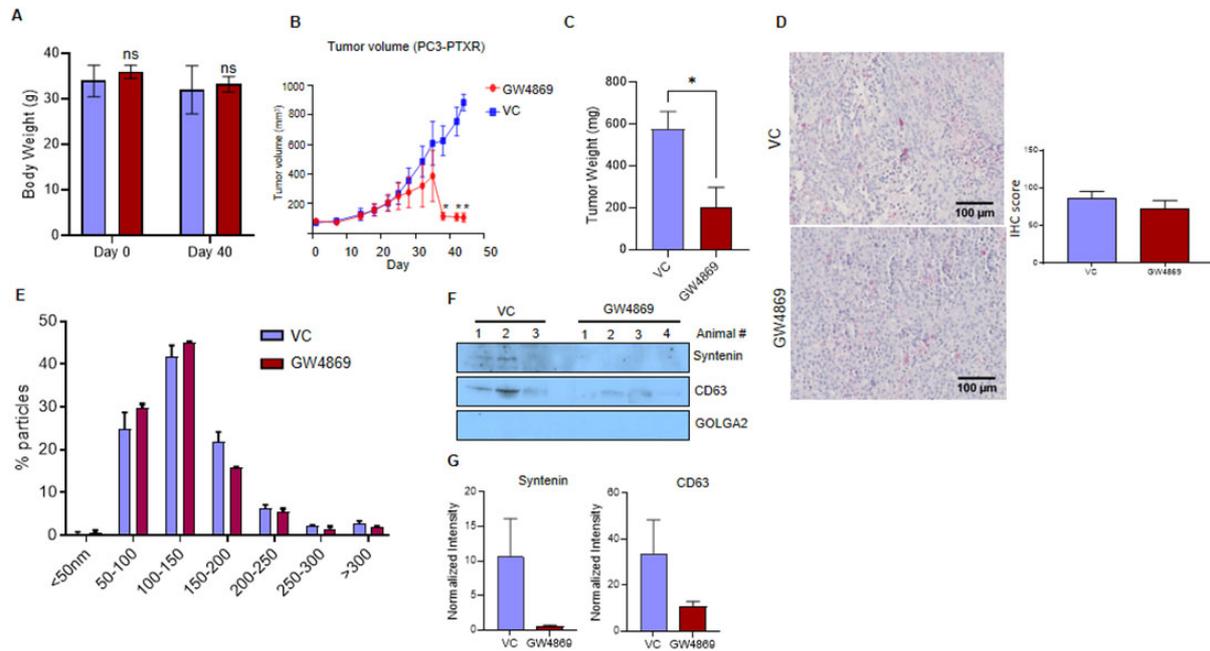

Figure 3. *In vivo* effect of GW4869 treatment on the growth of paclitaxel-resistant PC3-R cells' xenografts. Male athymic nude mice were treated with vehicle or GW4869, and various study parameters were assessed as described in the methods. (A) Average body weight (mean \pm SEM) at the start and day 40 of the study for control mice ($n = 3$) and GW4869 treated mice ($n = 4$) mice. (B) Average xenograft volume (mean \pm SEM) in control and GW4869 treated mice survived at measured time points is presented. (C) In the end, mice were sacrificed, xenografts were excised, and their weight was measured. Average tumor weight in the control group ($n = 6$ xenografts) and the GW4869 group ($n = 8$ xenografts) is presented as mean \pm SEM. Unpaired t test was used to calculate the statistical significance, $*P = 0.017$. (D) CD63 expression in xenograft tissues from the vehicle control (VC) group and GW4869 group ($n = 6$ each) was measured by IHC. For each image, ten random areas were analyzed for IHC scoring as described in the methods. Mean IHC scores are presented as mean \pm SEM in the bar diagram. Representative images are shown. (E) EVs isolated from the plasma of control ($n = 3$) and GW4869 treated mice ($n = 3$) were analyzed by NTA, and the size distribution (mean \pm SEM) of EVs was plotted as a percentage of total EVs. (F) EVs from VC ($n = 3$) and GW4869 treated ($n = 4$) mice were used for the analysis of syntenin, CD63, and GOLGA2 by Western blotting. Representative immunoblots are shown. (G) Densitometry analysis of syntenin and CD63 expression was performed and normalized with corresponding band intensity in Ponceau-stained membrane. The relative band intensity is presented as mean \pm SEM.

DISCUSSION

Chemotherapy is the major treatment option for CRPC; however, the acquisition of chemoresistance by PCa cells is considered as the main obstacle in the development of an effective anticancer strategy. Many molecular mechanisms that contribute to the development of chemoresistance in cancer cells have been suggested, including transporter pumps, altered metabolism, alteration in gene expression, epithelial to mesenchymal transition, cancer stemness, hypoxia, and acidic tumor microenvironment^[41-43]. Drug-resistant cancer cells utilize EVs to transfer the transporter pumps and other biomolecules involved in pro-survival and anti-apoptotic pathways to the sensitive cells for propagation of chemoresistance^[23,44]. Additionally, cancer cells can use EVs for direct loading of drugs and their efflux, which can undoubtedly contribute crucially to the development of chemoresistance in cancer cells. Using different cell line models, Shedden et al. have shown the physical incorporation of doxorubicin in EVs and its expulsion into the media^[18]. It indicated that cancer cells secrete the EVs as an intrinsic mechanism to enable the resistant cells to survive under stressful or toxic environments. Further, it is well accepted that in physiological and biochemical stress conditions like hypoxia or an acidic environment, cancer cells secrete higher amounts of EVs^[31,45,46] as a protective mechanism to remove metabolic and toxic waste. Treatment of PTX resistant PC3-R and DU145-R cells with GW4869 (a selective neutral sphingomyelin phosphodiesterase inhibitor) showed a specific reduction on 50-100 nm sized EVs, which are in the size range of exosomes/ small EVs, though increased

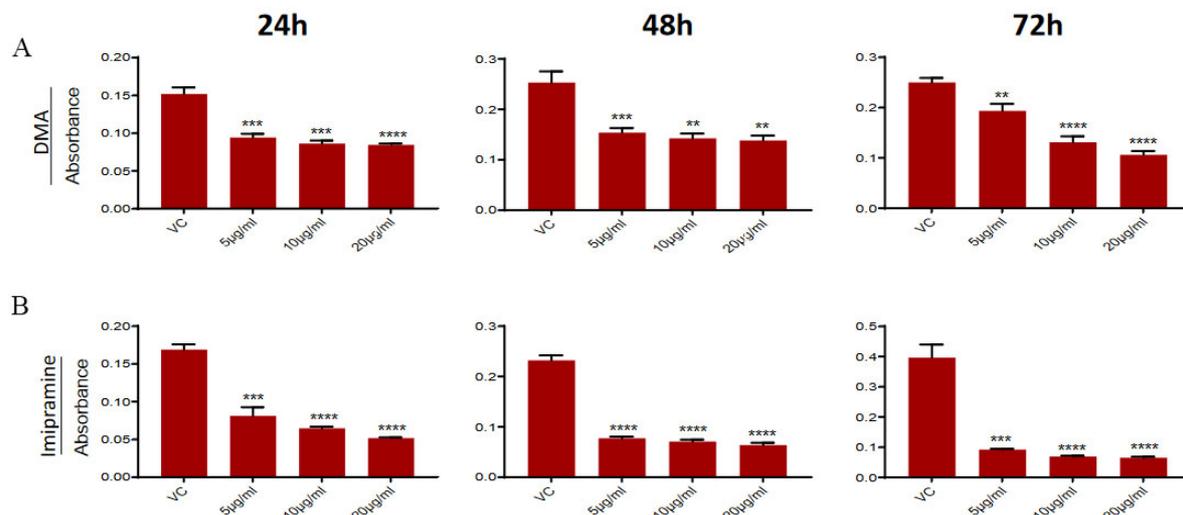

Figure 4. Effect of DMA and imipramine treatment on the survival of paclitaxel-resistant PC3-R cells. PC3-R cells were treated with (A) DMA (5-20 µg/mL) or (B) imipramine (5-20 µg/mL) for 24-72 h and analyzed for cell viability in the MTT assay. Data are presented as mean ± SEM ($n = 5$ replicates per group). ** $P < 0.005$, *** $P < 0.0005$; **** $P < 0.0001$.

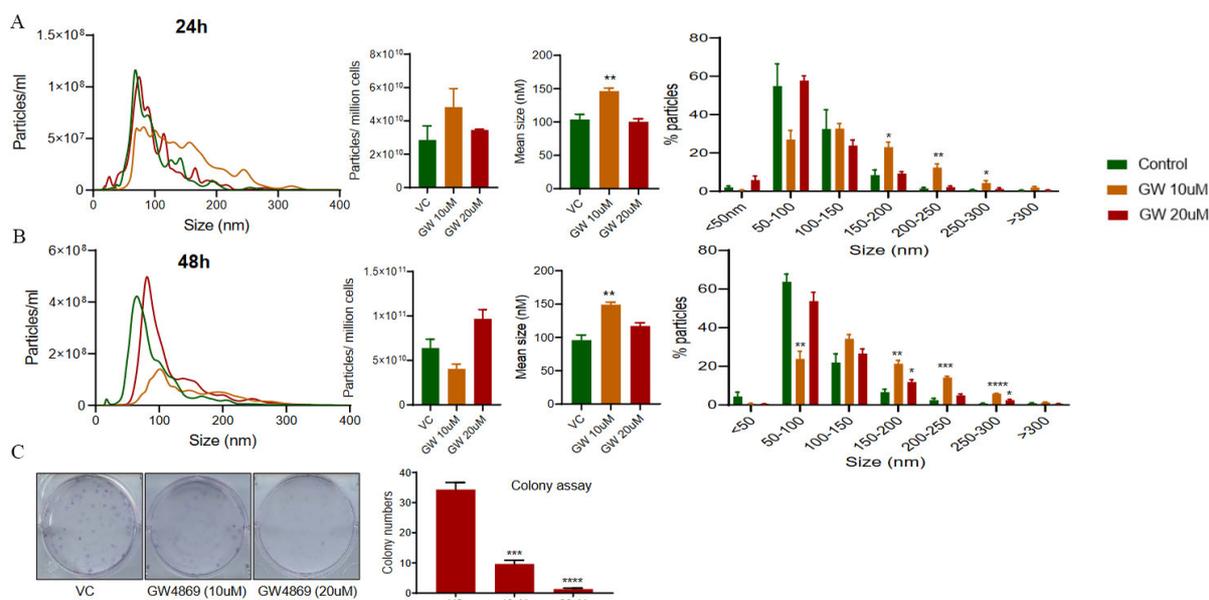

Figure 5. Effect of GW4869 treatment on paclitaxel-resistant DU145-R cells. EVs were isolated from the conditioned media of paclitaxel-resistant DU145-R cells following 24 h (upper panel) and 48 h (lower panel) of treatment with GW4869 (10-20 µM) and characterized for concentration and size distribution by NTA. (A-B) Each colored line in the left panel represents the mean of three samples, and an average data of 5 videos of 30 s each was used for each sample. Concentration (particles/mL)-size distribution, average EV concentration per million cells, average size, and percent particles for various size ranges are presented. Each bar represents mean ± SEM ($n = 3$). * $P < 0.05$, ** $P < 0.005$ *** $P < 0.0005$ **** $P < 0.0001$. (C) Colony formation was measured in DU145-R cells after GW4869 treatment (10 and 20 µM) as described in the methods. Representative images are shown (left panel), and the colony number is presented as mean ± SEM ($n = 3$ replicates per group). *** $P < 0.0005$, **** $P < 0.0001$.

the proportion of larger size (> 150 nm) EVs. The observation was in line with the previous report suggesting the treatment of human breast cancer cell line SKBR-3 with 5 µM GW4869 or siRNA against sphingomyelin phosphodiesterase 2/3 (also known as nSMase) resulted in a significant reduction of < 100 nm sized vesicles and increased quantities of vesicles with a size range of 100-200 nm; while overexpression

of sphingomyelin phosphodiesterase-3 (also known as nSMase2) decreased the amount of larger-sized (100-200 nm) vesicles^[47]. Interestingly, the increase in the EV fraction, following GW4869 treatment for 16 h, collected after 14,000 × g centrifugation (larger sized vesicles) was suggested to be stemming from plasma membrane representing MVs. Moreover, higher content of sphingomyelin in the MVs membrane was reported with respect to the overall cell membrane lipid composition, while no difference in EVs collected at 100,000 × g fraction (small EVs) was observed. Therefore, inhibiting the nSMase with GW4869 can interfere with the lipid composition, which may inhibit small EVs/exosome secretion but increase the secretion of larger EVs/MVs^[47]. Interestingly, in line with our observation, the treatment of SKBR3 cells with GW4869 was shown to affect the loading of proteins (including syntenin) in EVs and carry less protein per EV^[47].

Several studies have indicated that EVs or exosome secretion can be inhibited by the use of GW4869, imipramine, and DMA^[28,31,32,48-52]. Interestingly, treatment of PTX-resistant PCa cells with these known exosome biogenesis inhibitors resulted in a significant decrease in cell viability, especially in a long-term clonogenic assay. Similar inhibition of EVs secretion with GW4869 treatment leading to decreased growth of B16BL6 cells was reported earlier^[53]. We have also previously reported that the treatment with GW4869 and DMA decreased the cell survival of the enzalutamide-resistant PCa cells^[32] as well as clonogenicity of PCa cells under both normoxic and hypoxic conditions^[31].

The study by Corcoran *et al.* has shown that docetaxel resistant variants of DU145 and 22Rv1 cells transfer the docetaxel resistance to sensitive cells (DU145, 22Rv1 and LNCaP) partly through MDR-1/P-gp transfer, suggesting the role of exosomes in the propagation of chemoresistance^[54]. Moreover, other studies have reported the inhibition of EVs secretion in cell culture and/or suppression of tumor growth in mice after GW4869 treatment^[53,55-57]. *In vivo* experiment in the present study indicated that GW4869 treatment decreases the tumor growth significantly without affecting the overall bodyweight of the mice. Although, we did not observe a significant change in the total EV number isolated from the plasma of these mice and CD63 expression in the xenograft tissues. However, we observed a strong decrease in the loading of known exosomal cargo proteins (syntenin and CD63). Earlier, Dinkins *et al.* have shown the reduction in protein concentration and reduced levels of Alix (a marker for exosomes/EVs) in EVs isolated from the mice serum treated with intraperitoneal injections of 100 µg GW4869 (~4 µg/g) daily for 5 days^[51]. The effect of GW4869 treatment on the concentration of EVs was not measured in this study^[51]. Similarly, intraperitoneal treatment of C57BL/6J mice with GW4869 (1.25 mg/kg) decreased airway-secreted EVs *in vivo*, as measured directly with NTA and indirectly with miRNAs expression^[58]. Essandoh *et al.* also showed that treatment of wild-type mice with GW4869 at a dose of 2.5 µg/g of body weight reduced the levels of serum exosomes by 33%. Though, the concentration of exosomes was measured indirectly by acetylcholinesterase (AChE) activity assay^[59]. Interestingly, in an established multiple myeloma (MM) mouse model, intraperitoneal injection of 1.25 µg/g GW4869 for 2 weeks suppressed MM tumor growth, though no association with nSMase expression and sensitivity to GW4869 was observed. Moreover, the molar levels of sphingomyelin decreased while ceramide increased in GW4869 treated MM cells for a specific duration, suggesting that the cytotoxic effect of GW4869 may not be through direct nSMase2 inhibition^[60]. Overall, it appears that the dose and treatment duration of GW4869, as well as the cancer-type or study model, could also impact its effect on EV biogenesis and secretion in biofluids.

The mechanism by which GW4869 inhibits the survival and growth of the PTX-resistant PCa cells reported in this study could be partly through the inhibition of smaller EVs secretion (50-100 nm). The GW4869 mediated inhibition of the growth of the PTX resistant cells *in vitro* and *in vivo* indicated its usefulness in combating the chemoresistance in the PCa. The potential of the GW4869 as a combinational therapy to the PCa along with chemotherapeutic drugs needs to be explored further for the better management of chemoresistant PCa.

DECLARATIONS

Acknowledgment

We thank Ms. Frances Wheeler (Department of Cancer Biology; Atrium Health Wake Forest Baptist) for her help in providing PC3-R and DU145-R cells.

Authors' contributions

Conceived the study: Deep G

Designed the experiments: Deep G, Kumar A

Performed the experiment: Kumar A, Kumar P, Sharma M, Kim S, Singh S

Analyzed the data: Deep G, Kumar A

Abstract

The latest scientific knowledge has provided additional insights accountable for the worst prognosis for pancreatic ductal adenocarcinoma (PDAC). Among the causative factors, the aptitude to develop resistance towards approved medications denotes the master key for understanding the lack of improvement in PDAC survival over the years. Even though several compounds have achieved encouraging results at preclinical stage, no new adjuvant agents have reached the bedside of PDAC patients lately. The adiponectin receptor agonist AdipoRon is emerging as a promising anticancer drug in different cancer models, particularly in PDAC. Building on the existing findings, we recently reinforced its candidacy in PDAC cells, proposing AdipoRon either as a suitable partner in gemcitabine-based treatment or as an effective drug in resistant cells. Crossing the current state-of-the-art, herein we provide a critical perspective on AdipoRon to figure out whether this receptor agonist can potentially be considered a future therapeutic choice in overcoming chemotherapy-induced resistance, expressly in PDAC.

Keywords: PDAC, AdipoRon, gemcitabine, resistance

INTRODUCTION

Considered as one of the most aggressive malignancies, pancreatic ductal adenocarcinoma (PDAC)

accounts for almost all cases of pancreatic cancer^[1]. Due to the lack of specific and sensitive biomarkers, diagnosis usually happens too late, or rather when the advanced metastatic stage has already occurred^[2]. The disappointing outcomes provided by the available therapeutic regimes have further contributed to worsening PDAC prognosis, whose five-year survival rate currently stands at 10%^[3]. Regrettably, according to the existing predictive studies, PDAC will become the second leading cause of cancer death in the next decade.

Even though a combination of surgery and adjuvant chemotherapy represents the approved curative regimen for PDAC management^[4], due to the advanced or metastasized stage at diagnosis, not more than 20% of patients can undergo surgical removal^[5]. Therefore, in both resectable and non-resectable PDAC conditions, the only partially viable therapeutic strategy remains chemotherapy. Consistent with clinical practice guidelines, the first-line treatment involves the use of gemcitabine, which can be administered in combination with albumin-bound paclitaxel or FOLFIRINOX (oxaliplatin, irinotecan, leucovorin, and 5-fluorouracil) treatment cycles^[6]. Although both combination therapies have moderately improved either overall or median progression-free survival, the highest incidence of mild to severe adverse reactions has strongly restricted their usage in prolonged regimes^[7]. Therefore, gemcitabine represents the only alternative to palliative care sometimes. Disappointingly, while PDAC cells are initially extremely responsive to this cytotoxic agent, most patients easily develop resistance within a few weeks, thus compromising the success rate of the treatment^[8].

Underlying the fully fledged mechanism of chemotherapy resistance is very intricate in cancer, given that many determining factors may be involved. Essentially, both innate and adaptive mechanisms can concurrently lead to the PDAC-resistant phenotype^[9]. Analogously, native and acquired alterations in either nucleoside transporters or metabolic enzymes may prompt PDAC cells to gemcitabine resistance^[10]. Due to its hydrophilicity, cellular uptake is mediated by human equilibrative nucleoside transporters (hENTs) and human concentrative nucleoside transporters (hCNTs), although hENT1 accounts for transporting almost the entire amount of gemcitabine into cytosol^[11]. Once inside, gemcitabine is first phosphorylated by deoxycytidine kinase (dCK), and then converted to nucleoside diphosphate (dFdCDP) and triphosphate (dFdCTP), successively^[12]. Its metabolic inactivation, instead, is regulated by cytidine deaminase (CDA) or, after phosphorylation, deoxycytidylate deaminase (dCTD)^[13]. Conversely, gemcitabine can inhibit dCDT activity both directly and through its active metabolite, dFdCTP^[14,15]. Considering the gemcitabine-related metabolism as a whole, it is quite clear that changes in hENT1 levels, as well as CDA dysregulations, can play a decisive role in defining the degree of resistance against this chemotherapy drug. In PDAC, for instance, variations in CDA expression or activity have been correlated with impaired gemcitabine responsiveness^[16-18]. Although gemcitabine is not considered a canonical target of multidrug resistance-associated proteins (MRPs)^[19,20], different studies have displayed a sort of collateral modulation in ATP-binding cassettes (ABCs), expressly in PDAC cells unresponsive to deoxycytidine analog^[13,21-23]. Besides the tumor-related mechanisms, stroma may further contribute to the establishment of a non-permissive cytotoxic microenvironment^[24], both producing a barrier for drug delivery and influencing cancer cell behaviors^[25,26]. Secreting soluble factors, remodeling extracellular matrix, delivering exosomes, reprogramming the metabolic process, and the epigenetic landscape of tumor cells are some of the stroma-related properties leading to resistance^[27,28]. In addition, there is an ever-growing awareness of the crucial role driven by cancer cell metabolism in influencing drug response^[9,29]. In accordance with this perspective, targeting precise metabolic pathways, which include, among others, glycolysis and mitochondrial oxidative phosphorylation (OXPHOS)^[30-32], has recently been recognized as a promising pharmacological approach to overcome chemoresistance in PDAC.

Starting from the adiponectin (Acrp30) evidence in regulating pancreatic homeostasis and malignancies, herein we expressly review the adiponectin receptor agonist AdipoRon as both a potential anticancer agent and gemcitabine sensitizer in PDAC. Providing our personal point of view on criticism and feelings, we try to figure out whether this receptor agonist can potentially be considered a future therapeutic choice in overcoming chemotherapy-induced resistance, expressly in PDAC.

Adiponectin: an insight on its aptitudes in regulating pancreatic homeostasis

Encoded by the *ApM1* gene (adipose most abundant gene transcript 1), Acrp30 is a 244-amino acid adipokine synthesized by adipose cells and assembled in three distinct homopolymers, which differ in molecular weight and affinity for receptors^[33]. As one of the most abundant serum-related adipokines, Acrp30 physiologically influences a wide range of cellular functions, including either related or unrelated metabolic pathways^[34]. Acrp30 primarily regulates glucose and fatty acids homeostasis, and supplementary beneficial properties have extensively been reported. Acrp30 can indeed mitigate pathophysiological conditions such as inflammation, atherosclerosis, and immune-mediated response^[35].

The pivotal role of pancreas in regulating glucose uptake makes this organ extremely vulnerable to Acrp30 signaling, even though variable and inconsistent results still exist side by side. In this respect, while many studies provide evidence supporting the Acrp30-mediated insulin release in mouse islets, in humans, this stimulation appears to be ineffective against either basal or glucose-induced insulin secretion^[36,37]. However, there are certain considerations that could elucidate this controversy. Contrary to other adipokines, pancreas-specific Acrp30 knockout mouse models have not been engineered thus far; therefore, all the provided information merely recognizes systemic effects which could influence every single statement. Moreover, glucose levels and resistance status are two additional key issues which could contribute to Acrp30-related responses. In this connection, scrutinizing the insulin-resistant mouse islets, Winzell and colleagues warned that Acrp30 can display a dual opposite effect in stimulating this specific hypoglycemic agent, namely inhibiting insulin secretion at low glucose concentrations and promoting its release under hyperglycemic status^[38].

Quite convincing is the Acrp30-mediated role in protecting the maintenance and survival of functional β -cells. The available scientific research provides precise data about the anti-apoptotic properties of Acrp30 towards lipids, ceramides, and cytokines^[37,39]. In light of its cytoprotective effects, Acrp30 has also been proposed as a potential target to treat metabolic syndrome involving β -cell dysfunction. However, the lack of compounds capable of stimulating Acrp30 production or mimicking its action has made a chimera of this therapeutic strategy.

Almost no modulations have been reported for the remaining islets components, as well as for the exocrine portion of the pancreas. Albeit β -cells constitute nearly the totality of pancreatic islets, specific unrelated changes in pancreatic functions have been detected for other adipokines. In this respect, inducing variations in membrane potential and glucagon secretion, leptin-mediated regulation has been observed in both mouse and human α -cells^[40,41]. Alterations in lipases release were also obtained in response to leptin administration^[42]. Instead, resistin, a putative adipocyte-derived hormone involved in insulin resistance and diabetes, significantly increased the secretion of pancreatic amylase, thus worsening inflammatory response and acute pancreatitis severity^[43].

Scrutinizing the scientific production, it remains quite unclear why no Acrp30 results have been achieved with respect to other pancreatic components. Surely, the limited available indirect findings suggest a chance that even these portions may be responsive to Acrp30 fluctuations. In cystic fibrosis (CF), for instance, an

autosomal recessive inflammatory disorder that consistently results in pancreatic exocrine dysfunction^[44], Acrp30 serum levels are usually higher compared to healthy subjects^[45,46]. Acrp30 modulations have also been reported in non-functional pancreatic cells, particularly in vascular endothelial cells (VECs), where an unusual overexpression in this adipokine may serve as a protective angiogenic factor in mice fed a high-fat diet^[47].

Across the controversial relationship between adiponectin and PDAC

As recently examined in a theoretical study, the vast majority of the Acrp30-mediated functions are carried out by two highly homologous seven-transmembrane helices, termed AdipoR1 and AdipoR2, which recognized the canonical membrane receptors for this kind of adipokine^[48]. Once recognition and binding have occurred, Acrp30 promotes the recruitment of adaptor protein APPL1, which in turn activates AMP-activated protein kinase (AMPK) and peroxisome proliferator-activated receptor α (PPAR α)^[35]. Besides regulating energy homeostasis, Acrp30-related intracellular targets are actively engaged in controlling several signaling pathways that, depending on cell specialization, may lead to opposite effects^[49]. The third receptor in order of discovery is a calcium-dependent adhesion molecule, also referred to as T-cadherin, whereby a lack of its intracellular domain may serve as Acrp30 co-receptor for unknown signaling^[50].

Although the presence of Acrp30 receptors has not been confirmed in all pancreatic-derived cells yet, its involvement in PDAC initiation and progression has extensively been assessed over the years. The largest part of the existing preclinical studies designates Acrp30 as an effective anticancer molecule in PDAC models^[51,52]. There is one piece of evidence suggesting a tissue-dependent outcome on tumorigenesis, which proposes an unconventional Acrp30 role in promoting PDAC growth^[53]. The conflicting findings obtained by Huang and colleagues can be explained by the specific strain employed for their *in vivo* experiments. Specifically, inoculating H7 and Panc02 cells in Acrp30-KO and Acrp30-WT C57BL/6 mice, they observed that the size and weight of the resulting tumor in Acrp30-WT mice were larger compared to those achieved in Acrp30-KO. However, apart from connecting these results directly with the Acrp30 action, no accounts were taken of the potential metabolic alterations induced by its systemic ablation, which could constitute a hostile environment for tumor growth per se. However, more accurate experiments involving the use of an inducible system are mandatory to figure out the cause of this controversy.

The clinical findings supporting the Acrp30 involvement in pancreatic malignancy as a putative risk and prognostic factor remain inconclusive. While both US and European nested case-control studies revealed an inverse correlation between the pre-diagnostic plasma levels of Acrp30 and the subsequent risk of developing PDAC^[54,55], a recent Mendelian randomized analysis totally rejects this association^[56]. Two main limitations make the link between Acrp30 and PDAC risk inconclusive so far: (i) the absence of systematic reviews of randomized controlled trials; and (ii) the limited setting of PDAC patients whose Acrp30 levels were monitored before and during PDAC diagnosis. Moreover, rather than an ordinary relationship with blood levels, PDAC risk could be associated with the expression of specific genetic variants of Acrp30^[57]. More persuasive appears the hyperadiponectinemia observed in PDAC instead^[58-60]. While this connection could be interpreted as a compensatory response to the PDAC-induced cachexia, Acrp30 plasma levels seem unrelated to either BMI or leptin concentration^[58,59]. Therefore, an alternative explanation for this unexpected increase could be a sort of adaptive process for hindering tumor growth. This model could also account for the reduced levels of both Acrp30 receptors observed in PDAC cells relative to normal pancreatic tissue^[61]. Nevertheless, further designs are absolutely needed to investigate the above, as well as other possible conjectures. Only few and conflicting assumptions have been stated regarding Acrp30 as a prognostic factor in PDAC^[62,63].

AdipoRon and PDAC: more lights than shadows

Due to a combination of both intrinsic and extrinsic limitations, no translation has been conceived for Acrp30 in cancer clinical trials. While the controversial findings have not permitted any subsequent steps involving PDAC patients to date, Acrp30 translation floundered even in cancers showing very convincing preclinical results. The heavy molecular mass and the reduced half-life/stability of Acrp30 have substantially hampered any clinical application in malignancy as well as in other pathological conditions. Nevertheless, the recent characterization of a plausible Acrp30 active and binding site has broken new ground in the design of derived compounds, thus making different druggable options available^[64].

In regard to the Acrp30-mediated beneficial properties observed in cell disease models, adiponectin receptor agonists certainly denote the most promising class of compounds having potential therapeutic perspectives. Among the other agonists, AdipoRon is emerging as a fascinating anticancer agent in several malignancies, including osteosarcoma, myeloma, breast and ovarian cancer^[65,66]. Standing out as the top-scored in activating AMPK and bonding AdipoR1 and AdipoR2 in murine myeloblast C2C12 cells, AdipoRon is currently recognized as the first orally active adiponectin receptor agonist^[67].

Independent research groups have provided convincing evidence supporting the antiproliferative role played by AdipoRon in both *in vitro* and *in vivo* PDAC models^[61,68-71]. Unsurprisingly, querying the main scientific databases for AdipoRon, PDAC represents the most mentioned among the tumor models examined thus far. A detailed summary of the key findings obtained in PDAC is discussed hereafter.

Messaggio and co-workers were the first to prove that AdipoRon could suppress tumor growth in PDAC models^[61]. Specifically, employing both human and GEMM-derived mouse PDAC cells, they observed reduced proliferation and apoptosis induction in response to AdipoRon administration concurrently. Even though AdipoRon treatments decreased signal transducer and activator of transcription 3 (STAT3) phosphorylation, no experiments have been performed to address its impact on the AdipoRon-mediated action. In this respect, a more comprehensive mechanistic design was proposed by Akimoto and colleagues a year later, who drew attention to RIPK1-dependent necroptosis as the main tool for cell death induction in AdipoRon-treated cells^[68]. Nevertheless, based on the obtained results, they did not exclude that caspase-independent apoptosis and autophagy could be similarly involved. Mechanistically, a rise in calcium concentration triggered extracellular signal-regulated protein kinase 1/2 (ERK1/2) and calpain-1 activation, which in turn led to mitochondrial dysfunction and caspase-independent apoptosis induction. Activation of AMPK and p38 signaling were recognized as survival pathways in this specific experimental design, since their pharmacological inhibition enhanced the AdipoRon cytotoxic effects. The impairment of mitochondrial activity was further confirmed by Manley *et al.* in their latest study^[69]. Performing Seahorse-based assays, they noticed that AdipoRon treatments not only decreased basal and maximal mitochondrial respiration but also attenuated proton leak. As a compensatory response to defective mitochondrial ATP production, PDAC cells increased anaerobic glycolysis by consuming a greater amount of glucose and producing more lactic acid. Finally, based on these results, the authors recognized glycolysis inhibitors as potential targets to enhance AdipoRon effectiveness. Aimed at providing more insight into the AdipoRon-mediated antitumor properties in PDAC, Takenaga and colleagues revealed a concurrent angiogenesis inhibition in MSS31 endothelial cells, which may cause a shortage of nutrients and oxygen supply in tumor cells^[71]. Although AMPK, p38, and ERK1/2 were simultaneously activated by AdipoRon in this cell type, the MEK1 inhibitor U0126 was the only one capable of preserving tube formation. The anti-angiogenic features could also explain the reduced effectiveness observed in the AdipoRon-treated orthotopic pancreatic cancer mice fed a high-fat diet. Specifically, given that obese mice usually show high plasma levels of leptin, this anorexigenic adipokine may dynamically compete with AdipoRon in stimulating endothelial cells, thus overriding pro- rather than anti-angiogenic mechanisms.

AdipoRon improves gemcitabine-mediated outcomes in PDAC cells

While different studies convincingly propose AdipoRon as an anticancer agent in PDAC models, no data support a potential cooperating effect in gemcitabine-based therapy. In this respect, we recently provided evidence of increased responsiveness to gemcitabine when PDAC cells were concomitantly stimulated with AdipoRon. Using multiple biological approaches, we demonstrated that AdipoRon plus gemcitabine significantly decreased tumorigenesis in two distinct PDAC cell lines, MIA PaCa-2 and PANC-1.

In detail, adding AdipoRon to gemcitabine further compromised cell growth and colony-forming ability compared with single treatments, thus suggesting a positive correlation between these two compounds. For this purpose, CompuSyn analysis was subsequently performed, demonstrating a potential synergistic effect in either raising cell-growth inhibition or reducing colony formation. Precisely, this assay revealed a combination index (CI) ranging from 0.59-0.63 in MIA PaCa-2 and 0.05-0.22 in PANC-1. We also recorded G0/G1 and S phase accumulation after the individual release of AdipoRon and gemcitabine, respectively. Remarkably, when these two compounds were administered together, we noticed different but intermediate features in cell cycle distribution. Without statistically significant variations in SubG1 amount compared to the deoxycytidine analog ($P > 0.05$), AdipoRon plus gemcitabine induced G0/G1 accumulation closer to AdipoRon within 24 h and S-phase arrest similar to gemcitabine after 48 h. The observed variations in cell cycle distribution after AdipoRon, gemcitabine, and AdipoRon plus gemcitabine treatment were further corroborated by cyclins and cyclin-dependent kinase inhibitor levels. Considering the relevance of the ERK1/2 signaling in the AdipoRon-mediated action, we investigated its possible involvement in combination with gemcitabine. Without significant changes in total protein amount, we observed a phospho-ERK1/2 upregulation in combined treatment more than AdipoRon alone. Intriguingly, the usage of PD98059 as a potent MEK1/MEK2 inhibitor partially prevented the enhanced outcomes observed in reaction to AdipoRon plus gemcitabine, thus reinforcing the dynamic influence of this pathway in the AdipoRon-mediated sensitization. To further speculate on the usefulness of AdipoRon-based therapy in PDAC, we finally explored the combination impact in gemcitabine-resistant MIA PaCa-2 cells. While gemcitabine was ineffective in decreasing cell proliferation, AdipoRon treatments, either alone or in combination, hindered cell growth with an inhibition rate of 25% and 43%, respectively. We also observed a reduction in colony numbers after both AdipoRon and AdipoRon plus gemcitabine administration. As in gemcitabine-sensitive cells, AdipoRon was able to increase the G0/G1 phase in resistant ones, while the simultaneous presence of gemcitabine further intensified this tendency.

Critical issues and future perspectives for the AdipoRon usage in PDAC treatment

In light of the latest cancer statistics^[3], it is explicit that all clinically approved therapeutic strategies for treating PDAC have provided unsatisfactory responses. While the rest of the cancers are moving toward a chronic management, PDAC remains one of the deadliest malignancies worldwide^[72]. Even immunotherapy, which has been designed as the “breakthrough” in cancer treatment, has achieved only weak outcomes in PDAC^[73]. Consequently, identifying novel pharmacological approaches is categorically demanded to make PDAC more treatable.

AdipoRon has recently been found to be effective in contrasting PDAC cell growth at preclinical stage^[61,68,69,71], but, more interestingly, we recently provided evidence of potential cooperating effects between AdipoRon and gemcitabine^[70]. Due to the low rate of radiation and surgery eligibility, gemcitabine-based therapy constitutes the widely used approach in treating PDAC^[5]. Regrettably, even though gemcitabine is still considered a cornerstone in PDAC therapy, the chances of developing chemoresistance are extremely high for these patients, and thereby combinatory treatments are usually preferred over single-agent administration. Despite the huge efforts made to provide other pharmacological options, only two gemcitabine partners, erlotinib and nab-paclitaxel, have been approved in clinic^[74]. However, their success

Table 1. Metabolic pathways involved in gemcitabine resistance and potentially affected by AdipoRon exposure

Metabolic pathway	Molecular target	Drug inhibitor	Reference
OXPHOS	Complex I	Metformin, rotenone, phenformin	[31]
	Complex IV	Arsenic trioxide	[32]
	Complex V	Oligomycin	[78]
Glycolysis	Hexokinase	2-deoxy-D-glucose	[79]
	Pyruvate Dehydrogenase	CPI-613 (devimistat)	[32]
	LDH-A	N-hydroxyindole-based inhibitors	[80,81]

rate is strictly dependent on several factors, including genetic signatures and performance status scale^[75,76]. Recognizing AdipoRon as a potential candidate in gemcitabine-based therapy may provide additional hopes for advanced PDAC patients. However, to be fair, the possibility that AdipoRon may reach the bedside of PDAC patients is currently remote. While AdipoRon has already been tested in animal models as a single agent, showing a high degree of tolerability in normal tissues^[68], *in vivo* studies have not corroborated its effectiveness in combination with gemcitabine yet. Recently, another adiponectin receptor agonist has concluded phase 1/2a (NCT04201574) and is currently under evaluation in phase 2/3 clinical trials (NCT04899518). As a peptidomimetic agonist, ALY688 has shown no specific adverse reactions as ophthalmic solution in human patients, and now two distinct concentrations (0.4% and 1%) will be evaluated for their efficacy in subjects with dry eye disease. While extremely promising, a positive ALY688 outcome in human trials would not lead to AdipoRon approval in clinic, but it could pose a driving force for its testing in cancer patients. Adiponectin receptor agonists actually include a heterogeneous group of molecules, and thus they must be investigated individually at every stage. In this respect, dissimilarities in biological behaviors have been observed even between AdipoRon and Acrp30. Characterizing the AdipoRon-mediated mechanism of action in PDAC cells, Akimoto and colleagues noticed that, unlike AdipoRon, neither ERK1/2 activation nor cell death induction was detected in response to Acrp30 administration^[68]. These findings bring more doubts about the chemical and biological differences that may exist between these two molecules, as well as whether the AdipoRon-mediated effects are really due to the agonistic action towards Acrp30 receptors.

The ability to make gemcitabine-resistant MIA PaCa-2 cells responsive to AdipoRon denotes a fascinating aptitude that could open up new opportunities in overcoming chemotherapy refractoriness. On the basis of the standing knowledge, there is a rational explanation for corroborating the above biological outcome. Recently, mitochondria have been described to facilitate the survival of stem and dormant cells treated with cytotoxic agents in PDAC^[31]. Several mitochondrial-related pathways and mechanisms have been associated with chemoresistance, such as apoptosis, autophagy, and metabolic remodeling^[77]. In accordance with this latter operation, in both oncogene-ablated and gemcitabine-treated PDAC cells, targeting OXPHOS significantly shrank tumor recurrence^[31,32,78]. Since an OXPHOS impairment has also been observed in response to AdipoRon administration^[68,69], it is plausible to imagine a link between the damage that occurred at this organelle and the ability to sensitize PDAC resistant cells to gemcitabine. While the aberrant glycolysis usage is considered a metabolic feature of drug resistance in tumor cells^[30,79], after AdipoRon stimulation, this compensatory mechanism could be exploited to completely eradicate the minimal residual disease [Table 1]^[69,80,81]. Besides the metabolic outlook, another potential mechanistic way to corroborate the AdipoRon-mediated gemcitabine sensitization could be represented by the ABC transporters, which have recently been implicated in chemotherapy resistance, expressly in PDAC^[21-23]. Despite no proof currently demonstrating an AdipoRon-induced ABCs modulation, limited findings correlate Acrp30 and some members of this class of transporters. In this respect, Acrp30 has been described to increase both mRNA and protein levels of ABCA1 in hepatocellular carcinoma HepG2 cells^[82]. A positive

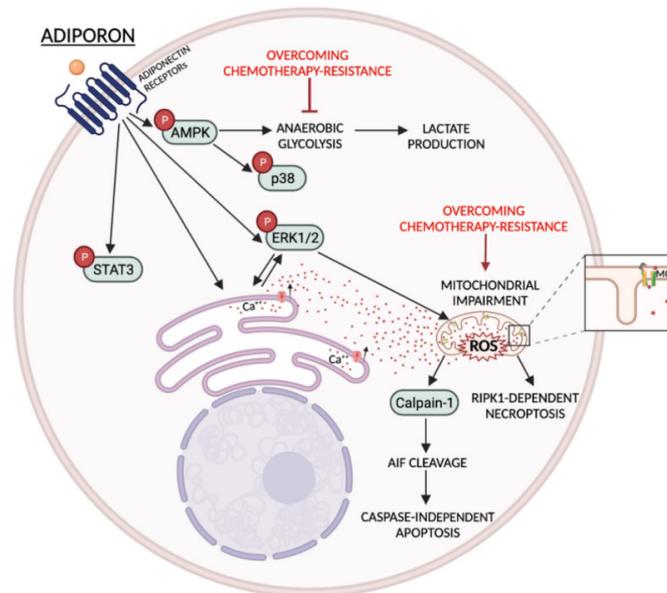

Figure 1. AdipoRon-mediated mechanisms and potential interconnection points to overcome gemcitabine resistance in PDAC. Schematic representation of the main metabolic and signaling pathways regulated by AdipoRon in PDAC cells. Red arrows indicate direct and indirect AdipoRon-related ways to hinder chemotherapy resistance.

correlation between Acp30 and ABCA1 levels has also been observed in visceral adipose tissue^[83]. However, the abovementioned speculation first warrants further investigation about the possible contribution of ABC transporters to gemcitabine resistance.

Although all these assumptions are largely based on logical reasoning, we strongly feel that all future inquiries should be moving in this direction. In addition, the next two steps should be aimed at defining the existence of potential cooperating effects with other approved chemo-drugs and translating the combination of AdipoRon plus gemcitabine into a more complex biological system such as *in vivo* models. Simultaneously, characterizing each mechanistic aspect of the AdipoRon-mediated features may contribute to outlining its wholesomeness in overcoming gemcitabine and, more in general, chemotherapy-induced resistance in PDAC [Figure 1].

In light of the current orphan status and the tremendously unfavorable prognosis, each promising molecule capable of improving both PDAC prognosis and survival should be fully explored. Analyzing the current scientific production, AdipoRon is emerging as a potential therapeutic choice in PDAC, either as a single compound or a partner in gemcitabine-based treatment. Therefore, its pharmacological properties perfectly fulfill the requirements that a candidate is supposed to have for ameliorating PDAC expectation. Whether this is enough to attain clinical approval will be based on the upcoming experiments.

DECLARATIONS

Authors' contributions

Conceptualization: Sapio L, Naviglio S

Investigation: Ragone A, Salzillo A

Writing-original draft preparation: Sapio L

Writing-review and editing: Spina A, Naviglio S

Abstract

Epithelial ovarian cancer remains the most lethal female malignancy despite options for systemic therapy and the emergence of targeted therapies. Although initial response to therapy is observed, recurrence and ultimately chemoresistance result in overall therapeutic failure. This pattern has been evident with platinum therapy since the 1980s. Significant excitement surrounded the approval of poly (ADP-ribose) polymerase inhibition (PARPi) as a novel therapeutic option, especially with the advent of personalized medicine, but resistance has similarly developed to these treatments. Novel agents are constantly being sought, but if the obstacle of chemoresistance remains, the durability of responses will remain tenuous. Unraveling the multifactorial mechanisms of platinum and PARPi resistance is increasingly important as a therapeutic failure with current strategies is almost assured. Focusing greater efforts on expanding the current understanding of the complex nature of platinum and PARPi chemoresistance has tremendous potential to improve clinical outcomes.

Keywords: Epithelial ovarian cancer, chemoresistance, platinum resistance, poly (ADP-ribose) polymerase inhibitor resistance, tumor microenvironment

EPITHELIAL OVARIAN CANCER AND THE LIMITATIONS OF CURRENT THERAPY

Epithelial ovarian cancer (EOC), primarily high-grade serous carcinoma (HGSOC), remains the leading

cause of death from gynecologic cancers primarily due to the advanced stage at the time of diagnosis and the inherent difficulty of treating tumors that become resistant to chemotherapy over varying amounts of time. Surgical cytoreduction and platinum-based chemotherapy have been the mainstay of ovarian cancer treatment since the 1980s. Platinum cytotoxicity results from its ability to cause an accumulation of deoxyribonucleic acid (DNA) double-strand breaks and cell death via the formation of intra-strand and inter-strand adducts which activate cellular DNA damage response (DDR) pathways, which inhibit replication and transcription of DNA, inducing cell cycle arrest and apoptosis^[1]. Platinum-based therapy has been the cornerstone of EOC treatment for decades, but the majority of patients relapse within two years, and eventual platinum resistance is accompanied by an extremely poor prognosis^[2,3]. Platinum-refractory disease is defined as a persistent or progressive disease while receiving platinum-based chemotherapy or within four weeks of therapy, and platinum resistance is defined as cancer recurrence or progression within six months of platinum therapy^[3]. The median survival in platinum-resistant disease is only 12 months, underscoring the need to identify novel therapies but also to understand and overcome the complex mechanisms of chemoresistance^[4].

The advent of poly (ADP-ribose) polymerase inhibition (PARPi) as a novel therapeutic option approved for EOC in 2014 presented significant excitement and marked the birth of personalized medicine in EOC. Poly (ADP-ribose) polymerases (PARP) are a family of proteins with several roles that include DNA repair (including nucleotide excision repair, non-homologous end joining, homologous recombination (HR) and DNA mismatch repair), apoptosis, chromatin remodeling and the stress response^[5]. Several clinical trials have demonstrated the impressive benefit of PARPi therapy, especially in patients who have responded to platinum-based therapy^[6,7]. This might be attributable to the high prevalence of tumors with homologous recombination deficiency (HRD), which is found in approximately 50% of all ovarian cancers^[6]. BReast CAncer gene (*BRCA1/2*) germline deficiency accounts for approximately 20% of these cases^[4]. Somatic BRCA mutations result in HGSOC phenotypes and platinum chemotherapy responses similar to germline BRCA mutation carriers and are referred to as HGSOC with “BRCAness”. BRCA variants, either germline or somatic, lead to an increased susceptibility to DNA double-strand breaks. PARPi elegantly capitalizes on synthetic lethality when PARP inhibition and HRD are combined to cause apoptosis of cancer cells^[8].

Resistance to platinum therapy is strongly predictive of resistance to PARPi therapy consistent with overlapping biologic mechanisms of susceptibility and resistance^[2,9]. A specific definition for PARPi resistance has not yet been developed as exists for platinum-based chemotherapy, and it remains to be seen if tumors are resistant to all PARPi once resistance is developed to a single PARPi^[6].

In this commentary, we will explain some of the most clinically relevant tumor biology contributing to platinum and PARPi resistance, two of the most significant therapies in use currently for EOC, as well as review future directions.

MECHANISMS OF CHEMORESISTANCE

There are several mechanisms, both intrinsic and acquired, that contribute to platinum chemoresistance. Platinum compounds may undergo decreased uptake into cells, increased efflux, or increased inactivation. For example, overexpression of the adenosine triphosphate-binding cassette (ABC) family of transporters, such as P-glycoprotein or multidrug resistance-related proteins (MRP1), affects the efflux of chemotherapeutic drugs. Although the exact mechanism of action is not clear, high levels of ABC subfamily A member 1 expression have been found to correlate with poor progression-free and overall survival in serous EOC^[10].

Once platinum cytotoxicity has occurred and adducts have begun to form, cells may still be able to thwart its effects by acquiring the ability to repair platinum-induced DNA adducts via counteraction of the cell's DDR response. The DDR response is an essential network of proteins that sense, signal and/or repair DNA damage to maintain genomic integrity and stability within the cell^[11]. Key proteins that signal DNA damage to cell-cycle checkpoints and DNA repair pathways include: ataxia-telangiectasia mutated (ATM), ATM- and RAD3-related, DNA-dependent protein kinases^[6]. These key proteins sense DNA damage and initiate repair signaling cascades by phosphorylation of key repair proteins: BRCA1, checkpoint kinase 1 (CHK1), checkpoint kinase 2, tumor protein p53 (P53) and *RAD17*^[12]. Cellular mechanisms that assist in the repair of DNA include base excision repair for single-strand breaks (SSBs); nucleotide excision repair (NER) for the repair of bulky adducts (such as observed with platinum therapy); mismatch repair (MMR) for mispaired bases; homologous recombination (HR) repair for double-stranded breaks (DSBs), intra-strand and inter-strand crosslinks; non-homologous end-joining (NHEJ) for DSB; or microhomology-mediated end joining for the repair of DSBs^[13].

When DNA damage is too severe for repair, apoptosis is triggered^[13]. Cells that have acquired platinum resistance subvert the normal DDR responses and instead demonstrate increased ability to initiate repair signaling, activate checkpoints to slow progression and allow repair, increase the pace of adduct repair or even develop the ability to tolerate DNA adducts without resorting to apoptosis^[1,14].

The NER and HR repair pathways work very closely together. The NER pathway recognizes and removes bulky helix-distorting crosslink lesions via a step-wise process: damage recognition, unwinding of the DNA locally around damage, incision of damaged DNA by endonucleases, and DNA resynthesis and ligation^[15]. This process allows NER to recognize DNA crosslinks and converts the crosslink to a DNA double-strand break. HR is then required to repair the double-strand break to prevent apoptosis^[16].

In preclinical trials, enhanced NER in ovarian cancer models has been associated with increased cisplatin resistance *in vitro*, supporting the importance of NER in the development of platinum chemoresistance^[17,18,19]. Specifically, the excision repair cross-complementation group 1 (ERCC1) protein plays a key role in nucleotide excision repair. Dimerization of ERCC1 with xeroderma pigmentosum complementation group F (XPF) enables excision and repair of bulky cisplatin lesions in damaged DNA^[18]. Overexpression of proteins in the NER pathway, including ERCC1, is associated with platinum resistance, likely via the ERCC1-XPF endonuclease^[19,20].

Additionally, P53 expression, common in HGSOC, promotes tumorigenesis as well as drug resistance via inhibition of apoptosis. Inhibited apoptosis contributes to proliferation and metastasis^[2]. P53 expression specifically leads to growth phase 1 (G1) / synthesis (S) checkpoint deficiencies and cell-cycle dysregulation, subsequently placing greater stress on the growth phase 2 (G2) / mitosis (M) checkpoint for survival. Wee1 kinase inhibits activation of Cyclin-dependent kinases 1 (CDK1) and CDK2, making it a key cell cycle regulator of the G2/M transition. Alterations in Wee1 kinase may have implications for chemoresistance^[21].

Although the majority of EOC responds to platinum therapy, even if only for a limited time, many do not exhibit any durable response to platinum therapy. Mechanisms of such intrinsic chemoresistance include proficient DNA repair, cyclin E1 (CCNE1) amplification, and mesenchymal or proliferative molecular subtypes. Approximately 20% of EOC cases have CCNE1 amplification, which are associated with primary resistance to platinum^[22].

The current understanding of the mechanism of PARPi resistance centers around Darwinian escape. Darwinian escape refers to an acquired secondary somatic mutation to restore HR in BRCA 1/2 (reversion mutations)^[7]. BRCA reversion mutations have been identified in progression biopsies as well as cell-free DNA (cfDNA). cfDNA has shown polyclonality of multiple reversion mutations within a single patient when under pressure from treatment^[8]. One mutation that has demonstrated restoration of DNA repair is *BRCA1-Δ11q*. Patients with *BRCA1-Δ11q* demonstrated decreased sensitivity to both cisplatin and PARPi^[23]. BRCA reversion mutations have been identified in 13% of patients with platinum-refractory disease and 18% of patients with platinum-resistant disease^[5]. Patients with BRCA reversion mutations experienced decreased progression-free survival when undergoing treatment with rucaparib^[24]. The initial strength of response to PARPi has been shown to correlate with the severity of eventual tumor resistance^[5].

TUMOR MICROENVIRONMENT AND METABOLISM IMPACT ON CHEMORESISTANCE

Numerous studies have demonstrated the critical role of hypoxia in the tumor microenvironment and its association with platinum resistance via signaling pathways in DNA damage, mitochondrial activity, apoptosis autophagy, and drug efflux^[25,26]. Chen *et al.*^[27] demonstrated that cisplatin-resistant cancer cells show increased intracellular hypoxia and decreased glucose uptake suggesting that platinum resistance might stem from alterations in glucose metabolism. Altered angiogenesis is another hallmark of intra-tumor vessels which also contributes to hypoxia, poor drug delivery, and chemoresistance^[28].

Cancer-associated fibroblasts, tumor-associated macrophages, and cancer stem cells have all been proposed influencers of prognosis and chemotherapy resistance. Stromal activation with extensive desmoplasia has been associated with poor clinical outcomes and acquired treatment resistance^[27,29]. Platinum chemotherapy is also thought to influence anti-tumor immunity. Increased infiltration of immunosuppressive Cluster of Differentiation 163-positive macrophages and increased infiltration of regulatory forkhead box P3-positive T cells have favored tumor growth^[6,30-32]. In contrast, the presence of tumor-infiltrating lymphocytes is positively correlated with survival^[6,33]. Data on immune checkpoint therapy in EOC has been contradictorily reflecting an incomplete understanding of the key regulators and pathways^[6]. Immunotherapy may yet play an important role in EOC.

Additionally, the omentum and cell metabolism are thought to play a pivotal role in cancer progression and chemoresistance. The omentum is a favored site for metastasis due to EOC's ability to use fatty acids to initiate and sustain peritoneal metastasis; in addition, it may also participate in ascites formation^[34,35]. Elevated cytokines and adipokines in the ascitic fluid are thought to protect malignant cells from chemotherapy-induced apoptosis, including via lysophosphatidic acid signaling and prostaglandin E₂ - mediated GFTR transporter upregulation^[19]. The metabolism of tumor cells is intricately intertwined with all cells of the microenvironment. Tumor cells have demonstrated an amazing ability to metabolically adjust to changes in their environment, as well as influence the metabolic function of neighboring cells for their own purposes^[34,35,36].

Cancer stem cells (CSCs) are theorized as a population of cells capable of self-renewal and repopulation following cancer treatment that may cause tumor initiation and metastasis^[37]. Stem cell pathways have recently been recognized as an important mediator of chemoresistance. CSCs have improved methods of chemotherapy removal from the cell, including the ABC cassette and drug transporters. Tumors containing heterogeneous cancer cells are linked to progression as they are more likely to undergo selection towards a population of drug-resistant tumor cells with treatment. CSCs are aided by their microenvironment and stimulated by hypoxia-inducible factors. Phosphoinositide kinase (PI3K) has an important role in apoptosis for maintaining stem cell "stemness" and drug resistance. Notch signaling and Wnt/beta-catenin are

important in CSCs signaling pathways and may be useful targets^[38]. CSCs are also able to grow in spheres and expand as sphere-like cellular aggregates more easily than other populations of cells^[39]. The ability to treat cancer stem cells is of particular importance since these cells can remain in patients with seemingly no evidence of disease or lead to metastasis.

FUTURE DIRECTIONS

Chemoresistance evolves over time as a response to the selective pressure of therapy. The multiple mechanisms of resistance are complex and not fully understood, but strategies to overcome chemoresistance are being developed. These methods include exploration of methods to improve drug delivery; identification of potentially useful biomarkers; identification of molecular targets; and exploitation of tumor weaknesses using modulation of the cell cycle, tumor microenvironment, or cellular metabolism. Combination therapies may improve this exploitation of tumor weaknesses.

Drug delivery

Improved drug delivery could also combat chemoresistance. Nanotechnology is being used to investigate the ability of nanoparticles to improve targeted treatment, including the encapsulation of cisplatin with dendrimers to aid in cell killing^[2,40]. Layer-by-layer nanoparticles have also been used to deliver cisplatin and a PARPi to mice, with improved bioavailability, cytotoxicity, and systemic toxicity compared with conventionally administered medication^[40]. Natural compounds including curcumin and piperine are being evaluated to attempt to induce G2/M phase arrest, caspase activation, the PI3K pathway (piperine), and apoptosis and phosphorylation of p53 (curcumin)^[2].

Biomarkers

A study of patients with durable responses may be useful for identifying biomarkers, especially patients with HR proficiency who have good responses^[7]. Improved understanding of why some patients with BRCA pathogenic variants do not respond to PARPi, and why some patients with no known BRCA mutation respond to PARPi treatment could be important for combatting drug resistance. Biomarkers that predict treatment success would be of significant benefit if they allowed improved treatment selection. However, our understanding of biomarkers that would be useful in guiding treatment selection is limited. A number of genes and proteins have been identified in patients with chemoresistance or poor prognosis and have yet to be evaluated in clinical trials to guide treatment. One gene amplification, 19q12, is associated with chemoresistance and has been identified in 20% of ovarian cancer patients^[3,40]. MMR deficiency has also been implicated in chemoresistance, but the correlation is controversial^[3,19,41].

Based on the leading roles played by ERCC1 and XPF in the NER pathway, they have been promising prospects as biomarkers for platinum-based therapy. A meta-analysis of retrospective *in vitro* studies in non-small cell lung cancer by Altaha *et al.*^[42] concluded that high levels of ERCC1-mRNA and/or ERCC1 protein were associated with resistance to platinum compounds. Despite the correlation between ERCC1 overexpression with platinum resistance and ERCC1 under expression with platinum sensitivity, translating ERCC1 as a predictive biomarker for response to platinum-based therapy in clinical trials has been challenging^[43]. ERCC1 has been investigated as a biomarker in both adrenocortical carcinomas and advanced non-small cell lung cancer and did not offer prognostic or treatment selection benefits^[44,45]. Continued study of ERCC1 and the NER pathway is needed.

Patients with PARPi resistance have been found to have reversions in *RAD51C* and *RAD51D*, and *in vitro* studies have demonstrated loss of TP53 binding protein 1^[3,46]. Studies of TP53 vary regarding its utility as a marker in platinum resistance, but it may be helpful in treatment planning^[47]. Pump P-glycoprotein (P-gp)

expression, which is related to drug efflux and multidrug resistance, has also been implicated in PARPi resistance^[3,48]. CSC markers of *Bmi-1*, *Nanog* and *Oct 4* with elevated stem cell factor and *c-Kit* levels indicated chemoresistance as well^[37]. Other proteins indicating resistance and poor prognosis include Notch3 and *LGR5*; CD24 correlates with poor prognosis, chemoresistance, metastasis, and recurrence; CD44+/CD117+ cells were associated with chemoresistance; CD133+ cells showed cisplatin resistance, and ALDH1A1 was associated with poor survival and drug resistance^[36,49]. AT-rich interaction domain 1A inactivation or loss of expression is also correlated with poor overall survival in patients receiving platinum. Micro ribonucleic acids (miRNAs), including let-7 g, miR-98-5p, miR-622 as well as others, have been associated with platinum and/or PARPi resistance^[50].

Newer technology in tumor surveillance may also be critical to the understanding of tumor chemoresistance and the discovery of biomarkers. Liquid biopsies may offer a unique opportunity for real-time tumor molecular profiling. Liquid biopsies enable the analysis of circulating tumor cells, circulating tumor DNA, circulating mRNA, and tumor-derived extracellular vesicles that are shed from primary tumors into the peripheral blood^[51]. Serial assessments would enable real-time patient assessment and comparison during therapy at the onset of resistance to therapy, which may increase our understanding of chemoresistance.

Genetics

Other possible areas of investigation involve the utilization of next-generation sequencing to aid the discovery of predictive signatures. Four molecular subtypes of HGSOC have been described and validated by the Cancer Genome Atlas Research Network study^[52]. Absolute copy number profiles have been generated using primary and relapsed HGSC samples. Macintyre *et al.*^[53] identified seven copy number signatures that were stable between diagnosis and disease relapse, indicating that copy number signatures at diagnosis may predict overall survival and platinum resistance^[54]. Different mutational processes generate unique combinations of mutation types, termed mutational signatures^[55]. The Catalogue of Somatic Mutations in Cancer (COSMIC) has revealed many mutational signatures across the spectrum of human cancer types. Analysis of COSMIC mutational signatures in ovarian cancer reveals a prevalence of signature 1B^[56].

Epigenetic modifications are mechanisms that alter the expression of a gene but do not change the DNA sequence. These modifications help to regulate normal genome functioning. Epigenetic modifications may also be contributing to chemoresistance. Identification of epigenetic changes in chemoresistant EOC may allow for the advanced development of epigenetic modulating drug therapy. Current agents such as demethylating agents, histone deacetylase inhibitors, and microRNA-targeting therapies have shown preclinical promise^[57].

Homologous recombination and combination therapies

Defining PARPi resistance and evaluating the utility of alternating PARPi therapy if resistance has developed to one PARP remains to be seen but may be answered by the OReO trial^[6,58]. PARPi do have different potencies due to the degree of PARP trapping; clinical implications have yet to be seen. Additionally, re-examining the definition of platinum sensitivity and resistance may be needed.

Combination therapies of PARPi and platinum together, or the addition of another agent to combat chemoresistance when using one or the other, may allow circumvention of treatment resistance. In a study by Gajan *et al.*^[58] of breast cancer patients with and without BRCA mutations and with resistance to both cisplatin and olaparib, a benefit of combined therapy with olaparib and cisplatin was identified. Interestingly, the combination treatment was not helpful in patients whose disease was still sensitive to either treatment^[59]. A similar investigation could be considered in EOC patients as well. Niraparib has been

investigated in combination with carboplatin and gemcitabine for patients with unresectable or recurrent platinum-sensitive ovarian cancer and showed a 57% radiographic response rate^[60]. Cisplatin-resistant ovarian cancer cells (C13) were treated with a PARPi, 3-aminobenzamide by Zhang *et al.*^[60] Cellular proliferation was inhibited more when treated with cisplatin and increasing doses of PARPi, pointing to chemosensitization^[61]. Additional studies investigating novel DDR-targeting agents and combination treatment approaches are underway.

As targetable pathways have been implicated in chemoresistance, translational researchers have also been searching for immunotherapies and molecular targets to use as combination therapies to improve the cytotoxic effect of therapy. Anti-angiogenesis with cediranib in combination with olaparib has been investigated with efficacy that varied by mutation identified following PARPi progression, with poorer outcomes identified for patients with HRD reversion mutations and ABCB1 upregulation^[62]. This treatment combination is under further investigation with the OVC2 trial^[6,63]. One promising target for therapeutics to combine with PARPi is mesenchymal-epithelial transition factor (c-Met), a receptor tyrosine kinase, since the high expression is associated with a poor prognosis. This biomarker and therapeutic target have been linked to PARP resistance and HR restoration^[7]. CDK have also been proposed as targets since they control cell cycle progression and DNA damage control. Loss of CDK inhibition impairs BRCA function (BRCAness)^[7]. PI3K inhibitors have been proposed as methods to extend the use of PARPi and are under investigation^[7,64,65]. Other therapies that have been trialed include PARPi with alkylating agents, topoisomerase I inhibitors, WEE1 kinase inhibitors, PI3K inhibitors, radiation, immunotherapy, and DNA methyltransferase inhibitors. PARPi with topoisomerase I inhibitor allows inhibition of TOP1-PARYlation, inhibition of homologous recombination and stimulation of NHEJ plus inhibition of tyrosyl-DNA-phosphodiesterase I. Clinical investigations of this combination have not been completed^[5]. However, promising combination treatments to overcome PARPi or platinum resistance have not been identified.

CONCLUSIONS

EOC is a disease marked by frequent relapses and responses to therapy before the eventual development of chemoresistance. Chemoresistance remains a steadfast obstacle to improving EOC survival. Platinum, the mainstay of EOC treatment, is limited by almost ubiquitous platinum resistance. While anti-angiogenic therapy and PARPi are promising new treatments, resistance has already been observed. The heterogeneity of EOC allows it to adapt in response to treatment and confounds attempts to identify clinically meaningful biomarkers and targets. Tumors constantly evolving with time and treatment seem to naturally develop resistance.

In some cancers, real-time collection of circulating tumor DNA is a reality that has enabled the characterization of drug response for tumors along with multiple time points^[62]. EOC, given its inherent heterogeneity, may require an equally malleable treatment approach: the serial integration of genomic, epigenomic, metabolomic, and immunogenic study at diagnosis and at each recurrence to optimize therapy. It would require a significant change in clinical practice and greater investment in bioinformatics, but it may not be possible to conquer all the nuances of EOC without it.

DECLARATIONS

Authors' contributions

Made substantial contributions to the conception and design of this study, performed literature review, wrote and edited the manuscript: Summey R

Conceived and designed this study, performed literature review, co-wrote and edited the manuscript: Uyar D

Abstract

Multiple myeloma (MM) remains an incurable, genetically heterogeneous disease characterized by the uncontrolled proliferation of transformed plasma cells nurtured within a permissive bone marrow (BM) microenvironment. Current therapies leverage the unique biology of MM cells and target the immune microenvironment that drives tumor growth and facilitates immune evasion. Proteasome inhibitors and immunomodulatory drugs were initially introduced to complement and have now supplanted cytotoxic chemotherapy as frontline anti-myeloma agents. Recently, monoclonal antibodies, bispecific antibodies, and chimeric antigen receptor T cells were developed to revamp the immune system to overcome immune suppression and improve patient responses. While current MM therapies have markedly extended patient survival, acquired drug resistance inevitably emerges and drives disease progression. The logical progression for the next generation of MM therapies would be to design and validate agents that prevent and/or overcome acquired resistance to immunotherapies. The complex BM microenvironment promotes resistance to both current anti-myeloma agents and emerging immunotherapies. Myeloma cells are intertwined with a complex BM immune microenvironment that contributes to the development of adaptive drug resistance. Here, we describe recently FDA-approved and investigational anti-myeloma agents that directly or indirectly target the BM microenvironment to prevent or overcome drug resistance. Synergistic effects of anti-myeloma agents may foster the development of rationally-designed drug cocktails that prevent BM-mediated resistance to immunotherapies.

Keywords: Multiple myeloma, drug resistance, proteasome inhibitors, immunomodulators, immunotherapeutics, adaptive resistance, bone marrow microenvironment

MULTIPLE MYELOMA

Multiple myeloma (MM) is described by clonally expanding plasma cells within the bone marrow (BM), monoclonal proteins detected in blood or urine, and end-organ damage^[1,2]. Approximately 13% of all hematologic cancers are classified as MM, which is the 2nd most common hematological cancer in high-income and Western countries^[3]. In the US in 2021, approximately 34,920 new cases of MM (19,320 men, 15,600 women) were reported^[3-6]. The lifetime risk of an MM diagnosis is 1 in 125 (0.8%). The annual incidence of MM/100,000 persons is 8.2 cases (Caucasian men), 5.0 cases (Caucasian women), 16.5 cases (African-American men), 12.0 cases (African-American women), 8.2 (Hispanic men), 5.7 (Hispanic women) and 5.0 (Asians/Pacific Islander men), and 3.2 (Asians/Pacific Islander women)^[3-6]. Approximately 12,410 deaths from MM (6,840 men, 5,570 women) were expected in 2021^[4]. Newly reported cases of MM did not change significantly over the past 10 years, staying in the range of 6.7/100,000 since 2010, while death rates declined slightly, from 3.4/100,000 in 2008 to 3.1/100,000 in 2018^[4]. Expected 5-year survival has improved to ~56%^[3-6]. Risk factors include obesity, chronic inflammation, exposure to pesticides, organic solvents, and radiation, and inherited genetic variants^[6-8].

MM starts as an asymptomatic precursor condition monoclonal gammopathy of undetermined significance (MGUS) or smoldering multiple myeloma (SMM). Genetic abnormalities, e.g., hyperdiploidy, translocations are already evident in MGUS and SMM^[9-11]. While these precursors may exhibit a significant burden of clonal plasma cells, they require additional genetic changes to drive end-organ damage and become MM.

Current MM therapy leverages the unique features of plasma cell biology that proliferate within the BM to promote deep clinical remissions with fewer side effects than cytotoxic chemotherapy. The first FDA-approved proteasome inhibitor (PI) bortezomib, immunomodulatory drugs (IMiDs) thalidomide, lenalidomide and pomalidomide (Celgene), and monoclonal antibodies that target CD38 and SLAMF7 have significantly extended patient outcome [Table 1]^[9,12,13]. These FDA-approved agents are used to treat newly diagnosed patients with related next-generation agents exhibiting activity in the relapsed and/or refractory MM (RRMM) in all stages of treatment^[9,12,13]. While these agents have markedly improved survival, MM remains incurable, with therapeutic resistance invariably emerging even in patients with an initial favorable response to therapy. Further efforts are needed to define tumor and BM-driven resistance mechanisms to inform next-generation therapies.

MM EFFECTS ON BONE MARROW

Evasion and suppression of antitumor immunity is an essential step in myelomagenesis. MM cells replicate and proliferate nearly exclusively within the BM niche, highlighting the role of the microenvironment in supporting cancer growth^[14-16]. The BM microenvironment is highly vascularized and consists of a cellular compartment divided into hematopoietic cells, e.g., hematopoietic stem cells (HSC), T and B lymphocytes, myeloid and natural killer (NK) cells, and osteoclasts. The non-hematopoietic cell types include bone marrow stromal cells (BMSCs), osteoblasts, endothelial cells (EC), and fibroblasts^[13-16]. The non-cellular compartment consists of an extracellular matrix (ECM), oxygen concentration, and a soluble cocktail milieu of growth factors, cytokines and chemokines. Plasma cell clones traffic in and out of the BM to foster metastatic progression while other cell types re-circulate into and out of the BM to promote cytokine-driven myeloma growth^[14-16]. The tumor-immune microenvironment supports the acquisition of resistance to

Table 1. Effects of FDA-approved and investigational agents on the myeloma immune microenvironment

Therapeutic agent	Stage	Target	Effect on myeloma-immune microenvironment
Proteasome inhibitors			
Bortezomib (Velcade)	FDA-approved	Proteasome 5	Bortezomib inhibits osteoclast differentiation induced by the RANKL, stimulates osteoblast differentiation and inhibits autocrine/paracrine signaling in MSCs and in ECM. Pls also reduce MM adhesion to BMSCs ^[15,16,17,24,33-35]
Carfilzomib (Kyprolis)	FDA-approved	Proteasome 5	
Ixazomib (Ninlaro)	FDA-approved	Proteasome 5	
IMiDs			
Thalidomide (Thalomid)	FDA-approved	CRBN	IMiDs promote anti-proliferative, T-cell co-stimulatory, anti-angiogenic and anti-inflammatory effects ^[38-44]
Lenalidomide (Revlimid)	FDA-approved	CRBN	
Pomalidomide (Pomalyst)	FDA-approved	CRBN	
Cel-MODCC-92480	Phase 1/2	CRBN E3 Ub ligase Modulator	Antitumor and immunostimulatory activities
CC-220 (Iberdomide)	Phase 1b/2a	CRBN E3 Ub ligase Modulator (CelMOD)	Antitumor and immunostimulatory activities
C-92480 (Mezigdomide)	Phase 1/2	CRBN E3 Ub ligase Modulator (CelMOD)	Antitumor and immunostimulatory activities
Monoclonal antibodies			
Daratumumab (Darzalex)	FDA-approved	CD38	Augments NK-cell cytotoxicity, induces robust increases in helper and cytotoxic T-cell absolute counts. Increases memory T cells while decreasing naïve T cells. Eliminates CD38+ immune suppressor cells, e.g., Tregs, Bregs, and MDSCs ^[61-69]
Elotuzumab (Empliciti)	FDA-approved	SLAMF7	Induces TAM activation and mediates ADCP through an FcγR-dependent manner <i>in vitro</i>
Isatuximab (Sarclisa)	FDA-approved	CD38	Eliminates CD38+ immunosuppressive Tregs and alleviates BM-induced immunosuppression
Nuclear export inhibitors			
Selinexor (Xpovio)	FDA-approved	Exportin 1, (XPO)	Increased NK cell cytotoxicity <i>in vitro</i> , potentiates ADCC, downregulates pro-survival signals from BM microenvironment, blunts the protective effects from pro-survival signals from TNF, IL-6, IL-4, BAFF BMSCs ^[82-87]
Bone-modifying agent			
Denosumab (Prolia)	FDA-approved	RANKL	Potent Inhibitor of osteoclast function ^[88-90]
Bisphosphonates			
Zoledronate (Zometa)	FDA-approved	Farnesyl diphosphate	Reduces osteoclast function, inhibits liberation of matrix-synthase (FDPS) bound cytokines, increases IFN-γ production by IL-2-primed NK cells, decrease tumor cell adhesion to bone, and activates T cells ^[91-94]
CAR T cells			
Idecabtagene vicleuceel (ida-cel, Abecma, bb2121)	FDA-approved	TNFRSF17 (BCMA)	T cells are physically recruited and linked to tumor surface Ags to elicit an anti-tumor immune response and overcome BM microenvironment-mediated immunosuppression ^[95-101]
Ciltacabtagene autoleuceel (Carvykti, cilta-cel LCAR-B38M, JNJ-4528)	FDA-approved	Two llama-derived Abs that bind human BCMA	Reduce BCMA-cell expression and microenvironment-mediated immunosuppression

Bispecific T Cell Engagers

Blinatumumab (Blincyto)	FDA-Approved (R/R ALL) Pilot Study (MM) (NCT03173430)	CD19-targeting engager (CD19xCD3)	BiTEs bind simultaneously to T cells and tumor Ags, recruits T cells to tumors and tumor T-cell microenvironment, leading to T cell activation, proliferation, and tumor cell death
Talquetamab	Phase I/II (MM) (NCT03399799)	GPRC5D-targeting bi-specific T-cell engager (GPRC5D x CD3)	Actively kills GPRC5D+ MM cell lines and primary MM cells <i>in vitro</i> ^[110-115,121]
AMG420 (NCT03836053)	Phase 1b (RRMM)	BCMA-targeting bi-specific T-cell engager (BCMA x CD3)	Short half-life with encouraging activity in RRMM. Three patients dosed with 400 µg/d had MRD-negative CRs, 2 more responders in the dose confirmation cohort, 3 patients at lower doses attained CRs. No major toxicities were observed up to 400 µg/d ^[110-115,122,123]
Teclistamab (JNJ-64007957)	Phase 1 (MM) (NCT03145181)	BCMA-targeting bi-specific T-cell engager (BCMA x CD3)	At the phase 2 dose, showed promising efficacy and durable responses, well tolerated ^[110-115,124]

Effect of FDA-approved and developmental agents on other cell types within the BM microenvironment. Listed are anti-myeloma agents, putative targets and effects within the myeloma microenvironment. FDA: Federal Drug Administration; IMiD: immunomodulatory drug; NF-κB: nuclear factor kappa-B; MSC: mesenchymal stem cell; ECM: extracellular matrix; BMSC: bone marrow stromal cell; CRBN: Cereblon (CUL4-CRBN E3 Ub ligase complex); Ub: ubiquitin; TAM: tumor-associated macrophage; RANKL: receptor activator of NF-κB ligand; RRMM: relapsed and/or refractory multiple myeloma; BiTE: bispecific T cell engager; SLAMF7: signaling lymphocytic activation molecule F7; TNF: tumor necrosis factor; IFN-γ: interferon-gamma; BAFF: B-cell activating factor; MDSCs: myeloid-derived suppressor cell; ADCP: antibody-dependent cell cytotoxicity; ALL: acute lymphoblastic leukemia; Ags: antigens; BCMA: B-cell maturation antigen; GPRC5D: G protein-coupled receptor, class C group 5 member D.

cytotoxic chemotherapy, biologic agents and immunotherapies leading to immune escape^[17-20]. Recently it was shown using a pumpless culture platform that adhesion of patient-derived MM cells (PMMCs) to osteoblasts and osteoblast long-term viability were critical factors for *ex vivo* survival of PMMCs^[21]. Osteoblasts can also subvert the anti-myeloma effect of NK cells. Since NK cells (and genetically-engineered chimeric antigen receptor-modified NKs) have clinical potential, a better understanding of the osteoblast role as immune regulators in BM is essential^[22]. Similarly, osteoclasts regulate antigen-dependent T cell activation and responses. Like macrophages, monocytes, and dendritic cells (DCs), osteoclasts display phenotypic and functional plasticity that is dependent on their origin and environment^[23].

The highly organized BM integrity is disrupted by the invasion of MM cells. A liquid milieu of cytokines, chemokines, growth factors, and inflammatory mediators mixed with matrix remodeling enzymes enables the communication between tumor, immune and microenvironment cells. Circulating tumor cells, exosomes, cell-free DNA, and apoptotic bodies negotiate the transfer of genetic information from myeloma cells to other tumor and non-tumor cell types^[24-29]. Exosomes are small, secreted vesicles that confer the bidirectional transfer of proteins, lipids, and nucleic acids between BM and tumor cells. Exosomes can support myelomagenesis by promoting angiogenesis, osteolytic lesions, and drug resistance^[17-21]. The content of exosomes from MM patients differs from that of healthy donors and could potentially serve as biomarkers and targets.

MM cells are decorated with adhesion molecules that localize myeloma cells to the ECM^[30]. Collagen I, collagen III, and elastin recently were shown to block the cytotoxic effect of NK cells and promote their production of chemokines and cytokines^[31]. NK cell cytotoxicity against major histocompatibility complex (MHC)-I-deficient melanoma was markedly increased by blocking tumor collagen deposition. MHC-I down-regulation occurred in solid cancers, which could be directly targeted by circulating cytotoxic NK cells. Prior studies have demonstrated that BMSCs produce paracrine factors and cytokines that drive cell-cell engagement and induce the generation of osteolytic lesions^[32-38]. Physical interaction between MM and BMSCs, as well as transforming growth factor (TGF) and interleukin (IL)-6 enhance the formation of lytic bone lesions^[32,33]. Cell-cell interactions and cell adhesion also enhance drug resistance in MM cells^[33-36]. Unlike healthy mesenchymal stem cells (MSCs), myeloma MSCs enhance tumor survival by producing elevated levels of IL-1 β and tumor necrosis factor-alpha (TNF- α)^[33-39].

PROTEASOME INHIBITORS

Proteasome inhibitors (PIs) are the backbone components of current anti-myeloma regimens^[40]. Bortezomib (Millennium-Takeda) demonstrates clinical efficacy and safety for newly diagnosed and RRMM disease. However, the emergence of chemoresistance and the development of adverse effects, especially peripheral neuropathy, can limit clinical utility. Second-generation PIs carfilzomib (Onyx/Amgen) and ixazomib (Millennium-Takeda) are approved for RRMM and may overcome resistance with better tolerability. Bortezomib has received regulatory approval for intravenous and subcutaneous administration, while ixazomib is the only orally bioavailable PI.

PIs also target components of the BM immune microenvironment [Figure 1]^[40,41]. Kim *et al.* reported that bortezomib impaired BMSCs proliferation *in vitro*^[41]. PIs downregulate autocrine and paracrine signaling signaled by ECM and MSCs, which impairs myeloma cell growth and survival^[14,42]. In addition, PIs suppress interleukin-6 (IL-6), IGF-1, and TNF- α production to decrease CXCL12 production by BMSCs^[43,44]. BM angiogenesis also plays an important role in myelomagenesis and suppresses angiogenesis by decreasing VEGF secretion. Roccaro *et al.* studied MM patient-derived endothelial cells to determine the effects of bortezomib on the angiogenic phenotype^[43]. At clinically achievable doses, bortezomib inhibited the proliferation of MM patient endothelial cells as well as human umbilical vein endothelial cells in a dose- and time-dependent manner. The binding of MM.1S cells to patient-derived endothelial cells augmented the proliferation of myeloma cells, which was abolished by bortezomib. Bortezomib blocked vascular endothelial growth factor (VEGF) and IL-6 secretion by endothelial cells from myeloma patients and reduced VEGF, IL-6, insulin-like growth factor-I, Angiopoietin (Ang1/Ang2) transcription. Taken together, the results illustrate that bortezomib elicits anti-angiogenic effects in BM.

IMMUNOMODULATORY DRUGS

Thalidomide, lenalidomide, and pomalidomide (Celgene/Bristol-Myers Squibb) are immunomodulatory drugs (IMiDs) that have contributed to the improvement in MM patient survival^[44]. Lenalidomide is employed to treat transplant-eligible and ineligible (NDMM) as maintenance post-transplant and for RRMM. IMiDs are thalidomide analogs, which exhibit pleiotropic anti-myeloma activities such as anti-proliferation, anti-angiogenesis, anti-inflammatory, immunomodulatory and cytotoxic effects^[44-47]. IMiDs also impact the BM microenvironment to lower IL-6 concentrations. Following the introduction of alkylating agents for MM, thalidomide was the next agent to change disease course through VEGF suppression, immunomodulatory and anti-inflammatory effects^[44-46]. IMiDs increase T cell and NK cell activity, downregulate cytokines, inhibit bone resorption, and decrease cell adhesion molecules (CAM) to disrupt MM-BMSC interactions and IL-6 production^[45-47].

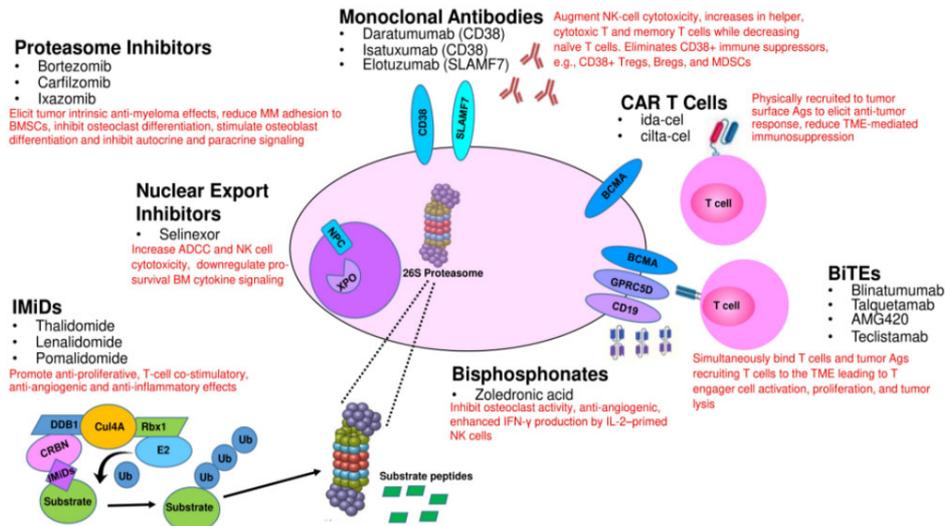

Figure 1. Direct and indirect effects of FDA-approved and developmental agents on MM cells and their interaction with other cell types within the tumor microenvironment. CAR: Chimeric antigen receptor.

Communication between myeloma cells and other cellular components of the tumor microenvironment, e.g., osteoclasts, osteoblasts, and BMSCs, is bidirectional and highly complex. Lenalidomide downregulates hyperactive osteoclasts and reduces the secretion of osteoclastogenic MIP-1 α , B-cell activating factor (BAFF), a proliferation-inducing ligand (APRIL), and receptor activator of nuclear factor kappa-B (NF- κ B) ligand (RANK-L)^[48,49]. Lenalidomide has also been shown to more significantly decrease TNF- α , IL-1 β , IL-6, and interleukin-12 (IL-12) levels and increases interleukin-2 (IL-2) and IFN- γ production compared to thalidomide^[50]. LeBlanc *et al.* found that IMiDs co-stimulated T cells through the B7-CD28 pathway^[51]. IMiDs prolonged T cell priming and boosted the uptake of tumor antigens by DCs to improve the efficacy of antigen presentation^[52,53]. IMiDs also enhance NK and NK T cell activities^[54] and inhibit T regulatory cells (Tregs) proliferation and activity^[55]. IMiDs decrease IL-2, IFN- γ , and SOCS1 expression in CD4+ T, CD8+ T, NK+ T, and NK cells from peripheral blood (PB) and B^[56].

Programmed death (PD)-1 and PD-ligand-1 (PD-L1) interactions attenuate the production of cytotoxic T lymphocytes (CTLs) that recognize tumor cells. PD-L1 expression on plasma cells from MM patients is markedly upregulated compared to those from MGUS patients and healthy volunteers^[57]. IMiDs downregulate PD-1 levels on T and NK cells and PD-L1 on myeloma cells to promote antibody-dependent cellular cytotoxicity (ADCC). Bortezomib and lenalidomide do not have the flexibility to subdue myeloid-derived suppressor cell (MDSC) activity, whereas CD38-targeting agents do have this capacity^[58,59]. Co-stimulatory effects of IMiDs on T and NK cells have been proposed to enhance anti-MM immunity but are yet to be demonstrated *in vivo*.

MONOCLONAL ANTIBODIES

The introduction of PIs and IMiDs represented an initial paradigm shift in MM treatment strategy. Subsequently, in 2015 two monoclonal antibodies were FDA-approved for RRMM treatment and represented a second shift in the treatment approach towards immunotherapies. Daratumumab (Janssen Oncology) is a humanized monoclonal IgG- κ antibody that binds to the transmembrane glycoprotein CD38 (cyclic ADP ribose hydrolase)^[60]. CD38 is expressed on immune cells, overexpressed on myeloma cells, and contributes to cell adhesion and ecto-enzymatic activities. Daratumumab binds CD38, causing cells to undergo ADCC, complement-dependent cytotoxicity (CDC), and antibody-dependent cellular phagocytosis

(ADCP). Combination regimens incorporating daratumumab have demonstrated promising results in the relapsed refractory setting and are increasingly used upfront and in transplant-eligible patients^[61-64]. Phase III trials showed promising results when daratumumab was combined with lenalidomide and dexamethasone, with bortezomib and dexamethasone, and, in quadruplet therapy with bortezomib, dexamethasone, and lenalidomide^[61-64].

Daratumumab also targets CD38+ immune, non-myeloma cell populations. PB and BM were obtained and analyzed before and during therapy and at relapse from RRMM patients enrolled in two daratumumab monotherapy studies^[65]. CD38-expressing regulatory B cells (Bregs) and MDSCs were evaluated to determine the effect of daratumumab on immunosuppressive activity. A unique subpopulation of CD38+ Tregs was found to be more immunosuppressive than CD38- Tregs *in vitro* and was reduced in daratumumab-treated patients. Likewise, daratumumab treatment generated significant elevations in helper and cytotoxic T-cell absolute counts. In PB and BM, daratumumab induced significant increases in CD8+:CD4+ and CD8+:Treg ratios and increased memory T cells while decreasing naïve T cells. The majority of patients demonstrated broad T-cell changes, although patients with a partial response or better showed greater maximum effector and helper T-cell increases. Greater increases in T-cell clonality, measured by T-cell receptor (TCR) sequencing, positively correlated with increased CD8+ PB T-cell counts. Depletion of CD38+ immunosuppressive cells, which is related to a rise in T-helper cells, cytotoxic T cells, T-cell functional response, and TCR clonality, represents an additional mechanism of action for daratumumab and deserves further exploration. The anti-myeloma benefit of daratumumab can be potentiated when combined with bortezomib which leads to increased expression of CD38 target on MM cells. However, daratumumab may also internalize CD38 in MM cells to inhibit adhesion to BMSCs and overcome CAM drug resistance (CAM-DR)^[66].

The second humanized monoclonal FDA-approved for MM is elotuzumab (Bristol-Myers Squibb), which binds the signaling lymphocytic activation molecule family 7 (SLAMF7, CD319, cell-surface glycoprotein CD2 subset 1/CS1), on the MM cell surface^[67]. SLAMF7 is also modestly expressed on NK cells and certain T cells^[68,69]. In combination with lenalidomide and dexamethasone, elotuzumab enhances progression-free survival (PFS) in RRMM.

Awwad *et al.* demonstrated that SLAMF7 was expressed at high levels on CD8+CD28-CD57+ Tregs from MM patients^[70]. SLAMF7 levels were also linked with the expression of T cell exhaustion transcription factor signatures and cell surface markers. Elotuzumab specifically depleted SLAMF7+CD8+ T cells *in vitro* and *in vivo* through macrophage-dependent ADCP. SLAMF7 may serve as an indicator to identify CD8+ Tregs and anti-SLAMF7 antibodies that enhance anti-myeloma responses.

Isatuximab (Sanofi/Genzyme) targets a specific epitope on the transmembrane glycoprotein CD38, different from that targeted by daratumumab, and inhibits CD38 hydrolase activity^[68-75]. CD38 regulates migration and receptor-mediated adhesion by binding to CD31 or hyaluronic acid. Isatuximab induces myeloma death through fragment crystallizable (Fc)-dependent mechanisms, e.g., ADCC, ADCP, and CDC, and direct Fc-independent mechanisms^[72]. Isatuximab downregulates constitutive and inducible Tregs resulting in enhancing the anti-myeloma response of other immune cell types^[73-75].

Isatuximab was evaluated as monotherapy and demonstrated promising results in a phase I study of 35 RRMM patients as well as a subsequent phase II study alone and in combination with dexamethasone in heavily-pretreated patients^[76,77]. Isatuximab added to a pomalidomide-dexamethasone regimen improved PFS, which represents another option to treat lenalidomide- and PI-refractory disease^[78]. When combined

with pomalidomide and low-dose dexamethasone, isatuximab led to improved PFS and a 40% reduction in the risk of disease progression or death. Patients had an overall response rate (ORR) of 60.4%, compared to 35.3% for patients who only received pomalidomide and dexamethasone. Isatuximab demonstrated a statistically significant increase in TCR clonality after treatment compared to that at treatment initiation, suggesting that isatuximab increases host antitumor immunity.

A recent study assessed isatuximab in heavily-pretreated RRMM patients despite receiving prior anti-CD38 therapy, most patients having been recently exposed to daratumumab combination therapy^[79]. Most patients (77%) experienced a response of MR or better with isatuximab. While objective responses were not observed, one patient achieved MR and 17 patients had stable disease as the best overall response^[80]. A prospective, randomized, open-label, phase 3 trial compared isatuximab combined with carfilzomib-dexamethasone to carfilzomib-dexamethasone in relapsed MM patients^[81]. Isatuximab addition significantly improved PFS and depth of response, representing a new standard of care for this group.

Daratumumab, elotuzumab, and isatuximab act by recruiting immune effectors to enhance cellular cytotoxicity directed against myeloma cells. The anti-myeloma activity of daratumumab and elotuzumab appears independent of the disease stage. These agents may adversely generate allergic-type infusion reactions. Potential complications in serum protein electrophoresis testing and daratumumab cross-reactivity with CD38 present on erythrocytes should be considered. The success of daratumumab and elotuzumab in RRMM has ignited enthusiasm for the development of additional CD38-targeting agents. To note, hypoxia within the BM microenvironment suppresses the maturation of MM cells as well as the expression of CD38 and SLAMF7. While antibody therapy was initially approved for RRMM, there is interest in incorporating monoclonal antibodies into conditioning regimens for NDMM as well.

NUCLEAR EXPORT INHIBITORS

Selinexor (Karyopharm Therapeutics) is a first-in-class orally bioavailable drug that inhibits the nuclear export protein exportin1 (XPO1)^[82]. Selinexor has been FDA-approved for use combined with dexamethasone and bortezomib in MM patients previously treated with four prior therapies, including at least two PIs and at least two IMiDs^[82,83]. XPO1 overexpression is linked with a worse prognosis in solid tumors and blood cancers^[84]. Selinexor also demonstrates an ability to modulate tumor immunology and the surrounding tumor microenvironment. Treatment of B cell lymphomas with selinexor led to increased NK cell-mediated cytotoxicity *in vitro* and selinexor potentiated ADCC-mediated by rituximab and obinutuzumab^[85]. NK cells exhibited greater IFN- γ and CD107a expression, both activities associated with NK activation, and lymphoma cells downregulated HLA-E, which binds the inhibitory NKG2A receptor. Zhong *et al.* demonstrated that selinexor may also downregulate pro-survival signals that originate from the BM microenvironment^[86]. Treatment of CLL cells with selinexor blunted protective effects from anti-apoptotic, pro-survival signals from TNF, IL-6, interleukin-4 (IL-4), BAFF, and CD40L *in vitro* and also blunted anti-apoptotic effects of marrow-derived fibroblast co-culture model. Selinexor may help overcome hypoxia-mediated PI resistance *in vitro* as well and restore PI sensitivity *in vivo*^[87].

DENOSUMAB

The receptor activator of nuclear factor- κ B ligand (RANKL)/RANK signaling system modulates osteoclastogenesis leading to bone resorption^[88]. Denosumab (Amgen) is a humanized monoclonal antibody that neutralizes RANKL, inhibits osteoclasts, and decreases the rate of skeletal-related events not only in MM but also in solid tumors^[89,90]. Denosumab treatment can inhibit the RANKL/RANKL receptor interaction and suppress osteoclastic bone resorption.

BISPHOSPHONATES

Zoledronate (Novartis) and pamidronate (Novartis) are pyrophosphate analogs (bisphosphonates), which demonstrate a high affinity for bone and the capacity to impair osteoclast function as well as anti-angiogenic activities^[91-93]. Bisphosphonates inhibit farnesyl pyrophosphate synthase and reduce isoprenylation of Rab, Rac, and Rho. The bisphosphonates are provided as supportive therapy in MM since they are associated with lower rates of vertebral fractures, reduced skeletal-related events, and decreased pain but are associated with an increased risk of jaw osteonecrosis. Nussbaumer *et al.* showed that zoledronic acid enhanced IFN- γ production by IL-2-primed NK cells in CD14+CD56+ DC-like cell-dependent process that may also require $\gamma\delta$ T cells^[94].

CAR T CELLS AND BISPECIFIC T CELL ENGAGERS

The adoptive transfer of chimeric antigen receptor (CAR)-expressing T cells is a transformative approach to improve cancer treatment. B-cell maturation antigen (BCMA) displays restricted RNA expression and is selectively expressed by B-lineage cells. BCMA is not detected in healthy tissues and was not detected on human CD34+ HSCs^[95]. T cells expressing a CAR-targeting BCMA had substantial activity against heavily-treated RRMM patients^[96]. BCMA-targeted CAR T-cell therapies that differ in the costimulatory domain demonstrate efficacy in early-phase trials^[97,98]. In 2021, the FDA approved idecabtagene vicleucel (ide-cel, Bristol-Myer Squibb), a BCMA-directed genetically modified autologous T cell therapy, for MM patients that had not responded to > 4 different prior treatments^[99]. In 2022, ciltacabtagene autoleucel (cilta-cel), a CAR T-cells with 2 BCMA-targeting single-domain antibodies, was evaluated in RRMM patients with poor prognosis^[100]. A single infusion of cilta-cel yielded early, deep, and sustained responses in heavily pretreated patients leading to regulatory approval. CAR T cell therapies have limitations that include life-threatening toxicities, modest antitumor activity, antigen escape, restricted trafficking, and limited tumor infiltration^[101-103]. The ECM is composed of fibrous glycosaminoglycans and proteoglycans that act as a physical barrier to CAR T cells and prevent their penetration and infiltration of tumors. Matrix-degrading agents that improve immune cell infiltration may enhance the efficacy of CAR-T cells^[104-108].

Bispecific T cell engagers (BiTEs) are novel antibody constructs targeting T cells to a tumor antigen. The prototypical BiTE- blinatumumab (Glaxo-Smith Kline) targets CD3 and CD19 to facilitate T cell-mediated killing of relapsed acute lymphocytic leukemia (ALL) cells [Table 1]^[109,110]. BiTEs may promote downregulation of their target antigen as a mechanism of immune escape, as evidenced by a meta-analysis of ALL patients initially treated with blinatumomab exhibiting increased relapse after CAR T therapy and decreased event-free survival with a trend towards exhibiting more CD19 dim disease. Thus, the development of BiTEs and CAR-T cells with differing target ligands is of clinical interest. Multiple BiTEs have shown promising results in MM including several anti-BCMA/CD3 conjugates as well as talquetamab (Janssen Pharmaceutical Companies of Johnson & Johnson), an anti-GPRC5DxCD3 conjugate that targets endogenous T cells to MM cells with a less severe side effect profile than CAR-T cells with step-up outpatient dosing that can be given to the transplant-ineligible patients^[111-113]. The immunosuppressive nature of BMSCs poses a significant hurdle to anti-myeloma immunotherapies. Recently, it was shown that MM or AML cell co-culture with the stromal cell lines HS-5 and HS-27a protected the tumor cells from bispecific antibodies that target CD123 and BCMA^[114]. The reduction in T cell effector responses was correlated with impaired CD3 redirection cytotoxicity. Cell-cell contact of tumor cells with stromal cells was thought to decrease T cell activation. Agents that inhibit the very late antigen 4 (VLA4) adhesion pathway may be combined with CD3 redirection to reduce stroma-mediated inhibition of T cell activation. The results lend support to inhibiting VLA4 functional activity as well as administering CD3 redirection therapeutics as a combinatorial regimen that enhances antitumor immunity.

CONCLUSIONS AND FUTURE PERSPECTIVES

The introduction of IMiDs demonstrated the clinical value of immunotherapeutic approaches for the treatment of MM. However, BM-mediated therapeutic resistance promotes tumor escape and immune evasion that represent obstacles to extending patient outcomes. Recently developed myeloma-directed immunotherapies, e.g., monoclonal antibodies, CAR-T cells, antibody-drug conjugates (ADCs), and BiTEs represent the emerging phase of myeloma care^[115-118]. Similar to the mechanisms of resistance observed following the administration of cytotoxic chemotherapy, PIs and IMiDs, novel strategies are needed to prevent or overcome resistance to immunotherapies. Numerous immune cell types, e.g., Tregs, Bregs, MDSCs, macrophages, dysfunctional DCs, MSCs, osteoclasts, as well as the ECM, modulate and suppress T- and NK cell activity. BM-mediated immune exhaustion as well as immune checkpoint proteins on T- and NK cells and their corresponding ligands on MM cells, e.g., PD1/PDL-1, or T cell immunoglobulin and tyrosine-based inhibitory motif (TIGIT) domains, represent additional obstacles^[119-121]. Innovative platforms will provide the foundation for the next paradigm shift in myeloma to overcome current limitations and improve high-risk and newly diagnosed patient survival^[115-117].

DECLARATIONS

Authors' contributions

Conceived the article, prepared the figure and table, and wrote the manuscript: Ignatz-Hoover JJ, Driscoll JJ
Made a substantial, direct and intellectual contribution to the work, and approved the final manuscript for publication: Ignatz-Hoover JJ, Driscoll JJ

Availability of data and materials

Not applicable.

Financial support and sponsorship

Research was supported by NIH R01 (5R01AI139141 to JJD), University Hospitals Cleveland Medical Center/Seidman Cancer Center, and the Case Comprehensive Cancer Center.

Conflicts of interest

Both authors declared that there are no conflicts of interest.

Ethical approval and consent to participate

Not applicable.

Consent for publication

Not applicable.

Copyright

Abstract

We report our experience in the management of a relapsed ovarian cancer patient with somatic *RAD51C* mutation, treated with olaparib monotherapy. The patient was diagnosed with stage 4 high-grade serous ovarian carcinoma and was treated with neoadjuvant chemotherapy, cytoreductive surgery, and postoperative chemotherapy. After a second cancer recurrence, she underwent FoundationOne CDx testing following disease progression on multiple lines of chemotherapy. Based on the FoundationOne CDx results, olaparib monotherapy was started. After 13 months of therapy, all lesions responded to the treatment, and she achieved complete response as demonstrated by normalization of the levels of CA125 and positron emission tomography-computed tomography (PET-CT). We plan to continue olaparib monotherapy until disease progression.

Keywords: Ovarian cancer, PARP inhibitor, *BRCA*, *RAD51C*

INTRODUCTION

Recommended treatment for patients with relapsed ovarian cancer depends on platinum-free intervals. Generally, patients who have recurrence after 6 months of completion of platinum-based chemotherapy are

considered platinum-sensitive, while those who recur within six months are considered platinum-resistant. Patients with platinum-sensitive relapse are typically treated with platinum-based regimens, while those with platinum-resistant disease are often given second-line single-agent chemotherapy such as gemcitabine, pegylated liposomal doxorubicin, weekly paclitaxel, or topotecan. It is well recognized that the time to progression usually shortens with subsequent relapses, so that patients encounter shorter treatment-free intervals. Following consecutive therapies, the median duration of progression-free survival often leaves patients with limited or no treatment-free interval and accumulating toxicities.

BRCA1 and *BRCA2* genes are the most identified germline mutations in patients with ovarian cancer, and their proteins are important for DNA repair. Mutations in these genes lead to homologous recombination (HR) deficiency, which may be targeted in the treatment of ovarian cancer with poly ADP-ribose polymerase inhibitors (PARPi)^[1]. Among other HR-related genes which have been found to significantly increased the ovarian cancer risk are *RAD51C* and *RAD51D*, coding for proteins that support the process of DNA repair^[2]. In epithelial ovarian cancers, *RAD51C* and *RAD51D* mutations were found in 0.41%-0.68% and 0.35%-1.13% of patients, respectively^[2-4]. Tumors with mutations in *RAD51C* and *RAD51D* have been found to be *BRCA*-like with high genomic loss of heterozygosity and responded to PARPi (rucaparib) at similar rates to *BRCA*-mutated disease^[5].

PARPi are a type of targeted cancer treatment that block the protein PARP, an enzyme that assists in the repair of damaged DNA. In cancer treatment, blocking PARP may help prevent cancer cells from repairing their damaged DNA, leading to cell death^[5]. Several PARPi have been approved by the US Food and Drug Administration (FDA) for the treatment of ovarian cancer including olaparib, niraparib, and rucaparib.

We report our experience in the management of a relapsed ovarian cancer patient with somatic *RAD51C* mutation, treated with olaparib monotherapy.

CASE REPORT

History, presentation, and initial treatment

A 74-year-old woman first presented in October 2016 with abdominal pain and distension. She had a history of breast cancer treated with lumpectomy and adjuvant radiotherapy in 2009 and autoimmune hypothyroidism. Pelvic ultrasound showed a 7 cm mass in the Pouch of Douglas and gross ascites. Tumor marker evaluations showed elevated levels of cancer antigen (CA) 125 (1762 U/mL). Paracentesis was performed and peritoneal fluid cytology showed metastatic adenocarcinoma with immunohistochemical markers favoring female genital tract origin (CK7 and PAX8 positive, CK20 negative). Subsequent positron emission tomography-computed tomography (PET-CT) scan showed extensive hypermetabolic lesions in the peritoneum and bilateral adnexa with metastasis to lymph nodes, liver, and spleen, consistent with stage 4 ovarian cancer. After four cycles of neoadjuvant carboplatin and paclitaxel, CA125 decreased to 60 U/mL. PET-CT showed good partial response: previous peritoneal, nodal, liver, and spleen metastases had all resolved, and there was a reduction in the size of the adnexal mass. She then underwent interval debulking surgery including total abdominal hysterectomy, bilateral salpingo-oophorectomy, and omentectomy in January 2017. There was some miliary disease left on the mesentery after the debulking surgery. Histology showed high-grade serous carcinoma involving both ovaries, omentum, and peritoneum. The patient received 6 cycles of post-surgical chemotherapy comprising cisplatin and paclitaxel until July 2017. Carboplatin was substituted with cisplatin due to thrombocytopenia. PET-CT performed upon completion of chemotherapy showed complete response and CA125 also normalized (11.1 U/mL). Germline *BRCA1/2* mutation test was negative.

Chemotherapy for recurrence

The patient had the first disease relapse seven months later, in February 2018. PET-CT showed recurrence in the peritoneum, liver, and lymph nodes. She was treated with 6 cycles of cisplatin, gemcitabine, and bevacizumab, due to which she had recurrent grade 4 thrombocytopenia and grade 3 anemia requiring platelet and blood transfusion during the course of the chemotherapy. Following 6 cycles of chemotherapy, PET-CT in September 2018 showed a complete response. She then received 11 more cycles of maintenance bevacizumab until May 2019. In June 2019 (nine months after completion of the last chemotherapy), she had a second relapse with nodal lesions in the abdomen and left supraclavicular fossa. In view of poor marrow reserve, advanced age, and previous chemotherapy, she was prescribed pegylated liposomal doxorubicin instead of platinum-based chemotherapy. Subsequently, the disease progressed despite multiple lines of chemotherapy including four cycles of pegylated liposomal doxorubicin, 6 cycles of topotecan, and five cycles of docetaxel until September 2020. PET-CT in October 2020 showed hypermetabolic lymphadenopathies in the abdomen, thorax, and left supraclavicular regions and liver metastasis.

PARPi monotherapy

She then underwent FoundationOne CDx™ (Foundation Medicine, Inc) testing, which found *RAD51C* mutations in the tumor. Testing for germline *RAD51C* had not been done due to limited availability for testing in our setting. The patient was started on 300 mg olaparib monotherapy twice daily in October 2020. The CA125 just before the commencement of olaparib was 685 U/mL. Due to grade 3 anemia (Hb 7.9 g/dL), the dose of olaparib was reduced to 200 mg twice a day in February 2021. The levels of CA125 gradually decreased and normalized, with the latest results of 9 U/mL [Figure 1]. PET-CT in November 2021 showed a complete response. Last seen in December 2021, the patient was well and continued olaparib therapy.

DISCUSSION

Recently, PARPi have significantly changed the landscape of treatment for advanced and relapsed ovarian cancer. Olaparib, a PARPi, has demonstrated antitumor activity among patients with relapsed ovarian cancer who have a *BRCA1/2* mutation^[6,7]. Olaparib monotherapy is approved by the US Food and FDA for the treatment of patients with relapsed ovarian cancer who have a germline *BRCA* mutation and have received three or more prior lines of chemotherapy. In pooled data from 6 trials, the overall response rate of olaparib was 31% in this group of patients, with responses seen in both platinum-sensitive and platinum-resistant diseases^[8]. In a phase II trial (ARIEL2, a single-arm, open-label study of the PARPi rucaparib in relapsed high-grade ovarian carcinoma), *RAD51C* and *RAD51D* mutations were associated with the clinically meaningful activity of rucaparib similar to that of *BRCA* mutations. Of 206 patients, there were four patients with *RAD51C* mutations, of whom three patients had a partial response and one patient had stable disease with rucaparib therapy^[5,9]. Furthermore, a case report on a heavily pretreated patient with ovarian carcinosarcoma harboring a germline *RAD51D* mutation demonstrated excellent and durable partial response with olaparib monotherapy^[10]. Extrapolated from this information and the suggestion from the FoundationOne CDx report of our patient, she was given olaparib monotherapy after she failed to respond to multiple lines of chemotherapy. Olaparib was used on our patient as rucaparib was not available locally. At the time of writing, our patient has been on olaparib monotherapy for 14 months and tolerated it well. To our surprise, all lesions responded to the treatment, and she achieved complete response after 13 months of therapy, as demonstrated by the normalization of the levels of CA125 and PET-CT. We plan to continue olaparib monotherapy for the foreseeable future until disease progression.

Recently, several guidelines, including the US National Comprehensive Cancer Network (NCCN), European Society for Medical Oncology (ESMO), and European Society of Gynaecological Oncology (ESGO), recommend *BRCA1/2* mutations testing upon confirmation of ovarian, fallopian tube, or primary

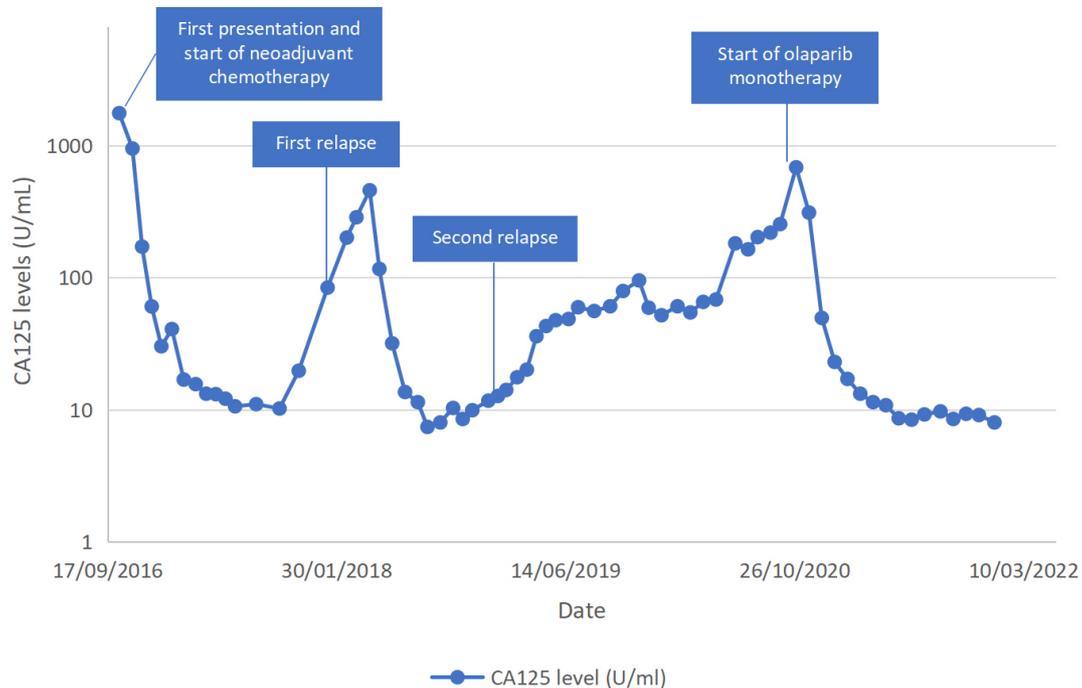

Figure 1. The blood levels of tumor marker CA125 of the patient.

peritoneal cancer, the results of which could be used for maintenance therapy selection following first-line treatment^[11,12]. With mutation testing earlier in the course of the disease nowadays, hopefully, the treatment for subsequent relapse can be improved. Although our patient did not have germline *BRCA1/2* mutations, she benefitted from the tumor mutation testing, which allowed for precision medicine, an innovative approach to tailoring cancer treatment to specific information of individuals, such as genetic makeup or genetic profile of the tumor. Our patient underwent FoundationOne CDx test, which is an FDA-approved comprehensive genomic profiling to identify patients who may benefit from specific FDA-approved targeted therapies. The test was performed following the failure of multiple lines of chemotherapy for second disease relapse. Retrospectively, if she had the somatic mutations testing earlier in the course of the disease, she could have benefitted from PARPi therapy sooner, without needing to undergo ineffective chemotherapy regimens and their toxicity. Therefore, patients who have disease relapse should be counseled for somatic and germline mutation testing sooner to allow for personalized targeted therapy.

Following treatment with PARPi, a key question is whether our patient should be rechallenged with platinum-based chemotherapy and would she respond to the treatment in the subsequent disease relapse. Germline or somatic mutations in HR genes are found in around one-third of patients with epithelial ovarian cancer^[3]. One study that investigated somatic and germline mutations in 13 HR genes including *RAD51C* demonstrated that somatic mutations in other HR genes have similar survival outcomes and response rates to platinum-based chemotherapy as germline *BRCA1/2* mutations^[3]. Theoretically, platinum-based chemotherapy could be considered for our patient in subsequent disease relapse. However, it is unclear whether she could tolerate the toxicities of the treatment in view of poor marrow reserve previously.

In conclusion, our case highlights the potential use of olaparib monotherapy in patients with relapsed ovarian cancer with somatic *RAD51C* mutations when another cytotoxic therapy has failed, as well as the importance of genomic testing to allow for personalized targeted cancer therapy.

Abstract

Prostate cancer (PCa) is a leading cause of cancer-related morbidity and mortality in men globally. Despite improvements in the diagnosis and treatment of PCa, a significant proportion of patients with high-risk localized disease and all patients with advanced disease at diagnosis will experience progression to metastatic castration-resistant prostate cancer (mCRPC). Multiple drugs are now approved as the standard of care treatments for patients with mCRPC that have been shown to prolong survival. Although the majority of patients will respond initially, primary and secondary resistance to these therapies make mCRPC an incurable disease. Several molecular mechanisms underlie the development of mCRPC, with the androgen receptor (AR) axis being the main driver as well as the key drug target. Understanding resistance mechanisms is crucial for discovering novel therapeutic strategies to delay or reverse the progression of the disease. In this review, we address the diverse mechanisms of drug resistance in mCRPC. In addition, we shed light on emerging targeted therapies currently being tested in clinical trials with promising potential to overcome mCRPC-drug resistance.

Keywords: Prostate cancer, mCRPC, androgen receptor, drug resistance, novel targeted therapeutics

INTRODUCTION

Prostate cancer (PCa) is a leading cause of mortality and morbidity among men worldwide, where 12.5% of men are prone to be diagnosed with PCa during their lifetime^[1]. According to the Globocan data collected from 185 countries in 2020, an estimated 1.4 million new PCa cases were diagnosed, with an incidence rate of 37.5 per 100,000 males, accounting for 14.1% of all male cancer diagnoses. In addition, 375,000 deaths due to PCa were recorded, comprising 6.8% of cancer deaths in men^[2]. PCa was discovered to be androgen-sensitive by Huggins and Hodges in 1941^[3]. The activation of androgen receptor (AR)-mediated signaling is an essential route for regulating PCa cell growth and proliferation; thereby, alterations in this cascade hold a great influence on cancer progression^[4]. This relation between androgen and PCa leads to androgen deprivation treatment (ADT), which includes surgical castration through orchiectomy to remove the source of androgen or medical castration through antiandrogen and gonadotropin-releasing hormone analogs, thus reducing androgens to castrate levels^[3]. Interventions such as prostatectomy or radiotherapy along with ADT for localized PCa are the standard of care for localized disease, yet ADT remains the backbone of first-line treatment for locally advanced and metastatic PCa^[5]. For patients treated with long-term gonadal androgen suppression, PCa cells become resistant to ADT within 2-3 years and the malignancy progresses even when the serum testosterone level is below the castrate level. This stage of prostate cancer, known as castration-resistant prostate cancer (CRPC), can progress to the lethal form of metastatic CRPC (mCRPC), resulting in rapid mortality with mean overall survival historically of 16-18 months^[6].

Although curative treatment has not yet been reached, multiple therapeutic modalities for mCRPC patients have been accomplished^[7-16] [Table 1].

Inhibitors of CYP17

The emerging speculative conveyance regarding the defiance of castration resistance classes to androgen manipulating therapies has been fully debunked recently, thus reemphasizing the chief role of the androgen signaling axis as a subject to therapy development^[17]. Cytochrome P450 enzyme 17 (CYP17) has been recognized as a vital mediator in steroidal biosynthesis, especially androgen. To impede this vicious pathway, several drugs, such as antifungal ketoconazole, were depicted as potential options; however, prohibitive toxicities paired with minute survival benefits raised the need for better alternatives^[18]. Abiraterone (ABI) acetate functions as an irreversible selective steroidal agent for the microsomal complex CYP17, thus restraining two functionalities: cortisol biosynthesis in the adrenal gland (via C21 17- α -hydroxylation) and steroid production in testis and adrenal gland (lyase property)^[19]. As a result, both testosterone supply and cortisol will be inhibited, causing a flux of augmented steroid levels upstream of the target halt. Therefore, prednisone (PDN), a corticosteroid that binds to the glucocorticoid receptor (GR), is often co-administered with ABI, seeking in return a diminished side effect for mineralocorticoid excess syndrome^[20]. Significantly ameliorated radiographic progression-free survival (rPFS) and overall survival were reported in a large Phase III trial for asymptomatic CRPC patients treated with ABI (Abiraterone) and PDN compared to PDN alone (16.5 vs. 8.2 months; HR: 0.52; 95%CI: 0.45-0.61; $P < 0.0001$)^[9]. Based on the data presented by such trials, the FDA approved ABI as a management therapy for CRPC patients. Subsequently, the drug has also been shown to improve survival in patients with hormone-sensitive metastatic disease and is also approved as first-line therapy in combination with ADT^[21].

AR antagonists

The oral AR antagonist enzalutamide (ENZ) lashes with high affinity, impeding nuclear receptor

Table 1. Summary table of the drugs and agents indicated for mCRPC

Class	Agent	MOA	Studies enrolled with indications	Trial result
Hormonal therapy	Abiraterone Acetate	Irreversible selective inhibitor of CYP17-alpha-hydroxylase and C17, 20-lyase coupled with a modest AR antagonist activity ^[7]	COU-AA-301; post-docetaxel ^[8]	ABI increased median overall survival when compared to the placebo group by 3.9 months
			COU-AA-302; pre-docetaxel ^[9]	ABI significantly increased median overall survival when compared to the placebo group by 8.2 months
AR antagonists	Enzalutamide	AR antagonist impedes nuclear receptor translocation and DNA binding, induces apoptosis	AFFIRM; post-docetaxel ^[10]	Overall survival increased by 4.8 months in comparison to the control group
	Darolutamide		ARCADES ^[11]	86% of patients treated with 1400 mg dose of darolutamide had a 50% or greater decrease in PSA
Cytotoxic chemotherapy	Docetaxel	Inhibits microtubular depolymerization arresting their function	TAX 327; first-line chemotherapy ^[12]	DOC combined with prednisone increased overall survival by 2.9 months when compared to the control group treated with mitoxantrone plus PDN
	Cabazitaxel		TROPIC, Phase III, randomized, open-label ^[13]	Overall survival increased by 2.4 months in the treatment group (CBZ+ PDN) compared to patients treated with a combination of PDN and mitoxantrone
Calcium-mimetic	Ra-223	Emits high energy alpha particles after adhering selectively to regions of elevated bone turnover	ALSYMPCA, Phase III, randomized ^[14]	Patients placed on Ra-223 treatment had 3.6 months increase in survival compared to the placebo group
PARP inhibitor	Olaparib	Impede PARP causing cumulative DNA and cell damage	PROfound Phase III, randomized ^[15]	Patients with mutations in <i>BRCA1</i> , <i>BRCA2</i> , or <i>ATM</i> genes assigned to receive olaparib experienced a 4.4-month increase in survival compared to the control arm receiving ENZ or ABI plus prednisone
Dendritic-cell vaccine	Sipuleucel-T	Infused within APCs to present PAP peptides <i>in vivo</i> activating CD4+ and CD8+ T cells	IMPACT trial, Phase III ^[16]	Utilizing sipuleucel-T extended overall survival among men with mCRPC by 10 months

MOA: Mode of action; AR: androgen receptor; CYP17: Cytochrome P450 enzyme 17; PSA: prostate-specific antigen; ABI: abiraterone; DOC: docetaxel; PDN: prednisone; CBZ: cabazitaxel; ENZ: enzalutamide; PARP: poly(ADP-ribose) polymerase; APC: antigen-presenting cells; PAP: prostatic acid phosphatase.

translocation and DNA binding, thereby inducing apoptosis^[22]. Based on the results of two Phase III placebo-controlled studies where a 4.8-month median overall survival benefit was reported in chemotherapy-naïve mCRPC patients, both the FDA and EMA ratified ENZ usage for mCRPC previously treated with docetaxel^[23]. Notably, the steroidal biosynthesis impact was nullified with ENZ utilization, thus shifting away from PDN prescription during the treatment regimen^[24].

Cytotoxic chemotherapy

By reversibly stabilizing the microtubules and promoting their assembly, docetaxel (DOC) fosters a mitotic block on cancerous cells. After augmentation of these bundles, the natural dynamics of mitosis would be impaired, consequently leading to apoptosis, which is further induced by phosphorylation of the Bcl-2 oncoprotein^[25]. Furthermore, impaired microtubules functionality surges p53 buildup in the nucleus, thus driving its downstream signaling forward^[26]. Notably, due to their impact on microtubules, it has been shown that taxanes also possess antiangiogenic capabilities paired with impeding AR trafficking and

accumulation^[27]. This drug was granted FDA and EMA approval based on the results of the TAX 327 study conducted on patients diagnosed with CRPC and subjected to DOC treatment paired with PDN compared to the standard approach of mitoxantrone and PDN in the control arm. The results demonstrate an overall increased survival benefit (19.2 months vs. 16.3 months; $P < 0.004$) reinforced with significant amelioration in pain relief^[27]. The incorporation of PDN augments the efficacy of DOC and results in superior outcomes as a result of the additive benefit from the two drugs, each known to be effective in PCa through targeting different signaling, AR and GR. In addition, prednisone also has anti-inflammatory properties and can treat pain, nausea, and edema^[28-30]. Moreover, the cytotoxic tubulin-binding drug cabazitaxel (CBZ) has demonstrated a prevailing advantage in enhancing the survival of patients with mCRPC after being assigned to a DOC-based treating regimen, causing a 30% decline in risk of death when compared to those treated with mitoxantrone (panel). These results granted CBZ US Food and Drug Administration approval for being prescribed as a second-line treatment in mCRPC^[13].

DRUG RESISTANCE IN MCRPC

Despite the significant survival benefit of the currently approved therapies, which can alleviate symptoms and prolong overall survival, mCRPC remains incurable as primary and secondary resistance develops rapidly^[31]. Drug resistance can develop due to mechanisms intrinsic to the biology of PCa or by more general mechanisms shared with diverse tumor types, as can be seen in [Figure 1](#).

AR amplification and overexpression

AR gene amplification has been recognized in clinical studies as the most common genetic alteration deriving AR reactivation and progression to CRPC^[32]. AR overexpression can result from different mechanisms such as gene amplification, increased histone acetylation/phosphorylation at enhancers sites, overexpression of co-regulators, or enhanced protein stability^[33,34]. The increase in AR expression was found to be consistently linked with the development of resistance to ADT, resulting in PCa progression from a castration-sensitive phenotype to a castration-resistant one. This increase is capable of sensitizing PCa cells to castrate concentrations of androgen and converting the action of AR antagonists to agonists^[24,35].

Among patients with CRPC, up to 80% exhibit a significant upregulation in AR transcripts and protein levels^[36], in comparison to < 1% of the primary androgen-dependent PCa cases^[37]. This aberration has been detected, at high frequency, in circulating tumor cells (CTCs) and circulating tumor DNA (ctDNA) and is more common in pretreated CRPC patients than in treatment-naïve patients. A study using liquid biopsies and ctDNA showed that 50% of CRPC patients, pretreated with either ENZ or orteronel (a CYP17A1 inhibitor), evidenced AR amplification^[38,39]. One *in vivo* study utilizing CRPC xenografts treated with ABI showed a three-fold increase in AR expression^[40]. In a separate *in vitro* study, a bicalutamide-resistant LNCaP cell line was shown to display an overexpressed AR and hyper-sensitivity to minimal levels of androgen^[41]. *In vitro* studies using ENZ-resistant LNCaP cells showed an increase in AR levels compared to naïve LNCaP cells^[42].

AR point mutations

AR point mutations are also more frequent in CRPC than in primary androgen-sensitive PCa, especially among patients pretreated with ADT. Several studies evidenced somatic AR point mutations in ~10% of CRPC tissues, whereas none were found in any of the primary PCa tissues examined^[36,37,43]. This is consistent with results obtained in a previous study that performed a targeted AR sequencing in a cohort of 181 primary cancers and 37 CRPCs. The study revealed that somatic AR point mutations were found to occur only in CRPC and more frequently in patients subjected to prior antiandrogen treatments^[44]. Supposedly, when AR signaling is more effectively suppressed, clonal selection of tumor cells will enhance AR somatic

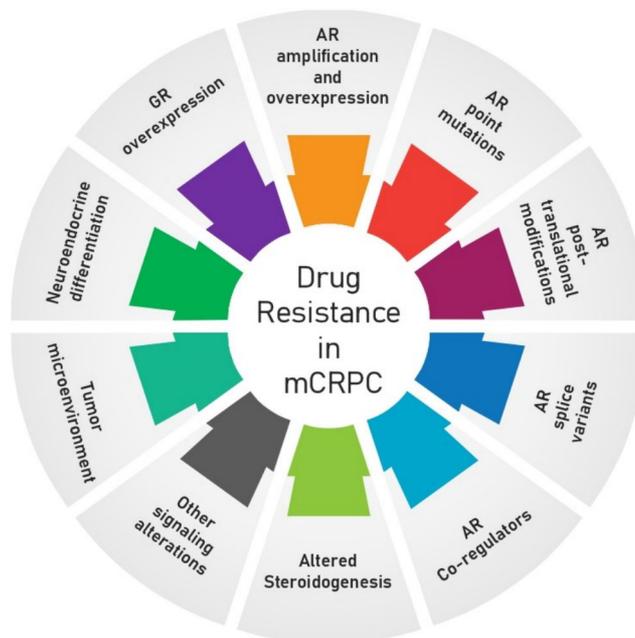

Figure 1. Mechanisms of drug resistance in mCRPC. Several mechanisms of drug resistance are well defined in CRPC, including AR amplification and overexpression, AR point mutations, AR post-translational modifications, AR splice variants, AR co-regulators, altered steroidogenesis, GR overexpression, neuroendocrine differentiation, tumor microenvironment, and other signaling alterations. AR: Androgen receptor; GR: glucocorticoid receptor; mCRPC: metastatic castration-resistance prostate cancer.

mutations, subsequently yielding aberrant transcriptomes^[43]. There are > 100 clinically-relevant somatic point mutations detected in AR^[44]; the majority are single-base substitutions and are clustered in the ligand-binding domain (LBD). The modifications in LBD alter the steroid-binding pocket and result in broadening ligand specificity and AR activation by alternative non-androgen ligands including progesterone, estrogen, and some AR antagonists^[45].

Four main recurrent LBD point mutations are described in several studies: (1) L702H, a leucine to histidine substitution at amino acid 702; (2) W742C, a tryptophan to cysteine substitution at amino acid 742; (3) H875Y, a histidine to tyrosine substitution at amino acid 875; and (4) T878A, a threonine to alanine substitution at amino acid 878 (T878A). These mutations are present in approximately 15%-20% of CRPC cases^[46,47]. The gain of function mutation “T878A” described in the LNCaP cell line was shown to confer an expansion of binding specificity to AR by both steroid hormones (e.g., progesterone) and first-generation antiandrogens (e.g., bicalutamide or flutamide)^[48,49]. L702H, a mutation that causes glucocorticoid-mediated AR activation, is associated with primary resistance to ABI^[50]. In another study, patients harboring T878A and L702H mutations showed poor prostate-specific antigen (PSA) response after ABI or ENZ treatment^[38]. In addition, several AR mutations were shown to be capable of converting the AR antagonists into agonists, as seen with F877L and F876L mutations associated with resistance to second-generation antiandrogens ENZ and ARN-509^[50,51]. In line with other studies, the data obtained validate the significance of AR mutations in deriving drug resistance.

AR post-translational modifications

AR post-translational modifications (PTMs), including serine/threonine and tyrosine phosphorylation, acetylation, methylation, ubiquitination, and sumoylation, have essential roles in enhancing AR activity through maintaining protein stability, nuclear localization, and transcriptional activity^[52,53]. Thereby, PTMs may contribute to AR reactivation and acquisition of drug resistance in mCRPC^[54]. A study indicated that

the usage of hypomethylating drugs has the effect of reversing and delaying progression to mCRPC. One potential underlying mechanism is through downregulating DNA methyltransferase 1-dependent STAT3 activity^[55]. Phosphorylation of AR residues plays a significant role in activating AR and promoting continued PCa cell growth. The treatment of the castrate-recurrent CWR-R1 cell line with EGF under low androgen conditions was shown to promote AR transcriptional activity through the phosphorylation of AR at serine 515 and serine 578, MAPK, and PKC consensus sites, respectively^[56]. A prostate tissue microarray analysis indicated the intracellular non-receptor tyrosine kinase (NRTK) Ack1 to induce AR phosphorylation at Tyrosine 284 and correlate positively with disease progression and negatively with the survival of PCa patients. In activated Ack1-expressing prostate cells, treatment with antiandrogens failed to affect the expression and activation of AR^[57]. In addition, the NTRK SRC proved clinically to be at high levels in mCRPC and to mediate AR tyrosine phosphorylation and subsequent pathway activation^[58-61].

Ubiquitination is another PTM that was shown to have an important role in regulating AR activity. RNF6, a ubiquitin ligase with an AR enhancing role, acts by inducing AR ubiquitination and promoting AR transcriptional activity. RNF6 was detected at elevated levels in hormone-refractory human PCa tissues^[62]. Another study identified ubiquitin-specific protease 12 (Usp12) as a positive regulator of AR. Usp12, in complex with the cofactors Uaf-1 and WDR20, interacts with and deubiquitinates AR, resulting in increased protein stability and transcriptional activity of AR^[63].

AR co-regulators: co-activators, co-repressors, and chromatin remodelers

A series of co-regulator protein factors such as co-activators, co-repressors, and chromatin remodelers are known to regulate AR transcriptional activity by being co-recruited to chromatin and binding directly or in a protein complex to AR to regulate gene activity. The balance of co-activator and co-repressors is required for the proper regulation of AR-mediated transcription. Misbalance in these factors leads to higher AR activity and less active antagonism by antiandrogens contributing to drug resistance and mCRPC progression^[64,65]. FKBP51, a co-activator and a target gene of AR, was detected at upregulated levels in relapsed LAPC-4 tumors grown in castrated mice^[66]. FKBP51 improved the formation of a super chaperone complex via recruiting p23 co-chaperone to ATP-bound Hsp90, which in line keeps AR with a high-affinity conformation for ligand-binding, consequently promoting androgen-mediated AR transcriptional activity and growth^[66,67].

Elevation of AR signaling can also occur through the loss of AR regulatory repressing signals. For example, retinoblastoma (Rb), a well-known tumor suppressor, was shown to be highly reduced in mCRPC and to be associated with tumor recurrence. The loss or inactivation of Rb induced an E2F1-mediated increase in the levels of AR mRNA/protein and two relevant target genes, PSA and *TMPRSS2*, consequently promoting castrate-resistant growth and resistance to bicalutamide in PCa cells^[68].

A recent study identified and verified myosin heavy chain 9 (MYH9) as a novel AR cofactor. The data show that inhibiting MYH9 in an androgen-independent cell line (LNCaP-AI) promoted AR nuclear translocation and enhanced the expression of PSA, indicative of the MYH9 role as a co-repressor to nuclear AR signaling and a novel factor mediating the progression of CRPC^[69].

Other pioneering factors, i.e., FOXA1 and GATA2, act as chromatin remodelers at enhancer sites to regulate the expression and activity of AR in mCRPC. FOXA1 induces open chromatin conformation to allow the binding of other transcription factors, aiding in an enhanced AR transactivation and mCRPC progression^[70]. CTCs isolated from patients with ABI- or ENZ-resistant metastasis showed amplification in the FOXA1 gene in > 30% of CRPC patients, pinpointing the crucial role of FOXA1 in AR regulation and

tumor progression^[71]. In addition, GATA2 was shown to boost AR activity and CRPC progression. Overexpression of GATA2 was correlated with more aggressiveness in PCa^[72]. High expression of GATA2 in CRPC cell line “ARCaPM” brings about an increased IGF-2 expression and consequently confers chemotherapy resistance^[73]. An additional important AR co-regulator and chromatin remodeling factor is homeobox B13 (HOXB13), which acts by interacting with AR and binding to its target loci^[74]. Analysis of transcriptome expression from several databases revealed that the expression of HOXB13 is elevated during the progression of the primary PCa to CRPC^[75]. In a separate study, HOXB13 was shown to be highly expressed in hormone-refractory tumors compared to tumors without PSA after initial treatment^[76]. Interestingly, HOXB13 also mediates the oncogenic function of AR splice variants, mainly ARV7, and acts as a pivotal upstream regulator of AR-V7–driven transcriptomes^[77]. These findings could explain HOXB13’s role in resistance towards antiandrogen treatment.

AR splice variants

Transcriptionally activated AR splice variants (ARVs) are truncated forms of AR that lack the C-terminal LBD region, the binding site for first- and second-generation drugs, hence remain constitutively activated independently of androgen or antagonist action. This ligand-independence feature makes ARVs potentially contributors to disease progression and treatment resistance in mCRPC. ARV1, ARV7, and ARV567 are the most common isoforms, while ARV7 is the most extensively studied one^[78,79]. ARV7 is associated with resistance to both ABI and ENZ. Studying ARV7 expression in CTCs revealed its association with clinical resistance to both drugs in men receiving ENZ. Patients with detectable ARV7 levels had poorer PSA response, shorter progression-free survival (PFS), and reduced overall survival (OS) compared to ARV7-negative patients. Similar results were observed in patients treated with ABI. Markedly, the ARV7 level was higher in males pretreated with ENZ and ABI than in treatment-naïve males^[80]. The selective siRNA-mediated knockdown of ARV7 in CWR22Rv1 cells inhibited androgen-independent growth and re-established the responsiveness to antiandrogen drugs^[81]. In one study, ARV567es was identified and characterized as a contributor to PCa progression and resistance to castration in human PCa xenograft models and a biomarker for patients with early recurrence. In addition, AR-V567es transcripts detected in 23% of CRPC bone metastases were shown to be associated with poor prognosis and short survival^[82]. These data strongly support the implication of ARVs as resistance-driving factors in CRPC.

Intra-tumoral and alternative androgen biosynthesis/altered steroidogenesis

Although CRPC develops in the presence of sub-physiological levels of circulating androgens, its progression is associated with the accumulation or synthesis of intra-tumoral androgen and accordingly maintained AR activity^[83]. The low plasma levels of androgens following ADT, can be bypassed by the local conversion of adrenal androgens to testosterone and de novo local synthesis of androgens through increased expression of enzymes involved in steroidogenesis, such as CYP17A, in the prostatic tissue. The elevated intra-tumor level of androgens stimulates AR paracrine and autocrine activation, regardless of serum androgen levels^[84,85].

The intra-tumor synthesis of steroid hormones was shown to be significantly increased in CRPC patients compared to naïve primary PCa. To compare the levels of androgen, a study utilized autopsies and tissue biopsies from hormone-sensitive and hormone-resistant patient tumors, and the latter was shown to possess high levels of continuous androgen production compared to primary tumors^[83]. A primary source of these de novo intra-prostatic androgens are the adrenal androgens dehydroepiandrosterone (DHEA) and androstenedione (AD), generated by the action CYP17A1 enzyme. In the prostate, DHEA and AD can act on the AR axis once converted to testosterone and DHT. DHEA also exists predominantly in a sulfated form (DHEA-S). In CRPC, although ABI (CYP17 inhibitor) results in a significant decline of both DHEA and AD, the persistent DHEA-S can serve as a precursor for testosterone and DHT synthesis in prostate

tissue, thus conferring resistance to ABI^[86-88]. Studies in CRPC xenografts have shown that several genes involved in the androgen synthesis pathway are upregulated during hormonal therapy. The overexpression of AKR1C3, an enzyme implicated in the steroidogenesis pathway, drives resistance to ABI acetate via increasing androgen synthesis and signaling^[89]. In line, downregulating AKR1C3 re-sensitizes resistant cells to ABI treatment. Consistently, AKR1C3 activation has been shown to be associated with ENZ resistance^[90]. Other enzymes implicated in steroidogenesis, i.e., SRD5A1 and HSD3B2, were found to be overexpressed in samples from CRPC bone marrow metastases^[91].

Glucocorticoid receptor overexpression

The role of glucocorticoids is complex in PCa because of their dual role. Despite that, it is shown that whenever adenosine diphosphate (ADP) is used to antagonize AR signaling, the GR is activated and overexpressed to confer resistance to the treatment used^[92]. Both GR and AR have similar structures and mechanisms of action; thus, in mCRPC, whenever a treatment is used to block AR signaling^[93], GR is usually activated to attach to nuclear AREs and activate genes that stimulate tumor progression and cell endurance^[94]. A preclinical study showed that GR was overexpressed and conferred resistance in *in vitro* cell lines (VCaP and LNCaP/AR) that were treated with apalutamide and ENZ. However, it was shown that VCaP was desensitized to ENZ when GR was knocked out^[93]. Another study also showed that CRPC was resistant to DOC when GR was overexpressed. In this study, GR antagonism was used to successfully re-sensitize the cells to DOC^[95]. Pühr *et al.*^[96] observed that GR is expressed minimally in primary PC tissue and the expression notably increases with long-term treatment with ENZ.

Neuroendocrine differentiation

While only about 1% of all primary PCa are diagnosed as neuroendocrine prostate cancer (NEPC), up to 30% of mCRPCs are NEPC^[97]. This profound phenotypic shift, as a result of selection pressure from ADT or potent antiandrogens, from tumors with histological features of adenocarcinoma that express AR to AR-negative neuroendocrine prostate tumors has been termed lineage plasticity^[98]. The loss or mutation of both tumor suppressors TP53 and RB1 has been found to be crucial in NEPC differentiation^[99]. Tan *et al.*^[100] observed Rb protein loss in 90% of NEPC with RB1 allelic loss in 85% of cases. A recent *in vivo* preclinical mouse study found that *Rb1* loss promotes plasticity and metastasis in PCa with TP53, and tumor suppressor phosphatase and tensin homolog (*Pten*) loss causes secondary resistance to therapies that target the AR signal axis^[101]. A different preclinical study of *in vitro* and *in vivo* models of human PCa showed evidence of lineage plasticity and a shift from androgen-dependent PCa to androgen-independent NEPC after treatment with ENZ^[102]. This phenotypic shift was induced by the loss of RB1 and TP53 and was facilitated through overexpression of the transcription factor SOX2. It was also demonstrated that the inhibition of SOX2 restored the function of TP53 and RB1^[102]. At the moment, there are no therapeutics in drug development studies that target the loss or mutations of TP53 or RB1. However, a Phase II study is currently ongoing to evaluate the potential use of alisertib (aurora kinase A inhibitor) in mCRPC and NEPC patients^[103].

Tumor microenvironment

The ability of the tumor microenvironment to promote drug resistance is likely linked to the role of the cancer-associated stromal cells in tumor initiation and progression. Tumor microenvironment-derived neuregulin 1 (NRG1), identified in cancer-associated fibroblast (CAF) supernatant, was shown to induce resistance in tumor cells through activation of human epidermal growth factor receptor-3 (HER3) and the subsequent downstream signaling molecules such as MAPK to promote cell proliferation and survival^[104]. Blocking the NRG1/HER3 axis was shown to re-sensitize tumors to hormone deprivation *in vitro* and *in vivo*. In addition, patients with mCRPC having increased tumor NRG1 activity showed an inferior response to second-generation antiandrogen therapy^[105,106]. Zhang *et al.*^[106] showed that ENZ drives in overproduction

of NRG1. It is still unclear how AR inhibitors affect the production of NRG1, but many studies have shown that NRG1 overexpression is correlated with poor outcomes and reaction to ADT.

SPP1, an important extracellular matrix component secreted by multiple kinds of cell types including immune cells, fibroblasts, osteoclasts, smooth muscle, and epithelial cells, is overexpressed in many types of tumors^[107,108]. In the GSE32269 dataset, SPP1 expression was shown to be significantly higher in the mCRPC group than in the primary PCa group. The Human Cancer Metastasis Database analysis showed that SPP1 expression levels were significantly higher in bone metastases than in lymph node and posterior peritoneum metastases, thus correlating the expression of SPP1 with the progression of mCRPC^[109]. To investigate the relationship between SPP1 expressions and ENZ resistance *in vivo*, Pang *et al.*^[108] studied the effect of ENZ treatment on SPP1 knock downed cells (22Rv1 cell line). The results show that SPP1 knockdown significantly inhibited 22Rv1 cell proliferation after ENZ treatment.

Other signaling alterations/implication of growth factors, kinases, cytokines, enzymes...

The aberrant activation of multiple signaling pathways plays a key role in deriving drug resistance in mCRPC. High levels of growth factors including IGF-1, EGF, and TGF- α/β have been reported in mCRPC^[110]. A study showed that the overexpression and activation of EGFR mediate DOC resistance in CRPC by inducing AKT-dependent ABCB1 (MDR1) expression^[111,112]. Besides, the stimulation of EGFR was shown to derive the activation of Ack1/Tnk2, which is known to correlate positively with the progression to the mCRPC stage^[113]. In addition, PCa patients whose tumors showed moderate to strong staining of activated Ack1 displayed a poor prognosis^[113].

Several studies assured the association of mCRPC with increased activation of the PI3K-AKT-mTOR pathway^[114,115]. Phosphatase and Tensin Homolog (PTEN) has been attributed to the radical amelioration of the PI3K/AKT pathway in nearly 50% of PCa patients. This atypical augmentation of the latter pathway distorts the protein-serine/threonine kinases promoting castration-resistant growth. PI3K-AKT-mTOR pathway interacts and cooperates with several key oncogenic signaling cascades such as MAPK and WNT signaling to facilitate PCa growth and drug resistance^[116]. Furthermore, augmented levels of ERKs activation have been reported in recurrent mCRPC patients, and correlative studies have further linked several mutations down the RAS isoforms with the tumorigenesis of PCa^[117]. Although collateral activation of the PI3K/AKT and RAS/MAPK pathways have been implicated in several studies, cell proliferation and invasiveness of p63-expressing prostate tumors were solely attributed to the MAPK signaling pathway, which suggests its critical involvement in mCRPC^[118].

Cytokines overexpression is also known to trigger tumor progression and drug resistance in CRPC^[119,120]. A study reported that inhibiting STAT3, a downstream target of IL-6, results in decreased growth of ENZ-resistant cells. Consistently, blocking STAT3 signaling by inhibiting its phosphorylation was shown to re-sensitize ENZ-resistant cells, hence supporting the implication of the IL-6-STAT3 pathway in ENZ-acquired resistance^[121]. Moreover, radically increased IL-6 expression is a direct consequence of the constitutive activation of the NF- κ B pathway^[122,123]. NF- κ B levels influence the expression of an essential PCa biological marker for progression, PSA. Additionally, NF- κ B is a key factor in the upregulation of IL-8 cytokine; the latter is involved in the regulation of prostate vasculature and apoptosis^[124]. High levels of circulating IL-8 were detected in advanced PCa at a stage when the tumors no longer respond to antiandrogens^[125,126]. PCa cells overexpressing IL-8 show reduced effectiveness of bicalutamide^[124]. The pro-inflammatory cytokine TNF- α has also been reported to be elevated in CRPC, and such chronic stimulus is a prototypical inducer of NF- κ B expression, thereby increasing metastasis, proliferation, and drug resistance^[127].

Analysis of whole-exome and transcriptome sequencing of mCRPC biopsies revealed that alterations in DNA-damage repair (DDR) genes including *BRCA2*, *BRCA1*, and *ATM* occur at higher frequencies in mCRPC (19.3%) than in primary PCa, of which 12.7% of the samples were identified with loss of *BRCA2*^[43]. Cells with deleterious mutations in *BRCA1* or *BRCA2* compensate for this loss by increasing their dependency on poly(ADP-ribose) polymerase (PARP) activity for DNA repair^[128,129].

Prostate-specific membrane antigen (PSMA) is a type II transmembrane glycoprotein that is normally expressed in the prostate epithelium. Although it is expressed in other tissues (such as the salivary glands, proximal tubules of the kidney, and small intestine), its levels there are minimal. Importantly, in PCa tissues, PSMA is significantly overexpressed, having the highest expression in advanced PCa and mCRPC. Moreover, following androgen deprivation and hormonal therapy, PSMA expression seems to be increased^[130-132].

EMERGING TREATMENTS TARGETING MCRPC

Based on the above, there is a crucial need for novel alternative approaches and drugs that could overcome resistance in advanced PCa stages. In fact, several treatments, which are under development and trials, could emerge as promising therapies for patients with mCRPC and become the next-generation standards of care. **Table 2** summarizes the evolving targeted treatments in mCRPC along with their relevant clinical trials^[15,133-156].

PARP inhibitors

The PARP superfamily, with at least 18 members, comprises nuclear enzymes involved in the DNA repair machinery of single-stranded breaks (SSBs), cell proliferation, and death^[157]. Inhibition of PARP proteins impedes the ligation of SSBs that consequently convert into double-stranded breaks (DSBs). When DDR genes are defective, PARP inhibition leads to the accumulation of DSBs, promoting an enhanced lethal effect known as the “synthetic lethality” that ultimately induces cell death. According to this rationale, PARP inhibitors (PARPi) emerged as a therapeutic approach targeting malignancies with defective DDR genes, particularly *BRCA1/2*^[158-160]. In fact, PARPi application showed success in *BRCA*-deficient breast and ovarian cancer and promising efficacy in clinical trials involving mCRPC patients^[129,161]. Several PARPi have been tested and approved in mCRPC including olaparib, rucaparib, niraparib, talazoparib, and veliparib.

Olaparib (Lynparza) is a small, oral, and bioavailable molecule that selectively binds and inhibits PARP^[162]. Mateo *et al.*^[134] published two Phase II clinical trials, “TOPARP-A” (NCT01682772) and “TOPARP-B” (NCT01682772), involving patients with mCRPC who had previously received standard treatments and who were treated with olaparib. Both studies demonstrated that patients with defective DDR genes and who were no longer responding to the current treatments exhibited a high response rate to olaparib. Importantly, response to treatment seemed dependent on specific DDR gene defects, as the highest response was achieved in the *BRCA1/2* aberrant subgroup^[133,134,163].

In May 2020, based on the results of the “PROfound” (NCT02987543) clinical study, olaparib was granted a “breakthrough” FDA approval for the treatment of men with mCRPC harboring germline and/or somatic mutations in DDR genes and who formerly received second-generation antiandrogens^[164]. PROfound is a prospective, randomized, Phase III trial. Patients with mCRPC and DDR genes alterations whose disease progressed while receiving ENZ or ABI were randomly assigned to receive either olaparib or ENZ/ABI (control). The results show that patients receiving olaparib had significantly longer median imaging-based PFS than the control group^[135]. Moreover, this study was the first to show that patients on olaparib had a significantly longer duration of survival compared to the control^[15].

Table 2. Summary of the completed and ongoing clinical trials of emerging therapies in mCRPC

Therapy	Agent(s)	Trial name/Clinicaltrials.gov identifier	Trial phase	Main findings/Comments
PARPi	Olaparib	TOPARP-A/NCT01682772 ^[133]	II	Olaparib improved the RR specifically in patients with DDR gene defects
	Olaparib	TOPARP-B/NCT01682772 ^[134]	II	Olaparib improved the RR specifically in patients with BRCA1/2 aberrations
	Olaparib or ENZ/ABI	PROfound/NCT02987543 ^[15,135]	III	Olaparib increased PFS and OS
	Rucaparib	TRITON2/NCT02952534 ^[136,137]	II	Rucaparib improved RR and PSA RR in patients with BRCA alterations
	Rucaparib or physician's choice of ABI/ENZ/DOC	TRITON3/NCT02975934	III	Ongoing trial
	Niraparib	GALAHAD/NCT02854436 ^[138,139]	II	Ongoing trial; interim results show that niraparib improved RR in patients with BRCA1/2 biallelic alterations
	Talazoparib	TALAPRO-1/NCT03148795 ^[140]	II	Ongoing trial; interim results show that talazoparib improved RR in patients with BRCA1/2 alterations
PSMA radioligand therapy	Talazoparib + ENZ or ENZ	TALAPRO-2/NCT03395197	III	Ongoing trial
	LuPSMA	[141,142]	II	LuPSMA showed high RR, low toxicity, and reduction of pain in patients LuPSMA showed a better response than other therapies when rechallenged upon progression
	LuPSMA or cabazitaxel	TheraP/NCT03392428 ^[143]	II	The percentage of patients who achieved PSA ₅₀ is higher in the LuPSMA group The percentage of patients with AEs is lower in the LuPSMA group
PSMA-targeted immunotherapy	LuPSMA + best supportive/best standard of care or best supportive/best standard of care	VISION/NCT03511664 ^[144]	III	LuPSMA improved PFS and OS
	CAR ⁺ T cells	NCT01140373 ^[145]	I	3 × 10 ⁷ CAR ⁺ T cells/kg was safe with persisting CAR-T cells in peripheral blood for up to two weeks One patient exhibited a long-term response with stable disease status for more than 16 months
	PSMA-targeted/TGFβ-resistant CAR-T cells	NCT03089203 ^[146]	I	Ongoing trial
	Fully humanized anti-PSMA monoclonal IgG1 antibody conjugated to MMAE PSMA-ADC	NCT01695044 ^[147]	II	Discontinued trial as 40% and 31% of the participants showed progressive disease and AEs, respectively
	MEDI3726 (PSMA-ADC linked to pyrrolobenzodiazepine)	NCT02991911 ^[148]	I	AEs occurred in 91% of the patients and 33% discontinued MEDI3726 exhibited responses at higher doses, but treatment was discontinued
	MLN2704 (PSMA-ADC with a humanized monoclonal antibody linked to the maytansinoid DM)	[149]	I/II	MLN2704 had a low PSA ₅₀ response Neurotoxicity was dose-limiting
	Pasotuzixumab (AMG 212 or BAY 2010112)	NCT01723475 ^[150]	I	AMG 212 had dose-dependent clinical efficacy and manageable safety Relatively long-term response was seen in two patients
Androgen receptor degraders	Acapatamab (AMG 160)	NCT03792841 ^[151,152]	I	Acapatamab had an acceptable safety profile, promising PSA ₅₀ response, stable disease in 8/15 patients, and 14% of the patients continued the treatment for more than 6 months
	ARV-110	NCT03888612 ^[153]	I	Ongoing trial
PI3K pathway	Ipat (GDC-0068) + ABI or placebo + ABI	NCT01485861 ^[154,155]	Ib/II	Ipat improved PFS and OS

inhibitors	Ipat + ABI or placebo + ABI	NCT03072238 ^[156]	III	Patients with PTEN loss had prolonged PFS Ongoing trial; interim results show that Ipat prolonged PFS Two treatment-related deaths occurred in both groups

ABI: Abiraterone; ADC: antibody-drug conjugate; AEs: adverse events; CAR-T cells: chimeric antigen receptor T cells; DDR: DNA-damage repair; DOC: docetaxel; ENZ: enzalutamide; IgG1: immunoglobulin G1; Ipat: ipatasertib; LuPSMA: Lutetium-177^[177]Lu]-PSMA-617; MMAE: monomethyl auristatin E; OS: overall survival; PARPi: poly(ADP-ribose) polymerase inhibitor; PFS: progression-free survival; PSA: prostate-specific antigen; PSA₅₀: > 50% decline in prostate-specific antigen; PSMA: prostate-specific membrane antigen; RR: response rate; TGFβ: transforming growth factor-β.

Recently, Marshall *et al.*^[165] performed a retrospective, observational study involving patients with mCRPC having somatic or germline mutations in *BRCA1*, *BRCA2*, or *ATM* who were treated with olaparib. This study aimed to assess whether responses to olaparib are different between men with mutations in *BRCA1/2* vs. *ATM*. Indeed, patients with *BRCA1/2* alterations exclusively achieved > 50% decline in prostate-specific antigen (PSA₅₀ response). Moreover, these patients had a longer median PFS. Thus, this study demonstrated that men with *BRCA1/2* respond better to olaparib than those harboring *ATM* mutations, and better alternatives should be considered for patients with *ATM* alterations^[165].

These clinical trials helped to establish the efficacy and safety of olaparib as a monotherapy. Other trials investigating olaparib as a monotherapy outside the scope of DDR genes are underway^[166]. Moreover, several preclinical and clinical studies testing the synergistic effects of olaparib with other cytotoxic drugs (chemotherapy, AR-directed therapy, immune checkpoint inhibitors, radioligand therapy, radiotherapy, *etc.*) on mCRPC are still ongoing or completed.

Rucaparib is a small, oral, bioavailable PARPi that was evaluated in clinical trials due to its chemosensitization, radiosensitization, and antineoplastic potency^[167]. Rucaparib elicits a cytotoxic effect comparable to olaparib^[168]. Results of “TRITON2” (NCT02952534) Phase II trial prompted an “accelerated” FDA approval of rucaparib for men with mCRPC and *BRCA* mutations who were previously treated with AR-directed therapy and taxane-based chemotherapy. In this study, rucaparib treatment on patients with *BRCA* alterations showed promising response rates, particularly in comparison to patients with non-*BRCA* DDR gene alteration^[136,137,169].

Based on the *ClinicalTrials.gov* website, a Phase III clinical trial, “TRITON3” (NCT02975934), is ongoing. Patients with mCRPC harboring *BRCA1*, *BRCA2*, or *ATM* mutations who progressed on AR-directed therapy but did not receive chemotherapy are actively being recruited. This study aims to assess the patients’ response to rucaparib monotherapy vs. a treatment of the physician’s choice of ABI, ENZ, or DOC to verify the clinical benefit of rucaparib. In addition to TRITON3, other studies are currently active to evaluate the efficacy of rucaparib in combination with nivolumab or chemotherapeutic treatments^[160].

Niraparib (Zejula) is a small, oral, once-daily, bioavailable, potent, and highly selective Poly (ADP-ribose) Polymerase Inhibitors (PARPi) with antineoplastic activity^[170]. “GALAHAD” (NCT02854436) is an active, ongoing, Phase II clinical trial that aims to assess the efficacy, safety, and pharmacokinetics of niraparib in men with treatment-refractory mCRPC and DNA repair alterations (biallelic alterations). Interim analysis shows that niraparib may have promising efficacy

as a monotherapy for men with mCRPC, specifically those harboring *BRCA1/2* biallelic alteration^[138,139]. Niraparib is also being tested in several trials as a combination therapy with other cytotoxic drugs (ABI and radium-223).

Talazoparib (Talzenna) is a small, oral, bioavailable molecule that was demonstrated to be the most potent among PARPi in terms of *in vitro* activity and trapping of PARP on DNA SSBs^[171,172]. Between October 2017 and March 2020, participants were recruited and enrolled in “TALAPRO-1” (NCT03148795), an ongoing Phase II clinical trial whereby patients with mCRPC and DDR gene alterations who progressed on standard treatments were eligible and provided with talazoparib. In addition, different clinical trials assessing the efficacy of combining talazoparib with other therapeutics are ongoing including the Phase III TALAPRO-2 (NCT03395197) trial, which compares the combination of talazoparib and ENZ vs. ENZ alone^[140].

PSMA-based therapies

The overexpression of PSMA, particularly in mCRPC, makes it a potential therapeutic target for PCa. Upon binding to their receptors, PSMA ligands are internalized, leading to persistent retention of the ligand intracellularly. This signaling process seems specific to cancer cells, as in normal cells, a relatively rapid washout takes place. Abusing this feature in cancer cells that have increased PSMA ligand uptake, targeting PSMA by radioligand therapy or by immunotherapy has become an emerging therapeutic approach to treat mCRPC^[173,174].

PSMA radioligand therapy

The radioligand targeting PSMA, which has come the farthest in development, is lutetium-177, [¹⁷⁷Lu]-PSMA-617 (LuPSMA). It is a small, radiolabeled beta-emitter with a high binding affinity to PSMA. LuPSMA is advantageous by the short-range path length of the emitted beta particle, allowing efficient delivery of the radiation to the target cells while minimizing off-target effects on surrounding tissues^[141]. Since 2014, many retrospective and prospective studies have been performed to assess the efficacy and safety of LuPSMA in treating mCRPC.

The German Society of Nuclear Medicine performed the largest multicenter retrospective data analysis that studied the toxicity and efficacy of LuPSMA on 145 mCRPC patients. This study showed promising results for LuPSMA in terms of high efficacy and desirable safety, whereby 40% of the patients responded after a single treatment cycle^[175].

Hofman *et al.*^[141] performed a Phase II prospective trial involving men with mCRPC who progressed after receiving conventional PCa treatments and had high expression of PSMA. This trial's sample size was expanded, and long-term outcomes were assessed by Violet *et al.*^[142]. Analysis of the results of those studies showed a high response rate, low toxicity, reduction of pain in patients with mCRPC who received LuPSMA, and better response over other therapies when rechallenged upon progression.

The results of two recent trials, the “TheraP” (NCT03392428) Phase II prospective study and the “VISION” (NCT03511664) Phase III trial, involving mCRPC patients treated with LuPSMA proved that the latter is a potential novel efficient therapeutic for mCRPC and possible alternative to the approved chemotherapeutic drug CBZ and taxane-based regimens^[143,144].

Finally, although LuPSMA is the most studied PSMA radioligand therapeutic agent in recent years, other molecules are also being investigated, such as the alpha-emitting actinium-225 (225Ac-PSMA-617). This is an alpha-emitter with higher potency and a shorter range than beta-emitters^[176]. A meta-analysis was

recently published in September 2021 that summarizes the effects of 225Ac-PSMA-617 in mCRPC from nine studies with 263 patients; the authors concluded that 225Ac-PSMA-617 might be a potentially effective therapeutic option for mCRPC patients^[177].

PSMA-targeted immunotherapy

In addition to its significantly high expression in mCRPC, PSMA has a large extracellular domain which makes it an ideal target for immune agents^[174]. Several approaches for PSMA-targeted immunotherapy exist including chimeric antigen receptor T cells, antibody-drug conjugates, bispecific T-cell engagers, and PSMA-directed vaccines.

a. Chimeric antigen receptor T cells

Chimeric antigen receptor (CAR) is a genetically engineered transgenic T-cell receptor. It consists of an antigen recognition moiety allowing T cells to identify intact specific tumor-associated antigens and T-cell signaling domains that activate T cells. Thus, CAR-T cells combine the properties of antibodies that recognize particular antigens with the cytolytic killing of T cells^[178-180].

A Phase I study (NCT01140373) was performed by Slovin *et al.*^[145] to assess the safety, tolerability, and efficiency of escalating doses of PSMA-targeted CAR-T cells. Seven patients included in this study received from 10^7 to 3×10^7 CAR-T cells/kg. The highest given dose was shown to be safe with persisting CAR-T cells in peripheral blood for up to two weeks. Importantly, one patient exhibited a long-term response having a stable disease status for more than 16 months^[145].

Moreover, a first-time Phase I clinical trial (NCT03089203) to test the safety, feasibility, and efficacy of PSMA-targeted/TGF β -resistant CAR-T cells is ongoing. The experimental approach strives to overcome the immunosuppressive tumor microenvironment (TME) in mCRPC, to which high levels of TGF β are a contributing factor. This rationale is based on *in vivo* disseminated PCa models results, where PSMA-redirected CAR-T cells expressing a dominant-negative TGF β receptor had an increased T-cell proliferation and cytokine release, long-term persistence, and greater tumor elimination^[146]. The results of this clinical trial are pending.

b. Antibody-drug conjugate

Antibody-drug conjugate (ADC) technology is an emerging therapeutic approach that is still in its early phases. ADCs are highly specific monoclonal antibodies targeted against specific tumor antigens and chemically conjugated to cytotoxic agents^[181]. Target selection is one of the key considerations in ADCs design. The target needs to be highly expressed on the surface of tumor cells *vs.* low to no expression in normal cells. Moreover, the target preferably needs to have internalization characteristics that allow the transport of the antibody to carry the cytotoxic payloads into cancerous cells. These requirements are met in PSMA, making it an attractive target; therefore, several ADCs targeting PSMA in PCa are in clinical development^[182].

A Phase II trial (NCT01695044) was performed by Petrylak *et al.*^[147], a Phase I trial (NCT02991911) by de Bono *et al.*^[148], and a Phase I/II multiple escalating dose trial by Milowsky *et al.*^[149] tested different PSMA-ADCs. The different trials showed that, although these drug conjugates had some activity in mCRPC, their effect was accompanied by significant adverse events (such as neutropenia and neuropathy), which led to the discontinuation of some of these treatments. Hence, it was noticed that toxicity related to the long

circulation in the system of PSMA-targeted ADCs limited the success of the clinical trials^[183].

c. Bispecific T-cell engagers

Bispecific T-cell engagers (BiTEs) are bispecific antibodies that simultaneously target a T-cell-specific molecule (almost always CD3 chain due to its conserved property) and a TAA, which could be PSMA in the case of PCa^[184]. BiTEs showed success in several types of cancer, such as acute lymphoblastic leukemia, where blinatumomab was the first FDA-approved BiTE^[185,186].

Hummel *et al.*^[150] conducted a first-in-human, dose-escalation, Phase I clinical trial (NCT01723475) to primarily test PSMA CD3 first-generation BiTE pasotuxizumab (known as AMG 212 or BAY 2010112) in patients with mCRPC refractory to standard therapy. In this study, data analysis demonstrated the dose-dependent clinical efficacy and manageable safety of pasotuxizumab in mCRPC, with 3 out of 16 patients exhibiting $\geq 50\%$ PSA response and two patients having a relatively long-term response^[150].

Another first-in-human, Phase I study (NCT03792841) to assess acapatamab (AMG 160), a novel next-generation PSMA CD3 BiTE with an extended half-life, in mCRPC was conducted^[151]. AMG 160 gave a promising PSA₅₀ response and acceptable safety profile in treated patients. This study prompted testing AMG 160 as a combination therapy with other agents (pembrolizumab, ENZ, ABI, AMG 404, and etanercept prophylaxis) in ongoing trials^[152,187,188].

d. PSMA-directed vaccines

Cancer vaccines, intended to enhance the immune response against tumor cells by increasing the pool of TAA-specific host T cells, have failed to demonstrate a considerable benefit in PCa thus far (such as the Phase III clinical trials “PROSTVAC” that targets PSA and “GVAX”, where both failed to meet their primary endpoint of enhancing the overall survival)^[189,190]. However, this approach continues to be investigated, given its potential efficacy, minimal side effects, limited cost, and easy synthesis. Specifically, PSMA is being considered as an appropriate target for the development of PCa vaccines^[191]. Using new computational tools to select suitable B-cell epitopes with high antigenicity, the “673RHVIYAPSSHNKYAGE25” peptide was predicted as having the best binding affinity. Future steps involve synthesis of the peptide and testing its *in vivo* efficacy as a potential PSMA-directed vaccine^[192].

Androgen receptor degraders

Androgen receptor degraders emerged as an alternative therapeutic strategy to manage mCRPC. One of the tools that allow targeting of AR to degradation is using proteolysis-targeting chimera (PROTAC) novel technology. PROTACs, also known as bivalent chemical protein degraders, are heterobifunctional compounds consisting of two recruiting ligands joined by a linker. One ligand moiety binds to the protein of interest, while the other is specific to E3 ubiquitin ligase (E3). Thus, PROTACs form a ternary complex with the target protein and E3 and consequently promote target ubiquitination and degradation^[193].

Salami *et al.*^[194] published a study in 2018 that aimed to assess whether ARCC-4, a low-nanomolar PROTAC ARD, was better at targeting AR signaling in CRPC cells than the currently approved competitive antagonist ENZ. Interestingly, ARCC-4 promoted the degradation of about 95% of cellular ARs, especially the clinically relevant AR with point mutations resistant to ENZ. Moreover, ARCC-4 induced apoptosis and maintained its antiproliferative effect in a hyperandrogenic environment that impedes ENZ activity. This study showed promising results where PROTAC-mediated AR degradation might overcome the mCRPC AR-dependent

mechanism of drug resistance^[194].

To date, several PROTACs reached clinical trials in different types of cancer, including ARV-110 in mCRPC. The oral and bioavailable ARV-110 was tested earlier *in vitro* and *in vivo*, where it led to the degradation of more than 95% of ARs in the tested PCa cell lines and demonstrated antitumor effects in both ENZ-naïve and -resistant PCa xenograft models. ARV-110, similar to ARCC-4, promoted the degradation of clinically relevant AR mutants and maintained its activity even in a milieu with high androgen levels. The first-in-human, Phase I clinical trial (NCT03888612) testing ARV-110 in mCRPC patients who received more than two prior treatments was performed. This trial is still ongoing; however, early data show that ARV-110 has a reasonable safety profile and a promising antitumor activity in mCRPC^[153].

The results from these preclinical and clinical trials, among others, show that ARD might be a novel alternative therapeutic option to treat mCRPC.

PI3K pathway inhibitors

As mentioned above, loss of PTEN and the atypical activation of the PI3K signaling network are one of the possible mechanisms driving mCRPC growth. This fact supported the development of several PI3K pathway inhibitors including ipatasertib (Ipat) (GDC-0068), which is an oral, bioavailable, AKT non-ATP-competitive inhibitor that impedes the PI3K/AKT pathway and subsequently tumorigenesis^[195].

Two clinical trials, a Phase Ib/II (NCT01485861) involving patients who formerly received DOC and an ongoing Phase III trial (NCT03072238) with treatment-naïve patients, tested the combination of Ipat and ABI in mCRPC. In general, both studies demonstrated enhanced antitumor effects when combining Ipat with ABI compared to ABI monotherapy, with increased benefit for patients with PTEN loss^[154-156]. Thus, the results of those trials suggest that a combination of AKT and AR signaling inhibitors might provide a promising therapeutic approach to treating men with mCRPC with a poor prognosis due to PTEN loss.

CONCLUSION

mCRPC remains a challenge for PCa disease management. AR signaling comprises a fundamental role in PCa pathogenesis even in the advanced androgen-insensitive stages. AR signaling, along with other various molecular pathways, is subjected to diverse modifications and aberrations that can be used as biomarkers to personalize treatment for mCRPC patients and overcome drug resistance to the standard therapy. Thus, further understanding of the mechanisms mediating drug resistance in mCRPC is crucial for identifying future targeted therapeutic modalities.

DECLARATIONS

Authors' contributions

Conceptualized, outlined, and drafted the review: Abou-Kheir W, Mukherji D

Made substantial contributions to study design, drafting the paper, generating tables and figures: Yehya A, Ghamlouche F, Zahwe A

Contributed to drafting parts of the paper: Zeid Y, Wakimian K

Reviewed the paper and approved the final version: Yehya A, Ghamlouche F, Zahwe A, Zeid Y, Wakimian K, Mukherji D, Abou-Kheir W

Availability of data and materials

Not applicable.

Financial support and sponsorship

None.

Conflicts of interest

DM reports institutional funding from Astellas, Personal travel support/honoraria from Astellas, Janssen, Bayer, Ipsen, BMS, and MSD. All authors declared that there are no conflicts of interest.

Abstract

Triple-negative breast cancer (TNBC) is the most aggressive breast cancer subtype. It disproportionately affects BRCA mutation carriers and young women, especially African American (AA) women. Chemoresistant TNBC is a heterogeneous and molecularly unstable disease that challenges our ability to apply personalized therapies. With the approval of immune checkpoint blockade (ICB) for TNBC, the addition of pembrolizumab to systemic chemotherapy has become standard of care (SOC) in neoadjuvant systemic therapy (NST) for high-risk early-stage TNBC. Pembrolizumab plus chemotherapy significantly increased the pathologic complete response (pCR) and improved event-free survival in TNBC. However, clinical uncertainties remain because similarly treated TNBC partial responders with comparable tumor responses to neoadjuvant therapy often experience disparate clinical outcomes. Current methods fall short in accurately predicting which high-risk patients will develop chemo-resistance and tumor relapse. Therefore, novel treatment strategies and innovative new research initiatives are needed. We propose that the EGFR-K-RAS-SIAH pathway activation is a major tumor driver in chemoresistant TNBC. Persistent high expression of SIAH in residual tumors following NACT/NST reflects that the EGFR/K-RAS

pathway remains activated (ON), indicating an ineffective response to treatment. These chemoresistant tumor clones persist in expressing SIAH (SIAH^{High/ON}) and are linked to early tumor relapse and poorer prognosis. Conversely, the loss of SIAH expression (SIAH^{Low/OFF}) in residual tumors post-NACT/NST reflects EGFR/K-RAS pathway inactivation (OFF), indicating effective therapy and chemo-sensitive tumor cells. SIAH^{Low/OFF} signal is linked to tumor remission and better prognosis post-NACT/NST. Therefore, SIAH is well-positioned to become a novel tumor-specific, therapy-responsive, and prognostic biomarker. Potentially, this new biomarker (SIAH^{High/ON}) could be used to quantify therapy response, predict chemo-resistance, and identify those patients at the highest risk for tumor relapse and poor survival in TNBC.

INTRODUCTION

Triple-negative breast cancer

Triple-negative breast cancer (TNBC) represents 15%-20% of all breast cancers diagnosed in the United States, and it is characterized by the absence of estrogen receptors (ER), progesterone receptors (PR), and human epidermal growth factor receptor 2 (HER2)^[1-5]. <https://seer.cancer.gov/statfacts/html/breast.html>. TNBC is the most aggressive subtype of breast cancer, and it disproportionately affects *BRCA1* mutation carriers and young women, especially those with Western African ancestry^[6-13]. This molecular subtype is nearly twice as common in African American women (AA) than in Caucasian women^[6,8,9,14-17]. TNBC is a genetically diverse, highly heterogeneous, and molecularly unstable disease, which challenges our ability to tailor effective individualized treatments for patients^[10,18]. TNBC has unique and aggressive tumor biology, and it constitutes a major health threat with the worst prognosis and the highest mortality of all breast cancer subtypes^[10,19,20]. Looking more closely, one in three patients with high-risk early-stage TNBC will develop tumor relapse, which typically occurs within the first three years of initial diagnosis; only a third of women with locoregional TNBC will survive their disease; and of those with metastatic TNBC, less than 1 in 9 will survive their disease^[5,10,21-23]. TNBC has a 5-year overall survival (OS) of 78.5%, and the 5-year survival rates for localized, regional, and metastatic diseases are 91.2%, 65.4%, and 12.2%, respectively, which is the worst among the major molecular subtypes in breast cancer (https://seer.cancer.gov/explorer/application.html?site=623&data_type=4&graph_type=5&compareBy=stage&chk_stage_101=101&chk_stage_104=104&chk_stage_105=105&chk_stage_106=106&series=9&hdn_sex=3&race=1&age_range=1&advopt_precision=1&advopt_show_ci=on&advopt_display=2). Thus, the dismal prognosis, chemo-resistance, and high mortality of regional and metastatic TNBC highlights a critical unmet need for the development of improved therapies and the discovery of reliable prognostic biomarkers such as SIAH, which can single out the highest risk patients at the first-line neoadjuvant setting, identify chemoresistant tumors that are difficult to treat and prone to develop early relapse, optimize effective treatment sequences, and select the best combinational strategies for better clinical outcomes and prolonged survival.

Standard treatment regimens in TNBC

Standard chemotherapy remains the backbone of systemic therapy in TNBC^[20,24-28]. <https://www.cancer.org/cancer/breast-cancer/treatment/treatment-of-triple-negative.html>. Neoadjuvant chemotherapy (NACT) was the previous standard of care (SOC) to treat high-risk and locally advanced TNBC prior to July 26, 2021^[10,29]. The addition of immune checkpoint blockade (ICB) to chemotherapy is now the current SOC for neoadjuvant systemic therapy (NST) to treat high-risk early-stage TNBC. Immuno-oncology (IO) therapy is an exciting scientific breakthrough in the treatment of TNBC^[30-32].

Immunotherapy that targets programmed death receptor-1 (PD-1) has shown great promise in treating a subset of TNBC patients in combination with chemotherapy^[33,34]. Pembrolizumab plus chemotherapy significantly improved the pCR rates in high-risk early-stage TNBC in the neoadjuvant setting^[35,36]. As shown in the KEYNOTE-522 trial, neoadjuvant pembrolizumab plus chemotherapy led to an improved pCR rate (65%) in high-risk early-stage TNBC^[35]. Notably, the TNBC pIR patients with residual disease at the time of surgery seemed to benefit the most from the addition of IO-therapy in the neoadjuvant and adjuvant settings^[37]. Surprisingly, the 3-year event-free survival (EFS) benefit associated with pembrolizumab was independent of PD-L1 expression in high-risk early-stage TNBC^[35]. Based on the I-SPY 2 trial, the pCR rate doubled to 60% when pembrolizumab was added to standard chemotherapy to treat stage II/III TNBC patients with T2/N1 or higher stage tumors^[30,36]. In contrast, as reported in KEYNOTE-355, KEYNOTE-119, Impassion130, and Impassion131, PD-(L)1-targeted immunotherapies plus chemotherapy have shown only modest survival benefit in PD-L1-positive TNBC in advanced and metastatic settings^[33,34,38]. At the same time, unfortunately, the grade 3 or 4 treatment-related adverse events were significantly increased in response to the new IO-regimens^[39].

Unmet needs in TNBC

As more and more TNBC patients are treated with pembrolizumab plus chemotherapy in both neoadjuvant and/or metastatic settings, ICB resistance is evidently emerging, and serious adverse side effects were reported in a subset of TNBC patients^[35,38]. Despite the benefit of this newly FDA-approved IO-therapy, 30%-44% of high-risk early-stage TNBC patients and 60%-70% of PD-L1-positive metastatic TNBC patients who receive the IO-therapy did not show any objective improvement^[35,38]. Without a proper guide, pembrolizumab plus chemotherapy is often administered “blindly” in the neoadjuvant setting following the newly FDA-approved standard IO-regimens to treat high-risk early-stage TNBC. How to maximize the current SOC chemo- and IO-therapy in combination while limiting chemo- and IO-resistance, and minimizing the side effects of immunotherapy is a difficult problem and an unmet need for a large number of TNBC patients.

Pathology following completion of NACT/NST, with or without immunotherapy (pembrolizumab), produces a binary response: pathologic complete response (pCR) or pathologic incomplete response (pIR)^[40,41]. pCR is a reliable prognostic marker that correlates with tumor remission and long-term survival, whereas pIR is associated with an increased risk of early tumor relapse and poor prognosis^[36,42-47]. Incomplete responders can be further classified by the residual cancer burden (RCB classes I-III); the higher the RCB classification, the higher the likelihood of tumor relapse and mortality^[21,40,41,48-51]. TNBC patients with high-risk and high-grade residual disease are now commonly treated with additional adjuvant chemotherapy, including capecitabine, which may be combined with immunotherapy (pembrolizumab) post-operatively^[35,36,38,52-54]. Clinical uncertainties remain, because although many TNBC patients with the identical clinical and pathological tumor stages by the American Joint Committee on Cancer (AJCC) TNM classification, and similar residual cancer burden (RCB) after a non-pCR (pIR) diagnosis post-NACT/NST, will often experience disparate clinical outcomes and survival^[55,56]. Current methods to stratify these high-risk patients fall short in predicting the risk of tumor recurrence and forecasting survival. There is no reliable prognostic biomarker that can be used to predict with certainty and molecular precision which RCB (I-II-III) tumors will stay in remission and which ones will relapse rapidly^[3]. Few therapeutic agents, alone or in combination, are effective at eradicating chemoresistant and metastatic TNBC^[57-60]. Therefore, the development of a new tumor-specific biomarker that can be used to stratify high-risk TNBC patients in the first-line neoadjuvant setting, quantifying treatment efficacy in real time in the clinical setting is essential. Additionally, utilizing this same biomarker to detect the emergence of chemoresistant tumor clones at a single tumor cell resolution, forecast risk for early tumor relapse, and predict patient survival would equip us with a new therapy-responsive prognostic biomarker to quantify, guide, and treat TNBC more

effectively^[3].

Chemo-resistance in TNBC

Chemo-resistance is a vexing problem and a major life-threatening feature of TNBC^[25,57,61]. Activation of multiple signaling pathways, context-dependent compensatory pathway cross-talk, synergy, antagonism, and signaling network “rewiring” are all implicated in the development of chemoresistant phenotypes in TNBC. These include Wnt/ β -catenin, Notch, Hedgehog, NF κ B, PI3K/mTOR, Hippo/YAP, JAK/Stat, TGF β , hypoxia, p53 loss of function and BRCA mutations, altered metabolism, and increased transporter and efflux pump activity^[25,57,62-66]. Single-cell sequencing has revealed that plasticity, heterogeneity, rapid molecular evolution of innate and acquired chemo-resistance, cellular senescence, and dynamic remodeling of epithelial-mesenchymal transition (TME)/mesenchymal-epithelial transition (MET) states of tumor-initiating cells or cancer stem cells in TNBC contribute to cancer recurrences^[49,62,67-71]. These aforementioned topics have been reviewed extensively in the TNBC literature. Here, our discussion will focus on persistent activation of the EGFR/K-RAS/MAPK/SIAH pathway, which drives chemo-resistance, early tumor relapse, and high mortality in TNBC^[3,72].

Persistent EGFR/K-RAS/MAPK/SIAH pathway activation drives TNBC malignancy

Genomic landscape studies indicate that EGFR/K-RAS/MAPK pathway activation is a major impetus driving TNBC malignancy, early tumor relapse, local invasion, and metastatic spread^[73,74]. Aberrant EGFR/K-RAS/MAPK/SIAH pathway activation is highly prevalent in chemoresistant, recurrent, locally advanced, and metastatic TNBC^[3,75-78]. Heightened EGFR/K-RAS/MAPK activation has multiple deleterious effects on the tumor/tumor microenvironment (TME), which is associated with decreased tumor-infiltrating lymphocytes (TIL) detection in TNBC and is correlated with increased metastases and poor prognosis in breast cancer^[73,74,78]. With the new FDA-approved chemo- and immunotherapy combination to treat high-risk early-stage TNBC, it is important to maximize the therapeutic benefit and identify chemoresistant tumor cells as early as possible, but also minimize the adverse toxicities and immune side-effects of these IO-combination therapies in the neoadjuvant and adjuvant settings.

SIAH is the most conserved downstream signaling gatekeeper in the EGFR/K-RAS/MAPK signaling pathway

Due to the extraordinary conservation of EGFR/RAS/MAPK/SIAH signaling pathway across metazoan species, the molecular insights and core principles gleaned from *Drosophila* EGFR/RAS/SINA studies have shed light on the evolutionarily conserved principles and fundamental aspects of mammalian EGFR/K-RAS/MAPK/SIAH signaling pathway, and guided anti-EGFR/K-RAS/MAPK/SIAH drug development in human cancer^[77,79-85]. As a RING-domain E3 ubiquitin ligase, the human homologs of SINA (SIAH) or *Drosophila* Seven-In-Absentia (SINA) are the most downstream gatekeeper and the most evolutionarily conserved signaling component in the EGFR/K-RAS/MEK/MAPK pathway identified thus far [Figure 1A, 1E and 1F]^[72,77,82-88]. Due to its conserved signaling gatekeeper function as a major network bottleneck, SIAH^{ON/OFF} expression is well-positioned to serve as a direct readout of tumor-driving EGFR/K-RAS/MEK/MAPK pathway activation (ON)/inactivation (OFF) in TNBC [Figure 1B]^[76,77,85,89]. SIAH^{Low/OFF} in TNBC post-NACT correlates with tumor remission, effective therapy, and good prognosis [Figure 1C], whereas SIAH^{High/ON} in TNBC post-NACT correlates with early relapse, ineffective therapy, and poor survival [Figure 1D]^[76]. Therefore, SIAH is likely to be an excellent prognostic biomarker to stratify incomplete responders in the first-line neoadjuvant setting^[3,76,89]. SIAH may be used to identify chemoresistant tumor cells as early as possible in the neoadjuvant setting as a therapy-responsive biomarker in order to identify the difficult-to-treat cancers at the highest-risk for early relapse and treatment-resistance. Furthermore, we propose that SIAH can be used to augment residual cancer burden (RCB I-III) classification in quantifying the efficacy of SOC treatment regimens, detect chemoresistant tumor clones,

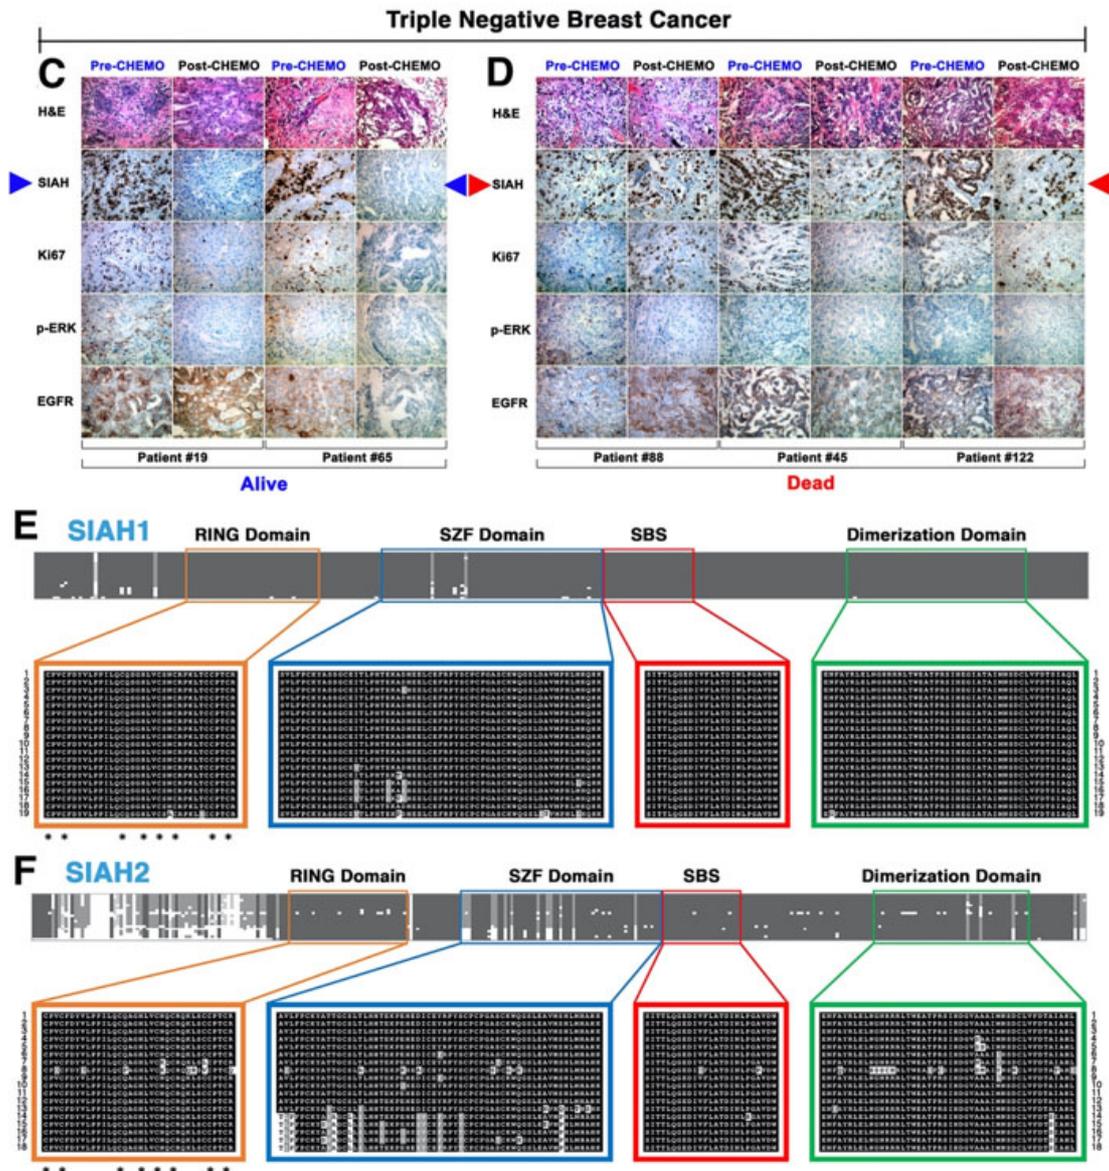

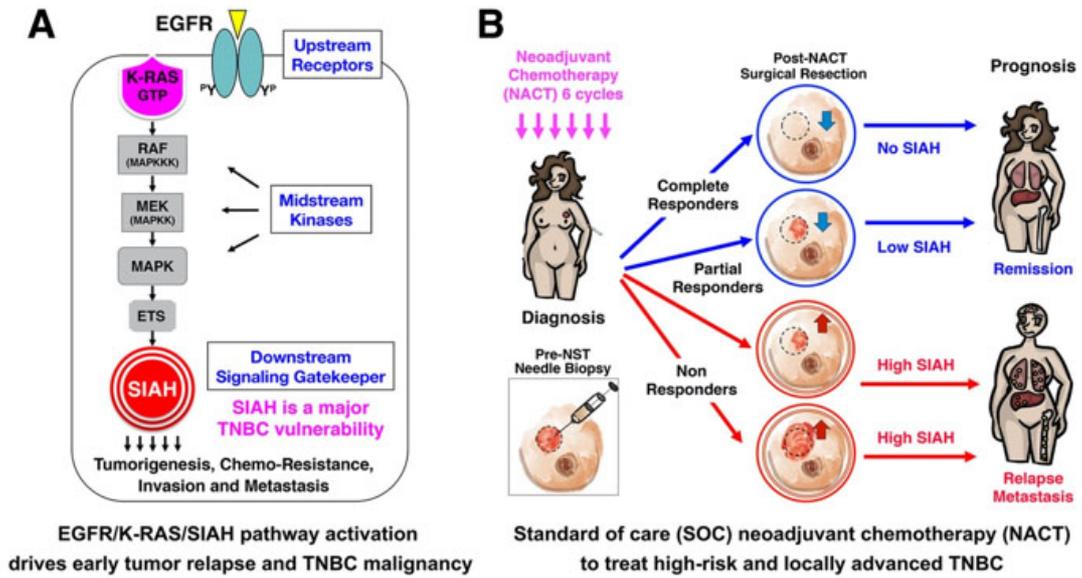

Figure 1. SIAH is the most conserved downstream signaling gatekeeper in the EGFR/K-RAS/SIAH pathway, whose persistent activation is driving TNBC malignancy, tumor relapse, and metastasis. (A) SIAH is the most evolutionarily conserved and the most downstream signaling module identified in the EGFR/K-RAS signaling pathway thus far. (B) Loss of SIAH expression (SIAH^{Low/OFF}) after effective NACT is correlated with EGFR/K-RAS pathway inactivation and tumor regression/remission, whereas persistent SIAH expression (SIAH^{High/ON}) after ineffective NACT is correlated with EGFR/K-RAS pathway activation and tumor progression/early relapse. Persistent high SIAH expression (SIAH^{High/ON}) in high-risk residual tumors post NACT is correlated with EGFR/K-RAS pathway activation, chemo-resistance, and early tumor relapse. (C-D) TNBC tumors were stained with H&E, SIAH, Ki67, phospho-ERK, and EGFR. SIAH outperforms Ki67. SIAH is prognostic and Ki67 is not prognostic in NACT-treated high-risk and locally advanced breast cancer. We found that SIAH^{Low/OFF} post-NACT correlates with tumor remission and prolonged survival (Alive at 5 years) (C). We found that persistent SIAH^{High/ON} expression in residual tumors post-NACT is associated with tumor relapse and poor survival (Dead before 3-5 years) (D). (E) SIAH1 and (F) SIAH2 are extraordinarily conserved across metazoan species. Conclusion: We found that SIAH^{ON/OFF} expression is a binary code that reflects tumor-driving EGFR/K-RAS/SIAH pathway activation^{ON}/inactivation^{OFF} in TNBC primary and residual tumors. As such, SIAH is strategically well positioned to become a new TNBC target, and a new tumor-specific, therapy-responsive, and prognostic biomarker to risk-stratify pIR patients, detect the emergence of treatment-refractory tumors, quantify NACT/NST efficacy, augment RCB classifications, forecast early relapse, and predict patient survival in real time in the clinic. SIAH: Human homologs of *Drosophila* Seven In Absentia (SINA); NACT: neoadjuvant chemotherapy; RCB: residual cancer burden; TNBC: triple-negative breast cancer.

forecast early tumor relapse, and predict patient survival. Having this accuracy in real time allows the clinician to pivot with precision to select more effective drugs and optimize the sequence of combination therapies for treatment-refractory TNBC [Figure 1]^[3,76,77,85].

The SIAH^{ON/OFF} binary code reflects this major tumor-driving EGFR/K-RAS/MAPK pathway activation (ON) and inactivation (OFF) in TNBC

Supported by strong evidence in developmental, evolutionary, and cancer biology, we hypothesize that persistent EGFR–K-RAS–SIAH pathway activation is a major tumor-driving force in TNBC, and that SIAH is a new tumor-specific, therapy-responsive, and prognostic biomarker for patient risk stratification, therapy quantification, and treatment optimization^[76,77,82–85,89]. We propose that the persistent high expression of SIAH (SIAH^{High/ON}) post-NACT/NST reflects tumor-driving EGFR/K-RAS/MAPK pathway activation (ON), resulting in tumor progression, immuno-suppression, and chemo-resistance, versus the loss of SIAH expression (SIAH^{Low/OFF}) post-NACT/NST reflects this tumor-driving pathway is inactivated (OFF), resulting in tumor regression, immune responsiveness, and chemo-sensitivity^[3,76]. This new tumor-specific, therapy-responsive, and prognostic SIAH^{ON/OFF} binary code can potentially be used to identify those TNBC pIR patients at the highest risk for early tumor relapse, detect multidrug-resistant residual tumor clones in real time, combine and guide precise therapies in the first-line setting.

Clinical utility of SIAH as a tumor-specific, therapy-responsive, and prognostic biomarker for risk stratification, early relapse, and survival prediction in TNBC

We generated an anti-SIAH monoclonal antibody for tumor IHC/IF/FACS staining^[82,83]. Our pilot study of 57 NACT-treated TNBC patients with residual disease showed that SIAH^{Low/OFF} correlates with tumor remission and good prognosis [Figure 1C]. For those with SIAH^{High/ON} in their residual tumors, it predicts chemoresistant tumor cells/clones, early tumor relapse, and poor prognosis post-NACT/NST [Figure 1D]^[76]. The prognostic impact of SIAH expression seemed to be far superior to that of Ki67 and phospho-ERK in NACT/NST-treated breast cancer^[76]. SIAH could be used to risk stratify incomplete responders, identify chemo- and IO-resistance, quantify therapy efficacy, and predict relapse and survival [Figure 2A]. SIAH^{Low/OFF} in TNBC residual tumors reflects that the EGFR/K-RAS/MAPK/SIAH pathway is OFF, and indicates chemo-sensitivity, effective NACT/NST, and good prognosis after surgery [Figure 2B]. SIAH^{High/ON} in TNBC residual tumors reflects that the EGFR/K-RAS/MAPK/SIAH pathway is ON, which indicates chemo-resistance, ineffective NACT/NST, and/or the need for additional adjuvant therapies to prevent progressive disease and early tumor relapse [Figure 2C]. Our studies have demonstrated that SIAH offers a tumor-specific, therapy-responsive, and prognostic biomarker in TNBC with high molecular precision and full dynamic range (0%-100%)^[76,89]. Therefore, SIAH^{ON/OFF} expression can be used to identify chemoresistant

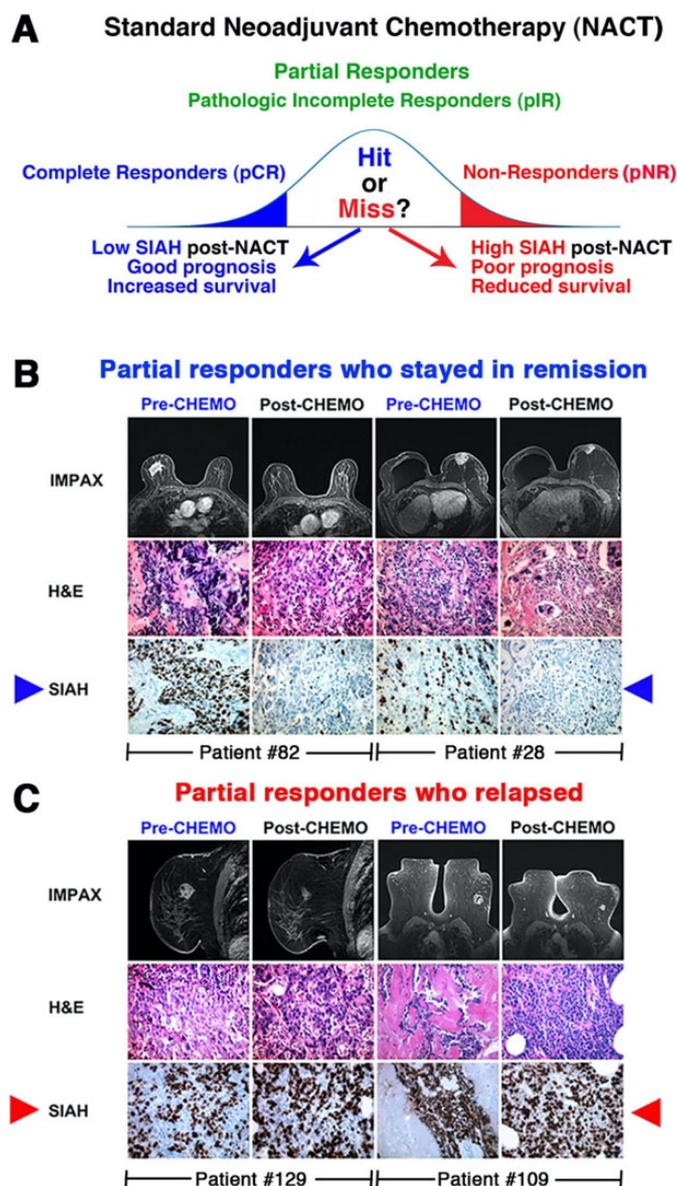

Figure 2. SIAH marks proliferating tumor cells at a single-cell resolution, and SIAH is a therapy-responsive and prognostic biomarker that can be used to risk-stratify incomplete responders in NACT/NST-treated high-risk and locally advanced breast cancer. IMPAX stands for the IMPAX digital mammography, a powerful diagnostic platform for breast imaging at the Sentara Breast Centers. (A) pCR is a good prognostic marker associated with long-term survival post-NACT/NST. However, for the pIR patients with residual disease, additional tools are needed to distinguish which patients are at high risk for early tumor relapse and thus who may need additional adjuvant chemotherapies. (B) The pIR patients with no or low SIAH expression in residual tumors post-NACT/NST stayed in remission and have prolonged survival (examples: patients #82 and #28). (C) In contrast, the pIR patients with persistent high SIAH expression in residual disease post-NACT/NST developed early relapse and succumbed to their chemoresistant and metastatic diseases (examples: patients #109 and #129). Conclusion: We propose that persistent high SIAH expression in residual tumors is associated with early tumor relapse and poor prognosis, while no or low SIAH expression in residual tumors is associated with tumor remission and good prognosis post-NACT/NST. SIAH: Human homologs of *Drosophila* Seven In Absentia (SINA); Pir: pathologic incomplete response; NACT: neoadjuvant chemotherapy; NST: neoadjuvant systemic therapy; PCR: athologic complete response.

tumor clones, differentiate partial responders, forecast tumor relapse, and predict patient survival in NACT-treated breast cancer^[76,89]. Moreover, we have shown that SIAH^{ON/OFF} expression is a direct readout of EGFR/K-RAS/MAPK pathway activation (ON)/inactivation (OFF)^[3,76,77,84,85]. Hence, studying the “ON/OFF” of the major tumor-driving EGFR/K-RAS/MAPK/SIAH pathway may represent an opportunity to risk-

stratify TNBC patients before and after NACT/NST (IO-therapy). As a binary biomarker with high tumor specificity and detection sensitivity as well as a full dynamic range (0%-100%), we propose to validate that SIAH is a powerful new prognostic biomarker that can be used to risk-stratify patients, detection of chemo-resistance, quantify NACT/NST efficacy, forecast early tumor relapse, and predict patient survival in TNBC^[72,76,77,82,83].

CONCLUSION

Focusing on EGFR/K-RAS/MAPK/SIAH pathway activation as a major tumor driver in TNBC to risk-stratify patients and detect chemo-resistance may represent a significant step forward. In our pilot study, we found that all TNBC primary tumors are highly proliferative, heavily decorated with SIAH, and the median SIAH expression in untreated TNBC tumors was 70% in both lymph node (LN) positive and LN-negative subsets^[76]. In contrast, 30% of patients with residual disease displayed persistent high SIAH expression and had high relapse rates and poor outcomes^[76]. As a tumor-specific, therapy-responsive, and prognostic biomarker in TNBC, SIAH has a full dynamic range, high sensitivity, high specificity, and molecular precision and could be used to risk-stratify patients and detect chemoresistant tumor cells in the first-line neoadjuvant settings. Ultimately, we hope to translate our findings (SIAH as a new prognostic biomarker) for clinical use to facilitate early detection of ineffective therapy in the first-line neoadjuvant setting, detect chemoresistant tumor cells at a single tumor cell resolution, augment RCB I-II-III classifications with high-precision, accurately calculate the risk of early tumor relapse and predict long-term survival in TNBC. If successful, we can use this new, dynamic, therapy-responsive, interactive, and tumor-specific biomarker, SIAH, to address the unmet need of identifying chemoresistant TNBC, and risk-stratify pIR patients by tumor relapse and poor prognosis in the first-line neoadjuvant setting. By leveraging the tumor-driving EGFR/K-RAS/SIAH pathway activation (ON)/inactivation (OFF) in TNBC, we hope to differentiate TNBC pIR patients by correlating SIAH^{High} (high-risk) versus SIAH^{Low} (low-risk) expression in residual tumors post-NACT/NST. This precision biomarker may also be used to detect treatment disparity amongst incomplete responders, forecast early tumor relapse, and predict survival. The next steps should include the successful executions of several independent large-scale multicenter biomarker validation studies leading to FDA approval of SIAH as a new tumor-specific, therapy-responsive, and prognostic biomarker for TNBC risk stratification, detection of chemo-resistance, therapy quantification in real time, treatment optimization in the clinic. Importantly, SIAH is a strategically positioned cancer target for us to develop a new anti-TNBC targeted therapy to eradicate multidrug-resistant, undruggable, and incurable TNBC malignancy in the future.

Abstract

Cancer cells, in which the RAS and PI3K pathways are activated, produce high levels of reactive oxygen species (ROS), which cause oxidative DNA damage and ultimately cellular senescence. This process has been documented in tissue culture, mouse models, and human pre-cancerous lesions. In this context, cellular senescence functions as a tumour suppressor mechanism. Some rare cancer cells, however, manage to adapt to avoid senescence and continue to proliferate. One well-documented mode of adaptation involves increased production of antioxidants often associated with inactivation of the *KEAP1* tumour suppressor gene and the resulting upregulation of the NRF2 transcription factor. In this review, we detail an alternative mode of adaptation to oxidative DNA damage induced by ROS: the increased activity of the base excision repair (BER) pathway, achieved through the enhanced expression of BER enzymes and DNA repair accessory factors. These proteins, exemplified here by the CUT domain proteins CUX1, CUX2, and SATB1, stimulate the activity of BER enzymes. The ensued accelerated repair of oxidative DNA damage enables cancer cells to avoid senescence despite high ROS levels. As a by-product of this adaptation, these cancer cells exhibit increased resistance to genotoxic treatments including ionizing radiation, temozolomide, and cisplatin. Moreover, considering the intrinsic error rate associated with DNA repair and translesion synthesis, the elevated number of oxidative DNA lesions caused by high ROS leads to the accumulation of mutations in the cancer cell population, thereby contributing to tumour heterogeneity and eventually to the acquisition of resistance, a major obstacle to clinical treatment.

BASE EXCISION REPAIR

Overview

Base excision repair (BER) repairs most base lesions including alkylated, deaminated and oxidized bases, as well as apurinic/apyrimidinic (AP) sites [Figure 1]^[1]. This pathway is initiated by one of many DNA glycosylases, which recognizes a specific base lesion and cleaves the N-glycosylic bond linking the altered base to the DNA backbone to produce an apyrimidinic/apurinic site (AP site)^[1,2]. In mammals, AP sites are targeted by the AP endonuclease 1, APE1, which incises the DNA backbone 5' to the AP site to generate a single-strand break with a 5'-deoxyribose phosphate (dRP)^[3]. In addition, DNA glycosylases for oxidized bases are also endowed with an AP/lyase activity that generates a single-strand nick 3' to the AP site. OGG1 and NTHL1 generate the single-strand nick through beta elimination, while NEIL1 and NEIL2 do this by beta delta elimination (reviewed in^[4]). 5' or 3' end processing of the resulting single-strand breaks is then performed by DNA Pol β , APE1, or PNKP, and repair synthesis and ligation are accomplished by the short-patch or long-patch pathways^[5-7]. In short-patch repair, DNA Pol β (Pol β) adds a single base and removes the 5'- dRP to allow ligation^[8]. In long patch repair, 2 to 13 bases are synthesized by Pol β or δ/ϵ , thereby generating a displaced strand that is cleaved by the flap structure-specific endonuclease FEN1 prior to ligation^[1,9].

The importance of BER is illustrated by its complex implications in cancer. On the one hand, inherited as well as somatic mutations in some BER genes were found in various cancers and in some cases have been linked to particular mutation signatures. On the other hand, overexpression of BER enzymes has been reported in many tumours and cancer cell lines and has been associated with increased resistance to genotoxic treatments.

Germ line and somatic mutations in BER genes that predispose to cancer

The role of Pol β in maintaining genome integrity is illustrated by the fact that mouse embryo fibroblasts from Pol β -null mice exhibit a 1.6-fold increase in spontaneous mutation frequency^[10]. However, it is important to consider that the role of Pol β in the repair of endogenous DNA lesions does contribute to the acquisition of mutations. The average Pol β error rate was estimated at 7×10^{-4} for 12 possible base substitution errors and at 3 to 9×10^{-4} for single base deletions^[11]. In a diploid mammalian cell, there are approximately 30,000 endogenous DNA base lesions per day^[12] (and table 2.1 in^[13]). The term "endogenous" here means that these lesions are caused by normal metabolism in contrast to exogenous sources of DNA damage. Considering a Pol β error rate of at least 1/1000, we can estimate that 30 mutations per cell are acquired every day as a result of BER activity. This said, inherited and somatic mutations that alter the function of BER enzymes increase the risk of cancer, and for this reason, BER is considered to function as a tumour suppressor mechanism.

Approximately 30% of tumours analyzed exhibit a mutation in the *Pol β* gene, and there is evidence that these Pol β variants can contribute to tumour development^[14]. The Pol β ^{K289M} variant was found to cause a 2.5-fold increase in mutation frequency^[15]. Moreover, stable expression of this Pol β ^{K289M} variant, as well as another variant, Pol β ^{I260M}, was found to induce a transformed phenotype in mouse cells, as judged from focus formation on a monolayer and a soft-agar assay^[16].

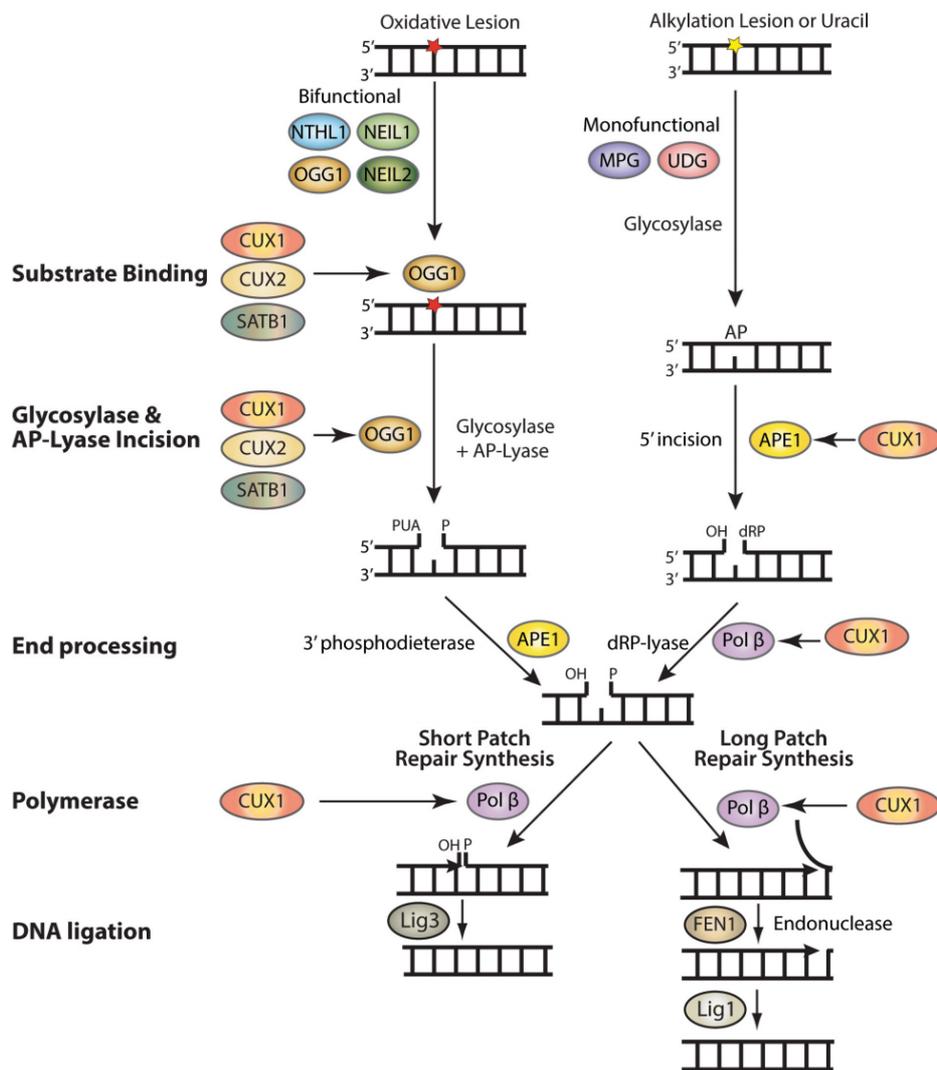

Figure 1. Auxiliary factors stimulate the enzymatic activities of several BER enzymes. BER is initiated by the removal of a damaged base by a glycosylase which creates an apyrimidinic or apurinic site (AP site). Bifunctional glycosylases such as NTHL1, OGG1, NEIL1, and NEIL2 have an AP-lyase activity and can introduce a single-strand break. APE1 then removes the phosphor- α,β -unsaturated aldehyde (PUA) to create a single-strand break with a 3'-OH and a 5'-phosphate. In the case of MPG and UDG, both monofunctional glycosylases, APE1 will cleave the backbone, leaving a single-strand break with a 3'dRP that will be removed by Pol β . In short patch repair, Pol β inserts the missing nucleotide and Lig3 seals the break. In long patch repair, Pol β inserts multiple nucleotides, FEN1 cleaves the displaced strand, and Lig1 seals the break. The CUT domain proteins CUX1, CUX2, and SATB1 stimulate the binding of OGG1 to 8-oxo-deoxyguanine as well as its glycosylase and AP-lyase enzymatic activities. The CUT domains of CUX1 have also been shown to stimulate the 5'-incision activity of APE1 as well as the dRP-lyase, DNA polymerase, and strand-displacement activities of DNA Pol β .

In addition to somatic mutations, some germline mutations in BER proteins predispose to cancer. MUTYH-associated polyposis (MAP) was first described when two inherited germline mutations in the *MUTYH* gene (Y165C and G382D) were identified in three siblings with clinical symptoms of familial adenomatous polyposis (FAP), an inherited condition that predisposes to colorectal cancer (CRC)^[17]. *MUTYH* is the human homologue of MutY, a DNA glycosylase that removes adenine from 8-oxoG:A base pairs, preventing G:C to T:A transversions (reviewed in^[18]). The adenine glycosylases encoded by the *MUTYH*^{Y165C} and *MUTYH*^{G382D} mutants displayed much reduced activity^[17]. Further investigations confirmed that inherited *MUTYH* mutations increase the risk of colorectal polyposis as well as other cancers including duodenal carcinoma, bladder, ovarian, and skin cancer^[19-23].

More recently, a homozygous nonsense mutation in the *NTHL1* DNA glycosylase gene was also identified in individuals with multiple colonic adenomas from three unrelated families, suggesting a new BER-associated predisposing condition for colorectal cancer^[24]. This mutation confers a highly penetrant predisposition to adenomatous polyposis and is also associated with other benign and malignant lesions^[25]. The *NTHL1*-associated polyposis (NAP) and findings of *NTHL1* variants and altered regulation in tumors, provide another evidence on the role of BER in maintaining genomic stability and preventing cell transformation^[26]. Note that the patterns of somatic mutations associated with MAP and NAP are distinct and are related to specific mutation signatures^[25,27,28].

COOPERATING EVENTS IN TUMOUR DEVELOPMENT

The notion of multi-step carcinogenesis arose from early experiments with chemical carcinogens that were classified as initiators and promoters^[29]. Following the identification of cellular oncogenes, experiments in tissue culture revealed that activation of a single oncogene is not sufficient for cell transformation and tumour development^[30]. Indeed, while the introduction of RAS oncogenes into immortalized rodent cells was able to produce transformed cell foci on a monolayer or in soft agar^[31], the same procedure was ineffective when applied to primary cells^[30]. Soon the concept of cooperation between oncogenes emerged when it was shown that the MYC and RAS oncogenes are able to produce transformed cell foci when co-expressed in primary rat fibroblasts^[30]. The family of RAS proteins comprises three homologous proteins, HRAS, KRAS, and NRAS. RAS proteins serve as transducers of cell surface receptors to intracellular effector pathways. They alternate between an inactive GDP-bound state and an active GTP-bound state. Most mutations occurring in a RAS oncogene will impair its GTP hydrolysis function such that RAS remains in a GTP-bound active state. This leads to sustained activation of downstream effector pathways such as proliferation and differentiation^[32,33]. In addition to missense mutations, there is evidence suggesting that RAS mutant overexpression is required for tumour development^[34]. Indeed, it was proposed that Ras-induced tumorigenesis involves two steps: the acquisition of an activating mutation and overexpression of the activated Ras allele^[34].

The cooperation between MYC and RAS received additional confirmation from experiments in transgenic mice: mice that expressed both MYC and RAS transgenes developed more tumours and with a shorter latency period^[35]. The concept of cooperating events was extended with the realization that a RAS oncogene could also collaborate with a dominant-negative mutant of p53 or a viral protein such as Large T or Adenovirus E1A that inactivates a tumour suppressor protein^[36-39]. Not only can two oncogenes cooperate, but an oncogene can also cooperate with the inactivation of a tumour suppressor gene. A further conceptual advance in our understanding of cooperating events was realized with the description of stress phenotypes of cancer cells^[40]. In essence, the tumorigenic state generates additional pressures that impose a block on cell proliferation and eventually induce cellular senescence or apoptosis. To surmount this block and continue to proliferate, cancer cells require extensive adaptation in cellular processes that are not oncogenic per se. As a result, cancer cells become acutely dependent on the increased activity of some normal proteins. The term “oncogene-addiction” had previously been introduced to illustrate the dependence of cancer cells on a tyrosine kinase oncogene such as BCR-ABL^[41,42]. The dependence of cancer cells on non-oncogenic proteins was designated “non-oncogene addiction”^[40]. In summary, tumour development involves cooperation between the activation of some oncogenes, the inactivation of some tumour suppressors and the increased expression and/or activity of several normal proteins. A striking case of extensive adaptation is illustrated by the response of cancer cells to oxidative stress and oxidative DNA damage.

OXIDATIVE STRESS IN CANCER CELLS AND CELLULAR SENESCENCE

Among the stress phenotypes of cancer cells, oxidative stress and resulting oxidative DNA damage have emerged as critical players. The study of mouse fibroblasts transformed with a RAS oncogene revealed that these cells produce large amounts of reactive oxygen species (ROS)^[43]. In fact, elevated ROS production is not limited to cancer cells that harbour a RAS oncogene but has also been observed in cancer cells that harbour a mutation in another gene of the RAS or the phosphatidylinositol-3 kinase (PI3K) pathway (NF1, PIK3CA, PTEN) or an upstream tyrosine kinase (Met or BCR-ABL)^[44-51]. Mechanistic studies identified multiple sources of ROS production in cancer cells, such as increased expression and activity of the enzymes NADPH oxidase 1 and 4 (NOX1, NOX4) and cyclooxygenase-2 (Cox-2), transcriptional repression of sestrin family genes, and increased ROS production by the cytochrome c-oxidoreductase in the mitochondrial electron transport chain^[52-59] [Figure 2]. Sestrins play an important role in the regeneration of peroxiredoxins and, as such, contribute to the antioxidant firewall^[60]. Importantly, as cell proliferation was inhibited by treatment with a chemical antioxidant or knockdown of genes encoding these respective enzymes, it was concluded that ROS play an important role in mediating the mitogenic effect of RAS^[43,52,54-57]. However, it was quickly realized that following an initial period of accelerated proliferation, elevated ROS levels also cause the appearance of cells that exhibit markers of cellular senescence such as p16^{INK4a} expression and β -galactosidase activity at pH 6^[61]. The induction of cellular senescence by oncogenes was rapidly confirmed in mouse models^[62,63]. Experiments in the animal also introduced an important twist to the unfolding story. Indeed, senescent cells were detected in premalignant tumours but not in malignant ones^[62]. For example, BRAF^{V600E} induced benign lung tumours that only rarely progressed to adenocarcinoma^[63]. Likewise, in human tissues, senescent cells were not detected in malignant tumours but were observed in pre-cancerous lesions such as colon adenomas^[64-66], benign tumours of melanocytes (naevi) caused by the BRAF^{V600E} mutation^[67], and neurofibromas resulting from Neurofibromatosis (NF1) inactivation^[68]. In this context, cellular senescence is deemed a tumour suppression mechanism that functions by eliminating early neoplastic cells from the proliferative pool (reviewed in^[69]). It should be noted, however, that the presence of senescent cells in tissues has the potential to stimulate the proliferation of tumour cells through the senescence-associated secretory pathway (reviewed in^[69]).

ADAPTATION OF CANCER CELLS TO OXIDATIVE STRESS

Cellular senescence protects us against tumour development by preventing the proliferation of cancer cells that exhibit higher ROS levels. Unfortunately, some rare cancer cells manage to adapt by developing mechanisms to prevent the deleterious effects of excessive ROS levels [Figure 2].

Increased production of antioxidants

One mechanism of adaptation involves the increased production of antioxidants [Figure 2]. Early studies using a proteomic approach documented the upregulation of enzymes involved in cellular redox balance, including catalase, peroxiredoxin 3, thioredoxin peroxidase, and γ -glutamyltransferase 2 (GGT2)^[70-72]. Subsequent studies described various mechanisms by which cancer cells maintain the ratio of reduced to oxidized glutathione (GSH/GSSG) and nicotinamide adenine dinucleotide phosphate (NADPH/NADP+), notably by reprogramming the metabolism of glutamine, glucose, and fatty-acid^[73-76]. Some important players in the response of cancer cells to elevated ROS levels are the nuclear factor erythroid-2 related factor 2 (NRF2) and its repressor protein Kelch-like ECH-associated protein 1 (KEAP1) [Figure 2]. NRF2 is a redox-sensitive transcription factor that binds to the antioxidant response element (ARE) and activates many genes that code for antioxidants and detoxification proteins^[77]. KEAP1 binds to NRF2 and negatively regulates its activity by targeting it to proteasomal degradation^[78]. In normal cells, the interaction between KEAP1 and NRF2 is disrupted by oxidants and electrophilic agents, thereby allowing NRF2 to translocate to the nucleus and activate the transcription of antioxidant genes^[78]. In many cancer cells, NRF2 has become

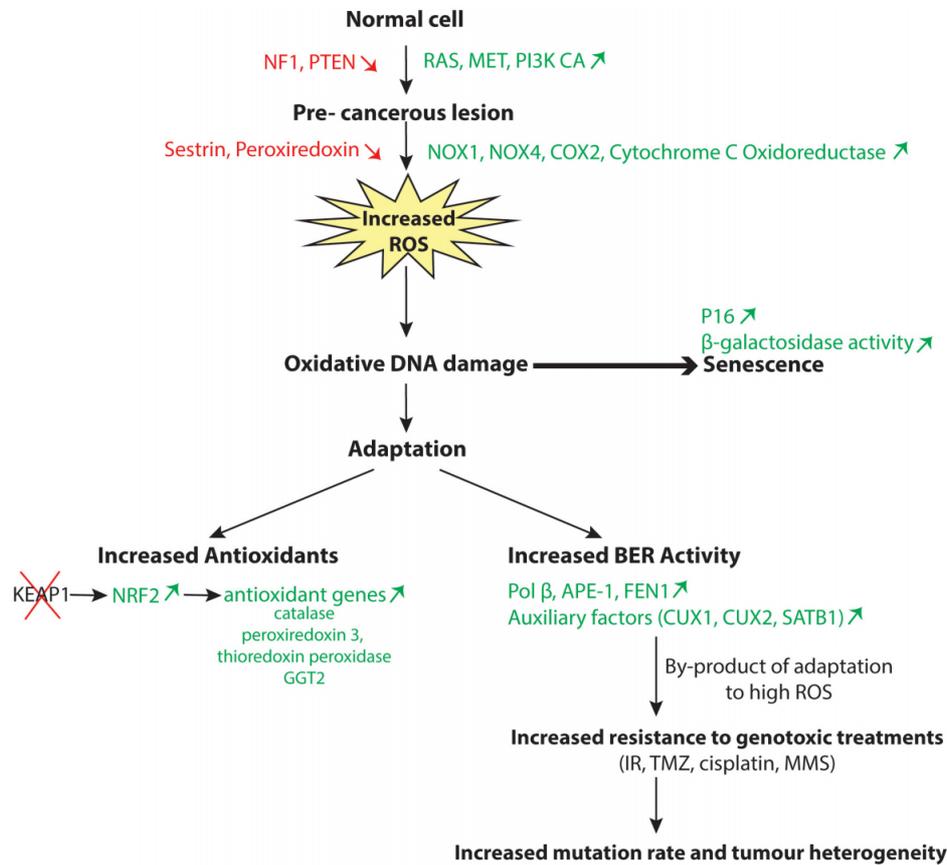

Figure 2. Adaptation of cancer cells to oxidative stress. Activation of the RAS or PI3K pathway leads to elevated production of reactive oxygen species (ROS), which causes oxidative DNA damage and, ultimately, cellular senescence. Two modes of adaptation have been described to enable cancer cells to avoid cellular senescence and continue to proliferate. Some cancer cells increase their antioxidant capabilities notably following genetic inactivation of the Kelch-like ECH-associated protein 1 (*KEAP1*) gene which leads to nuclear factor erythroid-2 related factor 2 (NRF2) upregulation and the subsequent transcriptional activation of antioxidant genes. Alternatively, some cancer cells increase their BER capacities by overexpressing BER enzymes such as Pol β , APE1, and FEN1 or auxiliary factors such as CUX1, CUX2, or SATB1. As a by-product of increased BER activity, these cancer cells exhibit resistance to genotoxic treatments like radiation therapy (IR), temozolomide (TMZ), cisplatin, or methyl methanesulfonate (MMS).

constitutively active following the acquisition of inactivating mutations within the *KEAP1* gene or missense mutations within either the *KEAP1* or *NRF2* gene that weaken the interaction between the two proteins^[79-83] (reviewed in^[84]). It was estimated that somatic mutations in *KEAP1* and *NRF2* are present in 15% and 10% of lung cancers, respectively^[84]. The existence of mutations that disrupt the *KEAP1*/*NRF2* regulatory system in cancer cells sheds new light on the observed “oncogene-directed” increased expression of *NRF2* whereby the expression of *KRAS*, *BRAF*, and *MYC* oncogenes in primary murine cells was found to cause an increase in *NRF2* mRNA and protein levels^[85]. This and other studies suggested a causal link between *RAS* and increased *NRF2* expression and its transcriptional targets as if a downstream effector of the *RAS* pathway would act directly to upregulate *NRF2*^[58,70-72,76,85]. Instead of direct induction of *NRF2* by the *RAS* pathway, we envision that cancer cells with higher expression of antioxidants emerge by a Darwinian process of natural selection. Following sustained activation of the *RAS* pathway, virtually all cells in a population will be negatively affected by excessive ROS levels, but rare cells that express high levels of antioxidants will continue to proliferate and will gradually represent an increasing fraction of the population. This notion is supported by two observations. First, ectopic expression of *KRAS* or other oncogenes in murine primary cells did not have any effect on *NRF2* expression when investigated one week

after the retroviral infection^[85]. Increased NRF2 expression was observed only in mouse embryo fibroblasts derived from mice that harbour the KRAS oncogene or another oncogene^[85]. Therefore, we suppose that embryonic development up to day 13 allowed enough time for some adaptation. Secondly, if the RAS pathway was able to directly upregulate NRF2 expression, tumour development would not require somatic mutations in *KEAP1* or *NRF2* that abrogate the interaction between the two proteins.

Increased capacity to repair oxidative DNA damage

Several observations concur to indicate that adaptation to elevated ROS production in cancer cells can involve an increase in DNA repair capacity, notably of the BER pathway [Figure 2].

Overexpression of BER enzymes in cancer

Early studies have documented the increased expression and/or activity of BER enzymes in tumour samples. Pol β was first reported to be overexpressed in many cancer cell lines as well as in breast, colon, and prostate adenocarcinomas^[86]. The analysis of 68 tumour samples of various tissue of origin estimated that Pol β was overexpressed between 2 to 12-fold in 40% of samples^[87]. Pol β expression and activity were significantly higher in blood samples from 9 chronic myelogenous leukemia patients than that from healthy donors^[88].

Immunohistochemistry analysis of a panel of ovarian cancers revealed a wide range of APE1 expression with considerable heterogeneity within the same tumour^[89]. In prostate tissue, APE1 overexpression correlates with tumour progression: it was detected in 6 out of 100 (6%) benign prostate hypertrophy, 58 out of 100 prostatic intraepithelial neoplasia, and 67 out of 100 (67%) prostate cancers^[90]. Measurements of APE1 activity in extracts of 58 glioblastomas and adjacent histologically normal brains revealed increased enzyme activity in 93% of tumour/normal pairs^[91]. APE1 activity was also greater in high-grade than in low-grade tumours^[91]. APE1 was found to be overexpressed in 43 out of 60 (72%) osteosarcomas, and a significant correlation was observed between elevated APE1 expression and shorter survival^[92]. The analysis of 82 cases of oral tongue squamous cell carcinoma showed higher APE1 expression in 53 (64%) samples^[93].

The flap structure-specific endonuclease (FEN1) has been reported to be highly expressed in lung cancer cell lines and in multiple types of tumours, including neuroblastomas, prostate, gastric, pancreatic, and non-small cell lung cancers^[94-98].

BER enzymes identified in a synthetic lethality screen of RAS-driven cancer cells

A requirement for an efficient BER pathway in RAS-driven cancer cells was first suggested from a genome-wide screen to identify synthetic lethal interactions with the RAS oncogene^[99]. The screen was performed using a pair of isogenic colorectal cell lines (DLD-1) that carry or not an endogenous activating KRAS^{G13D} mutation. While stringent statistical criteria ($P \leq 0.1$) identified 368 genes whose knockdown is synthetic lethal to KRAS^{G13D}-driven cancer cells, a more relaxed cut off ($P \leq 0.3$) extended this list to 1741 genes, among which were four genes involved in BER: *NEIL2*, *XRCC1*, *POL β* , *LIG3*^[99]. These results indicated that these four BER genes are required for the proliferation of KRAS^{G13D}-driven DLD-1 cells to a greater extent than for the control cells. The *CUX1* gene was also found in the list of potential synthetic lethality genes, but the molecular basis for its requirement was not understood until later.

Requirement for CUX1 function as a BER accessory factor in RAS-driven cancer cells

Transgenic mice expressing the p200 CUX1 protein under the control of the mouse mammary tumour virus regulatory sequences developed mammary tumours with a penetrance of ~40% but with a long latency period of 70 to 100 weeks^[100]. Such a long latency period indicates that *CUX1* is probably not an oncogene per se, and that, certainly, other cooperating events are required for tumour development in cells that

overexpress CUX1. Interestingly, 44% of tumours from *Cux1* transgenic mice harboured an activating mutation at codon 12 or 61 of *Kras*. Such a high frequency of spontaneous mutations is striking. This implies that the probability that a mouse will acquire an activating mutation in the *Kras* oncogene during its life is approximately 17% (40% × 44%). Yet, wild-type mice do not develop cancer at this rate. The reason for this, fortunately, is that RAS oncogenes trigger a cellular senescence response after an initial period of accelerated proliferation^[62-68] (reviewed in^[69]). Therefore, other cooperating events are required for pre-cancerous cancer cells to avoid senescence and continue to proliferate. The cooperation of CUX1 with a RAS oncogene in tumour development was confirmed by performing lentiviral infections in the lung of mice. The combination of CUX1 with RAS produced a higher number of cancerous lesions of a larger size than RAS alone. Importantly, while RAS alone caused the appearance of adenomas that exhibited hallmarks of cellular senescence, the combination of CUX1 and RAS produced higher grade adenomas which, in one case, evolved to the adenocarcinoma stage^[100]. DNA repair assays *in vitro* with purified proteins established that the p200 CUX1 protein functions as an accessory protein that stimulates the enzymatic activities of several BER enzymes: OGG1, APE1, and Pol β [Figure 1]^[100-102]. Overexpression of p200 CUX1 accelerates the repair of oxidative DNA damage following treatment with H₂O₂, whereas CUX1 knockdown increases genomic DNA damage, as observed by comet assays and the measurement of abasic sites and 8-oxo-deoxyguanine bases^[100]. While the introduction of a RAS oncogene into cells causes an increase in ROS levels that are associated with an increase in DNA damage and the number of senescent cells, simultaneous expression with p200 CUX1 eliminates the increase in genomic DNA damage and senescent cells without affecting ROS elevation^[100]. In normal cells, the role of CUX1 as a BER accessory factor is not essential for survival, as demonstrated from lethality screens in human cells and the viability of *Cux1*^{-/-} knockout mice^[103-106]. This biochemical activity of CUX1 appears to be needed only in abnormal situations of oxidative stress. For example, mouse embryo fibroblasts (MEFs) from *Cux1*^{-/-} mice proliferate normally in a 3% oxygen atmosphere but senesce immediately when placed at 20% oxygen^[107].

Studies in human cancers show that CUX1 is overexpressed in over 70% of cancers. The Cancer Genome Atlas (TCGA) characterization of 276 human colorectal cancers ranked *CUX1* as the fifth gene on a scale showing a correlation between tumor aggressiveness and a combined score based on gene expression and somatic copy number alterations^[108]. In glioblastomas, TCGA reveals that the chromosomal region including 7q22, where *CUX1* resides, is the most frequently and highly amplified chromosomal region^[109]. TCGA and REMBRANDT data also show shorter survival of glioblastoma patients with high *CUX1* mRNA expression^[109] (reviewed in^[101]). In smaller-scale studies, immunohistochemical analyses on breast, pancreas, and glioblastoma cancers reveal that CUX1 expression inversely correlates with relapse-free and overall survival^[101,110-112].

CUX1 knockdown does not impair the clonogenic efficiency of cancer cell lines that exhibit low ROS levels but is synthetic lethal in all cancer cells that display elevated ROS levels, whether this results from an activating mutation in a RAS gene (Hs578T^{HRAS}, MDA-MB-231^{KRAS}, DLD-1^{KRAS}, HCT116^{KRAS}, KE37^{NRAS}), another gene in the pathway (HT29^{BRAF}), or an upstream receptor tyrosine kinase (HCC827^{EGFR})^[100,113]. Strikingly, CUX1 knockdown does not affect the viability of A549 lung carcinoma cells which harbour an activating KRAS^{G12D} mutation^[113]. The reason for this discrepancy is that these cells also carry an inactivating mutation in the KEAP1 tumour suppressor gene^[82,83]. As a result, the NRF2 transcription factor accumulates in the nucleus of A549 cells and activates an antioxidant transcriptional program^[82].

Other CUT domain proteins as BER accessory factors

Structure-function analysis identified the CUT domains within CUX1 as the protein region responsible for the stimulation of OGG1, APE1, and Pol β *in vitro*^[100-102,107]. In cells, a protein containing the CUT domains 1

and 2, together with a nuclear localization signal, was sufficient for recruitment to laser-induced DNA damage^[113]. In cancer cells that exhibit high ROS levels, the CUT domains 1 and 2 reduced genomic DNA damage as measured by comet assay at pH 13, and comet assay at pH 10 after treatment with the Fapy DNA glycosylase (FPG)^[100-102]. Moreover, the CUT domains 1 and 2 conferred resistance to multiple genotoxic agents, including H₂O₂, ionizing radiation, temozolomide, MMS, and cisplatin^[100-102,107,113]. In addition, the CUT domains 1 and 2 can restore the capacity of *Cux1*^{-/-} MEFs to proliferate in 20% oxygen^[107].

The CUT domains are evolutionarily conserved domains that are present in a few transcription factors in humans [Figure 3]. While CUX1 is ubiquitously expressed, CUX2 is mainly expressed in the nervous system^[114-116] and can also function as a female-specific transcription factor in the liver^[117]. SATB1 is present in specific cell types such as thymocytes and basal layer cells of the epidermis where it regulates the expression of a large set of genes by organizing specific chromosome loci into small chromatin loops^[118-121]. SATB1 has been implicated in various cancers such as breast cancers, cutaneous malignant melanoma, gastric and colorectal cancers^[122-125].

Not surprisingly, these other CUT domain proteins were found to function as BER accessory factors [Figure 1]. Knockdown of CUX2 or SATB1 was found to cause a delay in the repair of oxidative DNA damage and an increase in oxidized purines in genomic DNA, whereas ectopic expression of these proteins accelerated DNA repair and reduced the amount of genomic DNA lesions^[126,127]. As for CUX1, enzymatic assays with purified proteins mapped the DNA repair activity of CUX2 and SATB1 to the CUT domains^[126,127]. Strikingly, both CUX2 and SATB1 are overexpressed in certain cancer cells where their knockdown increases genomic DNA damage and impairs the capacity of cancer cells to proliferate^[126,127]. The case of CUX2 is particularly remarkable. CUX2 is not expressed in the mammary gland. Yet, a genome-wide shRNA screen revealed that CUX2 is required for proliferation in several breast cancer cell lines^[128]. The aberrant overexpression of CUX2 in breast cancer cells suggests that elevated ROS levels in cancer cells can select rare cells that express any protein able to accelerate the repair of oxidative DNA damage.

The mechanism by which CUT domains stimulate the enzymatic activity of BER enzymes is not always clear. In the case of OGG1, electrophoretic mobility shift assays (EMSA) established that CUT domains stimulate the binding of OGG1 to DNA that contains oxidized purines^[107]. On the one hand, CUT domains can interact directly with OGG1^[107,126,127]. On the other hand, in EMSA, CUT domains were observed to exhibit affinity to DNA that contains an oxidized purine (Ramdzan and Nepveu, unpublished observation). CUT domains were also shown to interact directly with APE1 and Pol β ^[101,102]. However, whether CUT domains accelerate the binding of these enzymes to their DNA substrates remains to be verified.

Other transcription factors that function as BER accessory factors

Other transcription factors and DNA binding proteins were reported to play a role in BER. YB-1 and hnRNP-U were shown to stimulate NEIL1^[129,130]. HMGB1 was reported to stimulate the functions of the APE1 and FEN1 endonucleases^[131]. The FACT complex was also shown to facilitate uracil removal by UDG^[132]. *In vitro*, P53 stimulates the activity of Pol β ^[133]. These findings suggest that there may be a wide variety of accessory proteins acting to facilitate BER.

CONSEQUENCES OF INCREASED BER ACTIVITY IN CANCER CELLS

Apart from being able to avoid senescence and continue to proliferate, the increased DNA repair capability of cancer cells that overexpress BER enzymes and accessory factors confers additional properties that have a major impact on resistance to treatment, tumour progression, and ultimately, patient survival.

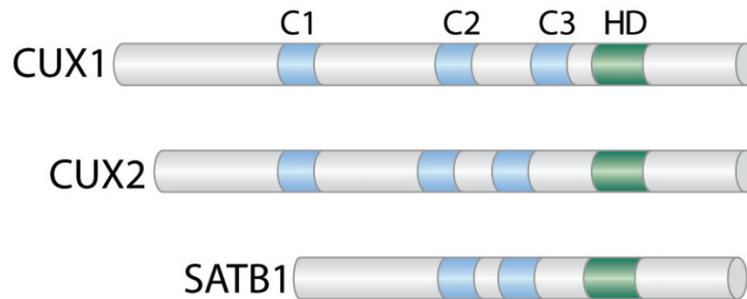

Figure 3. CUT Domain Proteins. Diagrammatic representation of the CUT domain proteins CUX1, CUX2, and SATB1. The evolutionarily conserved CUT domains (C) and Cut homeodomain (HD) are shown.

Impact of BER enzymes on resistance to treatments

There is ample evidence to demonstrate that resistance to genotoxic treatments correlates with expression and activity of several BER enzymes, notably Pol β , APE1, and FEN1 (reviewed in^[134]). High Pol β expression confers resistance to genotoxic treatments^[135-139]. Conversely, Pol β knockdown or inhibition sensitizes cancer cells to various treatments including temozolomide^[137,139-142], MMS^[143-146], oxaliplatin^[147], cisplatin and UV-radiation^[148]. Elevated APE1 expression in cancer cells has been associated with poor response to mono-alkylating agents^[91,149-151], whereas various approaches to reduce APE1 activity were shown to increase cancer cell sensitivity to temozolomide^[149,152-158]. Knockdown or inactivation of the FEN1 gene sensitized cells to gamma-radiation, MMS, temozolomide, and cisplatin^[159,160]. The N-methylpurine DNA glycosylase (MPG) was also shown to promote resistance to mono-alkylating agents^[161,162]. However, results also emphasized the importance of balancing glycosylase activity with that of Pol β ^[137,139]. Indeed, unless repair of the base lesion is brought to completion, removal of alkylated bases produces abasic sites and single-strand breaks that can be more toxic than the original lesions.

Impact of BER accessory factors on resistance to treatment

As a by-product of their adaptation to high ROS levels, cancer cells that have increased their capacity to repair oxidative DNA damage through elevated expression of BER accessory factors also exhibit increased resistance to genotoxic treatments. Here, we will describe the documented effects of BER accessory factors on resistance to treatment.

There exists old literature linking RAS oncogenes with radioresistance^[163-166]. We consider it likely that the higher resistance to ionizing radiation of some RAS-driven cancer cells is a by-product of their adaptation to elevated ROS levels through the enhanced expression of BER enzymes and accessory factors. We previously mentioned that *CUX1* knockdown did not affect the viability of cancer cell lines with low ROS levels. Strikingly, however, knockdown of *CUX1* or *SATB1* sensitized all tested cancer cell lines to ionizing radiation, whether they displayed high ROS levels or not^[101,113,127]. In turn, ectopic expression of *CUX1* or the small recombinant protein containing only two CUT domains increased the resistance to radiation^[101,113]. In glioblastoma cells, resistance to the mono-alkylating agent temozolomide was reduced by *CUX1* knockdown but increased by ectopic expression of *CUX1* or the two CUT domains^[101]. Similar results were obtained following treatment with another alkylating agent, MMS^[101]. The standard-of-care treatment for glioblastoma patients involves a combined treatment with ionizing radiation and temozolomide. Resistance to combined treatment was reduced by *CUX1* knockdown but increased by overexpression of *CUX1* or the two CUT domains^[101]. Moreover, the resistance of cancer cells to cisplatin treatment was decreased by *CUX1* knockdown but increased by ectopic expression of the two CUT domains^[102]. These findings are in line with the results of *in vitro* assays showing that the CUT domains stimulate the cleavage activity of APE1 as well as the deoxyribose phosphate lyase and the polymerase activities of Pol β , and the bypass of

intrastrand G-crosslink by Pol β ^[101,102].

Contribution of elevated ROS levels and BER activity to acquired resistance and tumour progression

We previously described that the ~30,000 endogenous, daily, damaged bases in diploid human cells combined with a Pol β error rate of at least 1/1000 contributes to the intrinsic mutation process that makes our somatic cells accumulate mutations through life. This process is exacerbated in cancer cells in which increased BER activity enables them to survive despite elevated ROS levels. These cells suffer a much higher number of oxidative DNA lesions than normal cells; and assuming a similar error rate by Pol β , it is reasonable to assume that these cells exhibit a mutator phenotype and acquire point mutations at a faster rate. This notion received confirmation from a study of acquired resistance to imatinib by chronic myelogenous leukemia (CML) cells^[49]. The authors showed that the BCR-ABL kinase causes an increase in ROS levels and oxidative DNA damage that is associated with a rise in mutation rates as measured by resistance to ouabain or imatinib^[49]. These effects were reduced by treatment with antioxidants or expression of a BCR-ABL^{Y177F} mutant that does not elevate ROS^[49]. ROS production induced by BCR-ABL was subsequently shown to increase chromosomal aberrations^[167].

The acquisition of resistance to imatinib by some BCR-ABL CML cells illustrates another consequence of elevated ROS levels and BER activity. The higher rate of mutation in these cancer cells contributes to tumour heterogeneity, a feature that constitutes a major obstacle to successful clinical treatments. Although a specific treatment can manage to kill more than 99.99% of cancer cells, if only one rare cancer cell acquires a mutation that allows its survival, selective pressure will promote the expansion of this cell clone. At the clinical level, this leads to cancer relapse.

CONCLUDING REMARKS

Evidence from *in vitro* assays with purified proteins, tissue culture cells, and transgenic mice reveals that the efficiency of BER in mammalian cells can be modulated by the action of auxiliary factors, notably the CUT domain proteins. Although these accessory factors are not essential, they appear to protect cells against oxidative DNA damage in situations of oxidative stress. This biochemical activity is hijacked by cancer cells to avoid senescence and continue to proliferate in the presence of excessive ROS levels [Figure 2]. As a by-product of this mechanism of adaptation to elevated ROS levels, cancer cells with enhanced BER activity exhibit increased resistance to genotoxic treatments and a higher mutation rate that contributes to tumour heterogeneity. However, the acute dependence of some cancer cells on DNA repair accessory factors may have uncovered an Achilles' heel that could be exploited in future therapeutic strategies. In the past, the realization that BER enzymes contribute to therapy resistance led to many drugs that inhibit BER enzymes being tested in the clinic with various treatment modalities. The drawback of such approaches is that BER enzymes are essential to normal cell viability, since over 30,000 base alterations per day are produced endogenously in a normal human cell^[12]. Consequently, although inhibitors of BER enzymes increase cell killing within the tumor, they also cause severe adverse effects that considerably reduce the therapeutic window. As DNA repair accessory factors are not essential to normal cells in regular physiological situations, specific inhibitors to these proteins could be deleterious to cancer cells without causing many adverse effects, thereby increasing the therapeutic window.

Abstract

Research has led to the development of tailored treatment options for different cancers in different patients. Despite some treatments being able to provide remarkable responses, nearly all current treatments encounter the same issue: resistance. Here, we discuss our experiences with how breast cancers resist therapies. The focus of our discussion revolves around the cancer stem cell subpopulation and their mechanisms for resistance.

Keywords: Drug resistance, breast cancer therapy, triple-negative breast cancer, cancer stem cells

INTRODUCTION

In 2021, breast cancer became the most common globally diagnosed cancer, accounting for 12% of all annual cases, with over 40,000 American women projected to die of breast cancer in 2022^[1]. Despite advancing therapies, treatment resistance has been shown to be responsible for up to 90% of cancer-related deaths^[2,3]. The purpose of this perspective is to share our group's cumulative experiences in researching breast cancer and the mechanisms of treatment resistance. To do this, we discuss literature and findings from our group and others. The discussions focus on the triple-negative breast cancer (TNBC) subtype and

the cancer stem cell (CSC) subpopulation. Furthermore, we will place emphasis on the CSC biomarker GD2 due to its novelty and integral role in our research. We hope that our text will promote discussions and encourage other research groups to incorporate our understanding and findings into their projects.

Breast cancer subtypes: TNBC and hormone receptor therapies

Breast cancer is a complex malignancy that can be molecularly characterized into subtypes with unique disease progressions, treatment regimens, and prognoses^[4]. Subtyping is based on the tumor's hormone receptor status and can be grouped as follows: Luminal A (ER+, PR+, HER2-, KI67-), Luminal B (ER+, PR+, HER2±, KI67+), HER2 overexpression (ER-, PR-, HER2+), and Basal/Triple Negative (ER-, PR-, HER2-)^[5]. Although TNBC can be further classified (basal-like 1, basal-like 2, immunomodulatory, mesenchymal, mesenchymal stem-like, and luminal androgen receptor), the overall characteristics are a highly invasive, metastatic, and recurrent breast cancer subtype with high mortality rates and few treatment options^[6,7]. TNBC's lack of receptor expression allows it to resist current hormone receptor therapies such as tamoxifen, aromatase inhibitors, luteinizing hormone-releasing hormone agonists, Faslodex, and trastuzumab^[8-10]. As a result, current treatments are limited to conventional therapeutics such as tumor resection, chemotherapy, and radiation therapies^[11]. Despite initial responses, TNBC patients have a higher rate of distant recurrence with significantly worse 3-year survival probabilities post-neoadjuvant treatment compared to other breast cancer subtypes^[12]. Therefore, identifying specific therapeutic targets for TNBC is imperative for improving treatment outcomes for patients.

Cancer stem cells: resisting chemo- and radiotherapies

Carcinogenesis, the transformation of healthy to cancerous cells, is due to an accumulation of mutations that results in uncontrolled replication and can often begin with a single cell. Despite their monoclonal origin, tumors are composed of a heterogeneous population of cells with only a small subpopulation possessing tumorigenic potential^[13]. CSCs are a sub-subpopulation of tumors that possess the ability to self-renew, have increased tumorigenic potential, and increased mobility. Additionally, CSCs are innately resistant to radiotherapy and chemotherapies^[14-16]. Although chemo- and radiotherapies may be initially successful in killing off most cells in a tumor, they confer a selection pressure for CSCs. This leads to the recurrence of a treatment-resistant tumor and an overall poorer outcome for TNBC patients in comparison to other breast cancer subtypes.

Chemotherapies and radiotherapy primarily affect rapidly dividing cells by interfering with DNA processing, leading to cellular apoptosis. Cancer stem cells have several mechanisms that allow them to resist and overcome the effects of chemotherapy. For example, CSCs have the ability to become quiescent in stressful conditions, hibernating in G₀ and re-entering the cell cycle once conditions have improved. Malladi *et al.* identified SOX2 and SOX9 transcription factors producing DKK1 to inhibit WNT as the mechanism for quiescence in early-stage human lung and breast carcinoma cell lines^[17]. This lack of cell division and, by association, DNA replication decreases the effectiveness of DNA targeting therapies such as chemo- and radiotherapy. In addition to becoming quiescent, CSCs can express ABC transporter proteins and efflux pumps that actively remove toxic compounds from within the cell. Das *et al.* were able to enhance the chemosensitivity of breast cancer stem cells by downregulating ABCG2 using nanoparticles^[18]. Similarly, Sun *et al.* enhanced doxorubicin sensitivity, demonstrated by a 90% decrease in IC₅₀, after 60% downregulation of ABCG2 was achieved by siRNA^[19]. Although these studies demonstrate the significance of ABC transporters and efflux pumps in CSCs, it is important to note that varying levels of these proteins can be expressed in the non-stem population of the tumor as well.

Apoptosis is the natural cell death response to DNA damage. If quiescence and ABC transport proteins fail to prevent DNA damage from chemo- and radiotherapies, cancer cells will undergo apoptosis. This can be seen during the initial responsiveness of tumors to chemo- and radiotherapies. However, cancer stem cells have intrinsic mechanisms that allow them to avoid apoptosis. Takeda *et al.* identified a ROCK-survivin anti-apoptotic axis in pancreatic cancer stem cells and that inhibiting ROCK resulted in decreased survivin expression, leading to the sensitization of cells to gemcitabine^[20]. Although there are more pathways associated with cancer stem cells and their resistance to therapies, such as Hippo/YAP1, Wnt/ β -catenin, Notch, and JAK/STAT, the main takeaway is that cancer stem cells can resist therapies through quiescence, drug efflux, and anti-apoptosis^[21]. Overall, these mechanisms make CSCs difficult to target. When combined with hormone receptor therapy resistance, these qualities make TNBC an especially difficult disease to treat. Consequently, understanding the cellular biology of CSCs in TNBC, and other cancers, can provide insight into future novel therapies^[22,23].

GD2: a cancer stem cell biomarker

Stem cells are essential for their abilities to self-renew and differentiate and are responsible for migrating to biological niches to replace damaged or depleted cell types^[24]. In cancer, these same qualities lead to disease progression, metastasis, and patient mortality. It is important, then, to characterize CSC-specific cell surface markers for targeted treatment. In 2003, Al-Hajj *et al.* identified CD44^{high}/CD24^{low} as breast CSC markers^[25]. Shortly after, ALDH1 was identified as another breast CSC marker, although primarily for luminal subtypes^[26]. However, these markers are poor targets for therapy because they are also expressed by normal human breast cells^[27].

In 2012, Battula *et al.* identified GD2 as a novel breast cancer stem cell marker in TNBC and that it is co-expressed with CD44^{high}/CD24^{low} cells^[28]. GD2, a b-series ganglioside located within lipid rafts on the outer side of the plasma membrane, is expressed during development but is highly restricted to cerebellar tissues and peripheral nerves in mature adults. It can also be found on tumors of neuroectodermal origin such as neuroblastoma and melanoma^[29,30]. Battula *et al.* and Jaggupilli *et al.* then went on to identify NF- κ B signaling, an inflammatory pathway, and metabolic stress, respectively, as primary drivers of GD2 expression^[31,32]. Further studies by Nguyen *et al.* identified GD2 as an activator of the FAK-AKT-mTOR signaling pathway, leading to increased tumor growth and metastasis in *in vivo* conditions^[33]. Furthermore, this study demonstrated that CRISPR knock-out of GD3S, the rate-limiting enzyme for GD2 synthesis, completely ablated GD2 cells. Interestingly, GD3S KO cells resulted in no *in vivo* tumor growth and metastasis, greatly reduced *in vitro* migration, invasion, and growth in 3D conditions, but had no effect on *in vitro* 2D proliferation. Patient studies have shown that high levels of GD2 have been associated with advanced cancer stage, larger tumor size, nodal invasion, and enhanced tumor proliferation and invasiveness^[34]. These clinical correlations make GD2 an ideal breast CSC therapeutic target.

Targeting GD2 to treat cancer stem cells

Characterized by its lack of hormone receptor status, patients diagnosed with TNBC are typically unresponsive to target-specific hormone receptor therapies. Treatment options primarily consist of surgery, neoadjuvant therapies, and chemotherapy with standard cytotoxic agents. Despite initial responses, the overall prognosis remains poor^[35,36]. GD2 has been identified as a suitable therapeutic biomarker for targeting breast CSCs because of its limited expression in normal, healthy tissues. Because of this, therapies that target GD2 could be a promising avenue for treatment development. Battula *et al.* identified BMS-345541 as a potential upstream small molecule inhibitor for GD2 by blocking IKK activity, thus suppressing NF- κ B signaling^[31]. Although NF- κ B is ubiquitous in normal tissues and cells, it is typically inactive until cellular stress responses such as inflammation occur. Furthermore, Jaggupilli *et al.* were able to reduce the GD2+ CSC population by 70%-80% using glutamine uptake inhibitor, V9302^[32]. Lastly, Nguyen *et al.* were

able to suppress the activity of GD2+ CSCs by inhibiting downstream activation of FAK and mTOR using PF-573228 and everolimus, respectively^[33].

In addition to targeting the upstream and downstream mechanisms of GD2 expression and activity, immune-based therapies that target GD2 expressing cells could also be pursued. Seitz *et al.* accomplished this by developing CAR T-cells (chimeric antigen receptor T-cells) that are genetically engineered to target GD2 expressing cells^[37]. Although their studies demonstrated anti-GD2 CAR T-cells to be effective at reducing metastasis *in vivo*, graft-versus-host disease (GVHD) is a major cause of clinical morbidity and mortality^[38]. To overcome the limitations associated with T-cells, natural killer (NK) cells could be generated instead. Esser *et al.* demonstrated that engineered GD2-specific NK cells were able to induce ADCC-like (antibody-dependent cellular cytotoxicity) killing effects against neuroectodermal tumors^[39]. Furthermore, Ly *et al.* determined that infusion of anti-GD2 antibody dinutuximab, a chimeric human-mouse monoclonal antibody, could inhibit tumor growth *in vivo* and extend the survival of mice with TNBC via NK cell-mediated antibody-dependent cellular cytotoxicity^[34]. The FDA has already approved GD2-specific therapies for the treatment of neuroblastoma, osteosarcoma, and other GD2+ cancers. Additionally, other anti-GD2 therapies, such as naxitamab and an anti-GD2-GD3 vaccine, have been granted FDA approval^[40,41]. Anti-GD2 antibodies, however, do confer toxicity and are associated with adverse side effects including neuropathy, fever, significant pain, and allergies^[42]. Neuropathic pain is likely due to GD2 expression in neural cells; however, *O*-acetyl-GD2 (OAcGD2), a GD2 derivative, is expressed on GD2+ solid tumor cells but not on neural fibers, and specific targeting OAcGD2 may reduce the aforementioned side effects^[43]. Overall, these compounds may be beneficial for the treatment of TNBC, in combination with other therapies, by targeting the CSC subpopulation.

SUMMARY

Breast cancer is now the most commonly diagnosed cancer, accounting for 12% of global cases. Although advances in breast cancer treatment have been made, treatment resistance remains a problem for many patients. This is especially true for patients diagnosed with triple-negative breast cancer because of this cancer subtype's inherent ability to resist hormone receptor targeted therapies. Additionally, treatment with chemo- and radiotherapies is selected for the cancer stem cell subpopulation, a subset of cancer cells that is resistant due to mechanisms involving quiescence, DNA replication and repair, and apoptosis. Furthermore, these CSCs have an increased tumorigenic and metastatic potential.

GD2 has been identified as a breast cancer stem cell marker and is a promising target for breast cancer therapy^[44]. Furthermore, dinutuximab is a GD2-specific monoclonal antibody that is FDA approved for neuroblastoma. Because of this, we believe incorporating methods for targeting CSCs, specifically by GD2, into current TNBC research may lead to promising results. Examples of this would be GD2 combination therapies with novel pathway inhibitors, analyzing the effects in the tumor microenvironment, and studying the role of CSCs on the tumor architecture by looking at the extracellular matrix. Any discoveries could potentially lead to rapid clinical turnarounds due to the FDA-approved status of dinutuximab.

DECLARATIONS

Authors' contributions

Contributed to the conception and writing of this manuscript: Nguyen K

Contributed to reviewing the latest literature in the field, writing, and generation of the graphical abstract: McConnell E, Edwards O

Contributed their experience and gave final approval for submission: Collins-Burow BM, Burow ME

Abstract

Cyclin-dependent kinase 4 and 6 (CDK4/6) inhibitors combined with endocrine therapy have transformed the treatment of estrogen receptor-positive (ER+) and human epidermal growth factor receptor 2 negative (HER2-) metastatic breast cancer. However, some patients do not respond to this treatment, and patients inevitably develop resistance, such that novel biomarkers are needed to predict primary resistance, monitor treatment response for acquired resistance, and personalize treatment strategies. Circumventing the spatial and temporal limitations of tissue biopsy, newly developed liquid biopsy approaches have the potential to uncover biomarkers that can predict CDK4/6 inhibitor efficacy and resistance in breast cancer patients through a simple blood test. Studies on circulating tumor DNA (ctDNA)-based liquid biopsy biomarkers of CDK4/6 inhibitor resistance have focused primarily on genomic alterations and have failed thus far to identify clear and clinically validated predictive biomarkers, but emerging epigenetic ctDNA methodologies hold promise for further discovery. The present review outlines recent advances and future directions in ctDNA-based biomarkers of CDK4/6 inhibitor treatment response.

Keywords: Breast cancer, liquid biopsy, circulating tumor DNA, cell-free DNA, CDK4/6 inhibitors, resistance mechanisms, predictive biomarkers, circulating biomarkers

INTRODUCTION

Breast cancer is the most diagnosed cancer in women globally, with approximately 70% of diagnoses being tumors that express estrogen receptors (ER+) but not human epidermal growth factor receptor 2 (HER2-)^[1]. In jurisdictions that have implemented breast cancer screening programs, many ER+/HER2- breast cancers are diagnosed in localized or locoregional stages and are amenable to curative intent therapy. However, despite multimodality treatments, patients have a lifelong risk of metastatic recurrence, and once distant metastasis presents clinically, it is typically incurable^[2,3].

In the past decade, novel therapeutic strategies for metastatic breast cancer patients have been implemented in the clinic. Among these, the new standard treatment for ER+/HER2- locally advanced and metastatic breast cancer consists of cyclin-dependent kinase 4 and 6 (CDK4/6) inhibitors combined with endocrine therapy^[4]. Three CDK4/6 inhibitors have been approved (i.e., abemaciclib, palbociclib, and ribociclib) after displaying significant clinical benefit in pivotal phase III clinical trials^[5-12]. CDK4/6 inhibitors have been shown to improve response rate, median progression-free survival (PFS), health-related quality of life, and overall survival (OS) of metastatic breast cancer patients^[13-19]. However, CDK4/6 inhibitor resistance remains a significant obstacle. A minority of patients have intrinsic resistance, defined as progression (without response) within six months of starting treatment. Even for patients who experience initial response and clinical benefit from these agents, acquired resistance inevitably develops over subsequent months (median PFS ranges from 23.8-28.2 months in the first-line metastatic setting)^[11,17,20]. Therefore, biomarkers are urgently needed to predict CDK4/6 inhibitor efficacy or resistance in metastatic breast cancer patients, allowing clinicians to tailor treatment and potentially add additional therapies for patients at high risk of early progression.

Biomarkers for CDK4/6 inhibitors have been thoroughly investigated through molecular profiling of tumor material, but to date, the only clinically available biomarker remains breast cancer subtype as defined by traditional tissue markers (i.e., ER+/HER2-)^[21,22]. Despite significant research efforts, tumor heterogeneity and difficulties distinguishing endocrine resistance from CDK4/6 inhibitor resistance have impeded predictive biomarker discovery^[23]. Given practical challenges to obtaining and repeating metastatic tissue biopsies, blood-based profiling of tumor-derived material (i.e., “liquid biopsy”) has significant potential to facilitate biomarker explorations. For instance, circulating tumor cells (CTCs) and circulating tumor DNA (ctDNA) are promising liquid biopsy analytes because they harbor cancer-specific molecular aberrations^[24].

In this review, we discuss biomarker-directed treatment for breast cancer, mechanisms of resistance to CDK4/6 inhibitors, and attempts to uncover ctDNA liquid biopsy biomarkers of efficacy and resistance to CDK4/6 inhibitors. Lastly, we highlight undeveloped areas for future advances, namely epigenetic-based liquid biopsy biomarkers for patients treated with CDK4/6 inhibitors.

BIOMARKER-DIRECTED PRECISION ONCOLOGY AND BREAST CANCER

Precision oncology relies on molecular information from each patient’s cancer to optimize and individualize treatment regimens. Leveraging these patient-specific molecular biomarkers allows clinicians to select the best treatment for individual patients to improve therapeutic efficacy and reduce adverse effects on healthy cells^[25]. Molecular biomarkers include prognostic biomarkers, which may provide information on the expected disease course independent of treatment, and predictive biomarkers, which provide insight into the effect of a specific therapy. Both prognostic and predictive biomarkers may be used to personalize treatment via risk-stratification or directing effective treatments.

Current standard-of-care breast cancer treatments provide several archetypal examples of biomarker-directed precision oncology. For instance, OncotypeDx is a commercial 21-gene assay for ER+ early-stage breast cancer that returns a recurrence score indicating the probability of relapse without adjuvant chemotherapy, with higher scores associated with a poorer prognosis. OncotypeDx serves a prognostic role; its clinical utility stems from identifying patients with a higher absolute recurrence risk and, therefore, a higher likelihood of benefiting from adjuvant chemotherapy^[26,27]. Similarly, the MammaPrint microarray assay is a prognostic biomarker that uses the expression levels of 70 genes to classify patients according to recurrence risk^[28,29].

Other breast cancer biomarkers highlight the impact of predictive biomarkers in precision oncology. Intrinsic molecular subtypes and associated hormone receptors (ER, PR) and HER2 expression levels are critical for drug selection in breast cancer patients^[30]. For instance, HER2+ breast cancer preferentially responds to HER2-targeted agents, such as trastuzumab and trastuzumab emtansine (T-DM1)^[31]. Likewise, hormone receptor expression denotes tumors that preferentially respond to endocrine therapy. Resistance to endocrine therapy can occur over time through a variety of mechanisms (e.g., genetic alterations of *ESR1*, increased activity of cyclin-dependent kinases (CDKs), and mitogen-signaling pathways such as PI3K and RAS, or a decrease in proteins that inhibit CDKs such as p16, p21, and p27), several of which converge on the cyclin D-CDK4/6 axis^[32]. Therefore, simultaneous treatment with endocrine therapy and CDK4/6 inhibitors has emerged as a highly successful treatment paradigm for ER+/HER2- metastatic breast cancer.

MOLECULAR MECHANISMS OF CDK4/6 INHIBITOR EFFICACY AND RESISTANCE

The cyclin D-CDK4/6-Retinoblastoma protein (Rb) axis regulates cell cycle progression from G1 to the S phase [Figure 1]. Before entering the cell cycle, Rb is hypophosphorylated and bound to the E2F transcription factors (TFs), causing their inhibition^[33]. When the appropriate mitogenic signals are present, quiescent cells may enter the cell cycle at the G1 phase. These mitogenic signals lead to the expression of cyclin D, which competes with CDKN2 family proteins to bind CDK4/6, forming the cyclin D-CDK4/6 complex^[34]. This active complex can then phosphorylate Rb, causing a conformational change and subsequent release of the E2F TFs, which drive S phase entry and further cell cycle progression via downstream transcriptional activation^[33]. Furthermore, the cyclin D-CDK4/6 complex triggers the forkhead box protein M1 (FOXO1) TF, promoting the advancement of later cell cycle phases (G2/M)^[35]. ER+ breast cancer is highly reliant on an intact cyclin D-CDK4/6-Rb axis, as estrogen drives cyclin D1 expression leading to the formation of the cyclin D-CDK4/6 complex, ultimately inducing cell proliferation through the CDK4/6 pathway^[36]. CDK4/6 inhibitors leverage this by binding the ATP domain of CDK4/6 and halting progression from the G1 to S phase of the cell cycle^[37].

The mechanisms of resistance to CDK4/6 inhibitors have yet to be fully elucidated, and in many cases, the clinical relevance of putative mechanisms discovered in preclinical models remains unconfirmed^[38,39]. Recognized resistance mechanisms include amplification of members of the cyclin D-CDK4/6 axis or downregulation of CDK4/6 repressor proteins, such as p21 and p27, which may thwart the direct effects of these drugs^[38,40-42]. Additionally, alterations in *RB1*, *FAT1*, or the PI3K/AKT/mTOR and KRAS signaling pathways may act to circumvent the G1/S checkpoint in the presence of CDK4/6 inhibitors, inducing cell cycle progression independent of the cyclin D-CDK4/6 axis^[38,39,43-46].

CIRCULATING CELL-FREE DNA FOR LIQUID BIOPSY AND COMPANION DIAGNOSTICS

In recent years, liquid biopsy approaches have emerged, intending to provide molecular information for biomarker-directed precision oncology from a fluid sample^[24]. Traditionally, accessing this information has required invasive procedures, like tissue biopsy, which are not always feasible depending on the nature and

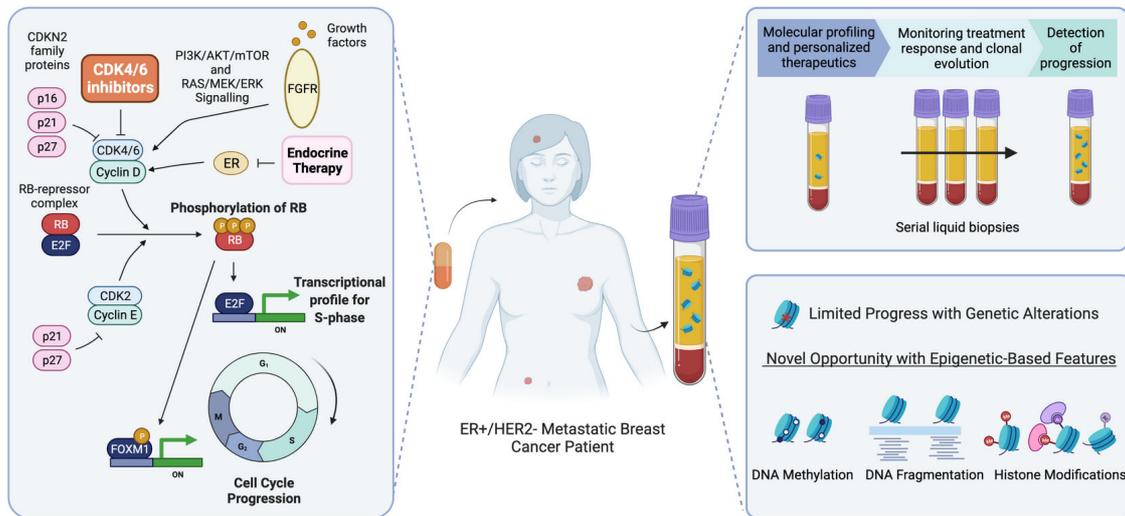

Figure 1. Overview of CDK4/6 inhibitor treatment and liquid biopsy in ER+/HER2- metastatic breast cancer patients. CDK4/6 inhibitors prevent the phosphorylation of Rb and downstream activation of the transcriptional profile required for progression to the S-phase of the cell cycle. In the anti-CDK4/6 therapy clinical setting, a liquid biopsy may be used to direct therapy, monitor patient response over time, and detect progression. Currently, research efforts focused on monitoring genetic alterations in cfDNA through liquid biopsy have made limited progress. Epigenetic profiling of cfDNA may reveal new biomarkers of CDK4/6 inhibitor efficacy or resistance.

location of the tumor, as well as the health of the patient. These limitations are particularly relevant for metastatic breast cancer patients, where ER+/HER2- breast cancer recurrences often occur past 5 years. In this clinical setting, the primary tissue sample may not represent metastatic disease, and the metastatic sites are often in areas difficult to biopsy (e.g., bone and lung)^[47,48]. Here, a liquid biopsy may bypass the procedural, spatial, and temporal obstacles of tissue biopsy by encompassing disease heterogeneity and new metastases while being easily repeated throughout tumor progression and different lines of treatment^[49]. Therefore, liquid biopsy is advancing as a valuable approach to enable contemporaneous and minimally invasive testing of tumor-specific analytes in cancer patients^[50].

For most liquid biopsy applications, the body fluid of choice is peripheral blood plasma. This has previously presented challenges in detecting brain tumors or metastatic sites, likely due to the blood-brain barrier; however, newer liquid biopsy technologies have led to improvements in sensitivity^[51,52]. Regardless, other accessible fluids may be more informative depending on the tumor type (e.g., saliva for oral cancer, urine for bladder cancer, and cerebrospinal fluid for glioma)^[53]. There are also a variety of components from the tumor which may be assessed through liquid biopsy, including intact tumor cells (e.g., CTCs), cell-free DNA (cfDNA), extracellular vesicles, cell-free RNA, and more^[24]. Herein, we focus our discussion on ctDNA as a liquid biopsy biomarker of response to anti-CDK4/6 therapy due to the wealth of recent studies on this topic and the precedent of ctDNA in other settings of precision oncology (e.g., for EGFR tyrosine kinase inhibitors in lung cancer)^[49,54]. Other liquid biopsy analytes and their role as biomarkers for CDK4/6 inhibitor treatment have been reviewed elsewhere^[23,55,56].

ctDNA molecules containing tumor-derived genetic and epigenetic features are released into the bloodstream as tumor cells die^[49]. ctDNA usually represents a small portion of the total circulating cfDNA pool, where most other cfDNA molecules are derived from cells of hematopoietic origin and alternative tissues^[57-59]. The release of ctDNA is related to cellular turnover (i.e., many apoptotic and necrotic cells), during which a subset of double-stranded DNA fragments associated with chromatin components enters

the extracellular space^[60-62]. ctDNA levels can be as low as < 0.01% of the entire cfDNA pool, with variations depending on tumor size, stage, anatomical location, treatment, and the biological propensity of tumor cells to release their DNA into the circulation^[51,58,63-65]. Once in the circulation, clearance of ctDNA by multiple mechanisms (e.g., nuclease-mediated degradation, phagocytosis, and renal excretion) occurs quickly with a half-life between 16 minutes and two hours^[66-68]. This property enables cfDNA to portray a “real-time” snapshot of the patient’s disease state^[49,69].

Analysis of ctDNA through liquid biopsy may be relevant in many clinical stages of CDK4/6 inhibitor treatment, such as prognostication, personalizing therapeutics (e.g., determining which patients should receive anti-CDK4/6 therapy or adding other agents), monitoring treatment response, and identifying resistance [Figure 1]. ctDNA can be analyzed by polymerase chain reaction (PCR)^[70,71], which targets a single gene locus, or next-generation sequencing (NGS), which simultaneously profiles dozens or hundreds of genes^[64,72-74]. Of relevance in ER+/HER2- advanced breast cancer, the *therascreen PIK3CA RGQ PCR kit* detects *PIK3CA* mutations to help direct PI3Ka inhibitor treatment (alpelisib)^[75,76]. NGS-based liquid biopsy assays often include *PIK3CA* in addition to genes of potential relevance to resistance mechanisms to endocrine therapy, such as *ESR1* and *PTEN*^[77]. Thus, although not yet established in the CDK4/6 setting, ctDNA shows considerable promise as means of biomarker detection for genotype-guided precision oncology.

GENETIC-BASED LIQUID BIOPSY BIOMARKERS OF CDK4/6 INHIBITOR EFFICACY AND RESISTANCE

Currently, there are no clinically validated liquid biopsy biomarkers to distinguish patients with differential benefits to anti-CDK4/6 therapy. Here we report the main ctDNA liquid biopsy biomarkers for CDK4/6 inhibitor treatment investigated at baseline or time of progression. The main focus of the studies outlined in this section are alterations of genes related to cell cycle regulation using ctDNA and their relationship to outcomes [Table 1].

Most studied resistance mechanisms converge on Rb modulation since it is the central target of CDK4/6 to control cell cycle progression^[38]. Genetic alterations of *RB1* may cause its inactivation and confer resistance to CDK4/6 inhibitors. For example, in the PALOMA-3 trial, loss of *RB1* detected via baseline ctDNA was associated with worse PFS for patients in the palbociclib plus fulvestrant treatment group^[78]. These results suggest that *RB1* alterations may be prognostic and potentially predictive; however, this study could not determine the treatment interaction effect due to the small sample size. This was further supported by an analysis of ctDNA from patients in the MONALEESA 2, 3, and 7 trials, which found that for patients with *RB1* mutations, ribociclib plus endocrine therapy did not significantly improve median PFS^[79]. Furthermore, a small clinical report of three patients was the first to identify loss-of-function *RB1* mutations in ctDNA sampled at the time of acquired CDK4/6 inhibitor resistance^[44]. This was later supported by an analysis of PALOMA-3 matched baseline and end-of-treatment ctDNA samples, which found loss-of-function *RB1* mutations were exclusively acquired in 4.7% of patients treated with palbociclib plus fulvestrant, suggesting they were selected for in treatment resistance. However, due to the small number of acquired *RB1* mutations, no associations were made to PFS^[39]. Altogether, these results and biological support of *RB1* loss-of-function as a resistance mechanism suggest that genomic alterations of *RB1* detected in ctDNA may be predictive of CDK4/6 inhibitor resistance. However, the low prevalence of these alterations suggests other resistance mechanisms are involved, and *RB1* mutations may serve as a predictive biomarker of resistance for a limited portion of patients on CDK4/6 inhibitors.

Table 1. Summary of the main genomic alterations interrogated in ctDNA as biomarkers for CDK4/6 inhibitor resistance

Genomic alteration	ctDNA sample	Cohort	Prevalence	Technique	Main findings	Reference
RB1	Baseline	PALOMA-3: Palbociclib plus fulvestrant	27 of 156 patients (17.3%)	Target panel NGS (17 genes)	Patients in the palbociclib treatment arm with loss of <i>RB1</i> had worse median PFS compared to wild-type (exact PFS not reported)	O'Leary et al. ^[78]
	Baseline	MONALEESA 2,3,7: Ribociclib plus endocrine therapy	26 of 1,534 patients (1.7%)	Target panel NGS (~600 genes)	Patients with <i>RB1</i> mutated tumors did not have significantly different median PFS with ribociclib treatment compared to placebo (mutant: 9.2 vs. 3.7 months placebo vs. ribociclib arm)	Bertucci et al. ^[79]
	Progression	Three case reports: Palbociclib plus fulvestrant or ribociclib plus letrozole	NA	Custom library for <i>RB1</i> and TP53 coding sequence/ Guardant 360 assay (73 genes)	Patients had five different loss-of-function genetic alterations of <i>RB1</i> after exposure to CDK4/6 inhibitors and coinciding with resistance	Condorelli et al. ^[44]
	Baseline and End-of-treatment	PALOMA-3: Palbociclib plus fulvestrant	Acquired in 6 of 127 patients (4.7%)	Exome sequencing/ Target panel NGS/ ddPCR	Patients exclusively acquired <i>RB1</i> alterations in the palbociclib treatment arm	O'Leary et al. ^[39]
ESR1	Baseline	PALOMA-3: Palbociclib plus fulvestrant	91 of 360 patients (25.3%)	ddPCR	Patients in the palbociclib treatment arm had similarly improved median PFS regardless of <i>ESR1</i> status, although patients in the placebo arm with <i>ESR1</i> mutations had worse PFS compared to wild-type (palbociclib arm: 9.4 vs. 9.5 months mutant vs. wild-type; placebo arm: 3.6 vs. 5.4 months mutant vs. wild-type)	Fribbens et al. ^[80]
	Baseline and End-of-treatment	PALOMA-3: Palbociclib plus fulvestrant	Acquired in 25 of 195 patients (12.8%)	Exome sequencing/ Target panel NGS/ ddPCR	Patients acquired <i>ESR1</i> Y537S mutations in both treatment arms and were associated with improved median PFS compared to patients who did not acquire the mutation (13.7 vs. 7.4 months acquired vs. not acquired)	O'Leary et al. ^[39]
	Baseline	PALOMA-3: Palbociclib plus fulvestrant	72 of 331 patients (21.8%)	Target panel NGS (17 genes)	Patients in the placebo arm with <i>ESR1</i> mutations had worse PFS compared to wild-type (exact PFS not reported)	O'Leary et al. ^[78]
	Baseline	MONARCH-2: abemaciclib and fulvestrant	147 of 248 patients (59.3%)	ddPCR	Patients in the abemaciclib treatment arm had improved PFS regardless of <i>ESR1</i> status but observed a higher numerical median PFS in patients with <i>ESR1</i> mutant tumors compared to wild-type (abemaciclib arm: 20.7 vs. 15.3 months mutant vs. wild-type; placebo arm: 13.1 vs. 11.3 months mutant vs. wild-type). Patients with <i>ESR1</i> mutations also had improved OS (abemaciclib arm: not reached vs. 52.2 months mutants vs. wild-type; placebo arm: 42.2 vs. 29.4 months mutant vs. wild-type)	Tolaney et al. ^[81]
PIK3CA	Baseline	PALOMA-3: Palbociclib plus fulvestrant	129 of 395 patients (33%)	BEAMing assay	Patients in the palbociclib treatment arm had similarly improved PFS regardless of <i>PIK3CA</i> status (palbociclib arm: 9.5 vs. 9.9 months mutated vs. wild-type; placebo arm: 3.6 vs. 4.6 months mutated vs. wild-type)	Cristofanilli et al. ^[13]
	Baseline	MONARCH-2: abemaciclib and fulvestrant	96 of 219 patients (43.8%)	ddPCR	Patients in the abemaciclib treatment arm had similarly improved PFS regardless of <i>PIK3CA</i> status, although patients in the placebo treatment arm with <i>PIK3CA</i> mutations had worse median PFS compared to wild-type (abemaciclib arm: 17.1 vs. 16.9 months mutant vs. wild-type; placebo arm: 5.7 vs. 12.3 months mutant vs. wild-type)	Tolaney et al. ^[81]
	Baseline	Palbociclib or ribociclib plus fulvestrant or letrozole	12 of 30 patients (40%)	ddPCR	Patients treated with palbociclib or ribociclib plus endocrine therapy with <i>PIK3CA</i> mutations had a worse median PFS compared to wild-type (7.44 vs. 12.9 months mutant vs. wild-type)	Del Re et al. ^[82]
	Baseline	PALOMA-3: Palbociclib plus fulvestrant	55 of 331 patients (16.6%)	Target panel NGS (17 genes)	<i>PIK3CA</i> mutations were not identified as predictive (exact PFS not reported)	O'Leary et al. ^[78]
	Baseline and	PALOMA-3: Palbociclib	Acquired in 15 of	Exome sequencing/Target	Patients acquired <i>PIK3CA</i> mutations in both treatment arms and were associated with	O'Leary

	End-of-treatment	plus fulvestrant	195 patients (7.6%)	panel NGS/ddPCR	improved median PFS compared to patients who did not acquire a PIK3CA mutation (12.7 vs. 9.2 months acquired vs. not acquired)	et al. ^[39]
	Baseline	MONALEESA-7: Ribociclib plus endocrine therapy	139 of 489 patients (28%)	Target panel NGS (~600 genes)	Patients in the ribociclib treatment arm had improved median PFS compared to the placebo arm, and this was more prominent in patients with wild-type <i>PIK3CA</i> compared to <i>PIK3CA</i> mutations (ribociclib arm: 14.8 vs. 24.7 months mutant vs. wild-type; placebo arm 12.9 vs. 12.2 months mutant vs. wild-type)	Bardia et al. ^[83]
FGFR	Progression	MONALEESA-2: Ribociclib plus letrozole	20 of 427 patients (5%)	Guardant360 assay (73 genes)	Patients in the ribociclib treatment arm with <i>FGFR1</i> alterations had a worse median PFS (10.61 vs. 24.84 months mutant vs. wild-type), although significance was not achieved due to the small sample size	Formisano et al. ^[41]
	Baseline	PALOMA-3: Palbociclib plus fulvestrant	20 of 401 patients (4.9%)	Target panel NGS (17 genes)	Patients with <i>FGFR1</i> amplifications had a worse median PFS in both treatment arms (palbociclib arm: 3.9 vs. 12 months mutant vs. wild-type; placebo arm: 1.8 vs. 4.8 months mutant vs. wild-type)	O'Leary et al. ^[78]
	Baseline and End-of-treatment	PALOMA-3: Palbociclib plus fulvestrant	Acquired in 2 of 195 patients (1%)	Exome sequencing/Target panel NGS/ddPCR	Patients acquired <i>FGFR2</i> alterations with no apparent difference between treatment arms.	O'Leary et al. ^[39]
TP53	Baseline	PALOMA-3: Palbociclib plus fulvestrant	52 of 331 patients (15.7%)	Target panel NGS (17 genes)	Patients with <i>TP53</i> mutations had a worse median PFS in both treatment arms, and no interaction with treatment was observed (palbociclib arm: 3.7 vs. 12.7 months mutant vs. wild-type; placebo arm: 1.8 vs. 5.4 months mutant vs. wild-type)	O'Leary et al. ^[78]
	Baseline	MONALEESA-7: Ribociclib plus endocrine therapy	92 of 489 patients (19%)	Target panel NGS (~600 genes)	Patients with <i>TP53</i> mutations had a worse median PFS in both treatment groups (ribociclib arm: 9.2 vs. 24.7 months mutant vs. wild-type; placebo arm: 7.2 vs. 13.0 months mutant vs. wild-type)	Bardia et al. ^[83]
KRAS	Baseline and on treatment	Palbociclib plus fulvestrant	66 of 106 patients (62.2%)	ddPCR	Patients treated with palbociclib and fulvestrant with baseline <i>KRAS</i> mutations had a worse median PFS compared to wild-type (3 vs. 17.8 months mutant vs. wild-type)	Raimondi et al. ^[45]
CCND1	Baseline	MONALEESA-7: Ribociclib plus endocrine therapy	51 of 489 patients (10%)	Target panel NGS (~600 genes)	Patients with <i>CCND1</i> alterations had a worse median PFS in both treatment arms and patients with altered <i>CCND1</i> also had a significant treatment interaction effect (ribociclib arm: 12.9 vs. 22.1 months mutant vs. wild-type; placebo arm: 5.5 vs. 11.3 months mutant vs. wild-type)	Bardia et al. ^[83]
MYC	Baseline	MONALEESA-7: Ribociclib plus endocrine therapy	35 of 489 patients (7.1%)	Target panel NGS (~600 genes)	Patients with <i>MYC</i> alterations had a worse median PFS in both treatment arms (ribociclib arm: 7.3 vs. 24.7 months mutant vs. wild-type; placebo arm: 7.2 vs. 12.9 months mutant vs. wild-type)	Bardia et al. ^[83]

ctDNA: Circulating tumor DNA; NGS: next-generation sequencing; PFS: progression-free survival; ddPCR: droplet digital polymerase chain reaction; OS: overall survival.

In addition to *RB1* mutations, genomic alterations in *ESR1* have been investigated due to the ER mitogenic pathway being critical to cyclin D-CDK4/6 dependence and the inactivation having a potential role in resistance to CDK4/6 inhibitors^[46]. First, multiple analyses of the PALOMA-3 trial revealed that patients with baseline ctDNA *ESR1* mutations had a worse median PFS solely in the placebo treatment arm^[78,80]. These findings support the role of *ESR1* mutations as a biomarker of endocrine resistance, and no treatment interaction effect was observed, indicating the lack of predictive potential of *ESR1* mutations for CDK4/6 inhibitor resistance. A later study of PALOMA-3 found that 13 of 195 patients lost *ESR1* mutations between baseline and end-of-treatment, whereas 25 patients in both treatment groups acquired the alteration, suggesting *ESR1* mutations promote resistance to fulvestrant and do not predict CDK4/6 inhibitor treatment benefit^[39]. Lastly, a recent analysis of ctDNA from the MONARCH-2 trial found that abemaciclib plus fulvestrant

improved PFS regardless of *ESR1* status, but patients with *ESR1* mutations had a higher numerical median PFS in both treatment arms^[81]. This study also observed an unexpectedly high prevalence of *ESR1* mutations and increased OS for patients with *ESR1* mutations. The contrast of these findings is unclear but may be explained by differences in sample size, patient criteria, and analytical techniques. Altogether, *ESR1* mutations are not a promising candidate biomarker for CDK4/6 inhibitor resistance and may be more informative for endocrine resistance.

PIK3CA mutations have also been interrogated by ctDNA due to their upstream role in cell cycle regulation through the PI3K/AKT/mTOR pathway, which interacts with estrogen receptors and potentially impacts CDK4/6 inhibitor resistance^[38]. For instance, analyses of the PALOMA-3 trial found that palbociclib plus fulvestrant treatment similarly improved PFS in patients with mutated or wild-type *PIK3CA* in baseline ctDNA, indicating that *PIK3CA* genomic alterations are not predictive of CDK4/6 inhibitor benefit^[13,78]. In support of this finding, a study of baseline ctDNA from the MONARCH-2 trial found patients in the abemaciclib treatment arm had similarly improved PFS regardless of *PIK3CA* mutation status^[81]. In addition, patients in the placebo arm with mutant *PIK3CA* had a worse median PFS, suggesting the role of *PIK3CA* mutations in endocrine therapy resistance instead of as a biomarker of CDK4/6 inhibitor treatment. In contrast, another study of baseline ctDNA of advanced breast cancer patients treated with palbociclib or ribociclib found that patients with *PIK3CA* mutations had a shorter median PFS than wild-type^[82]. Due to a lack of a control treatment arm, this study could not assess the treatment effect with *PIK3CA*. Still, these findings suggest *PIK3CA* mutations may act as a prognostic biomarker for advanced breast cancer patients receiving treatment with CDK4/6 inhibitors.

Furthermore, the lack of predictive potential of *PIK3CA* has been supported in multiple studies. An additional PALOMA-3 analysis of matched baseline and end-of-treatment ctDNA samples found that 7.6% of patients acquired *PIK3CA* mutations across both treatment arms, suggesting that *PIK3CA* mutations emerge due to fulvestrant resistance^[39]. Interestingly, patients with acquired *PIK3CA* mutations had an improved PFS than those who did not; however, this trend was seen with the acquisition of any new mutation (including *ESR1*), suggesting that novel alterations are more likely to emerge in patients with a longer duration of treatment. Moreover, a recent study analyzing ctDNA from the MONALEESA-7 trial found that patients in the ribociclib treatment arm had an improved median PFS, but this was more pronounced in patients with wild-type *PIK3CA*^[83]. However, this difference was not statistically significant, reinforcing the limited potential of *PIK3CA* as a predictive biomarker of CDK4/6 inhibitor resistance.

In addition, FGFR genetic alterations have been investigated in plasma ctDNA of patients treated with CDK4/6 inhibitors due to evidence of abnormal FGFR signaling, driving *CCND1* overexpression and MAPK activation, contributing to resistance^[38]. One analysis of baseline ctDNA from the MONALEESA-2 trial found that for patients in the ribociclib treatment arm, *FGFR1* alterations were related to worse PFS, although significance was not achieved due to the small sample size^[41]. In further support, a study of ctDNA from the PALOMA-3 trial found that *FGFR1* amplifications were associated with worse PFS in both treatment groups, suggesting that the alteration may be related to endocrine resistance^[78]. Furthermore, in an assessment of pre- and post-treatment ctDNA samples from PALOMA-3, *FGFR2* was acquired in 2 of 195 patients, with no apparent difference between treatment groups^[39]. Altogether these findings support FGFR alterations, specifically *FGFR1* amplifications, as a possible prognostic biomarker for patients treated with CDK4/6 inhibitors and endocrine therapy.

TP53 is a tumor suppressor gene whose product induces antiproliferative factors, such as *CDKN1A*, and its modification in ctDNA has also been investigated in many studies. For example, genomic alterations of

TP53 in ctDNA from the PALOMA-3 trial were assessed, revealing that patients with *TP53* mutations had significantly worse PFS in both treatment arms, and no interaction with treatment was observed^[78]. This work also found that *TP53* mutations were connected to a distinct aggressive phenotype with more metastases but could not rule out the presence of these mutations due to clonal hematopoiesis. Moreover, a MONALEESA-7 biomarker analysis found that *TP53* mutations in baseline ctDNA were associated with progression independently from treatment with ribociclib and did not predict response to therapy^[83]. Overall, these studies support *TP53* alterations as prognostic biomarkers and suggest they are not candidate predictive biomarkers of anti-CDK4/6 therapy.

In addition, genomic alterations of *KRAS* in ctDNA have recently been interrogated due to its role upstream of CDK4/6, transducing mitogenic signaling and affecting cyclin D1^[38]. One study investigated *KRAS* mutations in ctDNA of 106 HR+/HER2- metastatic breast cancer patients treated with palbociclib plus fulvestrant and found that after 18 months, all patients with *KRAS* alterations had progressive disease^[45]. In contrast, only one *KRAS* wild-type patient had progressed. Accordingly, patients with mutated *KRAS* had a worse median PFS compared to wild-type, supporting the potential of *KRAS* mutations as a prognostic biomarker. Further study with a control treatment group is required to determine the treatment interaction effect before conclusions can be made. For instance, previous studies on ctDNA from the PALOMA-3 trial have investigated *KRAS* mutations, but likely due to the low frequency of aberrations, have not made associations with PFS^[39,78].

Many other genomic alterations have been investigated in plasma ctDNA of patients treated with CDK4/6 inhibitors due to their role around the cyclin D-CDK4/6-Rb axis or in breast cancer in general, namely *CCND1*, *CDK4*, *CDK6*, *CDKN1*, *CDKN2*, *NF1*, *ERBB2*, *AKT1*, *NRAS*, *HRAS*, *GATA3*, and *MYC*^[39,78,83]. In particular, a recent study of the MONALEESA-7 samples found that patients with *CCND1* alterations in baseline ctDNA had a worse median PFS for both treatment arms, indicating the role of *CCND1* as a prognostic biomarker^[83]. The benefit of ribociclib was also greater in patients with *CCND1* altered ctDNA, supporting *CCND1* as a candidate predictive biomarker. Alterations in *MYC* have also been reported as a potential prognostic biomarker for patients treated with CDK4/6 inhibitors in combination with or solo endocrine therapy^[83]. Otherwise, associations with PFS and treatment have not been reported for many of the above alterations.

In summary, current work suggests *ESR1* and *PIK3CA* mutations in ctDNA have limited CDK4/6 inhibitor biomarker potential, which may be clouded due to implications with endocrine resistance. Alterations in *FGFR1*, *TP53*, and *MYC* may also be prognostic biomarkers of resistance to anti-CDK4/6 therapy, whereas *RB1*, *KRAS*, and *CCND1* may be prognostic and putative predictive biomarkers of CDK4/6 inhibitor resistance. Although numerous potential biomarkers have been identified, many studies have not confirmed the effect of interaction with treatment, and further validation is needed. While considering this, the evidence so far indicates that no singular genetic alteration will serve as an ideal prognostic or significantly predictive biomarker for CDK4/6 inhibitor efficacy or resistance. While some potential predictive biomarkers, such as *RB1* alterations, seem promising, their low prevalence indicates multifactorial resistance mechanisms. As such, analyses that only evaluate one genomic alteration are limited in assessing whether other alterations add predictive value. To assess the vast landscape of CDK4/6 inhibitor resistance mechanisms, future studies should consider a broader range of genomic alterations in ctDNA or, as discussed in later sections, expand to longitudinal monitoring to assess ctDNA dynamics or investigate epigenetic-based features.

DYNAMIC CTDNA BIOMARKERS OF CDK4/6 INHIBITOR EFFICACY AND RESISTANCE

Monitoring changes in ctDNA levels throughout treatment may reveal more prognostic and predictive information than a single time point measurement. Serial monitoring of ctDNA levels could provide a dynamic biomarker that allows personalized modifications to treatment, such as adding or switching to a more effective therapy for non-responsive patients^[84]. In investigations of the utility of dynamic liquid biopsy biomarkers, questions remain concerning sampling time points, assays used, and change thresholds. This section discusses research on dynamic ctDNA biomarkers relevant to CDK4/6 inhibitor treatment [Table 2].

Dynamic ctDNA levels in response to CDK4/6 inhibitor treatment were first investigated by monitoring *PIK3CA* and *ESR1* mutant ctDNA from the PALOMA-3 trial collected at baseline, cycle one day 15, and progression^[85]. *PIK3CA* and *ESR1* mutations were detected in 100 and 114 of 455 baseline samples (22% and 25.6%), with 73 and 65 matched day 15 samples, respectively. For both *PIK3CA* and *ESR1*, a significant decline in ctDNA occurred on day 15, with a more apparent decrease in mutant *PIK3CA* ctDNA in the palbociclib arm and mutant *ESR1* ctDNA in the placebo arm. This group also defined a circulating DNA ratio (CDR15) as the concentration of ctDNA on day 15 compared to baseline. They found that all patients on palbociclib had a CDR15 less than one, possibly due to the cytostatic effect of CDK4/6 inhibitors. For *PIK3CA*, patients with CDR15 above the median had a worse PFS than those below the median; however, this was not seen for *ESR1*. Using an optimal threshold determined by Harrell's c-index and Benjamini-Hochberg p-value corrections, they found that patients with a high *PIK3CA* CDR15 had an inferior median PFS than those with a low CDR15. Ultimately, this study determined that relative change in ctDNA based on commonly truncal *PIK3CA* mutations was predictive of PFS for patients treated with palbociclib and fulvestrant. Alternatively, ctDNA dynamics based on *ESR1* mutations, which are generally subclonal due to selection of prior endocrine therapy, were not predictive of clinical outcome. Altogether, these results indicate that early evaluation of ctDNA dynamics with truncal mutations may be a predictive biomarker of PFS for patients on CDK4/6 inhibitor treatment.

In addition, a subsequent study also assessed *ESR1* mutations longitudinally in the ACLINA cohort of 59 ER+/HER2- metastatic breast cancer patients treated with palbociclib plus fulvestrant^[86]. They found *ESR1* mutations in 28.8% of the baseline samples, but these were not associated with PFS. In addition, they found that all patients experienced a decrease in ctDNA on day 15 relative to baseline. In contrast, on day 30, patients with early progression had increased ctDNA, and patients with longer PFS had lower or consistent ctDNA levels. They found that the presence of *ESR1* mutant ctDNA on day 30, as opposed to ctDNA clearance, was correlated with worse PFS, suggesting the potential of ctDNA detection on day 30 of treatment as a prognostic biomarker.

Further support for ctDNA ratios on day 30 as a biomarker comes from additional analysis of ctDNA from patients in the ALCINA cohort^[87]. First, this study used archived tumor tissue to identify trackable mutations based on a panel of 15 driver genes. Next, they assessed serial plasma samples for 25 patients with either *PIK3CA*, *TP53*, or *AKT1* mutations and found that baseline ctDNA levels had no association with PFS. In addition, they found that all patients had a decrease in ctDNA on day 15, which was not associated with PFS. In contrast, three kinetic patterns appeared on day 30, with nine patients displaying a continuous decreased or undetectable ctDNA, one patient with consistent ctDNA levels, and five patients with an increase in ctDNA. Patients with undetectable ctDNA on day 30 had an improved PFS compared to those with detectable ctDNA. Furthermore, the radiological response had high concordance with ctDNA detection, with general decreases or undetectable ctDNA for non-progressive disease compared to rising ctDNA between days 15 and 30 for progressive disease. However, this study assessed concentrations of

Table 2. Summary of dynamic ctDNA biomarkers investigated in the CDK4/6 inhibitor treatment setting

Technique	ctDNA sample time points	Genetic alteration	Cohort	Metric	Main findings	Reference
ddPCR	Baseline, cycle 1 day 15, and progression	<i>ESR1</i> and <i>PIK3CA</i>	PALOMA-3: Palbociclib plus fulvestrant	High and low CDR15 based on a threshold determined by Harrell's c-index and Benjamini-Hochberg p-value corrections	All patients in the palbociclib treatment arm had a CDR15 less than one. For <i>PIK3CA</i> , patients with a high CDR15 had a worse median PFS than those with a low CDR15 (4.1 vs. 11.2 months high vs. low)	O'Leary et al. ^[85]
ddPCR	Baseline, day 15, day 30, and progression	<i>ESR1</i>	ALCINA: Palbociclib plus fulvestrant	Ratio relative to baseline (mutant copies/mL)	All patients experienced a decrease in ctDNA on day 15 relative to baseline. Patients with early progression had increased ctDNA on day 30, and patients with longer PFS had lower or consistent ctDNA levels relative to baseline. <i>ESR1</i> mutations ctDNA on day 30, as opposed to ctDNA clearance, was correlated with worse PFS	Jeannot et al. ^[86]
ddPCR monitoring one tumor-specific mutation per patient	Baseline, day 15, day 30 and progression	<i>PIK3CA</i> (n = 21), <i>TP53</i> (n = 2), or <i>AKT1</i> (n = 2)	ALCINA: Palbociclib plus fulvestrant	Ratio relative to baseline (mutant copies/mL)	All patients had a decrease in ctDNA on day 15, but this was not associated with PFS. Patients with undetectable ctDNA on day 30 had an improved PFS compared to those with detectable ctDNA (25 vs. 3 months undetectable vs. detectable, respectively). ctDNA ratios (day 30/baseline) greater than or less than one were significantly associated with PFS	Darrigues et al. ^[87]
Guardant360 assay	Baseline, four weeks	73 genes	Palbociclib or ribociclib plus endocrine therapy	mVAFR for the 79 mutations found between baseline and week 4 assess in groups of high, medium, and low mVAFR groups and as a continuous variable	mVAFR was significantly associated with PFS, whereas single timepoint mean VAFs or absolute changes in mean VAF were not. Patients with high mVAFR had a worse median PFS than those with low mVAFR (4.2 months vs. not reached high vs. low)	Martinez-Saez et al. ^[88]
mFAST-seq	Various	Aneuploidy	CDK4/6 inhibitor plus endocrine therapy	z-score trajectories	Raised z-score trajectories were significantly related to worse PFS, whereas baseline z-scores were not predictive of progression. A single z-score increased in a consecutive blood sample at any follow-up point was not associated with PFS	Dandachi et al. ^[89]

ctDNA: Circulating tumor DNA; ddPCR: droplet digital polymerase chain reaction; CDR15: circulating DNA ratio at cycle one day 15 compared to baseline; PFS: progression-free survival; mVAFR: mean variant allele fraction ratio; mFAST-seq: modified Fast Aneuploidy Screening Test-Sequencing System.

ctDNA with respect to disease progression and found overlap in progressive versus non-progressive disease at all time points, highlighting the challenge of absolute abundance as a biomarker. Therefore, they assessed ctDNA ratios relative to baseline and found low ratios on day 15, with no significant difference in decline between patients with and without disease progression. Instead, they found that ctDNA ratios on day 30 relative to baseline distinguished patients with non-progressive disease (ratio < 1) and progressive disease (ratio > 1) and that high ctDNA ratios were associated with worse PFS. This study supports that monitoring of ctDNA is related to radiological progression and demonstrates the potential of ctDNA dynamics on day 30 relative to baseline as a prognostic biomarker for patients treated with CDK4/6 inhibitors.

In contrast to the studies highlighted above, ctDNA dynamics can be monitored using the combined signal from profiling changes in many mutated genes instead of specific mutations. For instance, a recent study assessed ctDNA levels at baseline and four weeks for 45 patients treated with CDK4/6 inhibitors and

endocrine therapy using the 73-gene Guardant360 assay^[88]. This work defined a mean variant allele fraction (mVAFR) as an average of mutations found between baseline and week 4 for each patient. They found that mVAFR was significantly associated with PFS, whereas single timepoint mean VAFs or absolute changes in mean VAF were not. One consideration of this study is that they assessed PFS with respect to three mVAFR groups (high, medium, and low) with cutoffs based on their cohort before assessing mVAFR as a continuous variable. Another limitation of this study was that they could not distinguish mutations from clonal hematopoiesis. Altogether, this study illustrates that early ctDNA dynamics in multiple genes may act as a biomarker to identify patients who are likely to progress on CDK4/6 inhibitors and endocrine therapy, which may provide the opportunity to modify or add treatments early on.

An additional study evaluated ctDNA using an untargeted sequencing technique, modified Fast Aneuploidy Screening Test-Sequencing System (mFAST-seq) in longitudinal samples from 49 HR+/HER2- metastatic breast cancer patients treated with CDK4/6 inhibitors^[89]. In this work, associations between z-score measurements, which are surrogate measurements to ctDNA fraction, were made to clinical outcomes using joint models, which link data over a protracted period of time and time-to-event. They found that raised z-score trajectories were significantly related to worse PFS, whereas baseline z-scores were not predictive of progression. Interestingly, they found that a single rise z-score in a consecutive blood sample at any follow-up point was not associated with PFS. This study highlights the use of different assays in dynamic monitoring and reinforces that trajectories, as opposed to single time points, may be useful biomarkers of progression on anti-CDK4/6 therapy. A limitation of this approach is that mutations were not assessed, which may be relevant in the future for potential interventions or modifications to treatments. Also, this study evaluated z-score measurements at 181 time points for 49 patients, but these were not standardized and did not address the optimal time to sample. They also observed that some patients with progressive disease did not have raised z-scores over time and may be due to long intervals in sampling failing to detect an increase. This may be elucidated by shorter and more consistent sampling in future studies.

Overall, the current literature on monitoring ctDNA dynamics for patients treated with CDK4/6 inhibitors is limited. Differences in methods, patient populations, sampling time points, assays, and change thresholds lead to discordance across studies. Determining ideal change thresholds and timepoints will be essential for downstream clinical decisions. Future research should evaluate a more comprehensive range of consistent time points. Another important consideration is the way mutations are interrogated in ctDNA. Methods can vary dramatically by the number of tumor-specific markers assessed. ddPCR and related single-locus approaches can have high analytical sensitivity and specificity for a specific mutation, but other mutations and subclones that may be relevant to treatment resistance are ignored. Broader targeted panel sequencing approaches can be more robust by simultaneously interrogating multiple mutations and accounting for potential mechanisms of resistance^[64,72]. Bespoke assays designed for each patient based on tumor tissue sequencing results [e.g., TARgeted DIgital Sequencing (TARDIS) and Signatera] show promise for sensitive and specific ctDNA detection^[63,73,90,91], although emergent subclones that are not present in the tissue specimen can be missed^[54]. Future studies may benefit from combining these approaches to achieve high analytical performance while enabling broad discovery.

EPIGENETIC-BASED LIQUID BIOPSY BIOMARKERS OF CDK4/6 INHIBITOR EFFICACY AND RESISTANCE

As outlined in the previous sections, most CDK4/6 inhibitor ctDNA studies have focused on genetic alterations (e.g., small nucleotide variants, copy number aberrations, *etc.*). In contrast, epigenetic alterations have been relatively understudied in this context. Emerging methodologies now make it easier to profile epigenetic aberrations in ctDNA, including DNA methylation, fragmentation, and histone modifications^[92].

This new generation of liquid biopsy investigations has expanded the potential diagnostic use of cfDNA compared to genetic alterations on their own (e.g., providing information on the tissue of origin). Investigating epigenetic-based features has also expanded the number of cfDNA fragments of interest beyond solely mutated tumor-derived fragments. Supporting these new methods is a maturing research infrastructure (e.g., bioinformatics infrastructure, machine learning tools) for handling increasingly complex cancer liquid biopsy data^[93]. Since genetic alterations in ctDNA have failed to identify clear predictive biomarkers of CDK4/6 inhibitor efficacy and resistance, there is interest in exploring the potential value of epigenetic-based biomarkers in this setting.

Phenotype of CDK4/6 inhibitor resistance and gene expression profiling

Support for epigenetic liquid biopsy approaches comes from previous work highlighting that phenotypic biomarkers that reflect transcriptomic programs are likely to predict response to CDK4/6 inhibitors. As summarized below, multiple gene expression analyses have demonstrated the effect of CDK4/6 inhibitors on proliferation and cell cycle genes, and patterns associated with resistance have been proposed.

An analysis of ER+/HER2- breast cancer patients in the NeoPalAna trial explored gene expression changes through serial tissue biopsies at baseline, cycle one day 1, cycle one day 15, and surgery. High expression of *CCNE1*, *CCND3*, and *CDKN2D* at cycle one day 15 was associated with resistance to neoadjuvant palbociclib plus anastrozole but not anastrozole alone^[94]. These gene expression changes suggest that resistant tumors have continual E2F1 activity. Similarly, a gene expression analysis on tissue samples from baseline and surgery from patients treated with preoperative palbociclib found large-scale changes in genes related to proliferation and cell cycle after treatment, including a significant decrease in *CCNE2* expression in antiproliferative responders compared to nonresponders^[95].

A substudy of the PALOMA-3 trial yielded partially confirmatory findings^[96]. Gene expression of 2534 cancer-related genes from 302 patient tumors revealed that high expression of *CCNE1* - but not other genes related to cell cycle regulation (*CDK4*, *CDK6*, *CCND1*, and *RB1*) - was associated with resistance to palbociclib (median PFS palbociclib arm: 7.6 vs. 14.1 months high vs. low; placebo arm: 4.0 vs. 4.8 months high vs. low). The increased predictive power of *CCNE1* mRNA in metastatic biopsies suggests that sampling closer to treatment allows improved identification of predictive biomarkers, which may be facilitated by liquid biopsy. The authors also confirmed the potential role of *CCNE1* as a predictive biomarker in an independent validation cohort of breast cancer patients from the preoperative palbociclib study, where high *CCNE1* levels were associated with a decreased antiproliferative effect with palbociclib.

Further support for *CCNE1* mRNA as a predictive biomarker stems from a series of studies examining expression levels relative to those of *RB1*. One study of ER+/HER2- preclinical models found that joint decreased expression of *RB1* and increased expression of *CCNE1* commonly occurred at resistance^[97]. The ratio of *CCNE1* to *RB1* was then confirmed to be associated with palbociclib resistance among patients in the NeoPalAna trial. Another study of patients treated with abemaciclib and anastrozole alone or combined within the neoMONARCH trial found that resistant tumors had higher expression levels of *CCNE1* and lower levels of *RB1*^[98]. High tumor *CCNE1* expression was again associated with poor PFS among 391 patients treated with letrozole plus ribociclib in the MONALEESA-2 trial^[41]; interestingly, this study also identified *FGFR1* expression as a putative biomarker for CDK4/6 inhibitors (PFS of 22 months vs. not reached for patients with high vs. low *FGFR1* expression, respectively).

One limitation of many studies correlating gene expression and PFS is that high and low expression thresholds are often determined above and below the median expression level in the cohort. Thresholds that

are biased to the study cohort make it challenging to assess the prognostic or predictive potential, make comparisons across studies, and translate biomarker development to the clinic. Regardless, the current evidence supports that gene expression may predict CDK4/6 inhibitor efficacy or resistance. Considering gene signature assays can become routine in the clinical management of ER+ breast cancer patients, such as MammaPrint and OncotypeDx, specific gene signatures that are predictive of therapy with CDK4/6 inhibitors may be defined and developed^[27,29]. However, these assays require tissue samples, which have barriers to accessibility and are often limited by the quality and quantity of RNA after FFPE chemical degradation^[99]. This becomes especially difficult to derive from archival tissue specimens collected years before metastatic relapse. Many of these obstacles may be overcome by assessing transcriptional and epigenetic profiles with liquid biopsy.

Opportunities of non-mutational signatures of cfDNA

The potential of epigenetic mechanisms and biomarkers for CDK4/6 inhibitor resistance has so far not been examined in detail, and investigating these avenues may provide novel insight. For instance, one recent study showed that treatment with CDK4/6 inhibitors in ER+ breast cancer causes extensive enhancer activation through activator protein-1 (AP-1) transcriptional changes. They found that the widespread chromatin remodeling with CDK4/6 inhibitor treatment may explain the effects of these drugs beyond cell cycle arrest and may be involved in early adaptations leading to resistance^[100]. These epigenomic changes may also be inferred from various features of ctDNA, such as methylation, fragmentation patterns, and histone modifications [Figure 1].

DNA methylation, namely 5-methylcytosines at CpG sites, is a vital part of cell-type-specific transcriptional regulation, and methylation profiles differ between tumor and normal tissues^[101]. These differential methylation patterns are maintained in plasma cfDNA and can classify cancer types with high sensitivity in both early and late-stage disease^[102,103]. Differential plasma cfDNA methylation patterns can also be leveraged to delineate the contribution of various tissues to the cfDNA pool and infer the expression of genes implicated in cancer^[57,103,104]. One study investigated methylation-based biomarkers in the context of CDK4/6 inhibitors by assessing the methylation status of *ESR1* in plasma cfDNA from a cohort of 49 HR+/HER2- metastatic breast cancer patients treated mostly with endocrine therapy and CDK4/6 inhibitors. Using samples from baseline and at three months, they assessed methylation levels at two main promoters with methylation-specific ddPCR. They found that a greater than 2-fold increase in promoter B or both promoters was associated with a worse prognosis^[105]. While this study has various limitations, such as a small heterogeneous cohort, inability to dissect endocrine and CDK4/6 inhibitor effects, and analysis of limited loci, it paves the way for both epigenetic and dynamic cfDNA biomarker discovery approaches.

Future studies of DNA methylation in the CDK4/6 inhibitor treatment setting should consider other technical approaches. For instance, while the analysis of limited CpG sites is practical in many clinical settings for simplicity of interpretation and lower costs, expanding to genome-wide explorations may uncover novel candidate resistance biomarkers. Furthermore, bisulfite conversion is necessary for most methylation techniques but can result in excessive loss of DNA due to degradation, which is a substantial challenge for low-input cfDNA samples^[106]. Forthcoming research should leverage other methods that surpass these limitations by enriching specifically for methylated fragments of cfDNA before sequencing^[104,107,108]. Moreover, hydroxymethylation is a related epigenetic modification produced by TET enzymes during cytosine demethylation and acts as a marker of active promoters^[109]. Though less studied in cfDNA, similar enrichment techniques have been developed to assess regions with 5-hydroxymethyl cytosines^[110,111]. These approaches may be especially useful for revealing surrogates of gene expression that could confer sensitivity or resistance to CDK4/6 inhibitors.

Phenotypic information can also be inferred from distinct fragmentation patterns between ctDNA and other sources of cfDNA. The fragmentation of cfDNA is a non-random process associated with chromatin structure, gene expression, and nuclease content. Differences in nucleosome occupancy patterns at open versus closed chromatin and across varying gene expression levels affect where nucleases can access and fragment the DNA^[92]. This, in turn, is reflected in the physical characteristics of the cfDNA fragments and their distribution over the genome (i.e., fragmentation features), revealing information about cell and tissue of origin. Early work on cfDNA fragments revealed differences in fragment length, a phenomenon that multiple studies have leveraged to enrich ctDNA and improve the accuracy of cancer detection^[112-117].

Beyond fragment length, many other fragmentation features have also been investigated, including relative sequence coverage^[118-124], end motifs^[125-129], and more^[130-132]. There is substantial evidence that these features convey information about DNA protection from digestion, which multiple studies have used to create cfDNA deduced nucleosome maps^[58,118,120,133]. The fragmentation profiles from this work have been correlated with gene expression profiles and permitted identification of cancer type^[118,120,123].

The association of fragmentation profiles with transcriptional activity may present opportunities to infer existing candidate gene expression biomarkers of CDK4/6 inhibitor resistance (e.g., *CCNE1* expression) with cfDNA in blood plasma while simultaneously permitting assessment of clinically actionable mutations to direct subsequent therapies. While promising, there remain several practical hurdles to implementing such biomarkers in the clinic. Pre-analytical variables could influence fragmentation features, and their extraction from sequencing data requires complex bioinformatics analysis. However, if these hurdles can be overcome, fragmentation-based biomarkers could greatly extend the utility of ctDNA analysis in the CDK4/6 inhibitor biomarker setting and beyond.

Another class of epigenetic modification has recently been proposed for liquid biopsy applications: post-translational modifications of nucleosomal histones in circulation. These modifications differ in euchromatin compared to heterochromatin and may signal transcriptionally active (e.g., H3K4me3, H3K36me3) or repressed (e.g., H3K27me3, H3K9me3) regions of the genome^[134]. Furthermore, histone modifications may signal chromatin remodeling and transcriptional changes between cancer and healthy cells. Initial work found a global decrease in repressive histone markers across multiple cancer types^[135,136]. In a recent study, cell-free chromatin immunoprecipitation and sequencing (ChIP-seq) was conducted to identify regions associated with transcriptionally active histone modifications^[137]. This approach revealed signals reflective of distinct tissues and cancer types, potentially expanding the toolbox for biomarker discovery in the context of CDK4/6 inhibitors for breast cancer patients.

Overall, epigenetic profiling of cfDNA has many potential benefits that have gone mostly unexplored in the context of breast cancer resistance to CDK4/6 inhibitors. More investigation is needed to elucidate epigenetic signatures and determine which features are the most informative from the vast list growing in the literature. A combination of approaches may increase the predictive power compared to any method alone and increase the ability to direct subsequent therapies^[138-140].

CONCLUSION

Biomarkers are essential for precision oncology, and despite widespread research efforts, no clinically validated biomarkers beyond breast cancer subtype have been established to guide the use of CDK4/6 inhibitors. Liquid biopsy presents many benefits for biomarker development due to being minimally invasive and encompassing the heterogeneity of metastatic sites. Accordingly, putative predictive biomarkers of resistance to treatment with CDK4/6 inhibitors have been found in ctDNA such as *RB1*,

KRAS, and *CCND1* genomic alterations; dynamic changes in ctDNA, such as changes in truncal mutations between baseline and cycle one day 15 or 30, or ctDNA clearance on day 30. Expression of E2F target genes such as *CCNE1* is also associated with resistance and could someday be reflected through emerging epigenetic ctDNA analysis methodologies. In addition, prognostic biomarkers such as *ESR1*, *PIK3CA*, *FGFR1*, *TP53*, and *MYC* alterations have also been identified.

To advance further biomarker discovery, future studies of trials or cohorts that included a control arm (e.g., endocrine therapy alone) will be especially valuable to permit the assessment of treatment interaction effects. In addition, it would be beneficial to investigate a broader range of alterations within ctDNA, given the low likelihood that a single alteration will be an ideal biomarker to the vast mechanisms of resistance. Thresholds for expression or dynamic changes in ctDNA should also be determined independently from the patient cohort in which they are studied to increase generalizability and reproducibility. Moreover, future work on ctDNA dynamics should sample a larger range of time points. There is also enormous potential for phenotype-based biomarkers, which may reflect widespread epigenetic changes and inform changes in tumor biology associated with resistance. There is a lack of established mutation-based liquid biopsy biomarkers, and features of cfDNA related to methylation, fragmentation, and histone modifications are uncharted in the context of CDK4/6 inhibitor resistance. These ctDNA epigenomic profiles should be leveraged for new biomarker discovery. Although this review has focused on the ER+/HER2- subtype of breast cancer, it is conceivable that novel predictive biomarkers could identify other patients likely to respond. Lastly, there have been substantial investigations into novel targeted agents for treatment after CDK4/6 inhibitor resistance. For instance, preclinical and clinical data indicate that treatment with novel endocrine therapies, PI3K/MAPK pathway inhibitors, downstream mitotic kinase inhibitors, and DNA-damage related inhibitors may each have a role in the treatment of CDK4/6 inhibitor-resistant disease^[46]. With further development, liquid biopsy biomarkers may help direct these subsequent therapies in the future, increasing the likelihood of successful clinical development and the potential impact on patient outcomes.

DECLARATIONS

Authors' contributions

Conceptualized the manuscript: Main SC, Cescon DW, Bratman SV
Performed the literature review and wrote the original manuscript: Main SC
Supervised and edited the manuscript: Cescon DW, Bratman SV

Availability of data and materials

Not applicable.

Financial support and sponsorship

S.C.M. is supported by the Canadian Institutes of Health Research (CIHR) Frederick Banting and Charles Best Canadian Graduate Scholarship. S.V.B. is supported by the Gattuso-Slaight Personalized Cancer Medicine Fund at the Princess Margaret Cancer Centre and the Dr. Mariano Elia Chair in Head & Neck Cancer Research at University Health Network and the University of Toronto.

Conflicts of interest

Main SC has no conflicts of interest to declare. Cescon DW reports consultancy and advisory fees from AstraZeneca, Exact Sciences, Eisai, Gilead, GlaxoSmithKline, Merck, Novartis, Pfizer and Roche; research

funding to their institution from GlaxoSmithKline, Inivata, Merck, Pfizer and Roche; is a member of a trial steering committee for AstraZeneca, Merck and GlaxoSmithKline; and holds a holds a patent (US62/675,228) for methods of treating cancers characterized by a high expression level of spindle and kinetochore associated complex subunit 3 (ska3) gene. Bratman SV is inventor on patents related to cell-free DNA mutation and methylation analysis technologies that are unrelated to this work and have been licensed to Roche Molecular Diagnostics and Adela, respectively. Bratman SV is a co-founder of, has ownership in, and serves in a leadership role at Adela.

Abstract

Overcoming drug resistance in cancer therapies remains challenging, and the tumor microenvironment plays an important part in it. Microvesicles (MVs) are functional natural carriers of cellular information, participate in intercellular communication, and dynamically regulate the tumor microenvironment. They contribute to drug resistance by transferring functional molecules between cells. Conversely, due to their specific cell or tissue targeting ability, MVs are considered as carriers for therapeutic molecules to reverse drug resistance. Thus, in this mini-review, we aim to highlight the crucial role of MVs in cell-to-cell communication and therefore their diverse impact mainly on liver cancer progression and treatment. In addition, we summarize the possible mechanisms for sorafenib resistance (one of the main hurdles in hepatocellular carcinoma treatments) and recent advances in using MVs to reverse sorafenib resistance in liver cancer therapies. Identifying the functional role of MVs in cancer therapy might provide a new aspect for developing precise novel therapeutics in the future.

Keywords: Microvesicles (MVs), sorafenib resistance, tumor microenvironment, cancer therapy

INTRODUCTION

Liver cancer (LC), including hepatocellular carcinoma (HCC), hepatoblastoma, and cholangiocarcinoma, remains one of the malignant cancers worldwide with high mortality^[1]. Surgery, radiotherapy and chemotherapy are considered as the main treatments for LCs at present, but their therapeutic effects are limited in advanced stages^[2]. Sorafenib, an oral drug approved by the FDA for the treatment of advanced HCC, has shown excellent therapeutic effects by inhibiting tumor growth and angiogenesis *in vitro*^[3,4]. However, reported resistance limits its therapeutic effects^[5-9]. Microvesicles (MVs), functional mediators in cell-to-cell communication by transferring bioactive cargoes^[10], play an important role in tumor progression and metastasis^[11-14]. Interestingly, recent studies reported that HCC-derived MVs promoted sorafenib resistance in recipient liver cancer cells by transporting cancerous cargo compared to normal liver cell-derived MVs^[15]. Thus, the role of these tiny functional vesicles needs to be cautiously studied for the in-depth understanding and successful treatment of HCC over sorafenib resistance.

Considering the necessity of overcoming sorafenib resistance while developing a successful treatment process for the challenging HCC, in the present review, we summarize the mechanism of action of sorafenib and sorafenib resistance. In addition, recent advances of MVs in intercellular communication and the intriguing contribution of MVs in cancer treatment are discussed. Especially, the review closely considers the possibilities for utilizing MVs as a potential therapeutic tool to alleviate sorafenib resistance in future cancer treatments.

SORAFENIB DRUG AND RESISTANCE

Mechanism of action of sorafenib

The revelation of the crucial involvement of Raf1 and vascular endothelial growth factor (VEGF) mediated signaling pathways in the molecular pathogenesis of liver cancer provided an interesting theoretic basis for applying sorafenib drugs to liver cancer treatment^[16,17]. As a multikinase inhibitor, sorafenib strongly inhibits the tyrosine kinase Raf. Meanwhile, it has been shown to inhibit vascular endothelial growth factor receptor and platelet-derived growth factor receptor, which in turn inhibits the activation of other downstream multikinase that are normally essential for cell growth, angiogenesis, proliferation and metastasis of HCC cells [Figure 1]. Liu *et al.*^[18] recorded that sorafenib inhibited the proliferation of HCC cells and reduced angiogenesis signal transduction in HCC tumor xenograft, promoting tumor cell apoptosis as well. In addition, the same therapeutic advances have also been revealed in clinical studies^[19]. Nevertheless, several studies stated that the therapeutic effects of sorafenib varied among patients, some of whom experienced severe side effects^[20-23].

Mechanism of sorafenib resistance

Drug resistance limits the therapeutic effects of HCC treatments. Roughly 30% of patients were reported to respond to sorafenib well at the beginning, while the subsequently acquired resistance to sorafenib usually happens within six months^[24], which is far from satisfactory. As an obvious contributor that hinders the effectiveness of cancer treatment, sorafenib resistance and the possible molecular mechanisms involved in sorafenib resistance become prominently important to be discussed here.

Due to the heterogeneity of liver cancer, some patients are resistant to sorafenib primarily, while others obtain sorafenib resistance during treatment, which further limits the application of the drug and leaves the treatment process questionable. Thus, the acquired resistance of sorafenib attracted the attention of a wide range of researchers^[8,25]. To date, studies on the potential mechanism of sorafenib resistance have mainly focused on the activation of drug targets and downstream signaling, regulation of cell proliferation and apoptosis signaling^[5-9]. In addition, stemness and mesenchymal states of sorafenib-resistant HCC cells

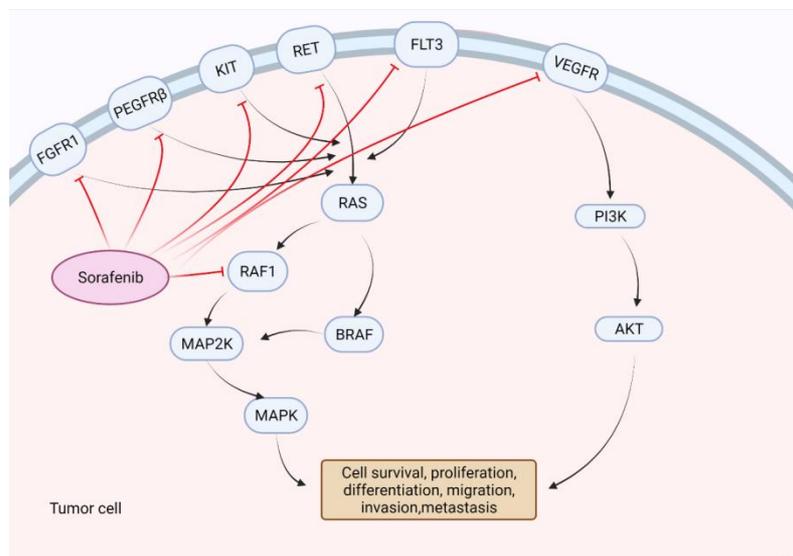

Figure 1. Mechanism of actions of sorafenib. Sorafenib inhibits tyrosine kinase receptor (VEGFR, PDGFR β , Kit and RET) signaling and suppresses the activation of Raf, thus could suppress tumor progression by inhibiting angiogenesis and cell proliferation. Created with BioRender.com. VEGFR: Vascular endothelial growth factor receptor.

provided a new aspect of this challenging problem^[26]. Altogether, the mechanism of sorafenib resistance and its influence on the treatment process remain complicated and require more research for a better understanding.

The epidermal growth factor receptor (EGFR) has been found to be overexpressed or hyperactivated in the cancer cells of most liver cancer patients as well as be the reason for continuous activation of its downstream signaling of the Ras/Raf/MEK/ERK pathway. This contributes to the abnormal proliferation of cancer cells and therefore might promote sorafenib resistance^[27]. For instance, an attenuated level of phosphorylated ERK was reported to be associated with sorafenib resistance in HCC^[28]. In addition, hyperactivated EGFR/HER3 and its overexpressed ligands were reported to suppress the curative effect of sorafenib by interfering with the phosphorylation of EGFR/HER3, by which the enhanced anti-proliferative and pro-apoptotic abilities of sorafenib could be achieved during the treatment^[29].

A body of evidence reveals that the PI3K/Akt pathway plays an important role in sorafenib resistance^[5,30]. For instance, Chen *et al.*^[5] found that exposure of Huh7 liver cancer cells to a high concentration of sorafenib could result in sorafenib resistance and an accelerated expression of Akt in the treated cells. Furthermore, the PI3K/Akt pathway has been identified to have a close relationship with cell apoptosis. In the pathway, the combination of pro-survival factor and tyrosine kinase receptor activates the kinase PI3K, which triggers the downstream cascade to endorse phosphorylation of Akt and thus contributes to the suppression of cell apoptosis. In turn, inhibition of Akt could make the tumor cell more responsive to sorafenib treatment^[31]. Hence, silencing of PI3K/Akt signaling with Akt inhibitor alone or with other combination therapy has gained attention for reversing sorafenib resistance for better HCC treatment^[32,33]. Furthermore, Src homology 2 domain-containing protein tyrosine phosphatase 1 (SHP-1) has been reported to be activated by sorafenib, which in turn could negatively regulate pSTAT3 and suppress transduction of JAK/STAT signaling. Dysfunctional JAK/STAT has been observed in sorafenib-resistant liver cancer cells, including induced expression of pSTAT3 and its downstream anti-apoptotic protein Mcl-1 and reduced expression of SHP-1/pSHP-1^[34].

Moreover, cancer stem cells (CSCs), which represent a subpopulation of cancer cells with a self-renewal nature, are considered to participate in tumorigenesis, drug resistance, tumor metastasis and recurrence, and they are innovative targets for cancer therapy^[35-37]. Label-retaining cancer cells (LRCCs) can be used to label CSCs. Xin *et al.*^[38] used this methodology to observe sorafenib treated HCC cells and found that LRCCs were highly enriched in the remaining HCC cells that escaped sorafenib treatment, which strongly evidenced the resistance to sorafenib-induced cytotoxicity and apoptosis. In addition, specific ATP binding box (ABC) transporters have been reported to be highly expressed on CSCs, which control the outflow of chemical agents to protect cells from toxic compound accumulation and damage, and hence could reduce the sensitivity of cells towards drug treatment^[39,40]. ABCB1 has been attested to have a close relationship with multidrug resistance; thereby, knocking out ABCB1 in drug-resistant cancer cell lines made those cells more responsive to chemotherapies^[41]. It was also revealed that CSCs isolated from HCC cell lines showed resistance to sorafenib both *in vitro* and *in vivo* with abnormal IL-6/STAT3 signaling^[6]. Through VEGF, liver cancer stem cells could promote tumor angiogenesis to sustain their stemness as well as drug resistance features^[42]. In addition, Wnt/ β -catenin signaling, one of the classic pathways involved in stemness regulation^[43,44], was proven to be hyperactivated in HCC cells, resulting in β -catenin accumulation in cytoplasm and nucleus, which finally led to enhanced self-renewal ability of CSCs^[45,46]. Inhibition of Wnt signaling has been shown to be beneficial to CSC clearance and tumor development^[46,47].

Dual biotransformation routes including oxidation and glucuronidation were witnessed in the sorafenib metabolism^[48-50]. After hepatocellular uptake, sorafenib was N-oxidized by CYP3A4, one of the drug-metabolizing enzymes, to the pharmacologically active sorafenib-N-oxide metabolites^[51,52]. However, CYP3A4 was identified as poorly expressed in liver cancer^[53]. Well-studied oncomiRs (e.g., miR 21, miR-142 and miR-27b) overexpressed in HCC, which could be transferred by tumor-derived microvesicles (TMVs), were proved to be negatively associated with CYP3A4 mRNA in human liver^[54], which might downregulate the expression of this main enzyme and thus could inhibit the active biotransformation of sorafenib drug. Apart from oxidation, sorafenib underwent glucuronidation, mainly mediated by UGT1A1 and UGT1A9, to inactive glucuronide metabolites^[48,55]. A recent study revealed that sorafenib inhibits the above-mentioned UGT enzyme^[56], which might be the blockage for sorafenib secretion to bile and later systemic circulation and clearance. Taken together, the insufficient oxidation and complex interaction between sorafenib and UGT enzymes need further investigation for a deep understanding of their role in resistance.

Anti-angiogenesis is one of the therapeutic effects of sorafenib, while the tumor vessel depletion along with pericyte could induce hypoxia and allow the maintenance and enhancement of CSCs in HCC^[57,58]. Apart from specific niches, different stroma cells in the microenvironment render sorafenib sensitivity^[59], where MVs play a significant role.

MVS: THE TINY MEDIATORS IN INTERCELLULAR COMMUNICATION

MVs, a subpopulation of extracellular vesicles (EVs), act as functional mediators by transferring bioactive molecules among various types of cells and thus have been considered as potential candidates in intercellular communication^[10]. Through unconventional secretion mechanisms, eukaryotic cells were reported to release membrane-enclosed vesicles both *in vivo* and *in vitro*^[60]. In general, MVs can be collected from cell culture media and blood from animals and patients via ultracentrifuge method, filtration, or commercial kits^[61]. MVs are also identified as shedding microvesicles or microparticles, budding directly from the plasma membrane and are 100 nm-1000 nm in diameter. They participate in cell-to-cell communication by carrying the information from parental cells to others and orchestrate complicated physiological and pathological processes^[14,62]. At the molecular level, symmetrical perturbation of membrane lipids leads to the surface expression of phospholipid serine acid pairs, which translocate from the inner

lobule to the outer surface lobule of the membrane bilayer through special biological enzymes (floppases, flippases and scramblases), contributing to MVs formation^[63]. However, the detailed mechanism of MVs formation and shedding remains to be further studied.

Evidence reveals that most MVs tend to be decomposed after shedding to release their cargo^[64]. Especially, various cytoplasmic proteins, excluded from the classic signal-peptide secretion pathways, are discharged out regularly through MV decomposition^[65]. For instance, fibroblast growth factor 2 (FGF2) was proved to be released in response to the breakdown of MVs derived from neurons, HCC and endothelial cells^[66]. Similarly, MVs secreted by dendritic cells, macrophages and microglia have been demonstrated to release the pro-inflammatory cytokine interleukin 1B (IL-1B); IL-1B has also been found to aggregate in MVs along with proteases such as caspase 1^[67]. A study on tumor-stromal interactions noted that when MVs were co-released with extracellular matrix metalloproteinase inducer (EMMPRIN/CD147), they prompted lung cancer cells to obtain increased mobility and invasion ability by promoting metalloproteinase to capture and digest extracellular matrix (ECM)^[68]. In addition, Kornek *et al.*^[69] demonstrated that EMMPRIN released by circulating T cell-derived MVs accelerated hepatic stellate cells to transform into a fibrolytic phenotype, which promotes ECM degradation.

Conversely, MVs are able to stimulate the receptor cells to complete signal transduction through their surface ligands. It has been confirmed that MVs derived from platelet arouse the intra-hemopoietic signal cascade by ligands such as CD40L/PF-4 and thus cause the proliferation and survival of hematopoietic cells^[70]. Simultaneously, the adhesion molecules could be transferred to hematopoietic cells via MVs to enhance their adhesion to fibrinogen or endothelium^[70]. Proteomic and transcriptomic studies have shown that MVs are natural vectors for transferring bioactive molecules, including protein, mRNA and miRNA, between cells^[71], effectively facilitating intercellular communication^[72,73]. In addition, MVs hold natural stability in the blood, low immunogenicity and special homing ability to specific organs or tissues^[74]. Evidence shows that vesicle-associated integrins $\alpha 6\beta 4$ and $\alpha 6\beta 1$ are correlated with lung metastasis while $\alpha V\beta 5$ with liver metastasis, which indicates the various origins of MVs encoded with different tags for the corresponding cells or organ targeting^[74]. Moreover, it has also been demonstrated that MVs could possibly transport even complete organelles (e.g., mitochondria) to target cells^[75], which declares its potential to act as a promising novel drug carrier system.

Several studies revealed that TMVs transport cancerous molecules to recipient cells, which eventually contribute to tumor progression and metastasis^[11-14,76] [Figure 2]. Interestingly, the transport of anti-cancer drugs out of ovarian cancer cells through their secreted EVs supported the role of EVs in cancer progression and treatment. Conversely, the observation of more sorafenib resistance in HCC tumors that were treated with tumor cell-derived MVs added evidence to the noticeable link between MVs and sorafenib resistance^[15,78].

THE DYNAMIC IMPACT OF MVs ON SORAFENIB RESISTANCE

MV-mediated sorafenib resistance

The physiological status of parental cells decides the composition of their secreted MVs, having direct or indirect effects on the uptake of MVs by recipient cells. Tumor cells that undergo hypoxic stress and obtain stemness or mesenchymal state for survival^[57,58] promote tumor progression and therapy resistance. By inducing hypoxic stress, the hypoxia-inducible factor-1 α could stimulate the release of MVs along with the modulation of its packed cargoes^[79]. Similarly, Wang *et al.*^[80] reported that chemotherapeutic agents could enhance the secretion of ABCB-1-enriched EVs, which promote resistant phenotype transformation in recipient cells. Specifically, growth and pro-angiogenic factors transferred between CSCs and vascular

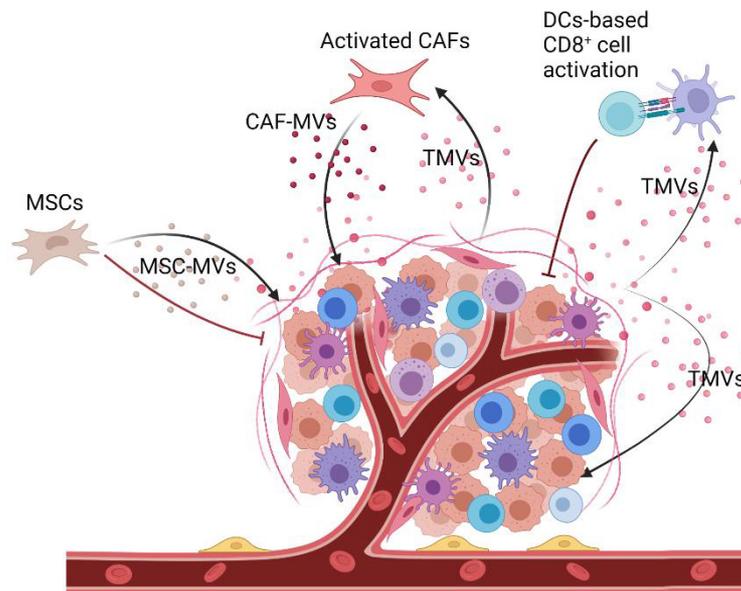

Figure 2. The bidirectional role of TMVs in tumor development. TMVs derived from tumor cells could promote tumor progression via transferring cancerous molecules^[13,62]. Simultaneously, they act as a functional regulator to modulate DC cells based on CD8⁺ T cell activation, which provokes cytotoxic T cell infiltration and inhibits tumor development^[77]. Created with BioRender.com. TMVs: Tumor-derived microvesicles.

niches via vesicles under hypoxia were witnessed^[81] to limit the therapeutic effect of sorafenib.

Cancer-associated fibroblasts (CAFs), one of the main stroma cells, advance the self-renewal feature of CSCs in HCC and thus could induce sorafenib resistance by secretion of hepatocyte growth factor (HGF)^[82,83]. A reduction in cancer cell stemness was recorded by inhibiting the paracrine behavior of CAFs^[84]. Conversely, TMVs have been shown to activate CAFs to improve the mobility of tumor cells, while the activated fibroblasts could secrete MVs and in turn facilitate tumor progression^[12,85]. Moreover, small GTPases and RHO-associated protein kinase, key factors in the biogenesis of MVs^[73], were found to be highly expressed in both CAFs and cancer cells^[86], which indicates the possible role of CAFs in the alteration of MVs secretion.

As the messengers and mediators between cells, MVs could regulate the sorafenib sensitivity in the recipient cells via their cargoes [Table 1]. For example, miRNAs involved in the regulation of multiple mRNA targets in recipient cells were found to be enriched in TMVs^[94-97]. In recent years, our group also found that HCC cell-derived MVs could increase sorafenib drug resistance by inducing FOXM1 expression via miR-25 transferred to the recipient liver cancer cells from the parent cells both *in vitro* and *in vivo*^[15]. Similarly, long non-coding RNA (lnc-ROR and lnc-VLDLR)-enriched HCC cells-secreted vesicles (especially after sorafenib exposure) were proved to reduce apoptosis induced by chemotherapy^[88,89]. However, MVs released from modified adipose tissue-derived MSCs have been shown to carry miR-199a/miR-122 and have the ability to improve chemosensitivity in HCC^[90,91]. Elevated miR-214 in human cerebral endothelial cell-released vesicles was noted to enhance the anti-tumor efficacy of sorafenib^[92] [Figure 3]. However, complete genomic and proteomic analyses of preclinical MVs cargoes need to be performed in the future.

Targeting MVs to reverse sorafenib resistance

Recently, the promising outcome of targeted gene therapy has motivated more researchers to meet sorafenib resistance in HCC. A lower expression of miR-34 has been found to have a direct relationship

Table 1. Key molecules transferred by MVs modulating sorafenib resistance

Key molecules	MVs sources	Function	Ref.
miR-25	HCC cells	Increase sorafenib resistance	[15]
miR-494-3p	GOLPH3 overexpressed HCC cells	Promote the angiogenesis ability of HUVECs and induce sorafenib resistance in HCC cells	[87]

with patient survival, while the restoration of the miR-34a expression level in HCC cells has been noted to significantly downregulate the expression of BCL2 and enhance the cells' sensitivity towards sorafenib-induced apoptosis and toxicity^[7]. Dai *et al.*^[98] found that BikDD gene therapy combined with low-dose sorafenib could enhance the anti-tumor efficacy of sorafenib and improve the survival rate of tumor-bearing mice. Furthermore, the simultaneous release of sorafenib and USP22 shRNA (shUSP22) by galactose-modified lipopolysaccharide revealed that the encapsulated sorafenib along with shUSP22 could obtain a synergistic anti-proliferative effect in HCC cells by inducing reactive oxygen cascade to promote the release of shUSP22 and inhibit the expression of USP22 in HCC cells, which promoted the accumulation of sorafenib by downregulating the expression level of multidrug resistance-related proteins^[99].

Several emerging studies reported utilizing modified EVs to overcome chemoresistance during cancer treatments. As a naturally secreted nanoparticle, MVs exhibited excellent specific tissue homing ability and acted as good functional carriers for various therapeutic molecules^[15,74,100]. To achieve bioactive and

continuous drug containing MVs, the pre-loading strategy has been applied to modify donor cells. This strategy includes incorporating cargo into donor cells, so the donor cells could encapsulate the cargo during secretion production. Both biologically produced molecules (proteins and nucleic acids) and synthetic chemicals can be encapsulated into secreted vesicles^[2]. By combined regulation of Akt/mTOR/PTEN, EVs secreted from human liver stem cells were proved to upgrade CSCs' sensitivity to sorafenib^[101]. Lou *et al.*^[91] stated that treating HCCs with exosomes derived from miR-122 overexpressed AMSCs rendered HCCs more responsive to sorafenib. In the same way, miR-744-enriched exosomes have been demonstrated to be a potential tool for reducing sorafenib resistance^[102]. Apart from utilizing the intrinsic homing ability, controllable targeting methods, including genetic engineering (pre-targeting)^[103] and conjugation of ligands (post-targeting)^[104], have also been developed for further clinical research. Engineering the donor cells by inserting sequences that encode desired targeting protein makes the affibody express on the surface of MVs^[105]. In this way, our group also recently recorded that CRISPR system-carried engineered MVs derived from HEK293 cells could precisely disrupt IQGAP1, which is involved in PI3K/Akt signaling, and achieved an enhanced synergistic anti-cancer effect when combined with sorafenib treatment^[106].

CONCLUSION

Sorafenib resistance remains challenging in HCC treatment, while targeting the suspicious genes involved in the resistance mechanism to shut off the pathological cycle provides a new chance for advancing the cancer treatment as well as the existing anti-cancer drug^[107]. For instance, by delivering sorafenib and CRISPR system via nanoparticles, Zhang *et al.*^[108] achieved effective modification of EGFR, following synergistic inhibition of angiogenesis and tumor cell proliferation. Even though emerging synthetic nanomaterials have shown great abilities as therapeutic vectors, their long-term safety remains uncertain.

MVs, cell-derived natural carriers, are advanced promising gene therapy vehicles that could specifically deliver therapeutic bioactive molecules^[109]. Platelet-derived MVs have been reported to hold good biocompatibility to target leukemia cells naturally and thus have been utilized as targeted delivery vehicles for multiple drugs in leukemia treatment^[110]. Macrophage-derived MVs have been noted to have the ability to transport cargoes specifically to hematopoietic stem and progenitor cells (HSPCs) both *in vivo* and *in vitro*. In addition, Kao *et al.*^[100] showed that plasmids and small RNAs (miRNA and siRNA) that were encapsulated by macrophage-derived MVs exhibit successful modification of heat shock protein in the recipient HSPCs. In addition, MVs were used to transport engineered minicircle DNA by researchers to achieve good gene-mediated prodrug transformation and effectively promote tumor cell death in breast cancer cells as well as mouse models^[111]. However, the unexpected combination, modification, and dissociation of the above-mentioned therapeutic nucleic acids are the main concerns in gene manipulation techniques, in which the off-target effect needs to be well controlled in future clinical trials.

Considering the challenges of sorafenib resistance and MVs as the functional regulator in cancer microenvironment, in this review, we discuss the potential role of MVs in sorafenib resistance. On the one hand, in cancer progression, MVs transport bioactive molecules to participate in cell-to-cell communication, making the microenvironment favor tumor growth, which could facilitate the tumor cells to be resistant to sorafenib treatment. On the other hand, therapeutic molecules could be transferred specifically to tumor cells to alleviate the sorafenib resistance via MVs. Thus, a better understanding of these tiny players' role in tumor microenvironment and cancer progression is necessary to appropriately use this double-edged sword for precise anti-cancer therapies in the future.

Abstract

Osteosarcoma (OS) is the most common type of bone sarcoma. Despite the availability of multimodal treatment with surgery and chemotherapy, the clinical results remain unsatisfactory. The main reason for the poor outcomes in patients with OS is the development of resistance to methotrexate, cisplatin, doxorubicin, and ifosfamide. Molecular and cellular mechanisms associated with resistance to chemotherapy include DNA repair and cell-cycle alterations, enhanced drug efflux, increased detoxification, resistance to apoptosis, autophagy, tumor extracellular matrix, and angiogenesis. This versatility of cells to generate chemoresistance has motivated the use of anti-angiogenic therapy based on tyrosine kinase inhibitors. This approach has shown that other therapies, along with standard chemotherapy, can improve responses to therapy in patients with OS. Moreover, microRNAs may act as predictors of drug resistance in OS. This review provides insight into the molecular and cellular mechanisms involved in the development of resistance during the treatment of OS and discusses promising novel therapies (e.g., afatinib and palbociclib) for overcoming resistance to chemotherapy in OS.

Keywords: Osteosarcoma, therapy resistance, tyrosine kinase inhibitor, tumoral extracellular microenvironment, cell cycle

INTRODUCTION

Osteosarcoma (OS) is the most common type of bone sarcoma; these tumors form a heterogeneous group of malignant neoplasms characterized by the production of osteoid matrix^[1,2]. OS is disseminated by the hematologic route, and the lungs are the main site of metastasis^[2-4]. It is considered that up to 70% of patients with OS have at least one micrometastatic disease at this site at the time of diagnosis^[5]. The addition of chemotherapy to the treatment of patients with localized disease OS improves their prognosis, increasing their survival rate by up to 70%^[1,4,6]. However, metastatic patients continue to have a poor prognosis at 20%-30%^[7].

The current standard treatment modalities for OS are neoadjuvant chemotherapy, surgery and adjuvant chemotherapy. Chemotherapy is based on different combinations of doxorubicin (DOX), cisplatin, and methotrexate (MTX). The administration of the latter depends on the age of the patient and may be combined with ifosfamide (IFO), etoposide, *etc.*^[8,9]. The current chemotherapy scheme was first introduced in the late 1970s and remains virtually unchanged despite numerous efforts to improve treatment outcomes^[10]. One of the current clinical challenges is drug resistance, which may be inherent or acquired^[11]. Additionally, patients with poor response and refractory disease (i.e., recurrent or progressive) have a bleak prognosis due to the limited number of effective options in second- or third-line chemotherapy^[12-14].

This situation has generated several lines of research to identify the pathophysiological mechanisms by which OS cells develop drug resistance and, thus, devise new strategies based on the utilization of biomarkers or targeted therapies^[11,15,16]. The high degree of heterogeneity observed in OS renders therapy even more problematic; for instance, the discovery of reliable biomarkers, recognition of the mechanism of recurrence, and identification of cell types that cause OS pose challenges to investigators^[17]. Cancer cells can utilize various mechanisms to circumvent or counteract the cytotoxic stimuli induced by anticancer therapy: (1) impairment of drug transport and enhancement of drug efflux; (2) increase in deoxyribonucleic acid (DNA) repair; (3) alterations in cell cycle and apoptosis; (4) activation of signal transduction pathways; (5) the tumor microenvironment (TME) and angiogenesis; (6) autophagy; (7) micro-RNA; and (8) maintenance of a stem cell-like phenotype^[18]. The purpose of the present narrative review is to summarize the advances achieved thus far in this setting and present some perspectives for the treatment of OS in the future using novel drug combinations.

IMPAIRED INTRACELLULAR ACCUMULATION

OS cells decrease drug accumulation to overcome the cytotoxic effects of chemotherapeutic agents. Insufficient drug transport can be related to reduced folate carriers on the cell membrane, increasing drug efflux, or inducing alterations in target enzymes^[18].

Insufficient drug transport

Impaired drug transport is a well-described mechanism of resistance to chemotherapy in OS. In particular, this is achieved through a decrease in transporters present on the membrane of tumor cells. MTX is an anti-folate that uses the reduced folate carrier (RFC) to enter OS cells. Following entry, MTX is polyglutamylated to be retained in the cells. Subsequently, MTX inhibits dihydrofolate reductase (DHFR) - the enzyme that converts the dihydrofolate to tetrahydrofolate - which is a one-carbon donor for the *de novo* synthesis of purine and thymidine. DHFR is essential for the *de novo* synthesis of DNA, and the interaction between

MTX and DHFR prevents DNA synthesis^[18]. Treatment-resistant OS cells have reduced expression of RFC^[19]. The decreased expression of RFC in the tumor is associated with the development of resistance to MTX and poor histological responses to preoperative chemotherapy^[20]. Drugs, such as trimetrexate, do not require RFC for transport. In a phase 2 clinical trial including patients with relapsed OS, toxicity was acceptable, myelosuppression was the major side effect, objective response was 8% ($n = 39$; complete response = 1, partial response = 2, mixed response = 1, and stable disease = 8)^[21-23]. The combination of trimetrexate with high-dose MTX is currently being tested in a phase 1 trial to evaluate the efficacy, safety profile, and most appropriate dose of trimetrexate (clinical trial identifier: NCT00119301)^[24] [Figure 1].

Enhancement of drug efflux

Drug resistance in OS has been linked to an increase in drug efflux, particularly for DOX. This acquired resistance mechanism is termed multidrug resistance (MDR) and is associated with the overexpression of members of the ATP-binding cassette (ABC) family of efflux transporters. Principally, this process involves the multidrug resistance protein 1 (*MDR1*) gene, which encodes P-glycoprotein (P-gp), also termed MDR1 or ATP-binding cassette subfamily B member 1 (*ABCB1*). These transporters are active pumps for drugs, such as DOX^[18,25]. OS cells exhibit high expression levels of ABC transporters, such as MDR1, and are resistant to DOX. An association between MDR1 overexpression and reduced DOX accumulation has been reported. In patients with OS, the overexpression of ABC transporters is associated with poor response to chemotherapeutic agents (e.g., DOX) and worse clinical outcomes^[20,26]. In preclinical models, the knockout of *ABCB1* restored sensitivity to DOX. Drugs, such as trabectedin, may inhibit the transcriptional activation of MDR1; trabectedin modulates gene expression in a promoter manner, affecting the MDR1 gene promoter, thereby emerging as a potential alternative therapeutic strategy for the restoration of sensitivity to DOX^[27].

Alterations in target enzymes

Secondary to alterations in enzymes, increased levels of target enzymes or decreased drug affinity can result in resistance to chemotherapeutic agents. MTX-resistant OS cell lines overexpress DHFR, and high expression of DHFR is also observed in OS metastasis^[28,29]. DNA topoisomerases II (TOP2) are nuclear enzymes involved in the regulation of DNA topology; TOP2 forms a homodimer that functions by cleaving double-stranded DNA, coiling a second DNA duplex through the gap, and re-binding the strands. TOP2 is essential for cell replication and viability and is recognized as a target of doxorubicin^[30]. In human cells, two isoforms are described, α and β ; in several tumors, low expression of *TOP2B* is described in DOX resistance, particularly OS DOX-resistant cells had reduced expression of *TOP2B* compared with DOX-sensitive cells^[31]. Amplification or deletion in TOP2 genes has been described in OS patients. *TOP2B* was deleted in 40.5% of cases and is related to worse event-free survival. *TOP2A* is amplified in 21% and deleted in 25% of OS tumors. Both gene alterations (amplification and deletion) in *TOP2A* have been correlated with a good response to neoadjuvant chemotherapy and also related to DOX resistance^[32]. Exploring these enzymes in clinical trials could give us possible utility as biomarkers to predict chemotherapy response.

Several mutations in tumor suppressor genes and other pathways are involved in OS failure to chemotherapy. The most frequent gene altered in this pathology is tumor suppression gene *P53*, and mutations in other cancer drivers such as *RB1*, *ATRX2*, *DLG23*, *RUNX2*, *WRN*, *RECQL4*, *CDKN2A/B*, *BLM*, *PTEN*, and PI3K/AKT/mTOR pathway members are described in OS tumors. Some of these genes are involved in cell cycle control and DNA damage repair^[33].

OS AND ALTERATIONS IN DNA REPAIR

It is established that chemotherapeutic agents cause DNA damage that leads to cell death. However, tumor

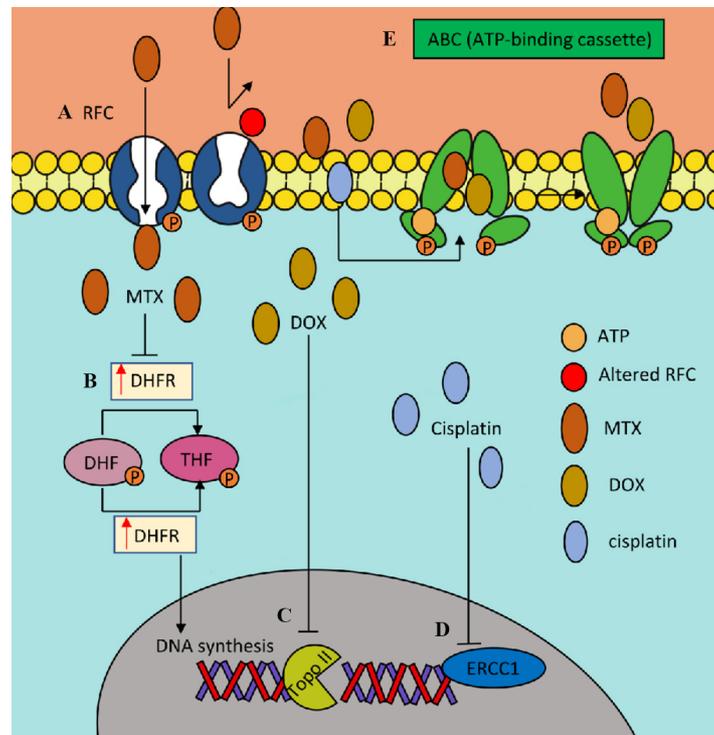

Figure 1. Reduced intracellular drug accumulation. (A) Decreased expression of the reduced folate transporter (RFC) or decreasing transporter function promotes methotrexate resistance. (B) Overexpression of dihydrofolate reductase (DHFR) responsible for the reduction of dihydrofolate (DHF) to tetrahydrofolate (THF) or alterations in the binding affinity of DHFR for methotrexate (MTX) are related with MTX resistance. (C) Decreased expression or mutation of topoisomerase II (Topo II) is associated with doxorubicin (DOX) resistance. (D) High levels of excision repair cross-complement protein 1 (ERCC1) proteins are related to cisplatin resistance. (E) Increased expression of multidrug resistance gene encoding the ATP-binding cassette (ABC) family leads to increased drug efflux and decreased intracellular drug accumulation increasing resistance to DOX and MTX.

cells can occasionally resist treatment by enhancing their DNA repair pathway. Cisplatin is one of the most studied drugs for which resistance due to an enhanced DNA repair in OS has been reported^[18,34,35]. Nucleotide excision repair (NER) is an important DNA damage removal pathway. It is implicated in cancer progression and response to platinum-based chemotherapy. Additionally, NER is one of the most studied pathways in the development of drug resistance in OS. NER proteins can repair chemical drug-induced DNA damage. Members of the NER pathway that have been studied thus far include DNA excision repair proteins and excision repair cross-complement proteins (ERCC); these endonucleases are involved in the excision of the lesion, followed by DNA replication and repair process. Defects in NER accumulate DNA damage favoring cancer phenotype. Single nucleotide polymorphism (SNPs) of *ERCC1* and *ERCC2* genes may decrease the expression of *ERCC1* and *ERCC2* genes and are associated with chemotherapy response for OS, particularly reduced resistance to cisplatin-based chemotherapy^[36,37]. In addition, silencing of the *ERCC1*, *ERCC2*, *ERCC3*, and *ERCC4* genes increases sensitivity in resistant OS cell cultures (U2OS/cisplatin 300 and U2OS/cisplatin 1)^[35]. Base excision repair (BER) is also involved in OS. BER is primarily active in DNA damage caused by small chemical alterations or base loss due to hydrolysis of glycosyl DNA bonds. DNA damage is removed by glycosylases, a complex formed by APEX1 endonuclease, poly(ADP-ribose) polymerase (PARP), and DNA ligase, and XRCC1 recognized the bases sites. Different members of BER are involved in OS; apurinic/apyrimidinic endonuclease (APE-1) has been associated with shorter survival in patients with OS^[18,37].

DNA double-strand breaks (DSBs) represent a challenge to genomic integrity. DSBs are detected by a cascade of proteins, involving the process of homologous recombination (HR) or nonhomologous end-join (NHEJ). DSBs activate pathways such as ATM and ATR that result in the phosphorylation of multiple targets, including histone H2AX and checkpoint mediator proteins (CHK) 1 and 2, to finally activate P53. ATR/CHK1 signaling is linked with the activation of BRCA2, recruiting BRCA1 and RAD51, which form filaments on the single-stranded DNA to repair the site of the DNA damage. *BRCA1* and -2 mutations lead to impairment to repair DSBs mediated by HR. Deficiency of inhibition of PARP1 in normal cells results in an impairment of the BER response, causing lesions that should be repaired by BER activating HR pathway; however, OS presents mutations in different “BRCA” genes such *PALB2*, *CHEK2*, *PTEN*, and *ATM*, resulting in chromosomal instability analogous to *BRCA1/2* mutations^[33], which make it difficult to repair DNA lesions. Exposing *BRCA1/2*-deficient cells to PARP inhibition results in lethal DNA damage accumulation; consequently, PARP inhibition results in the targeted tumor cell death in *BRCA*-deficient cancer. Preclinical data suggest the effect of PARP inhibitors in OS MNG/HOS cells carrying disruptive gain in the *PTEN* gene and deletion of *ATM* gene; the combination of talazoparib, a phase 3 PARP inhibitor, with topoisomerase I inhibitor SN-38 considerably decreases the viability of MNG/HOS cells, and olaparib was tested in HOS and MG-63 cells with good results. In addition to these preclinical data, it seems that the inhibition of PARP1/2 in *BRCA1/2* tumor suppressor mutated cells is involved in drug resistance in OS. The use of olaparib (a PARP1 inhibitor) sensitizes OS cell lines to treatment with DOX^[38]. These types of in vitro studies led to PARP inhibitors being tested in the clinical setting. The ongoing NCT03233204 study investigates the combination of olaparib plus DOX in patients with refractory OS^[39]. The TOMAS trial tested olaparib and trabectedin in sarcomas. This trial included seven patients with bone cancer; unfortunately, none of the patients showed an objective or clinical response^[40], probably due to the small number of patients included in the trial. Furthermore, other combinations, such as olaparib plus ceralasertib (AZD6738), an orally available morpholino-pyrimidine-based inhibitor of ataxia telangiectasia and rad 3-related (ATR) kinase, were tested in this trial (clinical trial identifier: NCT04417062)^[41]. Recently, the RB pathway has been described as PARP inhibitor (PARPi) sensitive; RB1-defective OS revealed hypersensitivity to the PARPi olaparib, and RB1-defective OS cells may yield BRCAness/HR defects by inducing RAD51 recruitment. Olaparib increases H2AX histone marker and CHK1 phosphorylation^[42]. RB is highly mutated in OS patients. The MATCH trial is a precision medicine cancer treatment clinical trial where patients are assigned to receive treatment based on their genetic changes. This trial involves children, adolescents, and young adults with advanced cancers, including rare cancers such as osteosarcoma. Olaparib will be tested in patients with defects in DNA damage repair genes and *BRCA1/2* mutations. We await the evolution in patients with RB1-mutated disease if they are included^[39,43]. The potential benefits of anti-PARP treatment will have to wait for the publication of the results of this trial to evaluate future areas of opportunity with this inhibitor.

CELL CYCLE AND APOPTOSIS DISTURBANCES

DNA damage is one of the principal action mechanisms of chemotherapy, leading to cell death through apoptosis. For their survival, tumor cells arrest their cell cycle to repair DNA damage, thereby evading apoptosis^[44]. Disturbances in the cell cycle and apoptosis are involved in the development of resistance to chemotherapy in OS cells. For example, following the overexpression of murine double minute 2 (*MDM2*) (a downstream mediator of p53) in tumor cells, p53-mediated apoptosis is inhibited, and cells develop resistance to DNA-damaging agents^[18,45]. The amplification of *MDM2* is present in 20% of OS cells^[46].

Cyclin-dependent kinase 4

Cyclin-dependent kinase 4 (CDK4) is an enzyme encoded by the *CDK4* gene. The activity of this kinase is restricted to the G1-S phase, and it is responsible for the phosphorylation of the retinoblastoma (RB) protein. The amplification of *CDK4* is found in 20% of OS cells^[46]. In a study of 50 pediatric and adolescent

patients diagnosed with high-grade OS, the copy number analysis detected a recurrent gain of chromosome 12q14.1. This observation was more frequent in the poor responder cohort than in the good responder cohort, where the *CDK4* gene was associated with copy number gains^[47]. *CDK4* is highly expressed in human OS tissues and cell lines compared with normal human osteoblasts. Elevated *CDK4* expression is associated with metastasis and poor prognosis in patients with OS^[48]. Overexpression of *CDK4* is also related to resistance to cisplatin; treatment of U2OS cells overexpressing *CDK4* with *CDK4/6* inhibitor palbociclib facilitates apoptosis and decreases cell viability in a dose-dependent manner^[47]. The combination of sorafenib (a multikinase inhibitor) and palbociclib in a cisplatin-resistant, patient-derived, orthotopic, xenograft mouse model of OS resulted in tumor regression and enhanced tumor necrosis^[49]. Patients with co-amplification of *MDM2* and *CDK4* were treated with the *MDM2* inhibitor ALRN-6924 and palbociclib; the study included ten liposarcomas, one OS, and one glioblastoma. The study concluded that the combination of ALRN-6924 and palbociclib was feasible and well tolerated^[50]. Palbociclib is currently tested in pediatric tumors, including osteosarcoma, with activated alterations in cell cycle genes in the pediatric MATCH treatment trial (NCT03526250)^[51]. Abemaciclib is an inhibitor of *CDK4/6*; Wang *et al.* evaluated the efficacy of abemaciclib in OS cells and an animal model^[52]. Abemaciclib inhibited growth and anchorage-independent colony formation of OS cells and inhibited tumor formation and growth in a dose-dependent manner in the animal model. Abemaciclib combined with DOX results in much greater efficacy than DOX alone in inhibiting tumor growth; it acts by suppressing the *CD4/6*-Cyclin D-Rb pathway. A clinical trial with OS and abemaciclib is ongoing (NCT04040205)^[52,53].

Myeloid cell leukemia-1 protein and its potential role in OS

Cell death signaling is orchestrated by members of the B cell lymphoma 2 (BCL2) family that contains antiapoptotic proteins (e.g., BCL2 and BCLXL) and proapoptotic proteins [e.g., BCL2 associated X (BAX)]. Inhibition of BCL1/BCLXL enhanced the chemosensitivity of OS to DOX and cisplatin. Myeloid cell leukemia-1 (MCL-1) is a pro-survival member of the BCL2 family, contributing to the avoidance of cell death by acting as a regulator of apoptosis in some human malignancies^[54]. In OS, MCL-1 expression is upregulated after chemotherapy, and high MCL-1 expression is associated with poor overall survival, increased recurrence rate, decreased sensitivity to MTX, and promotion of tumor proliferation^[55]. In OS cells, MCL-1 is a direct target of miR-375; overexpression of miR-375 enhances the effects of cisplatin-induced DNA damage mediated by MCL-1^[54]. Regorafenib is an oral type II multikinase inhibitor that inhibits the vascular endothelial growth factor receptor 1-3 (VEGFR1-3), platelet-derived growth factor receptors, fibroblast growth factor receptors (FGFR), tyrosine kinase receptor with immunoglobulin-like and EGFR-like domains 2 (TIE-2), and pathways involved in angiogenic and metastasis process. Sorafenib has been approved as a second-line treatment in OS, as discussed below^[56]. MCL-1 is an essential survival factor for endothelial cells (EC) required for blood vessel production during angiogenesis. Deletion of MCL-1 in EC cells resulted in a dose-dependent increase in EC apoptosis in the angiogenic vasculature and reduced vessel density. Inhibition of vascular endothelial growth factor A (VEGF-A) may cause EC apoptosis^[57]. The role of MCL-1 in regorafenib resistance has been evaluated in colorectal cancer. Regorafenib-resistant cells are deficient in MCL-1 degradation, MCL-1 is associated with PUMA and inhibits apoptosis, and MCL-1 inhibitor overcomes acquired resistance to regorafenib by liberating PUMA from MCL-1, restoring apoptosis. Thus, inhibition of MCL-1 also seems to overcome the resistance to regorafenib^[58].

MCL-1 appears to be a new therapeutic target in OS. Inhibitors of MCL-1 can be used in different settings, e.g., to restore sensitivity to chemotherapy or anti-angiogenic resistance or in combination with other agents to increase therapeutic efficacy. A phase 1 study of a MCL-1 inhibitor in solid tumors, including sarcomas, is currently ongoing^[59].

SIGNAL TRANSDUCTION PATHWAYS

Human epidermal growth factor receptor family and OS

Since the 1990s, the expression of human epidermal growth factor receptor 2 (HER2) has been reported in OS primary tumors and metastases^[60]. HER2 is overexpressed in approximately 32%-45% of OS samples. Some studies have associated HER2 with worse event-free survival and metastasis-free survival; they have also correlated the overexpression of HER2 with poor response to chemotherapy^[60]. Based on this evidence, strategies directed against HER2 to increase the survival of patients with OS HER2-positive tumors have emerged. The use of trastuzumab in combination with cytotoxic chemotherapy was investigated in a phase 2 trial of 96 patients newly diagnosed with metastatic OS; of those, 41 had tumors expressing HER2. There was no difference in event-free survival or overall survival between the HER2-positive and HER2-negative groups; trastuzumab has not been tested in other randomized trials^[61]. The location of HER2 in OS probably contributes to the failure of treatment with monoclonal antibodies; however, there is a need to develop other intracellular inhibitors for the blockage of this pathway. Overexpression of HER2 has been involved in mechanisms of resistance to cisplatin mediated by phosphoinositide 3-kinase/protein kinase B (PI3K/AKT) activation. The basal activity of PI3K/AKT1 upregulates cyclin-dependent kinase inhibitor 1A (CDKN1A; also termed p21), promoting cell cycle arrest and leading to time for DNA repair; additionally, HER2 overexpression mediates the nuclear exclusion of p21 and activation of PI3K/AKT, favoring cell proliferation. Both aforementioned mechanisms have been described in resistance to cisplatin^[34,62]. In addition, overexpression of HER2 has been associated with resistance to cisplatin in clinical settings^[62]. The inhibition of this pathway could be explored in second-line therapy to overcome this resistance in patients with OS. Now, a new drug is being tested in an ongoing phase 2 trial (identifier: NCT04616560) for the treatment of HER2-positive patients with recurrent OS. Trastuzumab-deruxtecan is a conjugated antibody-drug composed of a humanized monoclonal antibody specifically targeting HER2 and a potent topoisomerase I inhibitor as the cytotoxic drug. Trastuzumab attaches to HER2-positive cancer cells. HER2 receptor works as a target for trastuzumab to deliver deruxtecan into OS cells^[63] [Figure 2].

Other members of the HER family have been investigated in OS. A moderate-to-high expression of epidermal growth factor receptor (EGFR) is present in 50%-90% of OS samples, and the expression of EGFR is associated with a higher rate of metastasis, risk of recurrence, and resistance to chemotherapy^[64,65]. Treatments with EGFR inhibitors, such as gefitinib, inhibited OS cell growth and sensitized EGFR-expressing cells to chemotherapy, DOX, and MTX^[65]. The combination of gefitinib with DOX and MTX also showed a synergistic impact on cell proliferation and apoptosis^[66]. Furthermore, the monoclonal antibody cetuximab decreased OS cell motility via PI3K/AKT/mitogen-activated protein kinase (PI3K/AKT/MAPK) signaling^[67]. Canertinib (CI-1033), EGFR, and HER2 inhibitor induced apoptosis and decreased EGFR and HER2 phosphorylation in OS cells^[68]. ZD6474, a dual tyrosine kinase inhibitor (TKI) of EGFR and vascular endothelial growth factor receptor (VEGFR), inhibited OS cell growth, induced cell cycle arrest, and promoted apoptosis and tumor growth in nude mice^[69]. HER4 expression is associated with low probabilities of survival and metastasis-free survival. Knockdown of HER4 decreased cell viability upon treatment with MTX and DOX and increased apoptosis of OS cells based on cleaved PARP, suggesting that downregulation of HER4 increases the sensitivity of OS cells to chemotherapeutic drugs; HER4 also interacts with NDGR1 (N-myc downstream regulated gene), which contributes to cell growth and survival in OS cells^[70]. Afatinib is a TKI that selectively blocks the signaling of homodimers and heterodimers formed by EGFR, HER2, HER3, and HER4 in OS cell lines^[71]. It has been observed that afatinib inhibits the proliferation, migration, and invasion of non-metastatic and metastatic OS cell lines. Moreover, it decreases the phosphorylation of HER2/EGFR receptors and downstream molecules AKT and extracellular signal-regulated kinase 1/2 (ERK1/2)^[72]. Using sarcospheres from highly metastatic human OS cell lines, Collier *et al.* revealed that afatinib also has therapeutic potential with this technology^[73]. Recently, a meta-analysis of the gene expression signature of primary OS samples using the Gene Expression Omnibus microarrays series was performed to establish the OS gene signature. The Characteristic Direction Signature Search

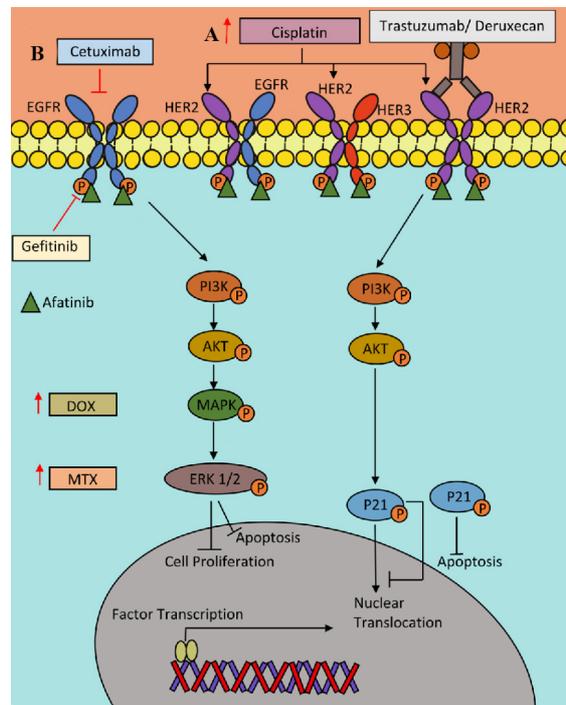

Figure 2. Role of Family HER Pathway in osteosarcoma chemotherapy resistance. (A) Cisplatin resistance is associated with HER2 overexpression, PI3K/AKT activation and promotion p21 nuclear exclusion, favoring cell cycle arrest and proliferation. (B) Anti-EGFR therapy such as cetuximab and gefitinib sensitized osteosarcoma cells to DOX and MTX. (C) Afatinib a pan-HER Family inhibitor have an inhibition effect in osteosarcoma cell proliferation, migration an invasion. (D) Trastuzumab deruxtecan is an antibody-drug conjugated composed by anti-HER2 humanized monoclonal antibody and a topoisomerase I inhibitor as cytotoxic drug, that is now been tasted in clinical trials. AKT: Protein kinase B; DOX: doxorubicin; EGFR: epidermal growth factor receptor; ERK: extracellular signal-regulated kinase; HER: human epidermal growth factor; MTX: methotrexate; PI3K/AKT: phosphoinositide 3-kinase.

Engine was used to identify the most appropriate molecules for reversing this gene expression signature in OS and propose new potential drugs. The authors found 266 genes (98 upregulated and 168 downregulated) in OS, and afatinib appeared as one of the top molecules for reversing this signature^[74]. Afatinib is currently being tested in a phase 2 trial in pediatric tumors, including rhabdomyosarcomas and those with HER deregulation recurrent/refractory disease after receiving at least one prior standard treatment regimen (identifier: NCT02372006)^[75]. This trial will let us see the activity of afatinib in sarcomas and patients with dysregulated HER pathway; its potential role in OS has to be evaluated directly in future clinical trials.

PI3K, mechanistic target of rapamycin, AKT, and microtubule affinity-regulating kinase 2 pathways in OS

The PI3K/AKT signaling pathway is involved in cell survival and the RAS, RAF, and ERK/MAPK pathways, which mediate tumor proliferation and growth and are downstream of cell-surface receptors in OS^[76]. One of the targets of this pathway is MARK2. MARK2 is a serine/threonine kinase implicated in microtubule-associated protein phosphorylation and cell cycle regulation. This protein is associated with neurological disorders, cell polarization, intracellular transport, and migration. Overexpression of MARK2 is associated with poor prognosis in patients with OS. Some mechanisms by which MARK2 may increase the resistance to cisplatin in OS have been proposed. For example, MARK2 may mediate resistance to cisplatin in OS by inhibiting apoptosis through the expression of BCL2. Another mechanism is the regulation of P-gp expression mediated by MARK2. The expression of P-gp and MARK2 in the MG-63 and MNNG/HOS OS cell lines is upregulated compared with that observed in osteoblasts. Silencing of MARK2 in OS cells also decreased P-gp expression, suggesting a relationship between these two proteins. In the case of cisplatin-

resistant cells, following blockage of MARK2, P-gp expression is reduced and sensitivity to this chemotherapeutic agent is improved. This regulation may be mediated by the activation of the PI3K/AKT/nuclear factor- κ B (PI3K/AKT/NF- κ B) pathway^[77]. MARK2 appears to regulate the DNA damage repair dependent on NHEJ mediated by DNA-dependent protein kinase (DNA-PK) and the catalytic subunit of the DNA-dependent protein kinase (DNA-PKcs). High levels of DNA-PKcs were correlated with poor prognosis as well as an increased risk of recurrence and metastasis in patients with OS. Furthermore, the expression of this catalytic subunit was increased in MG63 cells treated with cisplatin and etoposide^[78]; the expression of DNA-PKcs in cisplatin-resistant MG-63 OS cells appears to be regulated by MARK2 via the PI3K/AKT/mTOR pathway. In this pathway, the protein most strongly associated with DNA damage repair is AKT; it has been reported that DNA damage activates AKT. In addition, it appears that AKT phosphorylation on S473 is dependent on DNA-PK; AKT1 forms a complex with DNA-PKcs, resulting in the activation and auto-phosphorylation of the S2056 of DNA-PKcs^[79]. Another important protein is mTOR, a key regulator of the PI3K/AKT pathway; overactivation of mTOR is associated with resistance to cisplatin. The PI3K/AKT/mTOR and RAS/RAF/MEK/ERK pathways interact at different levels. RAS activates PI3K by interacting with its catalytic subunit, and ERK2 phosphorylates TSC complex subunit 2 (TSC2), suppressing its function and promoting the activation of mechanistic target of rapamycin complex 1 (mTORC1). Downstream of RAS/ERK is the 90 kDa ribosomal protein S6 (RPS6); this kinase phosphorylates TSC2 at Ser1798 and inactivates its tumor suppression function, allowing mTORC1 signaling^[79]. With regard to MAPK, a special activation was demonstrated in high-grade OS specimens, showing inhibition of ERK1/2 phosphorylation and increased expression of proapoptotic proteins (e.g., BAX) that induce apoptosis in OS cells; the inhibition of ERK1/2 also increased the sensitivity of OS cells to DOX^[80]. A phase 2 trial of sorafenib in combination with everolimus (an inhibitor of mTOR) in OS was designed to overcome the resistance to sorafenib. Sorafenib inhibits the activity of the mTORC1 complex but activates the mTORC2 complex and promotes tumor progression. Preclinical studies have shown that everolimus effectively overcomes this resistance mechanism. The study was designed to include high-grade patients with OS who had progressed after receiving a MTX/DOX/cisplatin /IFOS chemotherapy regimen that included MTX, DOX, cisplatin, and/or IFO. Interestingly, the group of patients who expressed phosphorylated-ERK1/2 (p-ERK1/2) and p-RPS6 presented a greater response to the combination of sorafenib and everolimus than the negative expression group (clinical trial identifier: NCT01804374)^[81]. These findings suggest that, after chemotherapy, the PI3K/AKT pathway appears to be active in a subgroup of patients. Therefore, establishing the activation of the PI3K pathway prior to treatment may assist physicians in selecting patients who would benefit from treatment with an mTOR inhibitor alone or in combination with other agents. Further clinical trials based on molecular profiles are warranted to explore the combination of a mTOR inhibitor with a multikinase inhibitor with a different profile that may include the RAS/MEK/ERK pathway as targets.

TME AND ANGIOGENESIS

OS therapy has only been partially effective, possibly due to the existence of compensatory pathways, the inherently heterogeneous nature of sarcomas, and the complex interaction with the TME. Multiple intermingled cell types, such as osteoblasts, osteoclasts, fibroblasts, immune cells, macrophages, vascular cells, mesenchymal stem cells (MSC), and hematologic progenitor cells, coexist in stroma bone^[82]. The heterogeneity observed in different tumor cell subpopulations is modulated by different mechanisms, including the extracellular matrix (ECM) and its interactions with intracellular and extracellular elements, metabolites, oxygen tension, pH, *etc.* For instance, an alteration of the RB pathway is sufficient to induce anchorage-independent growth of these tumors; additionally, clonal evolution is dependent on the environment (hypoxia and immune infiltrate) and can result in resistance or tolerance, while microenvironment communications (e.g., angiogenesis, immune stimulation, and initiation of signal

transduction) complicate this tumoral scenario^[83,84]. Crenn *et al.* evaluated the histological response to chemotherapy (i.e., IFO, cisplatin, and DOX) in murine MOS-J cell models, mimicking various microenvironments by injecting tumor cells into subcutaneous, intramuscular paratibial, and intra-osseous sites^[85]. A higher response to DOX was observed in the intra-osseous model compared with the intramuscular model in terms of tumor growth and necrosis, suggesting that a more vascularized intra-osseous ambient favors drug action^[25,85]. This conclusion was based on the premise that bisphosphonates inhibit osteoclast bone resorption, reduce therapy-induced bone loss, and improve anticancer activity by inhibiting angiogenesis, invasion, tumor cell adhesion, and enhancing immunity. Additionally, in preclinical murine models, zoledronate exerted antitumor effects on OS cells, reduced tumor growth, reduced lung metastasis, and improved survival. Based on this evidence, a phase 3 trial (OS2006) evaluated the addition of zoledronate to conventional chemotherapy; unfortunately, this therapeutic strategy failed to improve the pathological preoperative response to chemotherapy and clinical outcomes. The authors explained this negative result as the effect of zoledronate on immunological parameters such as NK-cell expansion, macrophage depletion, or polarization may affect the bone microenvironment; the absence of benefit with zoledronate combined with chemotherapy may be related to a potential upregulation of RANK expression that promotes osteosarcoma pathogenesis by osteosarcoma cells^[86,25,87].

Other members of TME are immune cells, which include cells of the innate and non-innate immune response. Osteosarcoma has several alterations in DNA repair that translates into mutation implicated in their carcinogenesis that may produce mutational antigens attractive to immune cells; however, similar to other sarcomas, tumor mutation burden (TMB) in OS is low. Nevertheless, the microenvironment tumor-associated inflammatory infiltrate is a strong prognostic indicator of response to therapy and overall survival. Osteosarcoma had consistently low expression of PD-L1 in studies and can be classified as a “cold tumor”; however, immune cells (e.g., CD8+ cytotoxic T-lymphocytes) are associated with a favorable prognosis in OS studies.

Based on this, the phase 2 PEMBROSARC trial evaluated the anti-programmed cell death 1 (anti-PD-1) pembrolizumab in combination with alternating cyclophosphamide in 17 patients with OS; only 13.3% of patients had stable disease at 6 months^[88]; the median progression-free survival was 1.4 months and median overall survival was 5.6 months. This study showed interesting results; for example, none of the three patients with tumor shrinkage had an expression of PD-L1 on sarcoma or immune cells and only 12% of the cases were PD-L1 positive in this study^[88]. One explanation could be the implication of other mechanisms implicated in immune response in OS, such as other members of TME and the tumor survival mechanism^[89]. In the PEMBROSARC trial, the authors observed an increase in the kynurenine to tryptophan ratio in the third cycle of pembrolizumab compared to the first cycle. The kynurenine pathway requires tryptophan and IDO. The authors of this trial mentioned the inhibition of IDO in combination with pembrolizumab as a strategy to be explored in these tumors^[90]. Tumor-derived exosomes can inhibit T cell and NK cell activity through different pathways, and T cell apoptosis favors immune surveillance escape and activation of bone marrow-derived suppressor cells (MDSC). Around 36% of patients with breast cancer have exosomes containing indoleamine deoxygenase (IDO), which regulates antitumor immunity by depletion of tryptophan levels, promoting inflammatory microenvironment and angiogenesis^[91,92]. As mentioned above, it can be related to immune checkpoint inhibitor response. Release of exosomes with soluble major histocompatibility complex I chain-related proteins (SMIC) and NKG2D (natural killer cells receptor) soluble receptors are implicated in the downregulation of NK cells and cytotoxic T lymphocytes^[91,93]. Another possible pathway implicated in OS immune response is transforming growth factor-beta (TGF- β), which plays an important role in excluding T cells from the tumor microenvironment and, unfortunately, is present in high levels in OS patients, especially in the metastatic OS setting; thus, the

inhibition of this pathway may improve the antitumor effects of immunotherapy^[91,94,95]. Combination therapy has emerged as a future strategy to enhance chemotherapy and immunotherapy; for example, in OS cells, DOX increases apoptosis in CD8+ T cells. However, this effect was reversed by the anti-PD-L1 antibody and the combination of the anti-PD-1 antibody and cisplatin inhibits tumor growth^[70].

This finding indicates that exploration of other pathways in the TME for the treatment of OS is warranted. Tumor-associated macrophages play a pivotal role in the regulation of local immunity, angiogenesis, and tumor cell migration; they are divided into two principal macrophage populations (M1 and M2). In OS, M1 and M2 infiltrations are associated with better and worse outcomes, respectively. It has been observed that patients with infiltration of CD68+ cells in OS tissues typically exhibit a poor response to neoadjuvant chemotherapy; however, after treatment with chemotherapy, macrophages secrete interleukin-1 β (IL-1 β) and reduce the sensitivity of OS to cisplatin^[96]. Macrophages promote angiogenesis and contribute to the development of resistance to chemotherapy; the deletion of vascular endothelial growth factor A (VEGFA) in macrophages leads to normalized vascular growth, reduces hypoxia, and increases sensitivity to cisplatin^[97,98]. Apatinib, a selective tyrosine kinase inhibitor to VEGFR2, inhibits epithelial-mesenchymal transition (EMT) and PD-L1 expression by targeting STAT3 *in vitro* and *in vivo*^[99]. Future strategies, such as the combination of immunotherapy, chemotherapy, and anti-angiogenesis therapy or more complex alternatives such as vaccines or modified immune cells, are being tested in osteosarcoma to overcome immune surveillance escape and chemotherapy resistance^[91].

The ECM constitutes a three-dimensional acellular network of macromolecules that provide structural and biochemical support to cells, including malignant cells^[100]. Moreover, the ECM is implicated in cell communication, migration, adhesion, proliferation, and differentiation. Components of the ECM (e.g., collagen, fibronectin, laminin, and proteoglycan) are implicated in OS cell growth, proliferation adhesion, invasion, metastasis, resistance to chemotherapy, and angiogenesis. A high expression of collagens, collagen triple helix repeat containing 1 (CTHRC1), and collagen type I alpha 1 chain (COL1A1) has been associated with shorter survival. Overexpression of collagen type III alpha 1 chain (COL3A1) may decrease apoptosis and promote resistance to MTX in OS cell lines^[101]. Tumstatin is a 28 kDa protein fragment of COL4A3 (a non-collagenous domain of the alpha 3 chain in collagen IV) with an anti-angiogenic capacity that inhibits cell proliferation and induces apoptosis in OS cells^[102-104]. Endostatin is a 20 kDa terminal-C fragment of collagen XVIII that inhibits angiogenesis by directly binding to both VEGFR1 and VEGFR2. Endostatin is also associated with different surface integrins; it competes with the fibronectin pro-angiogenic ligand for binding to integrin $\alpha 5\beta 1$ to disrupt cell migration, activates SRC and caveolin 1 (CAV1), disassembles focal adhesion fibers and actin stress fiber, and inhibits cell migration^[101,105]. Both tumstatin and endostatin inhibit the phosphorylation of focal adhesion kinase (FAK) downstream of FAK; subsequently, tumstatin FAK inhibits the PI3K/AKT/mTOR/4EBP1 pathway downstream, resulting in the inhibition of endothelial protein synthesis. Endostatin inhibits the activation of the ERK1/p38 MAPK pathway that inhibits the migration of endothelial cells^[75,106]. In preclinical models, the combination of recombinant human-endostatin (rh-endostatin) with DOX produced an important synergistic antitumor activity^[107]. Rh-endostatin has been investigated in combination with conventional chemotherapy (i.e., MTX, DOX, and cisplatin) in patients recently diagnosed with OS; this strategy improved the clinical outcomes of chemotherapy, prolonging the 2- and 5-year event-free survival of 81% and 75% of patients, respectively, in the rh-endostatin group vs. 67% and 57% of patients, respectively, in the chemotherapy alone group; the relative risk in the rh-endostatin group was 0.49 (95%CI: 0.36-0.078, $P = 0.010$). Rh-endostatin reduced the 2- and 5-year distant metastasis-free survival in 82% and 79% of patients, respectively, in the combination group compared with 71% and 61% of patients, respectively, in the chemotherapy alone group; the relative risk of distant metastasis in the rh-endostatin group was 0.48 (95%CI: 0.30-0.76, $P = 0.014$)^[108,109].

Interestingly, patients in the control group exhibited increased VEGF expression and microvascular density (MVD) after exposure to chemotherapy alone; however, patients in the rh-endostatin group showed reduced VEGF expression and MVD. Similar results have been observed in the neoadjuvant setting with DOX, cisplatin, MTX, and IFO, where rh-endostatin reduced VEGF expression and MVD, and improved distant metastasis-free survival and overall survival; these findings suggest again a protective effect in preventing lung metastasis^[110]. This supports the rationale that early intervention with anti-angiogenic therapy in combination with conventional chemotherapy may reduce the risk of angiogenesis-dependent metastasis. Endostatin also improved clinical outcomes in patients with stage IV OS; in combination with chemotherapy, endostatin increased the progression-free survival (8.6 vs. 4.4 months) and the clinical benefit response (47.8% vs. 16.7%)^[111].

Angiogenesis plays an important role in the development and progression of OS; tumor micro-vessel density and VEGF expression have been associated with the prognosis of OS^[112,113]. Chemokines promote angiogenesis in OS cells mainly through the following two pathways^[113]. Firstly, C-C motif chemokine ligand 3 (CCL3) enhances VEGFA expression, facilitates progenitor cell migration, and promotes tube formation by downregulating the expression of microRNA (miRNA) 374b via JUN N-terminal kinase/ERK (JNK/ERK) and p38^[114]. Secondly, CCL5 increases VEGF expression and promotes its pathway by the protein kinase C/cellular-SRC/hypoxia-inducible factor 1 alpha (PKC δ /c-SRC/HIF-1 α) signaling pathway^[115]. Higher expression of VEGFA is present in OS cells resistant to anoikis via the SRC, JNK, and ERK pathways. The use of a SRC inhibitor reduced the expression of VEGFA and angiogenesis via the inhibition of JNK and ERK activity. The overexpression of p-SRC and VEGFA is also correlated with metastatic potential in human tissues^[116]. Relaxin is a peptide family belonging to the insulin superfamily that promotes the tumor growth, invasion, and angiogenesis of Sao-2 cells via AKT/VEGF. Relaxin H2 (RLN2) confers migratory and invasive capabilities, as well as resistance to cisplatin by modeling the AKT/NF- κ B in U2OS and MG63 cells^[117]. In patients with OS, genes of the VEGF pathway are amplified; the most frequent copy-number aberration is the amplification at 6p12-21 that involves VEGFA (27%), and a subset of tumors had amplifications in 4q11-12, including platelet-derived growth factor receptor A (PDGFRA) and kinase insert domain receptor (KDR) (18%). These findings suggest angiogenesis as a target in OS^[46]. The activation of this pathway in OS affects survival outcomes. Notably, the receptors of the VEGFR pathway, VEGFR2 and VEGFR3, are associated with worse survival in patients with OS, while the ligand VEGFB is associated with poor histologic response to chemotherapy^[118]. High expression of VEGFR3 and PDGFRB is associated with high-grade OS tumors^[112,118]. Recently, a meta-analysis showed that high levels of VEGF are also associated with advanced tumor stage and metastasis, with negative consequences in terms of survival; high VEGF expression is implicated in worse disease-free survival (odds ratio = 0.25, 95%CI: 0.11-0.58, $P = 0.001$) and overall survival (odds ratio = 0.22, 95%CI: 0.13-0.35, $P \leq 0.001$)^[119]. These new pathways described in OS lead to the evaluation of different multikinase drugs in preclinical and clinical studies. Monotherapy with multikinase drugs has been explored in patients with OS who previously received chemotherapy. Table 1 presents the principal targeted therapies involved in signaling pathways in osteosarcoma, principally the angiogenic pathway, studied in phase 2 and observational trials as second-line therapy for OS.

FAK and SRC inhibitors to overcome resistance to chemotherapy

The signaling of integrins includes SRC AKT-ERK and FAK (a non-receptor cytoplasmic protein tyrosine kinase)^[128]. The inhibition of SRC in murine models inhibited tumor growth and decreased the metastatic potential of OS cells. Moreover, this inhibition overcame the resistance to DOX and induced apoptosis in chondrosarcoma cells^[129,130]. This approach has been evaluated in OS in the clinical setting; monotherapy with saracatinib (AZD530) was well tolerated in patients with OS, showing a median progression-free survival of 19.4 months vs. 8.6 months in the placebo group ($P = 0.47$). The investigators concluded that the

Table 1. Principal targeted therapies involved in the signaling pathways in osteosarcoma

Agent	Signaling pathway	Pediatric dose	Adult dose	RR%	4-month PFS (%) (95%CI)	6-month PFS (%) (95%CI)	Median PFS (months) (95%CI)	Reference

Adapted from Just et al.^[127]. AKT: Protein kinase B; b.i.d.: twice daily; BSA: body surface area; CI: confidence interval; E: everolimus; FGFR: fibroblast growth factor receptor; KIT: stem cell factor receptor; mTORC: mammalian target of rapamycin complex; NR: not reported; PDGFR: platelet-derived growth factor receptor; PFS: progression-free survival; PI3K: phosphoinositide 3-kinase; RET: rearranged during transfection; RR: response rate = complete + partial responses; S: sorafenib; VEGFR: vascular endothelial growth factor receptor. ^aApatinib is not approved by the US Food and Drug Administration. ^bDose for patients with BSA < 1.5: 500 mg/day; dose for patients with BSA > 1.5: 750 mg/day. ^cDrug is administered daily for 21 days in 28-day cycles. ^dStudy reported a 10-week PFS.

results of SRC inhibition alone are insufficient to suppress metastatic progression^[131]. Dasatinib combined with ceritinib, an off-target inhibitor of insulin-like growth factor 1 receptor (IGF1R), was tested in one patient; the treatment was well tolerated and showed limited toxicity. Additionally, patient tissue analysis revealed high necrosis and extensive infiltration of macrophages, suggesting that this combination is a promising strategy^[132]. FAK is downstream of SRC, and tyrosine 397 is the major site of autophosphorylation in the FAK catalytic domain. FAK is related to several tumor processes, such as vascular and microenvironment regulation, proliferation, motility, invasion, and survival^[133]. Integrin-β1 (ITGβ1) activates FAK and ERK in MG63 OS cells, and plays an important role in the proliferation and differentiation process of osteoblasts^[134]. High expression levels of FAK are associated with advanced disease and recurrence in patients with OS, rendering it a potential biomarker^[135,136]. The levels of total FAK and p-FAK-Y397 have been evaluated in OS tissues. Overexpression of FAK was detected in OS, and overexpression of thep-FAK-Y387 was correlated with poor histologic response to chemotherapy (i.e., MTX, DOX, cisplatin, etoposide, cyclophosphamide, IFO, and carboplatin)^[135]. In xenograft models, the decrease in FAK expression using FAK inhibitors impaired OS cell proliferation and colony formation and reduced tumor growth^[136]. Platinum-resistant tumorspheres can acquire a dependence on FAK for growth, and the combination of a FAK inhibitor with platinum overcomes resistance to cisplatin^[137]. Ongoing clinical trials evaluate the safety and efficacy of FAK inhibitors in different solid tumors^[138-145]. **Figure 3** shows the signal pathways involved in OS.

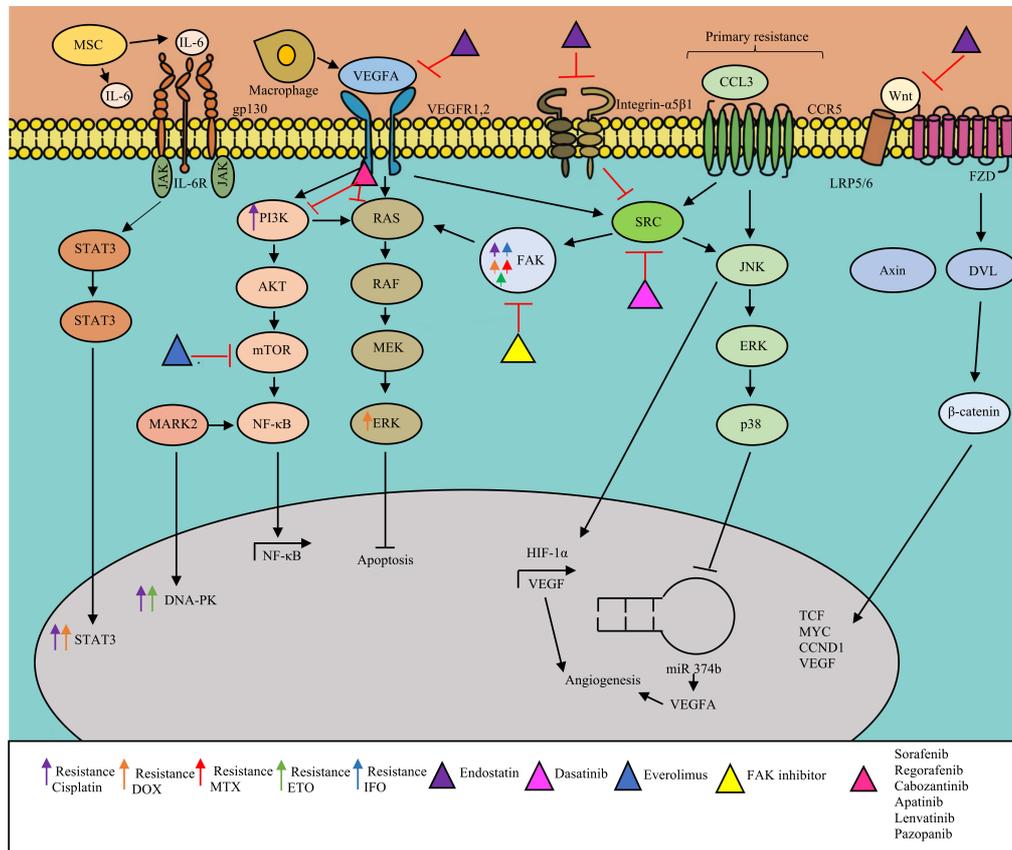

Figure 3. Angiogenesis and osteosarcoma microenvironment. (A) Mesenchymal stem cells (MSCs) produce IL-6 and STAT3 pathway activation promoting cisplatin and DOX resistance. (B) Macrophages promotes angiogenesis by VEGFA production in osteosarcoma. (C) VEGFA ligand binds to VEGFR activating angiogenesis pathway, through PI3K/AKT/mTOR or Ras. Some anti-angiogenesis tyrosine kinase inhibitors alone or in combination with mTOR inhibitors are approved in second line in osteosarcoma. (D) Integrin pathway activates SRC and FAK promoting angiogenesis and apoptosis inhibition. (E) Chemokine (C-C motif) ligand 3 (CCL3) binding to G-protein coupled C-C chemokine receptor 5 (CCR5) promoting VEGFA expression by downregulation of miR-374b, activation of JNK/ERK/p38 and hypoxia-inducible factor (HIF) in human osteosarcoma cells. (F) The canonical Wnt/ β -catenin pathway contributes to chemotherapy resistance and osteosarcoma progression. WNT activates the Frizzled (FZD) and low-density lipoprotein receptor 5/6 (LRP5/6) binding disheveled (DVL) and Axin protein complex release of β -catenin and lead the translocation of β -catenin to the nucleus to activates genes active in chemoresistance. (G) Endostatin inhibits the activity of integrin, VEGFR and WNT pathways. AKT: Protein kinase B; CCND1: CyclinD1; DOX: doxorubicin; DNA-PK: DNA-dependent protein kinase; ERK: extracellular signal-regulated kinase; FAK: focal adhesion kinase; gp130: glycoprotein 130; mTOR: mammalian target of rapamycin; PI3K: phosphoinositide 3-kinase; IL-6: interleukine-6; IL-6R: IL-6 receptor; JAK: Janus Kinase; JNK: JUN N-terminal kinase; MARK2: microtubule affinity-regulating kinase 2; MYC: myc proto-oncogene; NF- κ B: nuclear factor- κ B; SRC: SRC protein kinase; STAT3: signal transducer and activator of transcription 3; VEGF: vascular epidermal growth factor; VEGFR: vascular epidermal growth factor receptor.

TME hypoxic condition: the roles of acidosis, lactate, and adenosine in OS and therapy resistance

Angiogenesis implies newly formed microvessels with altered morphology compared with normal vessels. These abnormalities work as a biophysical barrier to the delivery of oxygen, nutrients, and antitumor therapies to a solid tumor. Oxygen delivery difficulties favor metabolic changes in TME characterized by hypoxic conditions, extracellular acidosis, substantial elevated adenosine and lactate concentrations, and nutrient deprivation^[146]. TME hypoxic condition contributes to genetic instability, intratumorally heterogeneity, malignant progression, tumor stem cell maintenance, angiogenesis, development of treatment resistance, and metabolic reprogramming dependent on HIF-1 α phenotype. These stress conditions that activate HIF-1 α may serve as major drivers for recruitment, activation, polarization, and expansion of immune-suppressive stromal cells and affect the antitumor activity of the innate and adaptive immune system, as well as cancer immunotherapy. Hypoxia-/HIF-driven factors include generation and

accumulation in the extracellular space of adenosine, extracellular acidosis, and favor overexpression of VEGF and activation of VEGFR related to immune suppression and anti-angiogenic therapy response^[146,147]. Metabolic reprogramming induced by hypoxia/ HIF-1 α is characterized by glycolytic enzyme lactate dehydrogenase A (LDH-A) and accelerated glycolysis (Warburg effect) that contribute to lactate accumulation, affecting tumor T cell infiltration and cytokine productions, inhibits the NK and CD8+T cells cytotoxic activity and favors MDSCs infiltration. Tumor extracellular acidosis depends on: (A) the Warburg effect or upregulation/acceleration of glycolysis characterized by an intensive conversion of glucose to lactic acid and insufficient adenosine triphosphate (ATP) production to favor very fast energy supply; (B) increase in glutaminolysis; (C) ketogenesis; (D) increased ATP-hydrolysis, i.e., hydration of CO₂-derived from oxidative metabolism and pentose phosphate pathway; and (F) bicarbonate depletion in TME^[146]. Acidosis (extracellular pH \approx 6.8) has immune-suppressive actions such as inhibition of the proliferative and cytotoxic activity of NK and CD8+ T cells, secretion of IFN-, and reducing the expression of T cell receptors^[148,149]. Acid tumor microenvironment may be related to resistance in osteosarcoma. Extracellular pH in P-gp-negative cell lines reduced sensibility to DOX, and the combination of DOX with the proton pump inhibitor omeprazole enhanced its cytotoxicity capacity and reduced tumor volume in OS animal models; similarly, the pH gradient rendered in OS cells increased response to cisplatin and MTX^[150,151]. Hypoxic stress induces cancer cells' ATP to release through pannexin 1 PANX-1 channels and exocytosis of adenosine and promotes the accumulation of adenosine in the extracellular space of hypoxic tumors. Adenosine attenuates the activity of T cells, NK cells, and dendritic cells and enhances the suppressive capacity of T regulatory cells (Tregs) and MDSCs. Hypoxia increases the accumulation of extracellular adenosine mainly produced by enzymatic ATP catabolism; adenosine induces the expression of adenosine receptors in tumor cells, promoting growth, survival, and metastasis^[152]. Non-regulated release of adenosine occurs from dying and damaged cells, whereas the active release involves exocytotic granules, plasma membrane-derived macrovesicles, specific ATP-binding cassette (ABC) transporters and membrane channels (connexin hemichannels and PANX1), calcium homeostasis modulator 1 (CALHM1), volume-regulated anion channels (VRACs), and maxi-anion channels (MACs). The extracellular ATP (eATP) activity is via P2 purinergic receptors, P2X7R^[153]. TME extracellular ATP is degraded by different ectonucleotidases, principally CD39 and CD73: the ectonucleoside triphosphate diphosphohydrolase CD39 hydrolyzes ATP to ADP and AMP, while the ecto-5'-nucleotidase (CD73) hydrolyzes AMP to adenosine. CD39 is expressed in dendritic cells, tumor-infiltrating Th17 lymphocytes, and M2 macrophages. CD73 is expressed in lymphocytes T and B, stromal cells, and dendritic cells^[152,153]; it is expressed in Treg and in higher levels on anergic CD4+ T cells, preserving self-tolerance in healthy individuals. CD73 has a role as an immune-inhibitory checkpoint molecule, contributing to tumor infiltration of regulatory immune cells such as Treg, MDSCs, or DCs, favoring an immunosuppressive microenvironment^[154]. CD73 is overexpressed in many tumors and promotes cell migration, invasion, and chemotherapy resistance^[155]. In human osteosarcoma cell lines, miR-16 indirectly downregulates CD73 expression and inhibits the expression of transcription factors SMAD3 and SMAD4, both implicated in CD73 expression^[154,156]. In hypoxic TME, hypoxia induces CD73 expression via HIF-1 α regulating EMT and promotes lung metastasis in triple-negative breast cancer^[157]. Different combination strategies of CD73 pharmacological inhibition with A2BR antagonist, chemotherapy and radiotherapy, anti-PD1/PD-L1 therapy, and anti-cytotoxic T-lymphocyte antigen 4 (CTLA-4) improve cancer therapies^[152]; Durvalumab (monoclonal antibody anti-PD-L1) and oleclumab (anti-CD73 monoclonal antibody) are being tested in NCT04668300 trial; this study includes osteosarcoma patients. The CD73 activity is mediated by P1 purinergic receptors (P1Rs), G-protein-coupled receptors divided into 4 subtypes: A1R, A2AR, A2BR, and A3R^[158]. A1 receptor is involved in proinflammatory and anti-inflammatory processes, especially in the neurological system. A2AR protects host tissue from destruction secondary to an over-reaction of the immune response. A2AR activation inhibits DC4+ and CD8+ T-cell function and selectively inhibits proinflammatory cytokine expression, promoting the upregulation of PD-1. CTLA-4 promotes T-cell tolerance and prevents the development of IL-17,

promoting the development of Foxp3+ and LAG3+ regulatory T-cells. Adenosine acting via A2AR inhibits dendritic cell function. Since chemotherapy and radiation increase eATP, a concomitant administration of A2AR antagonists during chemotherapy or radiation might lead to the expansion of tumor T cells and prevent Treg cell induction. These drugs are being explored in a clinical trial with anti-PD1-PD-L1 therapy^[159]. A2BR is related to pathophysiological conditions associated with adenosine releases, such as ischemia and tumor hypoxia. A2BR regulates several functions including vascular tone, cytokine release, and angiogenesis. The A2B receptor promotes mesenchymal stem cell differentiation to osteoblasts and bone formation *in vivo*^[160]. ATP release channels are also involved in osteosarcoma. Connexin 43 (Cx43), an implicated gap junction-mediated intercellular communication, is involved in proliferation suppression of human osteosarcoma U2OS cells by inhibition of the cell cycle transition, attributed to significant accumulation of hypophosphorylated RB protein that secondarily decreases kinase activities of CDK2 and -4. Cx43 seems to inhibit U2OS cells by increasing the levels of p27 protein via post-transcriptional regulatory mechanisms^[161]. Cx43 is regulated by small ubiquitin-like modifiers (SUMOs); SUMO-conjugating enzyme UBc9 protein is overexpressed in osteosarcoma. Silencing UBc9 by siRNA inhibits osteosarcoma cell proliferation^[162]. ALMB-0168, a humanized monoclonal antibody that specifically binds to the extracellular domain of Cx43 and activates the Cx43 hemichannels in osteocytes, enhances the activation of Cx43 hemichannels in both cultured osteocytes and mice osteocytes and promotes ATP release. ALMB-0168 reduces bone cancer growth in murine models WT Cx43; this drug also increases levels of cytotoxic lymphocytes (CD3/CD8+) and helpers (CD3/CD4+), increases the survival rate, and reduces tumor metastasis^[163]. Another adenosine receptor, P2X7, is highly expressed in osteosarcoma tissues. The OSc receptor promotes the growth and metastasis of human HOS/MNNG cells via PI2K7AKTGSK3β/β and mTOR/HIF/VEGF signaling. Nevertheless, eATP increases plasma membrane permeability for cytotoxic molecules such as doxorubicin by opening P2X7R pores^[164]. P2X7RA and -B are present in osteosarcoma tissue, and P2X7RB positive tumors show increased cell density depending on TME^[165]. Shock wave-induced ATP release forms osteosarcoma U2OS cells and promotes cellular uptake and cytotoxicity of methotrexate by altering cell membrane permeability in a P2X7 receptor-dependent manner^[166]. Adenosine, its receptors, eATP, and its transport channels are implicated in diverse pathways of osteosarcoma carcinogenesis, which makes their use attractive for managing this disease and reversing resistance mechanisms.

Nanoparticles

The tumor microenvironment is pivotal to drug delivery in solid tumors; the different components of TME act as barriers, limit drug accumulation, and induce drug resistance. Nanoparticles are a novel tool against cancer; they accumulate passively within solid tumors via pores and fenestration of tumoral blood vessels, reaching the tumoral zone. Then, they are able to penetrate deeper into the solid tumor, where they could have high therapeutic efficacy, facing elevated interstitial fluid pressure and denser extracellular matrices. Several strategies have emerged to overcome these difficulties: surface penetrating peptides combined with magnetic field guidance, proteolytic enzymes prior to nanocarrier treatment, polymeric nanocapsules to preserve their activity for longer times, gold NPs, liposomes micelles, and micelleplexes have been tested in osteosarcoma^[167,168]. Villegas *et al.* designed an enzyme nanocapsule attached to the surface of mesoporous silica nanoparticles as a nanocarrier model and observed higher penetrance of the nanoparticles within 3D collagen matrices of HOS OSc^[169]. Other proposed nanoparticles include biogenic calcium carbonate with better biocompatibility, slow biodegradability, pH-sensitivity, and osteoconductivity. Specific carriers or ligands with drugs include bisphosphonates (BP), N-(2-hydroxypropyl) methacrylamide (HPMA), and tetracycline (TC), as they have potential bone targeting and are ideal for treating metastatic cancer due to their high affinity towards hydroxyapatite (HA)^[168]. Preclinical studies using *in vitro* and *in vivo* osteosarcoma models show efficacy using thermo-sensitive hydrogel conjugated with methotrexate and alendronate, a microparticle delivery system loaded with cerium dioxide (CeO₂) nanoparticles and

doxorubicin. The developed pH-sensitive microparticles were combined with doxorubicin, liposomes of doxorubicin, lipopolymer encapsulating CRISP/Cas9 plasmids encoding VEGFA gRNA and Cas9, and more complex nanoparticles used in gene therapy, such as micelleplexes loaded with miR-145^[168]. In the context of eATP described above, different strategies using this technology are used to prevent fast eATP degradation including highly biocompatible and biodegradable albumin nanoparticles loaded with ATP release^[170], a pH-sensitive nanoplatform made up of chitosan (Cs) and mesoporous HA to deliver ATP to tumor cells^[171].

MIRNA-MODULATED DRUG RESISTANCE IN OS

The miRNAs are small non-coding RNAs (length: 18-25 nucleotides) that repress translation and cleave mRNA by base pairing with the 3'-untranslated region of target genes. They have the potential to regulate several critical biological processes, including the differentiation, progression, apoptosis, and proliferation of tumor cells. It has been estimated that there are up to 1000 miRNAs in the human genome. More than 30% of the human genome is regulated by miRNAs that simultaneously target multiple genes; recent differences in miRNA expression profiles detected between cancer cells and their normal counterparts revealed that miRNAs are involved in the pathogenesis of cancer^[172]. In recent years, in-depth miRNA research has validated the involvement of miRNAs in OS drug resistance, tumor initiation, and progression. These oncogenic or tumor suppressor miRNAs play a role in sensitivity to chemotherapy through several mechanisms, including DNA damage response, apoptosis evasion, autophagy induction, tumor stem cell activation, and alteration of signaling pathways. Maire *et al.* performed miRNA expression profiling for 723 human miRNAs in seven OS tumors; they identified 38 miRNAs differentially expressed by ≥ 10 -fold (28 and 10 were downregulated and upregulated, respectively)^[172]. These miRNAs are involved in intracellular signaling pathways associated with drug resistance, proliferation, and metastasis in OS, including the Notch, RAS/p21, MAPK, Wnt, and Jun/FOS pathways^[172]. It was recently shown that the upregulated miR-124 enhances the cellular response to various DNA-damaging drugs by binding to the 3'-untranslated region of the ATM interactor (ATMIN) and PARP1 mRNAs in U2OS cells^[173,174].

Different miRNAs have been identified as direct targets of p53, which are closely associated with drug resistance and progression in OS. Among them, members of the highly conserved miR-34 family (miR-34a, -34b, and -34c) are important components of the p53 tumor suppressor pathway. It has been observed that the expression of these miRNAs is induced by p53 in response to DNA damage or oncogenic stress^[175]. He *et al.* reported that the miR-34 family induced G1 arrest and apoptosis in OS cells through its targets CDK6, E2F transcription factor 3 (E2F3), cyclin E2 (CCNE2), and BCL2 in a p53-dependent manner^[176]. Additionally, it has been observed that the loss of miR-31 is associated with defects in the p53 pathway, and the overexpression of miR-31 significantly inhibits the proliferation of OS cell lines^[177].

In OS cells, miR-513a-5p suppressed the expression of APE-1, rendering tumor cells radiosensitive^[178]. The use of APE-1-targeted small interfering RNA (siRNA) (i.e., pSilenceAPE-1) sensitized OS cells and tumors xenografts to the anti-angiogenic endostatin, while miR-765 downregulated APE-1 and sensitized OS cells to cisplatin. Therefore, targeting APE1 with miRNA or siRNA may be a treatment option for overcoming drug resistance in OS^[179].

miR-138 is the most recently discovered miRNA involved in resistance to cisplatin, which shows lower expression in OS tissue than in normal tissue. This decrease may be related to its tumor suppressor capacity. When the levels of miR-138 are restored, there is a marked inhibition of cell proliferation and invasion, as well as increased sensitivity to cisplatin. It has been observed that this change in sensitivity can be partially abolished by overexpression of the enhancer of zeste 2 polycomb repressive complex 2 subunit (EZH2)

gene, which can block the activity of caspase 3 (CASP3), a critical enzyme for apoptosis. Therefore, *EZH2* is the specific target gene for miR-138, and this miRNA acts as a tumor suppressor in OS by enhancing the sensitivity to cisplatin^[180]. Recent studies revealed that miR-367 executes several functions in tumors and acts as an onco-miRNA in OS. Overexpression of miR-367 is associated with strong resistance to treatment with DOX. This effect is mediated by the decreased expression of the Kruppel-like factor 4 (KLF4), BAX, and cleaved CASP3 genes, which are related to the apoptotic process and are targets of miR-367. In fact, following the downregulation of miR-367 expression, treatment of OS cells with DOX results in apoptosis^[181].

Based on this evidence, Wei *et al.* investigated the role of autophagy in OS cells. They observed that treatment with DOX and cisplatin increased the levels of miR-140-5p in OS cells, which stimulates autophagy^[182]. Therefore, upregulation of miR-140-5p inhibits cell survival and resistance to DOX and cisplatin, thereby inducing autophagy^[182]. The other miRNA involved in the process of chemoresistance is miR-184, which was investigated in OS cell lines by Lin *et al.*^[183]. They observed that treatment with DOX induces the time-dependent expression of miR-184 in OS cell lines. It was also observed that miR-184 reduces the number of apoptotic cells after treatment by targeting and inhibiting the *BCL2*-like 1 (*BCL2L1*) gene, which is involved in the apoptotic process. Therefore, the upregulation of miR-184 and suppression of *BCL2L1* (which inhibits apoptosis) increased the resistance of OS cells to DOX. This study also indicated that downregulation of the expression of miR-184 increased DOX-induced apoptosis^[183].

Various studies have aimed to elucidate the molecular mechanisms which confer resistance to treatments, identify miRNAs that could be biomarkers of resistance to DOX and cisplatin, and recognize potential targets for future therapies based on increased sensitivity to chemotherapy. The results indicate that miRNAs are involved in the sensitivity of OS cells to several therapeutic agents [Table 2].

Non-coding miRNA in OS resistance: circRNA and lncRNA

Within the classification of non-coding RNAs are circular RNAs (circRNA) and long non-coding RNAs (lncRNA). circRNAs are characterized by a class of non-coding RNAs with a closed covalently loop without 5'-3' polarity, with a ring structure that gives them resistance and stability to degradation by exonucleases^[202]. circRNAs are determined for transcription^[203]. They can be classified according to their site of origin and splicing as intron (cell nucleus)^[204], exon (cytoplasm)^[203], or exon-intron combination^[205]. Currently, it has been revealed that circRNA can regulate gene expression at the transcriptional and post-transcriptional level by harvesting RNA-binding proteins, acting as miRNA sponges and nuclear transcriptional regulators^[206,207,208]. In OS, circRNA has been implicated in different processes such as proliferation, invasion, apoptosis, and chemoresistance. Zhang *et al.* reported that circ_1569 is upregulated in osteosarcoma^[209]. Overexpression of circ_001569 in OS correlated with distant metastasis, advanced tumor stage, and poor prognosis. In U2OS and MG63 cells, circ_001569 expression was elevated and increased cell proliferation. The deletion of circ_001569 decreased the proliferative capacity of OS cells. In addition, the up-regulation of circ_001569 promoted resistance to cisplatin, DOX, and MTX, allowing increased cell proliferation and colony formation mediated by Wnt- β -catenin pathway activation. circ_001569 deletion in OS cells decreased the expression of p-GSK3 β and β -catenin. The inhibition of Wnt/ β -catenin with XAV939 inhibitor decreased resistance to cisplatin, DOX, and MTX; on the contrary, LiCl (Wnt/ β -catenin agonist) increased resistance to chemotherapy^[209].

Previous studies have identified that overexpression of circPVT1 increases the expression of the ABCB1 gene, related to classical multidrug resistance in OS cells^[210]. circPVT1 is derived from a long non-coding RNA region located on chromosome 8q24 within the oncogene PVT1, a cancer susceptibility locus^[211]. Table 2. miRNAs regulating mechanisms of drug resistance, autophagy, cancer stem cells, and signaling pathways

miRNA	Alteration	Target gene	Mechanism	Effect on resistance	Drug	Reference
miR-124	Downregulation	<i>ATMIN</i> <i>PARP1</i>	DNA damage response	Increase	CPT, VP 16, and DOX	[173]
miR-15b	Downregulation	<i>WEE1</i>			DOX	[184]
miR 101	Downregulation	<i>ATG4,5</i>	Blockage of autophagy	Increase	DOX	[185]
miR 22	Downregulation	<i>HMGB1</i>		Increase	DOX and cisplatin	[186,187]
miR 30a	Downregulation	<i>BECN1</i>		Increase	DOX	[188]
miR 199a 5p	Downregulation	<i>BECN1</i>		Increase	Cisplatin	[189]
miR 155	Upregulation	<i>ATG5</i>	Induction of autophagy	Increase	DOX and cisplatin	[190]
miR 140 5p	Upregulation	<i>IP3K2</i>		Increase	DOX and cisplatin	[182]
miR 143	Downregulation	<i>ATG2B</i> <i>BCL2</i> <i>LC3-II</i>	Activation of autophagy and stem cells	Increase	DOX	[191]
miR let 7d	Downregulation or Upregulation	<i>HMGA2</i> <i>Lin28B</i> <i>Nanog</i> <i>Oct3,4</i> <i>Sox2</i>	Induction of EMT and plastic transition of CSC	Increase	DOX, cisplatin, VP-16, paclitaxel	[192]
miR 29b 1	Downregulation	<i>CD133</i> <i>N-Myc</i> <i>Nanog</i> <i>Oct3,4</i> <i>Sox2</i>	Reduction of CSC	Increase	DOX, cisplatin, and VP 16	[193]
miR 34c	Downregulation	<i>NOTCH1</i> <i>LEF1</i>	Inhibition of metastasis	Increase	DOX, cisplatin, and MTX	[194]
miR 34b	Downregulation	<i>PAK1</i> <i>MDR1</i>	Induction of cell apoptosis	Increase	DOX, GEM, and MTX	[195]
miR 497	Downregulation	<i>VEGFA</i>	Inhibition of proliferation	Increase	Cisplatin	[196]
miR 221	Upregulation	<i>PTEN</i>	Promotion of proliferation and inhibition of apoptosis	Increase	Cisplatin	[197]
miR 146b 5p	Upregulation	<i>ZNRF3</i>	Induction of migration and metastasis	Increase	DOX, cisplatin, and MTX	[198]
miR-488	Upregulation	<i>BIM</i>	Promotion of proliferation, reduction of apoptosis	Increase	DOX	[199]
miR-765	Downregulation	<i>APE-1</i>	Inhibition of DNA damage response	Decrease	Cisplatin	[179]
miR-21	Upregulation	<i>Spry1</i> , <i>Spry2</i> <i>PTEN</i>	Inhibition of migration/proliferation	Decrease	Cisplatin	[200] [201]
miR-138	Downregulation	<i>EZH2</i>	Inhibition of migration/proliferation	Decrease	Cisplatin	[180]
miR-140-5p	Downregulation	<i>IP3K2</i>	Induction of cell apoptosis	Decrease	DOX and cisplatin	[182]
miR-184	Upregulation	<i>BCL2L1</i>	Inhibition of cell apoptosis	Decrease	DOX	[183]
miR-367	Upregulation	<i>BAX</i> , <i>cleaved</i> <i>CASP3</i> , <i>KLF4</i>	Promotion of metastasis and EMT	Decrease	DOX	[181]

APE-1: Apurinic endonuclease; ATG2B: autophagy-related 2B protein; ATMIN: ataxia telangiectasia mutated interactor; BAX: BCL2 associated X; BCL2: B-cell lymphoma 2 protein; BCL2L1: BCL2-like 1; BECN1: beclin 1; BIM: B-cell lymphoma-like protein 11; CASP3: caspase 3; CPT: camptothecin; CD133: prominin-1; CSC: cancer stem cells; DOX: doxorubicin; EMT: epithelial-to-mesenchymal transition; EZH2: enhancer of zeste 2 polycomb repressive complex 2 subunit; GEM: gemcitabine; HMGA2: high mobility group AT-hook 2; HMGB1: high mobility group box 1; IP3K2: inositol 1,4,5 trisphosphate kinase 2; KLF4: Kruppel-like factor 4; LC3-II: light chain 3 type II protein; LEF1: lymphoid enhancer binding factor 1; LIN28B: lin-28 homolog B; MDR1: multidrug resistance 1; MTX: methotrexate; Nanog: Nanog homeobox; N-myc: mycn proto-oncogene; NOTCH1: Notch receptor 1; Oct 3 and 4: octamer-binding transcription factor 3 and 4; PAK1: p21 activated protein kinase 1; PARP1: poly(ADP ribose) polymerase 1; PTEN: phosphatase and tensin homolog; RAB10: Ras-related protein 10; Sox2: SRY-box transcription factor 2; Spry1 and -2: sprouty; VEGFA: vascular endothelial growth factor A; VP 16: etoposide; ZNRF3: zinc and ring finger 3.

Peng et al. demonstrated that circPVT1 overexpression in OS patients correlated with the presence of

metastasis and shorter survival^[210]. The expression of circPVT1 is related to DOX and cisplatin resistance. The downregulation of circPVT1 in OS cells decreased resistance to DOX and cisplatin in OS; it appears that circPVT1 deletion decreases resistance to DOX and cisplatin through downregulation of ABCB1 gene expression^[210].

lncRNAs, distinguished by having more than 200 nucleotides, do not encode proteins or their coding is limited^[212]. lncRNAs act as competitive endogenous RNA (ceRNA) regulators of miRNA expression and are driven to downstream genes^[213]. In addition, similar to circRNAs, their functions depend on their location^[214]. lncRNAs are involved in chromatin restoration, epigenetic organization, RNA splicing and phase splicing^[215]. lncRNA function is involved in transcriptional and post-transcriptional signaling at the cytoplasmic level^[216,217]. Thus, emerging evidence shows that lncRNAs are involved in OS chemoresistance. The lncRNA HOXA transcription at the distal tip (HOTTIP) located at the 5' end of the HOXA cluster potentiates the trimethylation of lysine 4 of histone H3 for the activation of multiple 5'Hoxa genes through the WDR5/MLL complex, which will trigger tumor progression^[218,219,220]. Recently, in osteosarcoma, upregulated HOTTIP expression correlates with advanced clinical stage, distant metastasis, and unfavorable prognosis^[221]. Li *et al.* demonstrated that upregulated HOTTIP in OS increased the expression of cyclin D1, CDK4, and β -catenin involved in cell cycle progression^[222]. Increased HOTTIP expression in MG63 cells promoted S-phase cell cycle and increased cisplatin resistance, which can be reversed by XAV939 (Wnt/ β -catenin inhibitor). Other lncRNAs have been implicated in OS proliferation, migration, and risk of metastasis and inhibition of apoptosis, a mechanism implicated in chemotherapy resistance, suggesting an important role of lncRNAs in OS tumorigenesis and chemotherapy resistance^[222]. A list of the most relevant circRNAs in drug resistance is presented in Table 3 and lncRNAs in Table 4.

AUTOPHAGY

Autophagy is the process through which cells protect and recycle cellular components (e.g., organelles and damaged proteins) that are degraded by autophagosomes. This process allows cells to survive under stress conditions^[18]. Autophagy is one of the most important strategies for malignant tumors to promote survival and induce resistance to chemotherapy^[236]. Some miRNAs regulate cytotoxic activity; therefore, these miRNAs can improve the sensitivity of OS drug-resistant cell lines to chemotherapy. Li *et al.* developed a model of OS resistant MG-63 cells^[189]. Following treatment with cisplatin, the expression of miRNA-199a-5p was decreased, the regulatory target gene Beclin 1 (*BECN1*) negative, and the expression and proportion of LC3-II to LC3-I were increased. These findings indicate the activation of autophagy. Forced overexpression of miRNA-199a-5p in OS cells resulted in the opposite result, inhibiting autophagy, enhancing the cytotoxicity of cisplatin, and reversing the resistance to cisplatin^[189]. Chang *et al.* found that miRNA-101 can block autophagy in OS and improve the chemosensitivity of cells to DOX *in vitro*^[185]. The results also reveal that autophagy could be induced with a certain dose of DOX in U2OS cells, while the expression of acidic vesicular organelles and another autophagy-related protein, A2g4, was decreased after transfection with miRNA-101, thereby blocking autophagy^[185]; this blockage increased the sensitivity of OS cells to DOX. In autophagy, miRNA-199a-3p can promote multidrug resistance by inhibiting the expression of the target gene adenylate kinase 4 (*AK4*). In this process, the reduction of miRNA-199a-3p can upregulate the activated NF- κ B pathway^[237]. Regarding autophagy, Wei *et al.* found that miRNA-140-5p was upregulated in OS cells treated with cisplatin and DOX^[182]. This effect inhibited the inositol 1,4,5-trisphosphate kinase 2 (*IP3K2*) gene and increased autophagy, leading to the development of drug resistance in OS^[182]. The use of chloroquine for reversing the autophagy mechanism is currently being explored in various types of tumors. In OS, chloroquine blocks the autophagic process in cisplatin-resistant OS cells; combination with rapamycin enhances the antitumor effect of this agent^[238,239]. Autophagy has been shown to be involved in the maintenance of OS cancer stem cell (CSC) characteristics^[240]. Stemness in CSCs is

Table 3. List of circular RNAs involved in drug resistance in osteosarcoma

circRNA	Alteration	Target gene	Mechanism	Effect on resistance	Drug	Reference
circ_001569	Upregulation	<i>Wnt/β catenin</i>	Promotes Proliferation	Increase	Cisplatin, DOX and MTX	[209]
circPVT1	Upregulation	<i>ABCB1</i>	Promotes proliferation	Increase	DOX and cisplatin	[210]
circ_0004674	Upregulation	<i>miR-137/TRIAP1</i>	Reduce apoptosis	Increase	DOX	[223]
		<i>circ_0004674/miR-490-3p/ABCC2</i>	Promotion of proliferation, migration, cell cycle progression, and reduction of apoptosis			[224]
		<i>circ_0004674/miR-1254/EGFR</i>				[225]

ABCB1: ATP-binding cassette subfamily B member 1; ABCC1: ATP binding cassette subfamily C member 1; DOX: doxorubicin; MTX: methotrexate; FENDRR: FOXF1 adjacent non-coding developmental regulatory RNA; FOXC2-AS1: Forkhead box C2 antisense RNA 1; HIF-1α: hypoxia-inducible factor 1 alpha; IFIT2: interferon-induced protein with tetratricopeptide repeats 2; LINC00161: long intergenic non-protein coding RNA 161; LUCAT1: lung cancer-related transcript 1.

avored by autophagy in some types of tumors, e.g., breast cancer, pancreatic ductal adenocarcinoma, colon cancer, etc. Osteosarcoma CD271+ cells have stem cell characteristics that seem dependent on autophagic activity, with an increased expression of essential autophagy genes such as *Beclin1*, *LC3B*, *Atg5*, and *Atg7* compared to CD271 OS cells. Autophagy confers to CD271+ OS cells several advantages including resistance to hypoxic conditions, chemotherapy resistance to cisplatin and epirubicin, and tumorigenicity

compared to CD271⁻ OS cells. Autophagy-deficient CD271⁺ OS cells had no remarkable difference with autophagy-deficient CD271⁻OS, suggesting an important contribution of autophagy to the stemness of CD271⁺ OS cells under stress conditions. Interestingly, the inhibition of the autophagy in CD271⁺ OS cells reversed chemotherapy resistance, resulting in a potential pathway to be explored in OS chemotherapy resistance^[241].

CANCER STEM CELLS

Cancer stem cells are a subset of cells within the microenvironment that self-renew and aberrantly mature into OS cells. These cells are characterized by a highly active DNA repair mechanism or enhanced protection against reactive oxygen species (ROS), increased expression of markers such as CD117 and CD133, and upregulation of *MDR1* protein transport genes (e.g., ABCG2) related to resistance to chemotherapy with DOX or drug efflux pumps^[18,242], which correspond to a combination of intrinsic and extrinsic factors contributing to CSC-mediated resistance to chemotherapy in OS. CSCs have an effective autophagy system and a complex EMT regulator capacity that lead to adaptation to TME stress conditions such as nutritional, metabolic, and oxygen privation^[243]. Other potential biomarkers have been reported in CSCs. Honoki *et al.* found an association of high expression of ALDH-1 (aldehyde dehydrogenase 1) with resistance to chemotherapy, as well as its metastatic potential^[244]. Schiavone *et al.* mentioned at least 20 biomarkers expressed by stem cells in OS, some of them related to chemoresistance, such as Oct4, Nanog, Sox2, CD24, CD44, Stro-1, CD133, KLF4, CBX3, and ABCA5^[245]. Despite recognizing the role of stem cells in this tumor, an important limitation to making them a potential therapeutic target for treatment or research is that the tumor stem cell population in OS that corresponds to a population of < 1%^[246]. Other cells with pluripotent stem cell characteristics are MSCs, which are cells highly associated with carcinogenesis, disease progression, metastasis, and drug resistance. Funes *et al.* evidenced MSC transformation in OS related to genetic alterations, such as p53 (*TP53*) and *RB* gene deficiency^[247]. For example, *Rb* pathway deficiency is sufficient to induce tumor growth and progression in hypoxic conditions and favor immune system infiltrations; both conditions may contribute to chemotherapy resistance. Mutations of p53 and *Rb* occur in one clone of OS cells and drive to chromosomal instability and further pro-tumoral events inherited to next-generation clones, resistant to chemotherapy^[33,248]. Additionally, aneuploidization and genomic loss of p16/CDKN2A are common causes of the transition from MSC to OS cells, and loss of p16/CDKN2A protein is a predictor of poor response to chemotherapy and worse overall survival in OS patients^[84,249,250]. Tu *et al.* observed that activation of the signal transducer and activator of transcription 3 (STAT3) by IL-6 regulated MSCs and induced resistance to DOX and cisplatin^[251]. Furthermore, the expression of p-STAT3 contributed to high resistance to chemotherapy in clinical samples of OS cells^[251]. Stem cells are involved in OS tumorigenesis and treatment response and are an important research topic in this tumor.

CONCLUSIONS

Although the application of chemotherapeutic agents contributes greatly to the effective treatment of OS, the emergence of acquired multidrug resistance remains a serious challenge. This is particularly important when using drugs that have shown greater efficacy in these tumors (e.g., cisplatin, DOX, and MTX). Several universal mechanisms underlying acquired resistance have been discovered, including drug transport, drug metabolism, aberrant drug targets, DNA damage response, apoptosis evasion, autophagy, epithelial-to-mesenchymal transition, *etc.* These mechanisms offer new directions for future management strategies that could improve oncological outcomes in patients with OS. Anti-angiogenic TKIs show that targeted therapy can improve the prognosis of this type of cancer. Novel pan-HER pathway TKIs, such as afatinib, may be effective in treating OS. New therapies that target tumor ECM pathways and the cell cycle may be helpful in overcoming resistance to chemotherapy and targeted therapy in OS.

Abstract

Gastric cancer (GC) is one of the most common causes of cancer-related death worldwide, and gastric cancer stem cells (GCSCs) are considered as the major factor for resistance to conventional radio- and chemotherapy. Accumulating evidence in recent years implies that GCSCs regulate the drug resistance in GC through multiple mechanisms, including dormancy, drug trafficking, drug metabolism and targeting, apoptosis, DNA damage, epithelial-mesenchymal transition, and tumor microenvironment. In this review, we summarize current advancements regarding the relationship between GCSCs and drug resistance and evaluate the molecular bases of GCSCs in drug resistance.

Keywords: Gastric cancer, gastric cancer stem cells, drug resistance, chemotherapy, molecular mechanisms

INTRODUCTION

According to GLOBOCAN estimates in 2020, gastric cancer (GC) is the fifth cause of global cancer incidence and the fourth leading cause of cancer mortality^[1]. The incidence rates of GC vary widely across the world, with the highest rates in East Asia and Eastern Europe^[1]. GC, most cases of which are gastric adenocarcinoma (GAC), is histologically divided into two subtypes [intestinal and diffuse (Lauren

classification)]^[2] or four subtypes [papillary, tubular, mucinous, and poorly cohesive (WHO classification)]^[3]. Based on genomic and epigenomic alterations, the most well-defined molecular-based classification systems include The Cancer Genome Atlas (TCGA) classification [EBV positive (EBV), microsatellite instable (MSI), genomically stable (GS), and chromosomal instable (CIN)]^[4] and the Asian Cancer Research Group (ACRG) classification [microsatellite instable (MSI), microsatellite stable TP53 inactive (MSS/TP53 inactive), MSS TP53 active (MSS/TP53 active), and MSS with epithelial–mesenchymal transition (EMT) features (MSS/EMT)]^[5]. Despite advances in the field of early diagnosis in GC, most cases are still diagnosed at an advanced stage^[6] with unresectable or metastatic disease. Although current systemic treatments, including surgery, chemotherapy, radiotherapy, immunotherapy, and targeted therapy [Table 1] for advanced GC patients, have been considerably improved during recent decades, most patients with advanced GC die from tumor relapse and metastasis. The prognosis of advanced and metastatic GC remains poor, and the 5-year survival rate is < 10%^[7].

Early GC patients can be cured with surgery alone. For advanced unresectable patients, chemotherapy represents the backbone of systemic therapy, and chemotherapy with or without radiotherapy has been integrated into standard-of-care therapies. Cytotoxic chemotherapy has been demonstrated to be effective for advanced GC patients, and the common cytotoxic chemotherapy drugs include fluoropyrimidines (e.g., fluorouracil, capecitabine, and S-1), platinum (e.g., cisplatin and oxaliplatin), taxanes (e.g., paclitaxel and docetaxel), topoisomerase inhibitors (e.g., irinotecan), and anthracyclines (e.g., doxorubicin and epirubicin). In patients with human epidermal growth factor 2 (HER2)-negative, advanced gastric adenocarcinoma, the current first-line treatment consists of two- or three-drug regimens. Doublet therapies are the combination of platinum derivatives (cisplatin and oxaliplatin) and fluoropyrimidine analogs (5-fluorouracil, capecitabine, and S-1). Three-drug regimens are the triplet combinations adding taxanes or anthracyclines (doxorubicin and epirubicin) to the doublet regimen. Table 2 summarizes the landmark trials for first-line treatment of advanced gastric cancer. However, the clinical benefit from these treatments is limited due to the toxicity of chemotherapeutic drugs and the development of drug resistance.

More recently, targeted therapies have been developed for gastric cancer patients. These include trastuzumab, lapatinib, and margetuximab for epidermal growth factor receptor-2 (HER-2); bevacizumab for vascular endothelial growth factor (VEGF); ramucirumab, apatinib, and regorafenib for vascular endothelial growth factor receptor (VEGFR); cetuximab and panitumumab for endothelial growth factor receptor (EGFR); bemarituzumab for fibroblast growth factor receptor (FGFR); everolimus for mTOR; and zolbetuximab for Claudin 18.2. Various targeted therapy approaches have been investigated; however, several clinical trials in gastric cancer have failed due to the tumor heterogeneity and the difficulty of screening the beneficiary population for targeted therapeutic drugs. Furthermore, immunotherapy is being developed to block the binding of ligands to checkpoint receptors and re-activate the human cellular immune response. These are immune checkpoint inhibitors (ICIs) including nivolumab and pembrolizumab as PD-1 inhibitors, durvalumab and avelumab as PD-L1 inhibitors, and ipilimumab and tremelimumab as CTLA-4 inhibitors. Several trials have demonstrated that the benefits of immunotherapy only or with cytotoxic chemotherapy are relatively limited^[17]. Thus, with relatively low response rates, the use of immunotherapy has only led to limited approval in the second-line treatment setting for GC^[18]. More and more promising targeted therapies and immunotherapies are being investigated, and these will likely further improve outcomes for patients. Table 3 summarizes the landmark trials for targeted therapy and immunotherapy of advanced gastric cancer.

Drug resistance leads to pharmacological treatment failure and poor outcomes for advanced GC patients. The mechanisms of drug resistance of GC are divided into seven groups, according to the previously

Table 1. A summary of systemic treatments in gastric cancer

Treatment approaches	Mechanisms	Regimen	Efficacy	Adverse effects
Surgery	Surgical resection	Open surgery, laparoscopic surgery, endoscopic resection, robotic surgery	Primary choice for early-stage GC	Low
Chemotherapy	Target and kill fast-dividing cells	Fluoropyrimidines, platinum, taxanes, irinotecan, etc.	The standard-of-care treatment for advanced GC	Damage to normal and healthy tissues
Radiotherapy	Ionizing radiation to target and kill tumor tissue	Ionizing radiation	Curative and palliative treatment	Damage to normal and healthy tissues
Targeted therapy	Target the specific molecules (HER2, VEGF, VEGFR, etc.)	Monoclonal antibodies and small molecule inhibitors	Use in combination with chemotherapy in first- and second-line settings	Relatively low
Immunotherapy	Block the binding of ligands to checkpoint receptors and re-activate the human cellular immune response	Immune checkpoint inhibitors (PD-1, PD-L1, and CTLA-4)	Use in second- and third-line settings	Relatively low

GC: Gastric cancer; HER2: human epidermal growth factor receptor 2; VEGF: vascular endothelial growth factor; VEGFR: vascular endothelial growth factor receptor; PD-1: programmed cell death protein 1; PD-L1: programmed cell death 1 ligand 1; CTLA-4: cytotoxic T-lymphocyte-associated protein 4.

Table 2. Landmark trials in first-line treatment of advanced gastric cancer

Studies	Treatment regimen	ORR	mPFS (mo), P-value	mOS (mo), P-value	Reference
MacDonald, <i>et al.</i> 1980	Fluorouracil, doxorubicin, mitomycin (FAM)	42%	NR	5.5	[8]

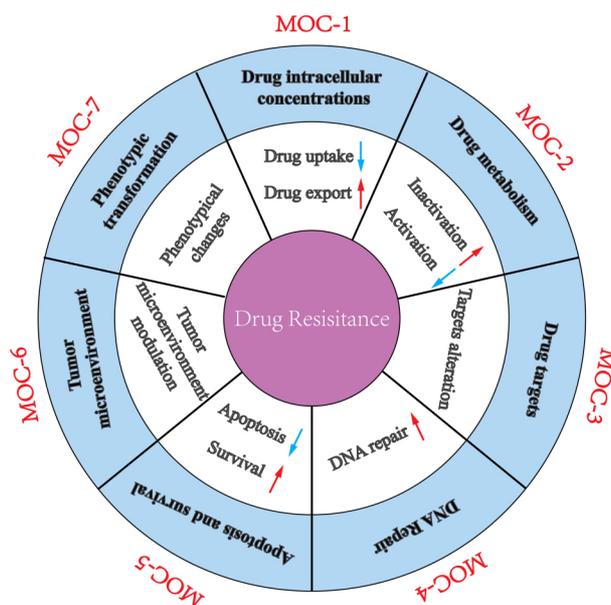

Figure 1. A schematic diagram depicting the molecular mechanisms accounting for drug resistance in gastric cancer.

Cancer stem cells (CSCs) are a subpopulation of stem cell-like cancer cells that are responsible for cancer pathogenesis including initiation, development, drug resistance, metastasis, and cancer recurrence^[41-43]. In recent years, accumulating evidence indicates the presence of CSCs in various types of cancers, including brain^[44], breast cancer^[45], head and neck cancer^[46], renal cancer^[47], colon cancer^[48-50], pancreatic cancer^[51-52], liver cancer^[53], lung cancer^[54], prostate cancer^[55], and melanoma^[56], and targeting CSCs may be essential to prevent tumor relapse and spread^[57]. Moreover, growing evidence suggests that there are several signaling pathways preferentially associated with CSCs^[58-60], including Hedgehog, Notch, WNT/ β -catenin, JAK/STAT, PI3K/PTEN, and NF- κ B pathways, which contribute to the survival, self-renewal, and differentiation

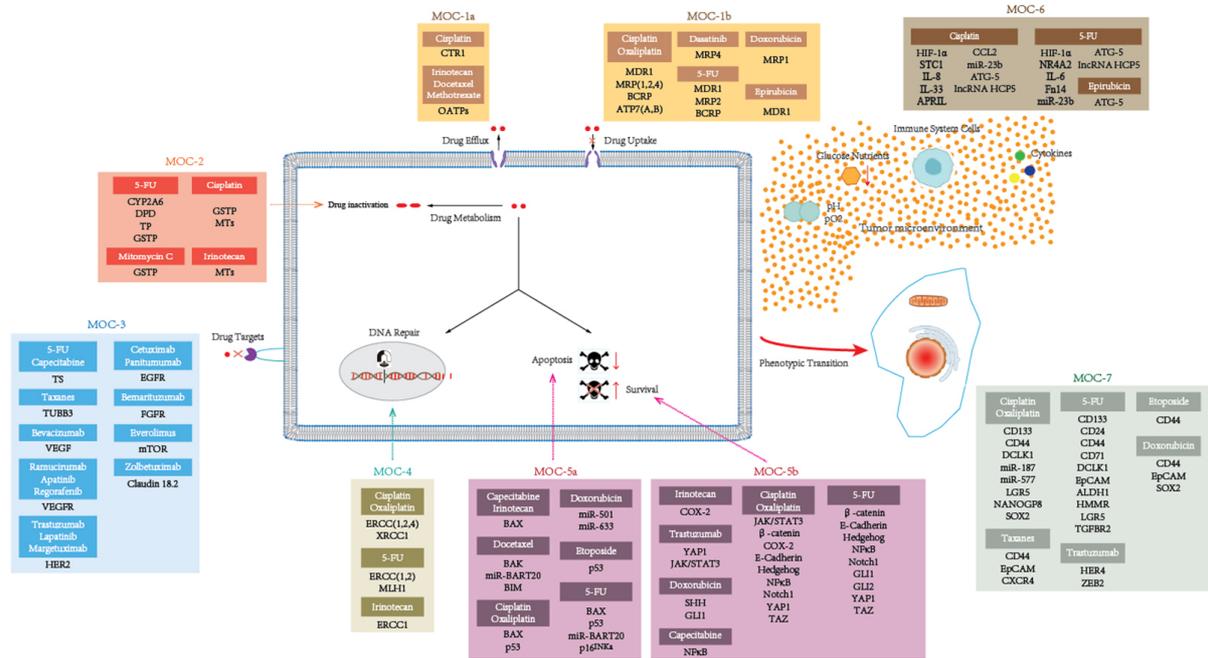

Figure 2. Proteins and non-coding RNAs accounting for drug resistance in gastric cancer. This figure is based on the work of Marin et al.^[40].

properties of CSCs^[61].

CSC-targeting therapies are currently being investigated to reverse chemoresistance, including chemotherapeutic and biological agents that target stemness pathways including Hedgehog, Notch, Hippo/YAP1, JAK/STAT, and Wnt/ β -catenin pathways; cancer stem cell surface markers including CD24, CD44, CD54, CD71, CD90, CD133, ALDH, CXCR4, EpCAM, LGR5, Sox2, and Oct4; the CSC microenvironment; and others^[62-64]. However, these current strategies to target CSCs are not specific to CSCs, leading to toxic effects on normal tissues.

CSCs in GC were first identified from a panel of human GC cell lines^[65]. Cancer stem cells from either human GC cell lines or tumor tissues were isolated using cell surface markers such as CD24, CD44, CD54, CD71, CD90, CD133, Lgr5, ALDH1, EpCAM, and CXCR4^[63, 66-67]. Although studies suggest the presence of gastric cancer stem cells (GCSCs), the origin of GCSCs is currently unclear and controversial. Two major hypotheses propose that GCSCs are derived from normal gastric stem cells (GSCs) or from bone marrow-derived mesenchymal stem cells (BM-MSCs)^[68, 69].

In recent years, growing evidence shows that GCSCs play important roles in drug resistance in GC. Thus, understanding GCSC functions and their roles in drug resistance, as well as defining the molecular mechanisms of drug resistance, will help identify potential anticancer drug targets and develop new chemotherapeutic drugs and effective therapeutic strategies to improve the clinical outcomes of GC patients. In this review, we summarize our current understanding of the roles of GCSCs in GC drug resistance, as well as provide a comprehensive analysis of the potential molecular mechanisms by which CSCs contribute to drug resistance in GC.

GCSCS AND DRUG RESISTANCE

Substantial studies have demonstrated that GCSCs are resistant to conventional radio-/chemotherapy. Aldehyde dehydrogenase (ALDH) is generally highly expressed in stem cells and considered as a CSC marker^[70]. Gastric cancer cells with high expression of ALDH showed strong resistance to 5-fluorouracil (FU) and cisplatin; thus, high expression of ALDH in GC cell lines is believed to play a key role in resistance to chemotherapeutic drugs in GC^[71,72]. Similarly, upregulation of LGR5, another GCSC marker, significantly enhanced cell stemness and drug resistance in MGC803 cells^[73]. Further studies have shown that LGR5+ GCSCs are resistant to cisplatin treatment^[74]. We recently showed that CD44+/CD54+ GCSCs isolated from cancer tissues can survive and expand after treatment with 5-FU and cisplatin^[75]. Consistent with our results, another study showed that KHDRBS3 plays an important role in the acquisition of 5-FU resistance by regulating CD44 variant expression^[76]. These results show that GCSCs play a key role in the acquisition of drug resistance in GC.

Accumulating evidence suggests the drug resistance capability of GCSCs is significantly higher than that of GC cells, and GCSCs can be enriched in GC after chemotherapy. Compared with GC cells, GCSCs showed stronger resistance to chemotherapeutic drugs 5-FU and oxaliplatin^[77]. CSCs can be isolated or enriched by CSC-specific surface markers or through stem cell side population (SP) analysis^[78]. Similarly, GCSCs isolated from GC cell lines by the SP method showed more resistance to chemotherapy^[79]. Further study showed that CD44+ GCSCs isolated from tumor tissues were significantly enriched after treatment with 5-FU^[80]. Another study demonstrated that ALDH+ CSCs in GC cell cultures can be enriched after treatment with cisplatin and 5-fluorouracil^[81]. Meanwhile, clinical studies have revealed that resistance to anticancer drugs of GC is mainly associated with GCSCs. Patients with high CD133 expression exhibited stronger drug resistance, higher relapse rate, and lower five-year survival rate compared with patients with low CD133 expression^[82]. Similarly, patients with high CD44 and CD133 expression showed worse survival^[83]. Furthermore, expression of LGR5 and CD133 was identified to be significantly associated with poor clinical outcomes, and patients who are LGR5+ and CD133+ showed a lower overall survival rate than those who are LGR5- and CD133-^[84]. The results from a phase II clinical trial show that GC patients with high expression CD44 who received chemotherapy with vismodegib, a hedgehog inhibitor, held a survival advantage^[85]. Therefore, GCSCs are a major factor in GC resistance to radiation and chemotherapy.

THE UNDERLYING MECHANISMS FOR GCSCS REGULATING THE DRUG RESISTANCE

Drug resistance is a multifactorial phenomenon involving various components and multiple interrelated pathways, which work together to contribute to the development of this phenomenon. Various CSC-associated signaling pathways and molecular mechanisms have been described as implicated in CSC drug resistance^[86]. To our knowledge, the underlying molecular mechanisms by which GCSCs contribute to chemoresistance include dormancy, drug trafficking, drug metabolism and targeting, apoptosis and cell death, DNA damage, epithelial-mesenchymal transition (EMT), and tumor microenvironment. The molecular mechanisms attributed to drug resistance in GCSCs are described below based on the previously proposed classification (MOC-1-7)^[40], and a schematic outline is summarized in [Figure 3](#).

Dormancy

Tumor dormancy contributes to the development of chemoresistance, metastasis, and cancer recurrence. CSCs are frequently in a quiescent state in which CSCs can remain in the G0/G1 stage with a low proliferation rate^[87,88]. As most conventional chemotherapeutic drugs target proliferating cells, quiescence properties support CSCs to become resistant to radio- and chemotherapy^[72,89-90]. Accordingly, 5-FU-resistant GC cells with CSC features were found to be mainly quiescent cells, which remained in the G0/1 phase^[91]. Similarly, IL-17 enhances the proliferative capacity of quiescent gastric stem cells^[92], potentially promoting

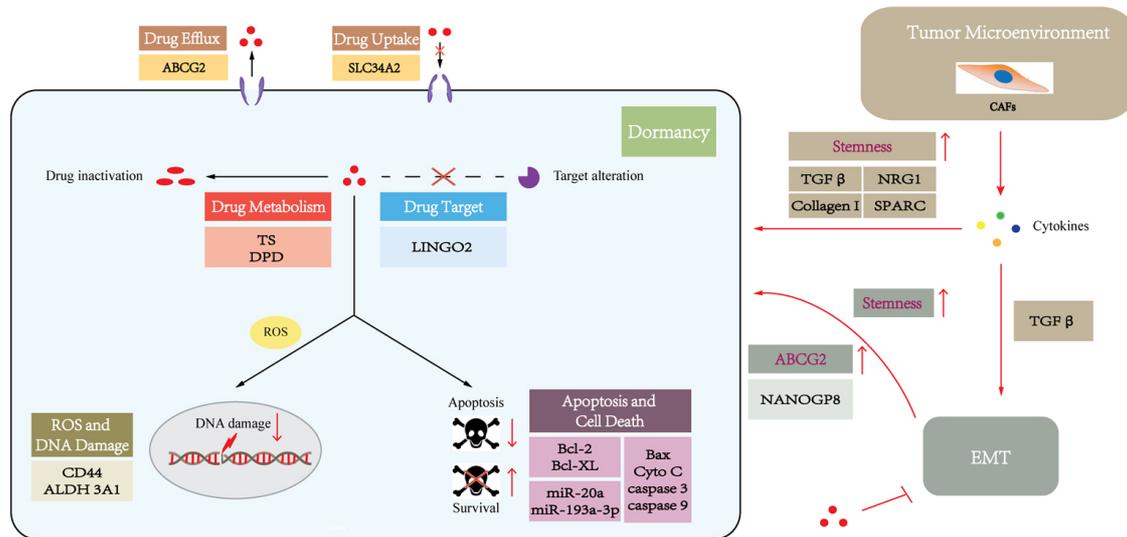

Figure 3. A schematic diagram depicting the molecular mechanisms accounting for chemoresistance in GCSCs. This figure is based on the work of Marin et al.^[40].

these transformed GCSCs to be sensitive to chemotherapy.

Changes in drug uptake, efflux, metabolism, and targeting

Reduced drug uptake

One of the most studied mechanisms of cancer drug resistance is reducing the uptake of drugs. The uptake of drugs into tumor cells can be active transportation mediated by the membrane transporters. Most of these membrane transporters are solute carrier (SLC) proteins, which play an essential role in drug uptake. The SLC protein family contains more than 300 proteins that mediate the absorption of multiple types of substrates, including amino acids, sugars, organic cations, anions, *etc.*, as well as chemotherapeutic drugs^[93]. Unexpectedly, SLC34A2 was found to be increased in CD44+ GCSCs, and suppression of SLC34A2 in GCSCs reduced the effects of chemoresistance^[94]. This result is consistent with SLC34A2 potentially having an oncogenic role in GC cells^[95]. However, the detailed molecular mechanism remains unclear, which requires further investigation.

Increased drug efflux

Another mechanism of drug resistance is associated with the increased efflux of cytotoxic drugs by active ATP-binding cassette (ABC) transporter proteins, which is known as “drug efflux”. Forty-eight ABC transporter members have been identified in humans and are divided into seven distinct subfamilies (ABCA-ABCG) with different functions. Only 13 ABC transporters (ABCA2/3, ABCB1/2/5, ABCC1/2/3/4/5/6/10, and ABCG2) have been directly associated with chemoresistance^[96]. Three major ABC transporters, including P-glycoprotein (P-gp/MDR1/ABCB1), multidrug resistance-associated protein 1 (MRP1/ABCC1), and breast cancer resistance protein (BCRP/ABCG2), have been found in various drug-resistant cancer cell lines and tissues and studied extensively for their correlation to multidrug resistance (MDR)^[97]. These ABC transporters can lower the intracellular drug concentration by pumping out chemotherapy-based agents, including vinblastine, vincristine, doxorubicin, daunorubicin, actinomycin-D, and taxanes^[98,99].

CSCs express a high number of ABC transporter proteins on their cell surface^[64,86], and ABC transporters in CSCs have been shown to play an important role in drug resistance^[72,100-101]. Therefore, ABC transporters are widely used as surface markers for CSC identification and isolation^[57].

ABCG2 is a major multidrug resistance pump, which is a downstream target of the sonic hedgehog (SHH)-glioma-associated oncogene homolog (GLI) signaling pathway^[102]. Recent studies have indicated ABCG2 plays a pivotal role in drug resistance in GCSCs. CD44+/Musashi-1+ GCSCs with increased expression of ABCG2 exhibited resistant to doxorubicin^[103]. Moreover, the inactivation of SHH-GLI signaling pathways decreased ABCG2 expression, rendering GCSCs more chemosensitive to doxorubicin^[103]. This result implies that ABCG2 is a potential therapeutic target against CSCs to overcome drug resistance. Moreover, inhibition of ABCG2 expression by genistein, which is the predominant isoflavone in soy products, could inhibit gastric cancer stem cell-like features and reduce the chemoresistance of GCSCs^[104]. Another study also demonstrated miR-132 could enhance cisplatin resistance in LGR5+ GCSCs via the SIRT1/CREB/ABCG2 signaling pathway^[74]. However, the roles of other ABC transporter proteins of GCSCs in drug resistance are not clearly defined, and further investigations are needed to explore the roles of ABCs in cancer therapies against GCSCs.

Altered drug metabolism

Thymidylate synthase (TS) and dihydropyrimidine dehydrogenase (DPD) are both key 5-FU metabolic enzymes. TS is a target enzyme of 5-FU, and 5-FU exerts an anticancer effect by its conversion into fluorodeoxyuridine monophosphate (FdUMP) which can form a ternary complex with TS to cause suppression of the de novo synthesis of dTMP. DPD is the initial and rate-limiting enzyme that translates 5-FU into metabolites without cytotoxicity. TS and DPD, which are representative markers of 5-FU resistance, were shown to be significantly upregulated in a 5-FU-resistant CSC-like cell population in GC^[76]. Hence, metabolic inactivation or alteration of the anticancer drugs in GCSCs enable CSCs to resist therapy and strengthen their stemness.

Changed drug targeting

Drug targeting altering by changing the expression and function of drug targets is also one of the major causes of drug resistance. Receptors of tyrosine kinase and its downstream signaling pathway play a pivotal role in carcinogenesis and tumor development and constitute the targets for tyrosine kinase inhibitors (TKIs). For instance, the EGFR signaling pathway is involved in the pathogenesis and progression of cancers by activation of either RAS/RAF/MEK/ERK or PI3K/AKT/mTOR cascade^[105]. The activation of MEK, a component of the EGFR/Ras/RAF/MEK/ERK signaling pathway, caused drug resistance to MEK inhibitors^[106]. Correspondingly, silencing LINGO2, a GCSC-related marker, reduced AKT, ERK, and MEK phosphorylation^[107], suggesting that activation of AKT, ERK, and MEK in GCSCs is responsible for chemoresistance to the inhibitors targeting these kinases.

Inhibition of apoptosis and cell death

One of the primary goals of most anticancer agents is to cause tumor-selective cell death. The resistance to apoptosis, one of the key regulatory events leading to cell death, is the hallmark of cancer. Apoptosis occurs through extrinsic and intrinsic pathways that are dependent on caspase activation and mitochondrial outer membrane permeabilization (MOMP), respectively. The extrinsic apoptotic pathway is often related to ligands such as TNF- α , TNF- α -related apoptosis-inducing ligand (TRAIL), and Fas-ligand (FasL) and cell death receptors such as TNFR, TRAILR, FasR, linker proteins, and caspases 3, 6, 7, and 8. The intrinsic pathway is triggered by mitochondrial membrane disturbance following various stimuli including DNA damage and radio-/chemotherapy. Pro-apoptotic proteins such as Bax and Bak, as well as anti-apoptotic

proteins such as Bcl2 and Bcl-XL are involved. Both intrinsic and extrinsic pathways activate caspases and ultimately lead to cell apoptosis. Increasing evidence suggests that disruption of the apoptotic pathway impacts resistance to anticancer drugs in GCSCs. Pro-apoptotic proteins including Bax, cytochrome C, caspase 9a, cleaved caspase 3, and cleaved caspase 9 were observed to be downregulated, while anti-apoptotic proteins Bcl-2 and Bcl-XL were upregulated in CD44+ GC cells compared with CD44- GC cells^[108]. Moreover, in CD44+ GC cells, inhibition of miR-193a-3p can induce apoptosis by activating the mitochondrial apoptotic pathway and enhance the chemotherapeutic response of cisplatin^[108]. Thus, GCSCs can induce resistance to drug-mediated apoptosis by upregulation or activation of anti-apoptotic proteins or downregulation or mutation of pro-apoptotic proteins. Similarly, miR-20a could increase cisplatin resistance in GC cells via modulating the anti-apoptotic factors livin and survivin^[109,110], whereas miRNA-19b, -20a, and -92a are proven to promote GCSCs properties^[111]. miR-20a may also be involved in the development of chemoresistance in GCSCs by modulating apoptosis through livin and survivin.

Repair and prevention of DNA damage

The dynamic balance between DNA damage and repair depends on the type of injury and the activity of a variety of repair mechanisms: nucleotide-excision repair (NER), base-excision repair (BER), mismatch repair (MMR), non-homologous end-joining (NHEJ), and homologous recombination (HR) systems. DNA damage-inducing agents are among the most effective treatment regimens in clinical chemotherapy. However, GCSCs can be resistant to DNA damage by drug treatment-induced reactive oxygen species (ROS) scavenging. Gastrointestinal cancer cells with high CD44 expression exhibited an enhanced capacity for GSH synthesis, resulting in defense against ROS^[112]. CSC marker ALDH can facilitate detoxification by scavenging of ROS, as well as by producing antioxidant compounds such as NADP^[113]. Aldehyde dehydrogenase 3A1 was found to be upregulated in gastric cancer stem-like cells^[114]. Moreover, in multiple GC cell lines and hematopoietic malignancies, ALDH is highly expressed in ROS-low cells, and ALDH-high/ROS-low cells may be cancer-initiating cells (CISs)^[115-117], which are also called CSCs. These data indicate that ALDH+ GCSCs can enhance the resistance to chemotherapy or radiochemotherapy by reducing the level of ROS and avoiding DNA damage.

Epithelial-mesenchymal transition

Epithelial-mesenchymal transition (EMT) is a process of lineage transition whereby epithelial cells lose their epithelial traits and acquire mesenchymal cell phenotypes, with corresponding changes in cell morphology and expression of surface markers^[118]. EMT facilitates tumor cell migration, invasion, metastasis, and drug resistance^[119]. Several cytokines, chemokines, and growth factors can trigger EMT by activation of a group of EMT-inducing transcription factors (EMT-TFs) such as SNAIL, SLUG, ZEB1/2, and TWIST^[120]. EMT is regulated by a wide, complex, interactive molecular network including exogenous inducers, intracellular regulatory miRNA, epigenetic modulators, and cellular signaling pathways including MAPK, ERK, PI3K, SMADs, and Wnt/ β -catenin^[121].

EMT has been shown to regulate the acquisition of stemness in multiple cancer cells^[122] and promote CSC stemness and quiescence that increase drug resistance^[123]. EMT could induce CSC characteristics that increase drug resistance through different mechanisms including the hedgehog, Wnt, Notch, and Musashi signaling pathways, as well as the epigenetic regulator Bmi1^[124,125].

EMT activation confers drug resistance in CSCs through other mechanisms, including promoting drug efflux by increased levels of ABC pumps or inhibition of cell apoptosis by elevated expression of anti-apoptotic proteins such as Bcl-XL^[123-124,126]. Correspondingly, NANOGP8, one of the pseudogenes in the NANOG gene family, is identified to be the main regulator of GCSCs, which can promote EMT/stemness and enhance chemoresistance^[127]. NANOGP8 may confer gastric cancer cells with chemoresistance by

upregulation of ABCG2^[127]. However, the exact molecular mechanisms responsible for EMT and the resulting drug resistance in GCSCs remain uncertain.

Adaptation to tumor microenvironment

CSCs are found in a specialized tumor microenvironment (TME), known as the niche, which is mainly composed of extracellular matrix (ECM), cancer-associated fibroblasts (CAFs), cancer-associated adipocytes (CAAs), and endothelial, mesenchymal, and immune cells, and those conditions promote CSC adaptation^[128-129]. Reciprocal interactions between CSCs and the niche are critical for CSCs to maintain their stemness properties and promote tumor initiation, metastasis, and drug resistance^[130].

Increasing evidence highlights that the TME takes part in therapeutic resistance in GCSCs, largely involving CAFs, which remarkably influence the TME via the secretion of various growth factors, cytokines, and chemokines^[131]. The main component secreted by CAFs is TGF β , which induces EMT^[132] and promotes the acquisition of GCSC features^[133], ultimately leading to drug resistance^[134]. Another study showed that CAFs can also promote stemness by the secretion of NRG1, which activates the NF- κ B signaling in GC^[135]. Moreover, CAFs can induce drug resistance not only by promoting stem-related signaling pathways in GCSCs but also by secreting type I collagen, which contributes to decreasing drug uptake^[136]. Additionally, a recent study demonstrated that low expression of gastric CAF-derived SPARC (secreted protein acidic and rich in cysteine) can promote GCSC transformation and 5-FU resistance^[137], suggesting that CAF-secreted SPARC may be involved in the regulation of drug resistance of GCSCs. Collectively, this evidence implicates an important role of the TME in the development of drug resistance of GC.

Exosomes

Exosomes (about 30-200 nm) are small extracellular vesicles (EVs) that originate from endosomes and are secreted by live cells into the extracellular space through the fusion of multivesicular bodies (MVBs) with the plasma membrane^[138]. They are composed of a transmembrane protein-containing lipid bilayer and cell-state-specific molecules including DNAs, mRNAs, ncRNAs, and proteins in the vesicle lumen. Exosomes, as carriers, mediate cell-to-cell communication and substance exchange via the transfer of donor cell-derived contents to recipient cells^[139]. Increasing evidence suggests that tumor-derived exosomes play critical roles in many aspects of cancer, including tumor growth, metastasis, angiogenesis, immunity, and other processes, and can be used as potential diagnostic biomarkers or therapeutic targets for cancer patients^[140-142]. Recent studies showed exosomes are associated with the transfer of the drug resistance phenotype, and cancer cells could develop drug resistance after the incorporation of exosomes from drug-resistant cancer cells. Studies indicated exosomal PD-L1 promotes chemoresistance via inducing T cell exhaustion, by which the T cells cannot be reinvigorated by anti-PD-1 treatment^[143]. Inhibition of exosomal PD-L1 has also been reported to enhance the efficacy of anti-PD-L1 treatment^[143,144]. Furthermore, another study showed chemotherapeutic agents stimulated the secretion of ABCB1-enriched exosomes from drug-resistant cells and increased the transfer of ABCB1 to the recipient cancer cells, thus assisting these sensitive cancer cells in developing the resistant phenotype^[145]. More recently, it has been shown that exosomal transference of wild-type EGFR to EGFR-mutated sensitive cancer cells promotes resistance to the mutant-selective EGFR inhibitor osimertinib by activating the MAPK and PI3K/AKT signaling pathways^[146]. Thus, exosomes could be novel therapeutic targets, which could overcome resistance to chemotherapeutic drugs^[105, 106] or antibody-based approaches^[143, 144], and they also might serve as a predictive biomarker for clinical responses to anti-PD-1 therapy^[144].

Increasing evidence also highlights that exosomes are involved in the drug resistance of CSCs. The underlying mechanisms are complex, including cell cycle blockage, increased drug efflux, upregulation of detoxifying enzymes, enhanced anti-apoptotic capacity and DNA repair efficiency, inducing EMT process,

and immunosuppression^[147,148]. However, the physiological and functional properties of exosomes in GCSCs are still unknown and need further investigation.

Extrachromosomal circular DNA

Extrachromosomal circular DNA (eccDNA) refers to a type of double-stranded circular DNA that originates from but is independent of chromosomes, which is widely present in various eukaryotic cells and can be derived from anywhere in a genome with sizes ranging from hundreds of base pairs (bp) to several megabases (Mb)^[149]. According to the size and origin, eccDNAs can be categorized into organelle eccDNAs such as mitochondrial DNAs (mtDNAs) or non-organelle eccDNA such as telomeric circle (t-circles), microDNA (100-400 bp), small polydispersed circular DNA (spcDNA) (100 bp-10 kb), episomes, and double minutes (DMs) (100 kb-3 Mb)^[150]. eccDNAs play important roles in gene regulation, sponging of transcription factors, environmental adaptation and evolution, aging, immune response, cell-to-cell communications, and tumor development^[151,152].

eccDNAs have been shown to help cancer cells develop drug resistance via various mechanisms [Figure 4]. (A) Amplification of drug target genes: For instance, DMs, which contain the gene coding for dihydrofolate reductase (DHFR), were identified to be amplified and associated with the development of methotrexate (MTX) resistance^[153]. (B) Amplification of multidrug resistance (MDR) genes: DMs, bearing the multidrug resistance 1 (MDR1) gene, were amplified in human epidermoid carcinoma cells and caused resistance to various anticancer drugs by upregulation of MDR1^[154]. (C) “Hide and seek” mechanism: EGFRvIII, an oncogenic variant, can induce tumor cells to be more sensitive to EGFR tyrosine kinase inhibitor (TKI). Previous studies have demonstrated that erlotinib resistance in glioblastoma is caused by the elimination of DMs containing EGFRvIII^[155,156]. However, after erlotinib withdrawal, the mutant EGFR re-emerged on DMs, which induced GBM cells to be re-sensitive to erlotinib treatment^[156]. Through this “hide and seek” mechanism, cancer cells can evade drug therapy by dynamic modulation of drug-targeted oncogenes residing on eccDNAs. (D) Increasing intratumoral heterogeneity: eccDNAs can drive heterogeneity among daughter tumor cells, thus inducing these cells to obtain survival advantage under drug pressure^[150]. (E) Increasing homologous recombination activity: Homologous recombination is associated with eccDNA biogenesis. Recent studies have shown that homologous recombination activity was increased in DM-carrying MTX-resistant colon cancer cells, whereas inhibition of homologous recombination activity decreased the expression of DM-containing genes and enhanced drug sensitivity in MTX-resistant cells^[157].

eccDNAs contribute to a variety of features in cancers and may serve as novel, promising molecular markers to shed new insights into the diagnosis, prognosis, and treatment of cancer patients. However, the functions and underlying mechanisms of eccDNA in CSCs are still unclear and require further exploration.

Helicobacter pylori infection

Helicobacter pylori (*H. pylori*) infection remains a main risk factor in the development of GC. In 1994, *H. pylori* was diagnosed as a Group I carcinogen by the WHO (World Health Organization)^[158]. The stem cell hypothesis of cancer formation is that stem or progenitor cells can acquire CSC characteristics, evade homeostatic control, and lead to carcinogenesis. *H. pylori* has been shown to induce EMT and cancer stem cell (CSC)-like properties in gastric epithelial cells^[159,160] and gastric cancer cells^[161,162]. Data from multiple studies show that *H. pylori* may directly interact with gastric stem/progenitor cells^[163-164] or bone marrow-derived cells (BMDCs)^[165] to impact the status and properties of these cells, which could be responsible for generating GCSCs. Moreover, *H. pylori* infection can induce inflammation, impact the local microenvironment, and affect gastric stem/progenitor cells and their differentiation by inducing genetic or epigenetic alterations^[166-168]. *H. pylori* infection can mediate oncogenic transformation by inducing GCSCs generation or affecting gastric stem/progenitor cells. However, the underlying mechanisms leading to GCSC

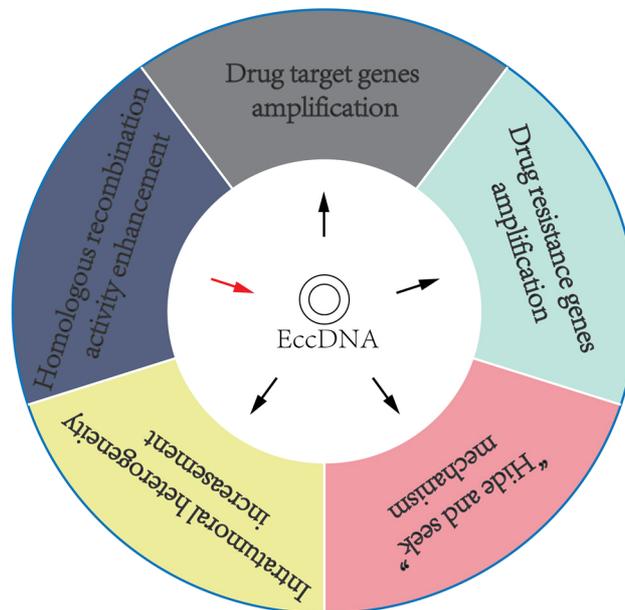

Figure 4. Overview of our current understanding of cancer drug resistance mechanisms induced by eccDNAs.

emergence and the resulting drug resistance in GCSCs in response to *H. pylori* infection are awaiting further investigation.

CONCLUSION

Conventional radio-/chemotherapy provides a limited effect on prolonging the survival of advanced GC patients, and, recently, accumulating evidence shows that GCSCs are resistant to conventional chemotherapy and play a direct role in tumor metastasis and relapse. Based on the extensive evidence presented in this review, it is obvious that GCSCs regulate tumor radio-/chemoresistance via multiple intrinsic and extrinsic mechanisms. This review aims to provide an understanding of the precise mechanisms underlying GCSC resistance to chemotherapeutic drugs. Identifying the molecules and revealing insight into their interaction networks through further investigations may help to discover novel targets of anticancer therapy, develop new therapeutic approaches for the prevention of tumor recurrence and resistance, and increase the lifespan of GC patients.

However, to date, molecular mechanisms of drug resistance in GCSC remain largely unclear. Many aspects are still in need of further clarification: (1) to find more key components or molecules for regulating GCSCs resistance to the anticancer agents; (2) to define the precise molecular mechanisms and clarify how GCSCs coordinate these different, complex molecular pathways to respond to the chemotherapeutic drugs; and (3) to find the specific GCSC markers related to its response to the anticancer agents, so as to evaluate the effectiveness of different drugs and therapeutic strategies. More importantly, many more need to be proven to be effective in the clinic. We are at the beginning of understanding drug resistance from gastric cells to GCSCs. More basic and clinical studies should be done to increase the knowledge about the mechanisms of drug resistance to improve the outcome of advanced GC patients.

DECLARATIONS

Abstract

Aim: Malignant pleural mesothelioma is a chemoresistant tumor, and biphasic and sarcomatoid histologies portend the worst prognosis for malignant pleural mesothelioma (MPM) patients. We obtained the microRNA expression profile of three biphasic-sarcomatoid MPM cell lines to identify commonly expressed microRNAs and evaluate the effect of butein, a chemo-sensitizing compound, on this microRNA subset.

Methods: Nanostring-based microRNA profiling and analysis through the ROSALIND platform were employed to identify the commonly modulated microRNAs and their targets. MicroRNA-mimic transfection, Luciferase assay, and Western blotting were employed to show specific perturbation of TWIST1 levels by miR-186-5p. Sphere-forming assays, invasion assay, and metabolic profiling were used to assess the biological consequences of the butein-instigated miR-186-5p-mediated perturbation of TWIST1 levels. TGCA analysis was used to search for the correlation between TWIST1 and miR-186-5p levels in biphasic and epithelioid MPM specimens.

© The Author(s) 2022. **Open Access** This article is licensed under a Creative Commons Attribution 4.0 International License (<https://creativecommons.org/licenses/by/4.0/>), which permits unrestricted use, sharing, adaptation, distribution and reproduction in any medium or format, for any purpose, even commercially, as long as you give appropriate credit to the original author(s) and the source, provide a link to the Creative Commons license, and indicate if changes were made.

Results: We identified a set of perturbed microRNAs, common to three biphasic/sarcomatoid MPM cell lines, after butein treatment. When focusing on miR-186-5p, we unraveled a butein-ignited and miR-186-5p-mediated modulation of TWIST1 levels which affected the 3D anchorage-independent growth, cisplatin resistance, invasion, and bioenergetics of the MPM cell lines tested. We showed that miR-186-5p and TWIST1 levels are anti-correlated in biphasic MPM specimens from TCGA.

Conclusion: We unraveled a novel mechanism of action of butein, which attenuated the pro-tumorigenic features of MPM at least through a miR-186-5p-TWIST1 axis. We suggest that those activities converge into the chemo-sensitizing effect of this compound and may be of translational relevance.

Keywords: Mesothelioma, butein, miR-186-5p, TWIST1, epithelial-to-mesenchymal transition (EMT), chemoresistance, cancer metabolism, invasion, anchorage-independent growth

INTRODUCTION

Mesothelioma is a neoplastic disease arising from the mesothelial linings of the pleural and peritoneal space. Its pathogenesis and progression envisage genomics alterations and environment-derived chronic inflammation in a complex interplay, with much left to be understood^[1,2]. Three main histological presentations characterize malignant pleural mesothelioma (MPM), named epithelioid, biphasic, and sarcomatoid^[3]. Rather than being separate entities, these histotypes may represent a structural–functional continuum where epithelial-to-mesenchymal transition (EMT) plays an important role^[4]. EMT may correlate with specific pro-tumorigenic features^[5], which contribute to the worse prognosis of biphasic and sarcomatoid MPMs. In fact, the expression of EMT genes has prognostic significance in MPM^[6]. MPM exhibits long clinical latency and significant resistance to therapy, with the latter impacting only to a limited extent the natural history of the disease. As a result, prognosis for MPM patients results in poor PFS and OS^[1,7,8]. The mainstay of MPM treatment is still represented, for first-line or inoperable patients, by cisplatin and antifolate^[1,9]. *Ex vivo* studies have shown that MPM cells are endowed with high resistance to therapy^[10]; therefore, attenuating such a process is an unmet need. We and others showed that specific rearrangement of cell subpopulations, sustained by the acquisition of a senescence-associated secretory phenotype (SASP), may underlie the emergence of MPM chemoresistance^[11-14]. We found that a naturally occurring compound with pleiotropic functions, butein (20,40,3,4-tetrahydroxychalcone), interfered with the emergence of those chemoresistant aldehyde dehydrogenase-positive (ALDH^{Pos}) cell subpopulations, by simultaneously blocking NFκB and STAT3 signaling^[15,16]. Such interference with the intra-tumor heterogeneity of MPM translates into reduced adaptive stress responses and, ultimately, chemo-sensitizing effects, partially sustained by changes in the gene expression profile of the treated cells^[17]. Butein is also known to exert chemo-sensitizing effects via AKT signaling and modulate the MAPK pathway through its antioxidant functions^[18-20]. We also recently showed that butein modulates the levels of DNA repair genes, which further contributes to its chemo-sensitizing activity^[17].

miRNAs are non-protein-coding single-stranded RNAs^[21]. miRNAs bind generally to the 3' untranslated region (3'-UTR) of mRNAs of target genes, thereby functioning as the negative posttranscriptional regulators of gene expression^[22]. miRNAs modulate key processes of tumor initiation and progression, ranging from the acquisition of pro-metastatic features to metabolic reprogramming and chemoresistance^[23-26].

miR-186-5p is a debated miRNA since its role ranges from oncogenic to a tumor suppressive one, in a cancer-tissue and stage-specific manner^[27]. There is an established link between miR-186-5p expression and resistance to therapy including cisplatin, taxol, and methotrexate^[28-33]. miR-186-5p was shown to target

twist-related-protein-1 (TWIST1), a key EMT-related transcription factor, in three different settings^[28,30,34]. Changes in TWIST1 level could portend a poor prognosis in TCGA cohorts of several cancer settings^[6]. TWIST1 modulates aerobic glycolysis in pancreatic cancer cells by increasing the expression of key glycolytic genes, including *HK2* and *PKM2*^[35]. Insightfully, the ability of TWIST1 to impinge on EMT and metabolic reprogramming may converge toward the acquisition of chemoresistant phenotype. In fact, EMT is a key process toward the acquisition of chemoresistance^[36,37]. TWIST1 is upregulated in MPM tumors and cell lines and may play a role in the development of MPM^[6,38]. Further, vaccines against TWIST1 were recently shown to enhance CTLA-4 blockade in experimental mesothelioma immunotherapy approaches^[39].

Butein was shown by others and us to be capable of reversing chemoresistance to cisplatin and pemetrexed in MPM^[15,16,18]. We hypothesized that butein exerted its chemo-sensitizing effects at least partially through microRNA modulation. Thus, we performed a microRNA expression analysis of three MPM cell lines with sarcomatoid and biphasic originating histotypes and identified 33 microRNAs modulated by butein. Among the identified targets, we focused on the miR-186-5p axis and demonstrated a miR-186-5p-mediated modulation of TWIST1 expression level. We showed that such modulation may explain at least in part the chemo-sensitizing effect of butein, thereby perturbing 3D anchorage-independent growth, cisplatin resistance, invasion, and bioenergetics of the MPM cells.

METHODS

Reagents

Butein (C₁₅H₁₂O₅) was purchased from Cayman Chemicals (Ann Harbor, MI, USA) and dissolved in DMSO (Sigma-Aldrich, St. Louis, MO, USA). Cisplatin (CDDP) was purchased from Selleckchem (Houston, TX, USA).

Cell culture

Cells were cultured in Ham's F12 supplemented with L-glutamine 10% fetal calf serum (Gibco BRL, Grand Island, NY), 100 U/mL penicillin, and 100 µg/mL streptomycin in a humidified atmosphere containing 5% CO₂ at 37 °C. The human MPM cell lines MSTO-211H, NCI-H2373, and HP1 were described previously^[12]. All cell lines were in-house tested for mycoplasma contamination by using a commercially available PCR-based assay (R&D Systems, Minneapolis, USA).

Cell metabolism

A Seahorse Bioscience XF24 Extracellular Flux Analyzer was used to measure the extracellular acidification rate (ECAR) and oxygen consumption rate (OCR). Logarithmically growing mesothelioma cell lines were maintained in normal complete growth media and seeded onto a gelatin-coated 24-well XF Flux Analyzer assay plate at 80,000 cells/well (NCI-H2373) or 40,000 cells/well (HP1 and MSTO.211H) 24 h prior to assay. These seeding numbers were determined based on the doubling time of the mentioned cell lines. Cells were switched to serum-free XF assay media (Seahorse Biosciences, Billerica, MA, USA) with 25 mM glucose, 1 mM sodium pyruvate, and 2 mM glutamine and placed in a CO₂-free incubator at least 2 h before the assay. Multiple measurements were obtained at baseline and following injection, sequentially of glucose (10 mM), oligomycin (2 µM), and 2-deoxyglucose (100 mM) (Merck Life Science, Milan, Italy) for ECAR measurement and oligomycin (1 µM), FCCP (0.25 µM), and rotenone (1 µM) (Merck Life Science, Milan, Italy) for OCR measurement. Values are reported as mpH/min for ECAR and pmoles/min for OCR.

Western blotting assay

Whole cell extracts (40-50 µg) from cells or tissues were separated by SDS-PAGE and then transferred to polyvinylidene difluoride membranes (PVDF; Bio-Rad, Hercules, CA, USA). The membranes were blocked and then probed with antibodies against TWIST1 (ab50887) and anti-alpha tubulin (ab176560) as a loading

control (Abcam, Cambridge, MA, USA). After washing, the blots were incubated with horseradish peroxidase-conjugated secondary antibodies.

Transfection of mimic-186-5p

The miR-186 mimics (mirVana® miRNA mimic) and its negative control (mirVana™ miRNA Mimic Negative Control) (ctrl) mimics were from ThermoFisher (Waltham, MA, USA). Cells were seeded in 60 mm dishes and transfected (25 nM each) in Ham's F12 with reduced serum [2% fetal bovine serum (FBS)] using the JetPrime reagent (Polyplus Transfection, New York, NY) before being processed for downstream analyses.

Luciferase 3-UTR assays

The TWIST1 3' UTR fragment sequence containing the binding site with miR-186-5p was cloned into the pMIR-reporter vector (Addgene, Cambridge, MA). A quick-change site-directed mutagenesis kit (Stratagene, CA, USA) was used to mutate the miR-186-5p binding site. For reporter assays, the MPM cell lines and the HEK293 cells (as a technical control for higher transfection efficiency) were transiently co-transfected with the TWIST1 3' UTR luciferase vector or mutant 3' UTR with miR-186 mimic or ctrl by JetPrime reagent (Polyplus Transfection, New York, NY). The firefly luciferase activities were measured consecutively using the Luciferase Reporter assay system (Promega, Madison, NJ, USA), according to the manufacturer's protocol. The percentage of luc activity in the cells transfected with miR-186-5p mimics over the cells transfected with the ctrl mimics was reported.

Invasion assay

Cell invasion was assessed using a Matrigel invasion assay. Briefly, diluted Matrigel matrix was carefully added to the center of each Transwell® insert (8 µm PET membrane, Corning, NY, USA) for invasion assays. Cells were starved of serum for 24 h and then seeded in triplicate. Lower chambers contained serum-free medium or medium supplemented with 20% FBS. The inserts were washed twice with PBS1X before fixing and staining in crystal violet solution for 15 min and then air-dried. The invaded and migrated cells were observed and imaged under a microscope. The bound crystal violet was eluted with 33% acetic acid and the eluent absorbance at 590 nm was measured.

Sphere-forming assay

For generating cell spheroids, a variable number of single cells/well were seeded into BIOFLOAT™ 96-well plates (FaCellitate, Germany) in DMEM-F12/1:1 + Glutamax supplemented with B27 (no RA), BSA, bFGF (20 ng/mL), and hEGF (10 ng/mL) (Life Technologies Inc., Grand Island, NY, USA).

Assessing chemo-sensitivity to cisplatin

For the determination of IC₅₀, formed MPM spheroids at Passage 2 were incubated in media with or without the addition of cisplatin (0-100 µM) for 12 h before drug withdrawal. After 72 h, the IC₅₀ was defined as the cisplatin dose capable of reducing by 50% the average number of spheroids from four to six independent 96 wells.

Viability assay

Cells were shortly pulsed with butein (10 µM) or ctrl (0.01% DMSO) for 8 h and viability was assessed by flow cytometry-based detection of Sytox-Blue positive cells (Sytox Blue Dead cell stain, Thermo Fisher, CA USA) at 12, 24, 48, 72, and 96 h after drug withdrawal.

RNA expression analysis

Analysis was performed on all samples using the nCounter Analysis System (NanoString Technologies, Seattle, WA, USA) and the nCounter Human v2 miRNA Panel that contains 798 unique miRNA barcodes. Probes for housekeeping genes such as ribosomal protein L10 (RPL10), beta-actin (ACTB), beta-2-microglobulin (B2M), glyceraldehyde 3-phosphate dehydrogenase (GAPDH), and ribosomal protein L19 (RPL19) were used as internal controls.

ROSALIND® nanostring miRNA expression analysis

Data were analyzed by ROSALIND® (<https://rosalind.bio/>), with a HyperScale architecture developed by ROSALIND, Inc. (San Diego, CA). Normalization, fold changes, and *P*-values were calculated using criteria provided by Nanostring (Seattle, WA, USA). Following background subtraction based on POS_A probe correction factors, normalization was performed in two steps: positive control normalization and codeset normalization. During both steps, the geometric mean of each probeset was used to create a normalization factor. ROSALIND calculated fold changes and *P*-values for comparisons using the *t*-test method. *P*-value adjustment was performed using the Benjamini-Hochberg method of estimating false discovery rates (FDR).

Statistical analysis

Where appropriate, statistical analysis was performed using Student's *t*-test and $P \leq 0.05$ were considered statistically significant. Group analysis was performed by ANOVA and Prism GraphPad software.

Principal component analysis

For creating principal component analysis (PCA) plots, Clustvis was employed <https://biit.cs.ut.ee/clustvis>.

RESULTS

Butein treatment modulated microRNA expression levels

We performed microRNA profiling of three MPM cell lines: NCI-H2373, HP1, and MSTO-211H [Figure 1]. The three cell lines shared a biphasic (HP1, MSTO211H) and sarcomatoid (NCI-H2373) originating histo-type, both associated with worse prognosis and lower response to therapy. The three MPM cell lines exhibited different microRNA expression patterns, as assessed by PCA [Figure 1A]. We interrogated this microRNA expression profile to identify a set of microRNAs common to all three cell lines, thereby hypothesizing that commonly modulated sets of microRNAs can predict functions common to the biphasic/sarcomatoid cyto-type. We thus identified a limited set of commonly expressed microRNA ($n = 33$, Figure 1B, C and Supplementary Table 1). Butein treatment, executed at non-apoptotic concentrations and schedule of administration^[17] [Supplementary Figure 1A], determined a clear perturbation of microRNA levels, as assessed by the PCA analysis [Figure 1B and C]. This revealed a clear separation, on the main PC component (PC1: 81.9%), of the three MPM cell lines as a function of butein treatment [Figure 1D]. When focusing on microRNAs significantly modulated by butein treatment, we observed that microRNA downregulation prevailed after treatment with butein, with a much smaller subset ($n = 6$) of microRNAs upregulated by butein [Figure 1C].

TWIST1 is a miR-186-5p target in butein-treated MPM cells

Among the upregulated microRNAs, we focused on miR-186-5p for its important contribution to EMT and chemoresistance in other cancer settings and because one of its targets, TWIST1, is an important factor in MPM progression^[40,41] and a target of butein^[16]. To verify that TWIST1 was a target of miR-186-5p, we co-transfected the three MPM cell lines and a non-MPM cell line (HEK293, as a control) with either miR-186-5p mimics or its control (ctrl mimics) [Supplementary Figure 1B] at 25 nM and with expression vectors containing luciferase under the control of the TWIST1 3'-UTR region, wild-type (wt), or mutated (mut)

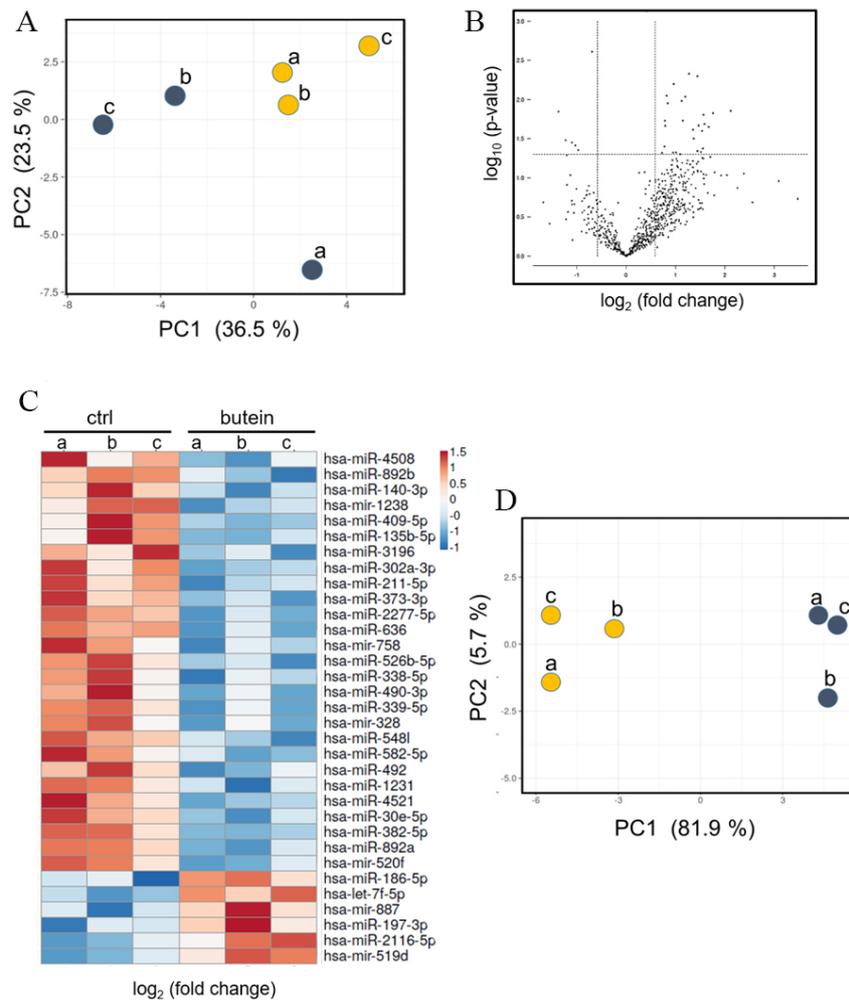

Figure 1. Butein treatment modulated microRNA expression levels. (A) PCA plot of the microRNAs expressed in: HP1 (a); NCI-H2373 (b); and MSTO-211H (c). Blue indicates samples treated with ctrl (DMSO 0.01%), while yellow indicates samples treated with butein for 8 h at 10 μ M. (B) Volcano Plot showing the microRNAs commonly modulated in all three MPM cell lines and whose perturbation by butein reached statistical significance. (C) Heatmap showing the normalized levels of the microRNAs common to the three MPM cell lines, treated as in (A). Log₂ fold changes are reported. The average of the two experiments is shown. (D) PCA plot showing the distribution of the three MPM cell lines treated as in (A), after selecting the commonly modulated miRNAs.

[Figure 2A, inset]. The luciferase activity in the MPM cells transfected with miR-186-5p mimics was significantly lower than that in the cells with control sequences [Figure 2A]. HEK293 cells exhibited the highest degree of luciferase downregulation, possibly as a consequence of increased transfection efficiency [Figure 2A]. To confirm that the reduced luciferase activity was caused by miR-186-5p binding to the seed site of 3'-UTR, the seed sequence of TWIST1 3'-UTR was mutated in the luciferase reporter construct. No significant changes in the luciferase activity were recorded when the mutated 3'-UTR-luc construct was co-transfected with the miR-186-5p mimics [Figure 2A]. We performed Western blotting experiments in NCI-H2373 cells transfected with either ctrl or miR-186-5p mimics or treated with ctrl (DMSO) or butein. We found that both butein treatment (10 μ M for 8 h) and miR-186-5p mimics similarly affected the TWIST1 protein levels, when compared to their respective controls [Figure 2B], and this held true for all three MPM cell lines tested [Figure 2C].

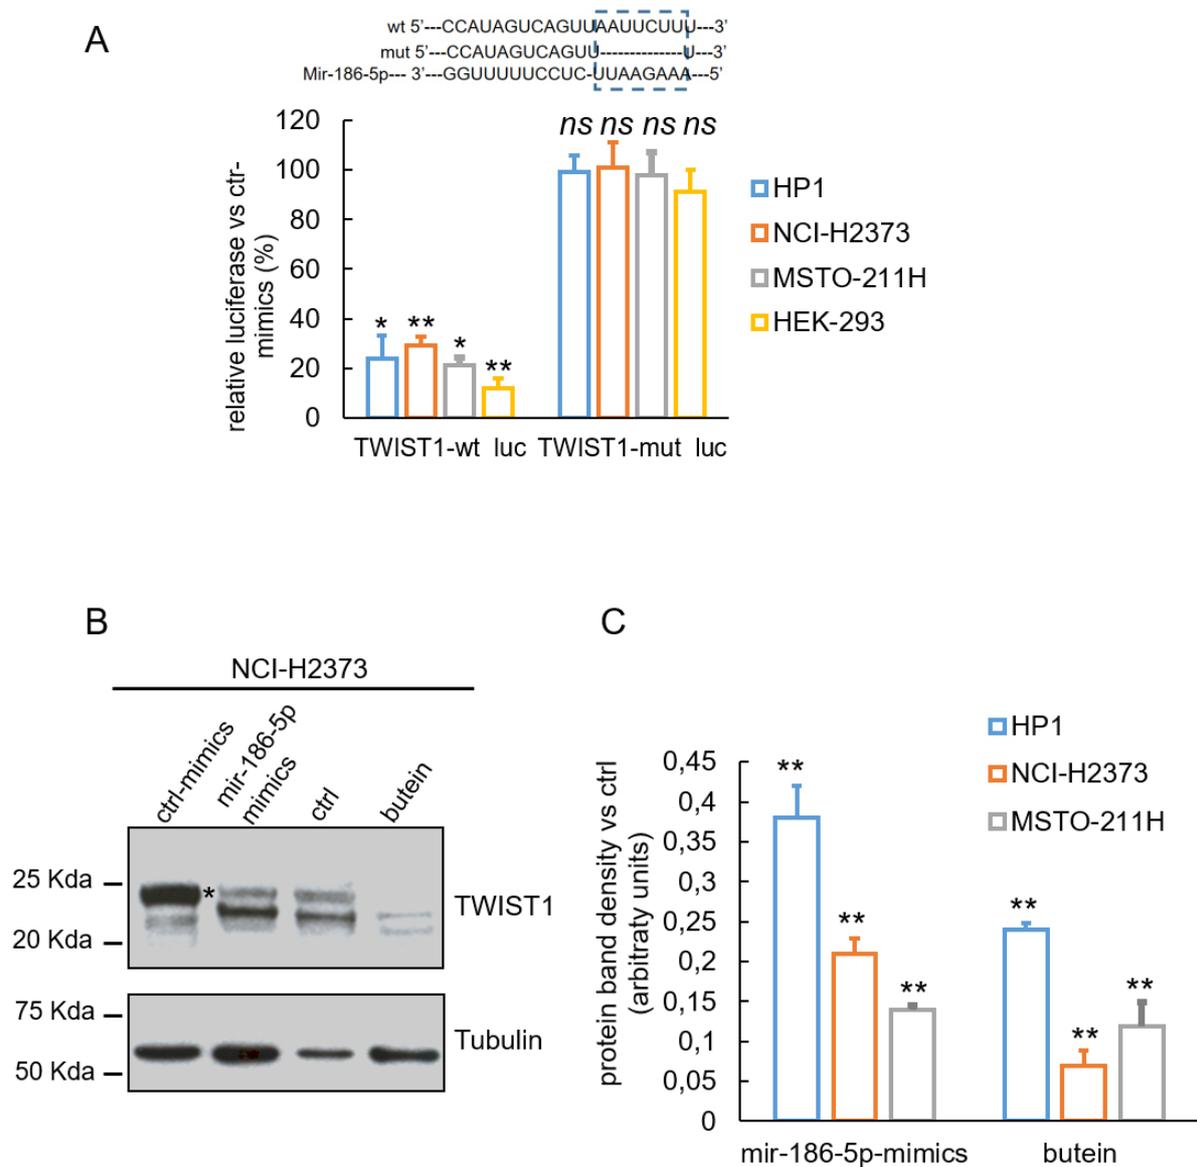

Figure 2. TWIST1 is a miR-186-5p target. Inset: The putative binding site of miR-186-5p within the Twist1 3'-UTR is shown, with the paired sequences of the wt and mutant (mut) constructs generated. (A) The pMIR-Twist1-WT and pMIR-Twist1-MT vectors were transfected into the three MPM cell lines and in HEK293 cells along with miR-186-5p or ctrl mimics and luciferase activity was assessed 48 h later. The percentage of luciferase activity in the cells transfected with miR-186-5p mimics over the cells transfected with the ctrl-mimics is reported. Means \pm SD of three replicates are shown. * $P < 0.05$, ** $P < 0.01$. (B) Twist1 protein levels in NCI-H2373 cells treated with ctrl or miR-186-5p mimics or butein and ctrl (DMSO 0.01%) as assessed by Western blotting. Anti-tubulin staining was used as a loading control. Asterisk (*) indicates the TWIST1-specific protein band. (C) Histograms reporting the relative (normalized) protein band intensity of TWIST1 from all three MPM cell lines treated as indicated in (B). The average values of two independent experiments are reported. ** $P < 0.01$ (vs. ctrl).

Butein-instigated increase of miR-186-5p affected the sphere forming ability and the cisplatin sensitivity of 3D-grown MPM cells

To study the effect of butein-instigated miR-186-5p-dependent TWIST1 modulation on pro-tumorigenic MPM features, we evaluated the effect of the mentioned treatments on the resistance of MPM 3D spheroids to cisplatin. Spheroid cultures are enriched for the expression of EMT factors and may represent a suitable system to study chemoresistance^[12,42,43]. MPM cells were grown as 3D spheroids after seeding in anchorage-

independent, quasi-clonal densities, and sphere forming efficiency (SFE) was evaluated for saline- and cisplatin-treated spheroids after a 12 h pulse of the drug at IC_{25} and IC_{50} doses (empirically determined for each cell line, [Supplementary Figure 2A](#)) [[Figure 3](#)]. Evaluation of the size, appearance, and number of the formed spheroids after an additional 48 h revealed a clear change in the morphology of the cisplatin- vs. ctrl-treated spheroids ([Figure 3A](#), top and bottom, respectively), with the cisplatin treated ones being much less compact and rounded and significantly reduced in number [[Figure 3A](#)]. Butein treatment (10 μ M, 8 h) [[Supplementary Figure 2B](#)] induced spheroid disaggregation in the ctrl-treated cultures, which was even more dramatic in the samples co-treated with cisplatin, suggesting an effect on cisplatin sensitivity of the spheroids [[Figure 3A](#) and [B](#)]. Transfection of the miR-186-5p constructs induced very similar effects when compared to butein, consisting of spheroid disaggregation in ctrl-treated samples, which was more prominent in the cisplatin treated ones [[Figure 3A](#) and [B](#)]. On the other hand, overexpression of TWIST1 induced the formation of round and compact spheroids, which were significantly resistant to cisplatin treatment, as evaluated by morphology and number [[Figure 3A](#) and [B](#)]. We observed similar effects when challenging the spheroids obtained from MSTO-211H and HP-1 MPM cell lines with a similar treatment scheme [[Supplementary Figure 3A](#) and [B](#)]. Thus, butein could both attenuate the SFE and reduce the resistance of MPM spheroids to cisplatin, at least partially through a miR-186-5p-mediated downregulation of TWIST1.

TWIST1 is a critical effector of miR-186-5p-mediated inhibition of invasion

Next, we evaluated the effect of butein-instigated miR-186-5p-dependent TWIST1 modulation on the invasive properties of NCI-H2373 cells [[Figure 4](#)]. Staining of the cells which invaded the Matrigel-coated surface and evaluation of the optical density in time revealed that, when compared to ctrl (DMSO), butein strongly affected NCI-2373 invasion [[Figure 4A](#)], and this inhibition appeared as early as 24 h after cell treatment and lasted over time [[Figure 4B](#)]. Overexpression of TWIST1 strongly increased the invasive ability of the NCI-H2373 cells, as compared to the cells transfected with the vector alone [[Figure 4A](#)], and this was maximal at 72 h after the transfection [[Figure 4B](#)]. These results were consistent in MSTO-211H [[Supplementary Figure 4](#)], while the HP1 cells did not show relevant invasion at steady state and were not tested further (data not shown). Thus, butein could inhibit the invasion of MPM cells at least partially through a miR-186-5p-mediated downregulation of TWIST1.

A butein-instigated increase of miR-186-5p modulated oxidative mitochondrial respiration and glycolytic activity of MPM cells

Next, we evaluated the effect of butein, miR-186-5p, and TWIST1 on the bioenergetics of the NCI-H2373 cells. We evaluated the basal ECAR and OCR of NCI-H2373 cells treated with ctrl or butein and transfected with ctrl or miR-186-5p mimics or TWIST1 [[Figure 5A](#) and [B](#)]. We found that butein treatment and, similarly, miR-186-5p mimics reduced the glycolytic flux of the NCI-H2373 cells [[Figure 5A](#)]. Both butein and miR-186-5p mimics reduced the OCR of NCI-H2373 [[Figure 5B](#)]. However, butein treatment affected the OCR rate to a larger extent than did the miR-186-5p mimics, suggesting that the deeper OCR inhibition by butein may involve additional mechanisms. TWIST1 overexpression did not significantly affect the OCR of NCI-H2373 cells ($P = 0.07$) while readily increasing their glycolytic flux [[Figure 5A](#) and [B](#)].

We extended our observations to the additional MPM cell lines MSTO-211H and HP1 [[Supplementary Figure 5A](#) and [B](#)]. This revealed that all three cell lines exhibited a significantly different metabolic profile, with NCI-H2373 being more reliant on mitochondrial oxidative respiration and MSTO-211H being more glycolytic. HP1 showed an intermediate metabolic profile [[Supplementary Figure 5A](#) and [B](#)]. Despite those differences, evaluation of the basal OCR and ECAR revealed that, in MSTO-211H and HP1 cells as well, butein and miR-186-5p mimic acted very similarly by reducing the glycolytic flux, with TWIST1 enhancing the latter in an opposite way. The OCR was affected to a larger extent by butein than by miR-186-5p mimics

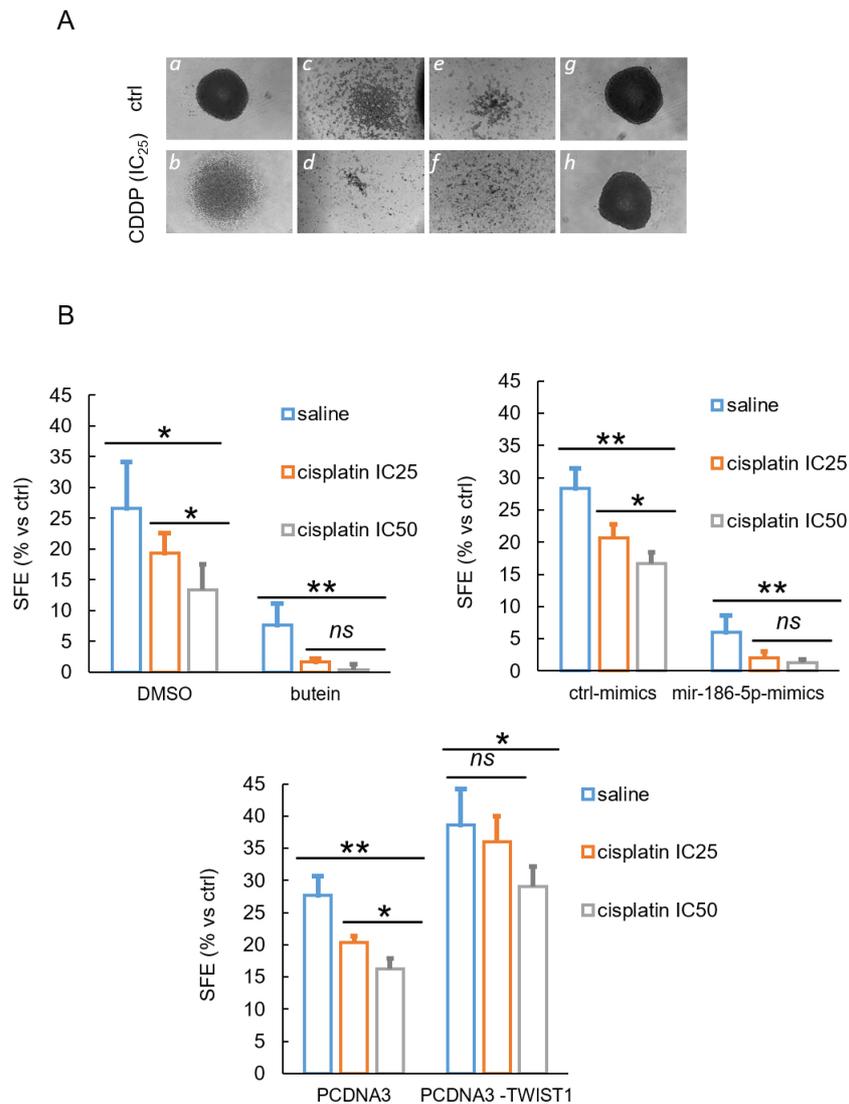

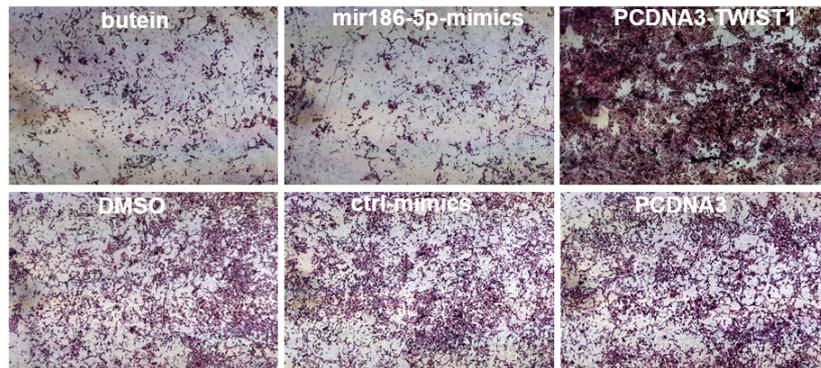

Figure 3. Butein-instigated increase of miR-186-5p affected the sphere forming ability and the cisplatin sensitivity of 3D-grown NCI-H2373 cells. (A) Spheroid formation assay: NCI-H2373 cells, treated with ctrl-(DMSO 0.01%) (a, b) or butein (10 μ M, 8 h) (c, d), transfected with miR-186-5p mimic (e, f), or with PCDNA3-TWIST1(g, h), were clonally seeded and allowed to form spheroids for 48 h. After that, ctrl (saline: a, c, e, g) or cisplatin (b, d, f, h) was added at the IC₂₅. Representative micrographs of the formed spheroids (on Day 2 after cisplatin or saline treatment). Scale bar, 200 μ m. (B) Histograms showing quantitation of the SFE from NCI-H2373 cells treated with saline or cisplatin at IC₂₅ and IC₅₀, respectively, and counted on Day 7 after treatment started. The percentage is relative to the control sample within the group except when otherwise indicated. Asterisk indicate statistical significance as follows: * P < 0.05; ** P < 0.01; ns: not significant (P > 0.05). The average of 3 experiments is shown.

[Supplementary Figure 5C and D]. Overexpression of TWIST1 significantly reduced the OCR in MSTO-211H and HP1 cells (P < 0.05), possibly as a consequence of the increased glycolytic flux following TWIST1 overexpression [Supplementary Figure 5D]. Those changes were evident by evaluating the OCR/ECAR ratio for all three cell lines [Figure 5C].

Altogether, we found that butein treatment and the transfection of miR-186-5p mimics exerted very similar effects on the 3D anchorage-independent growth, cisplatin resistance, invasion, and bioenergetics metabolism of the three MPM cell lines tested. Conversely, overexpression of TWIST1 induced rather

B

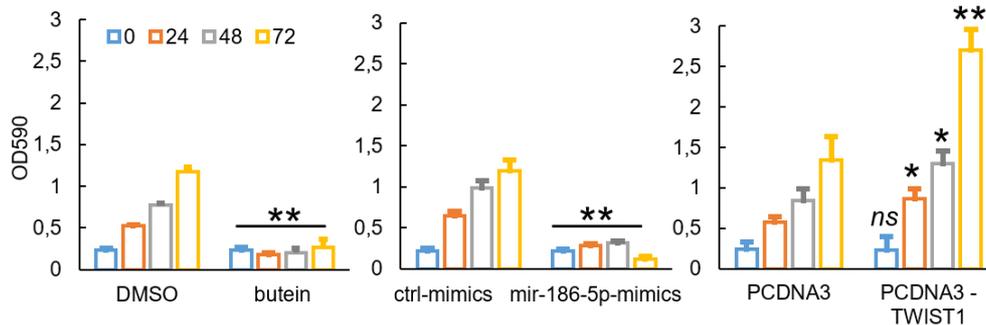

Figure 4. Butein-instigated miR-186-5p-mediated inhibition of TWIST1 attenuated invasion of NCI-H2373 cells. (A) Representative bright-field images of Transwell invasion assay inserts 48 h after seeding of the NCI-H2373 cells. Cells were stained with crystal violet. (B) Histograms showing quantitation of the migrated NCI-H2373 cells treated as in (A) and counted at 24, 48, and 72 h after treatment started. The bound crystal violet was eluted and the absorbance at 590 nm was measured using a plate reader. The average of three experiments is shown. The percentage is relative to the relative control group except where otherwise indicated. Asterisk indicate statistical significance as follows: * $P < 0.05$; ** $P < 0.01$; ns: not significant ($P > 0.05$).

opposite effects by enhancing all the mentioned pro-tumorigenic properties.

miR-186-5p and TWIST1 exhibited opposite behavior in biphasic MPM specimens

Finally, we explored the connection between miR-186-5p and TWIST1 in a more clinically relevant setting. When searching for a correlation between miR-186-5p and TWIST1 mRNA levels in the TCGA database, no significant correlation was observed between miR-186-5p and TWIST1 mRNA levels in MPMs (Spearman rho = -0.1936, $P = 0.0748$). However, we found a trend, for biphasic mesotheliomas ($n = 21$) toward exhibiting lower miR-186-5p ($0.05 < P < 0.10$) and higher TWIST1 expression, as compared to epithelioid mesotheliomas ($n = 58$) [Figure 6A and B].

DISCUSSION

We addressed the microRNA profile of three mesothelioma cell lines. We chose to profile biphasic/sarcomatoid cell lines because the originating histotype of those cell lines is linked to a worse prognosis and fewer data are available when compared to the epithelioid histotype MPMs^[44]. We uncovered a set of microRNAs commonly and significantly modulated in the mentioned cell lines. We found miR-186-5p as significantly and highly modulated by butein treatment. This focused our attention, given the involvement of one of the miR-186-5p targets, TWIST1, on both the biology of MPM^[38,40] and the possibility of explaining the mechanisms behind the chemo-sensitizing effects of butein^[16]. This helped us delineate a

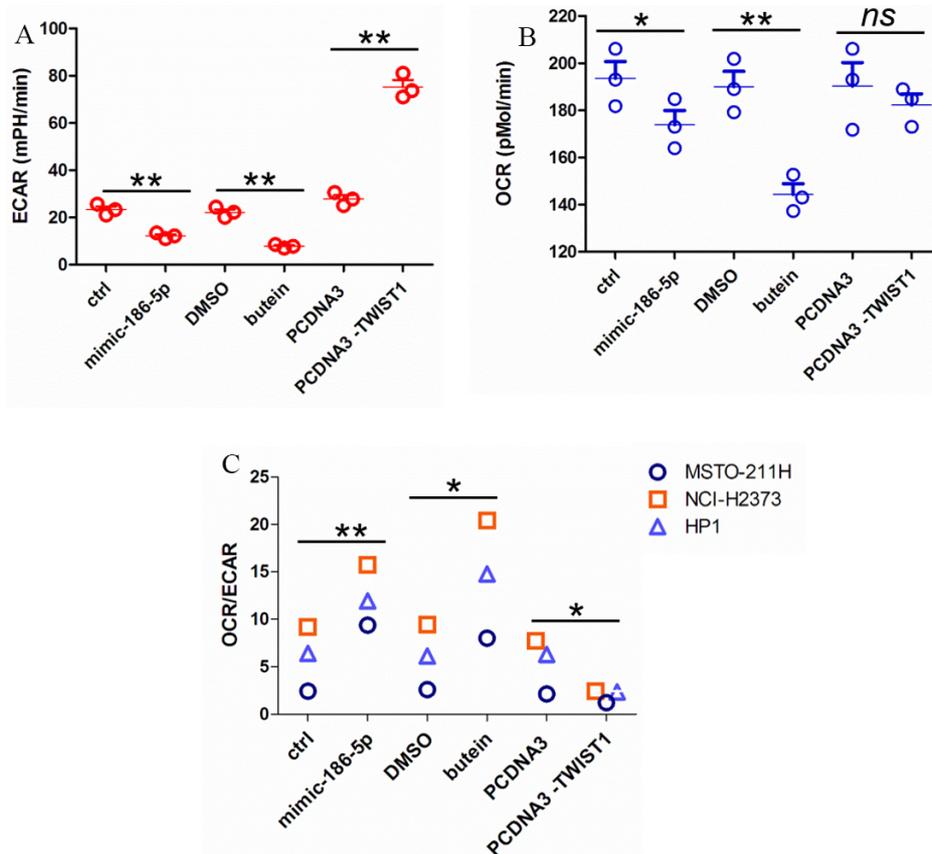

Figure 5. A butein-instigated increase of miR-186-5p modulated oxidative mitochondrial respiration and glycolytic activity of MPM cells. (A, B) Basal ECAR and OCR measured in NCI-H2373 cells treated or transfected as indicated. Values are reported as the mean \pm SEM of three independent experiments. Asterisk indicate statistical significance as follows: * $P < 0.05$, ** $P < 0.01$). (C) OCR to ECAR ratio assessed for all three MPM cell lines of this study.

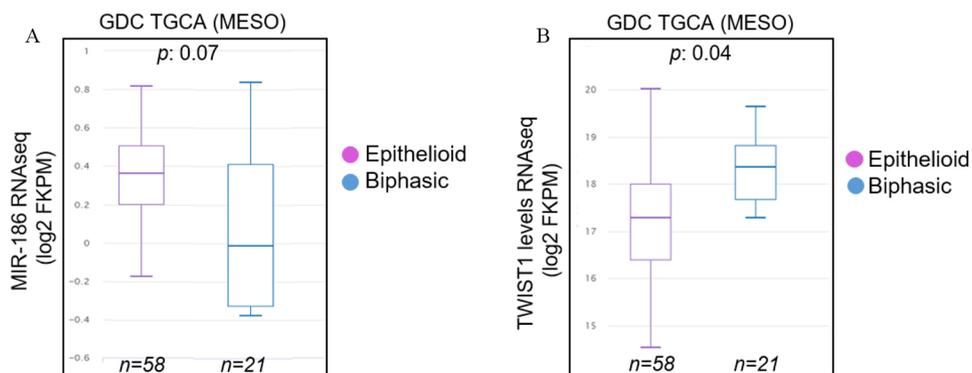

Figure 6. miR-186-5p and TWIST1 anti-correlated in biphasic MPM specimens. butein-instigated modulation of TWIST1 by miR-186-5p which impinges on the invasion, 3D growth, chemoresistance, and metabolic features of the MPM cells.

EMT is an important feature of MPM, since mesothelial cells show a proclivity to undergo EMT even in pathophysiological conditions, such as peritoneal dialysis^[45,46]. We and others showed that EMT sustains and accompanies a therapy-induced SASP which fuels the resistance of MPM cells to cisplatin and pemetrexed^[11,14]. More recently, an EMT-omic signature emerged as a distinct prognostic trait of MPM^[47] and as a determinant of anti-CTLA-4 immuno-response^[11,14,39]. TWIST1, being a key EMT player and a target of microRNA modulation by butein, may well find a place within the chemo-sensitizing actions of this versatile compound. In fact, we showed that, besides the effect on cell invasion and 3D growth, butein-modulated TWIST1 affects cisplatin resistance. A similar effect has recently been shown in epithelial ovarian cancer cells, where TWIST1 delineates a chemoresistant ovarian cancer phenotype^[48-50].

In addition to the mentioned anticancer effects, we found that the butein-miR-186-5p axis modulated MPM cell bioenergetics, by reducing glycolytic processing and mitochondrial respiration in all 3 cell lines tested. The degree of metabolic perturbation was similar in all three cell lines but varied in magnitude, according to differences in the three cell lines, already at steady state [Supplementary Figure 5]. Our investigation was limited to assessing ECAR and OCR rates. However, we, by using a more comprehensive metabolic assessment, and others, in different experimental settings^[51], showed how specific lipid species may mediate chemoresistance of MPM cells by activating NFκB signaling^[12]. Even if there was no demonstration that TWIST1 modulation may directly affect the release of signaling lipids, the fact that butein, TWIST1, and miR-186-5p are involved in chemoresistance and the high degree of connection between metabolic pathways suggests that this may be the case and prompts future detailed investigation.

Here, we identified a novel action of butein, which is the microRNA modulation. Such findings are in line with what we and others showed on the anticancer action of butein, i.e., that it inhibits migration, invasion, clonogenicity, and resistance of the cells to chemo-therapeutics^[18]. The effect of butein on TWIST1 matches what is known of the ability of TWIST1 to impinge on AKT signaling and drive resistance to cisplatin^[50]. However, this may not be the only mechanism for butein: for example, target prediction of the butein-modulated microRNAs suggested that additional targets may mediate the chemo-sensitization effect of butein (data not shown). In line with this, the effect of butein treatment on the OCR was similar but stronger when compared to that of the miR-186-5p mimic [Figure 5B]. Butein has pleiotropic, metabolic effects including modulation of lipid biosynthesis through NFκB/STAT3 inhibition and TGF-β-PPARγ interference^[52] and HMOX1 induction^[53]. Therefore, there is the possibility that butein affects OCR through miR-186-5p-independent mechanisms. Thus, engagement of additional microRNA-target modules and a broader metabolic action may also explain the more profound effects of butein on the OCR of the MPM cell lines when compared to miR-186-5p mimics alone [Figure 5B]. On the other hand, gene expression profiling has already shown how butein may modulate DNA damage associated and DNA repair pathways^[17], and it is very likely that several mechanisms converge onto the anticancer action of butein, possibly with different kinetics in time and with tumor-stage specificity *in vivo*.

An unsolved question within this work is how butein may modulate the levels of miR-186-5p. There is some indication that a transcriptional mechanism may be responsible for this. Resistin (RETN) is a proinflammatory cytokine secreted from adipocytes and monocytes^[54]. In addition to its pivotal role in inflammation-related diseases, RETN was shown to suppress the miR-186-5p levels, thereby contributing to cancer resistance in ovarian cancer^[55] and facilitating VEGF-C-associated lymphangiogenesis in human chondrosarcoma cells^[56]. RETN expression is downregulated by an NFκB-mediated transcriptional mechanism in human monocytes^[57]. Relevant to this, induction of RETN after butein treatment was recently shown in 3T3 mouse preadipocytes^[53]. It is possible that butein, as being a known NFκB inhibitor, modulates RETN levels, thereby attenuating the resistin-mediated downregulation of miR-186-5p.

One limitation of this study is that we did not investigate whether the modulation of miR-186-5p by butein takes place in specific cell subpopulations. In fact, we showed that butein exerts differential effects on FACS sorted, chemoresistant MPM cell subpopulations, such as the ALDH^{bright} MPM cells^[17]. Another limit of this study is that we did not address mechanistically how TWIST1 downregulation by butein may affect the pro-tumorigenic program. Since TWIST1 functionally interacts with AKT, and we and others showed that AKT is a downstream collector of survival signaling in pemetrexed-treated MPM cells^[50,58], it is possible that a TWIST1-AKT axis may be effective even in this experimental setting.

Finally, we did not make use in this work of primary MPM specimens, which may represent a more clinically relevant experimental setting. However, knowledge in the literature exists that TWIST1 was significantly increased in a gradient fashion when analyzing epithelioid, biphasic, and sarcomatoid primary MPMs^[40]. We expanded on these data by observing that TWIST1 mRNA levels are anti-correlated with miR-186-5p levels in TGCA biphasic but not in epithelioid MPM specimens [Figure 6A and B].

Abstract

Aim: Despite the huge advancements in cancer therapies and treatments over the past decade, most patients with metastasized melanoma still die from the disease. This poor prognosis largely results from resistance to conventional chemotherapies and other cytotoxic drugs. We have previously identified 6 antigenic peptides derived from melanomas that have proven efficacious for activating CD4⁺ T cells in clinical trials for melanoma. Our aim was to improve pharmacodynamics, pharmacokinetic and toxicological parameters by individually encapsulating each of the 6 melanoma helper peptides within their own immunogenic nanoliposomes.

© The Author(s) 2022. **Open Access** This article is licensed under a Creative Commons Attribution 4.0 International License (<https://creativecommons.org/licenses/by/4.0/>), which permits unrestricted use, sharing, adaptation, distribution and reproduction in any medium or format, for any purpose, even commercially, as long as you give appropriate credit to the original author(s) and the source, provide a link to the Creative Commons license, and indicate if changes were made.

Methods: We modified these liposomes as necessary to account for differences in the peptides' chemical properties, resulting in 3 distinct formulations. To further enhance immunogenicity, we also incorporated KDO2, a TLR4 agonist, into the lipid bilayer of all nanoliposome formulations. We then conducted *in vivo* imaging studies in mice and *ex vivo* cell studies from 2 patient samples who both strongly expressed one of the identified peptides.

Results: We demonstrate that these liposomes, loaded with the different melanoma helper peptides, can be readily mixed together and simultaneously delivered without toxicity *in vivo*. These liposomes are capable of being diffused to the secondary lymphoid organs very quickly and for at least 6 days. In addition, we show that these immunogenic liposomes enhance immune responses to specific peptides *ex vivo*.

Conclusion: Lipid-based delivery systems, including nanoliposomes and lipid nanoparticles, have now been validated for pharmacological (small molecules, bioactive lipids) and molecular (mRNA, siRNA) therapeutic approaches. However, the utility of these formulations as cancer vaccines, delivering antigenic peptides, has not yet achieved the same degree of commercial success. Here, we describe the novel and successful development of a nanoliposome-based cancer vaccine for melanoma. These vaccines help to circumvent drug resistance by increasing a patient's T cell response, making them more susceptible to checkpoint blockade therapy.

Keywords: Nanoliposomes, nanoscale drug delivery, cancer vaccines, metastasized melanoma, peptides, melanoma drug resistance

INTRODUCTION

Melanoma of the skin is the 5th most common cancer for both males and females in the United States.^[1] and currently, only complete surgical removal is considered curative. In advanced malignant and metastasized stages of melanoma, where surgery alone cannot offer remission, the prognosis is extremely poor. This is because human melanoma is particularly resistant to conventional chemotherapies and other cytotoxic drugs^[2-4], and this resistance has primarily been linked to dysregulations in apoptosis^[2].

Recent progress in cancer immunotherapy has prolonged median survival for metastatic melanoma from about nine months to about 3 years, but most patients with metastatic melanoma still do not survive^[5-7]. A lack of pre-existing T cell immunity to cancer antigens is commonly a root cause of failure. In addition, both intrinsic and adaptive resistance to immunotherapies in melanoma has been observed^[4]. Therefore, there is a significant need for new therapies to prevent melanoma recurrence by enhancing immune responses to melanoma. Cancer vaccines offer the promise to induce immune responses to cancer when spontaneous antitumor immunity is absent or weak. The effectiveness of immune checkpoint blockade therapy demonstrates that melanoma cells express antigens that can be recognized by CD4 and CD8 T cells, and also that T cell responses to those antigens can mediate tumor regression, when tumor-associated immune dysfunction is abrogated. There has been recent enthusiasm for approaches targeting antigens created by spontaneous mutations (mutated neoantigens)^[8]; however, recent data highlight the value of shared melanocytic antigens as relevant targets^[9], and other data highlight the value of vaccinating against shared cancer-testis antigens^[10].

Data from our group and others have highlighted the pivotal role of CD4⁺ (helper) T cells in cancer immunity and cancer control^[11-14]. We have previously developed a multi-peptide melanoma vaccine consisting of 6 melanoma helper peptides (6MHP) designed to induce melanoma-reactive CD4⁺ T cells, and found that they are immunogenic in humans, inducing objective clinical responses and very high rates of 5-year survival. Additionally, we found that the immune responses are enhanced when simultaneously injecting a toll-like receptor 3 (TLR3) agonist with the vaccine^[15]. With a different peptide vaccine, we also

found that agonists for TLR4 are useful vaccine adjuvants alone or with incomplete Freund's adjuvant^[16]. However, these responses are still modest in absolute magnitude, even with strong adjuvants, and even the best responses usually represent less than 1% of circulating CD4⁺ T cells. A major goal of current cancer vaccines is to induce stronger and more durable T cell responses, but optimal vaccine strategies in humans have not yet been defined.

Most cancer vaccines contain antigens plus vaccine adjuvants. However, when they are co-administered as soluble agents, there is no assurance that the antigens and the adjuvants will be delivered to the same antigen-presenting cell. Nanoliposomes provide a way to deliver antigens to phagocytic antigen-presenting cells, especially dendritic cells, while simultaneously delivering vaccine adjuvants to the same antigen-presenting cells. The use of nanoliposomes to deliver cancer therapeutics offers significant promise and has had several clinical successes^[17]. Indeed, many vaccines benefit from lipid-based delivery. Of particular note are the recently authorized COVID-19 vaccines, which utilize lipid nanoparticles containing antigen-encoding RNA^[18,19]. Our team has been successful in the use of nanotechnologies, including nanoliposomes, for a host of different therapies^[20-25]. Nanoliposomes have the capability of altering the pharmacokinetic properties of antigens and immunomodulators/adjuvants, with a marked reduction in off-target toxicity, protection of the therapeutic from degradation, along with more specific targeting to antigen-presenting cells^[26]. A theoretical benefit of using a nanoliposome vaccine over merely injecting antigens and adjuvants individually is that the nanoliposome ensures all adjuvants circulate together and are delivered to the antigen-presenting cells at the same time. Furthermore, nanoliposomes are readily taken up by the antigen-presenting dendritic cells (DCs)^[27-30]; therefore, having a TLR agonist incorporated into the liposome should provide increased CD4⁺ T cell activation. Taken together, nanoliposomes are ideal nano-carriers and delivery agents for emerging cancer vaccines due to their versatility, ease of modification, and ability to deliver several adjuvants simultaneously^[31].

As described above, one of the advantages of liposomal delivery is the ability to incorporate vaccine adjuvants into the peptide delivery vehicle. We have chosen to use the toll-like-receptor 4 (TLR4) agonist, KDO2-lipid A (herein KDO2, but also often referred to as KLA). KDO2 is a synthetic and homogenous form of Lipid A, an essential component of lipopolysaccharides (LPS) in Gram-negative bacteria^[32]. KDO2 stimulates potent and reproducible host immune responses through the complex of TLR4 and myeloid differentiation protein 2^[32-34]. In previous studies, we have used naturally-derived LPS as a TLR4 agonist^[16], and others have used KDO2 and other lipid A derivatives in several cancer immunotherapies^[35-38]; thus, it is an appropriate choice of agonist for this study. Here, we want to improve pharmacodynamics, pharmacokinetic and toxicological profiles by incorporating KDO2 directly into the delivery system to enhance CD4⁺ T cells via TLR4. Thus, we hypothesized that (1) we could develop stable KDO2-containing nanoliposomes for the encapsulation of each of the 6 melanoma helper peptides identified previously by our team; and (2) these nanoliposomes would trigger an increased CD4⁺ T-cell response over and above delivery of the peptide(s) or TLR4 agonist alone.

METHODS

Encapsulation of melanoma peptides within nanoliposomes

The 6 melanoma peptides that induce melanoma-reactive CD4⁺ T cells in patients, as well as their protein epitope and ideal pH range for solubility, are provided in [Table 1](#). We initially chose a neutral formulation to encapsulate all peptides and then, through an iterative process, modified formulations to optimize encapsulation efficiencies for several of the peptides. Through this process, we identified 3 different nanoliposome formulations (neutral, cationic and anionic) suitable for distinct peptides. However, all of our formulations contained the same base lipid components, including 1,2-distearoyl-sn-glycero-3-

Table 1. Amino acid sequence of the 6 melanoma helper peptides along with their abbreviation, Epitope (the sequence of amino acids recognized by the T cell receptor, which defines the specificity of the response) and ideal pH range required for stability and dissolution

Amino acid sequence (letter = 1 amino acid)	Abbreviation	Epitope (protein, residue numbers)	Ideal pH range
AQNILLSNAPLGPQFP	AQN	Tyrosinase ₅₆₋₇₀	8.5-9.0

phosphocholine (DSPC); 1,2-dioleoyl-sn-glycero-3-phosphoethanolamine (DOPE); 1,2-distearoyl-sn-glycero-3-phosphoethanolamine-N-[methoxy(polyethylene glycol)-2000] (ammonium salt) (PEG2000PE); KDO₂; cholesterol; and a fluorophore [either rhodamine or 1,1'-dioctadecyl-3,3,3',3'-tetramethylindodicarbocyanine, 4-chlorobenzenesulfonate salt (DiD)]. Each formulation contained DSPC and DOPE at a 2.14:1 molar ratio to form a stable, spherical nanoparticle. In addition, cholesterol at a 30 molar percent was incorporated to increase rigidity and reduce leakiness. PEG(2000)-PE at 2.5 molar percent was incorporated for biological stability, KDO₂ was added to all formulations at 0.1 molar percent, and a fluorescent probe (rhodamine or DiD) was added at 0.2 molar percent for subsequent biodistribution imaging studies. Keeping the molar ratios of these key components constant, we incorporated hexadecyl phosphate (DHP) at 10 molar percent for the anionic formulation and positively charged lipid 1,2-dioleoyl-3-trimethylammonium-propane (chloride salt) (DOTAP) at 7 molar percent for the cationic formulation. All lipid components were dissolved in chloroform and mixed in the ratios shown in table 2. The lipid mixtures were then dried down in a nitrogen blower for roughly 2 h until all of the chloroform was evaporated. Then, the peptide solutions (or 1× PBS for the “ghost” formulation) were added to the dried down lipids; the tubes were then vortexed and placed in a heat shaker at 60 °C for 2 h, followed by sonication in a 60 °C sonic bath for roughly five minutes. After sonication, the liposomes were extruded through a 100-nanometer pore membrane eleven times to create uniformly sized liposomes. The extruded liposomes were subsequently run through a Sepharose gel bead column to separate the liposomal drugs from the free drug. The solution was analyzed using dynamic light scattering (DLS) (polydispersity, an average hydrodynamic diameter of particles in solution) and mass spectrometry.

To further ensure optimal encapsulation efficiency of the MHPs, we utilized distinct dissolution buffers tailored to each peptide’s optimal pH range and previously optimized for *in vivo* injection of the free peptides into patients enrolled in our earlier clinical studies. Specifically, for the neutral peptide formulations, 1.33 mg/mL sodium bicarbonate (NaHCO₃) in a 1:2 solution of lactated Ringer’s solution (LR) and water, respectively (B1); for the cationic formulation, 5 mg/mL NaHCO₃ in water (B2); for the WNR anionic formulation, 1 mg/mL NaHCO₃ in water (B3); and for the TSYVKVLHHMVKISG (TSY) anionic formulation, 1:9 ratio of 2-(N-morpholino) methanesulfonic acid (MES) buffer and water (B4).

Liposomal stability and peptide release studies were conducted by storing the liposomes in different conditions and media. We monitored the liposomes over a 5-week period in both 1X PBS and 10% fetal bovine serum, under refrigerated, room temperature, and body temperature storage conditions. We ran DLS studies, as well as centrifugation followed by mass spectrometry of the supernatant and reconstituted liposome solutions to monitor liposome stability and peptide release, respectively.

***In vivo* murine studies**

A 6-day study was performed to determine the biodistribution of the fluorescent nanoliposomes, utilizing daily live-mouse imaging with an *in vivo* imaging system (IVIS). For this study, four mice received a DiD fluorescently labeled 6MHP-KDO2-nanoliposome injection. Two mice were injected subcutaneously (SQ) into either flank and 2 mice were injected intravenously (IV). Each peptide nanoliposome had been previously formulated and stored separately. On the day of the experiment, all 6 formulations were mixed together in ratios that contained 0.4 µg of each peptide. The mice were administered isoflurane anesthesia. On day zero, once asleep, the mice were injected with the 6MHP-KDO2-nanoliposome mixture and then transferred immediately to the IVIS instrument. Imaging was conducted within 30 s (or less) of injection. For IVIS® Spectrum Image collection and processing, tomographic fluorescent images were collected of all mice using epi-illumination on a Caliper IVIS® Spectrum scanner following anesthetization with inhaled isoflurane inside a conduction chamber. Live imaging was then performed daily for 6 days. On the 6th day, the mice were euthanized, and their organs were harvested for follow-up *ex vivo* studies. The organs selected for harvest included the lungs, liver, spleen, kidneys, and lymph nodes. Organs from the *in vivo* study were transferred to 24-well plates, and fluorescent imaging data were collected on the IVIS® Spectrum Image system for qualitative determination of biodistribution. Fluorescent image collection used Living Image® software by Caliper Life Sciences. Image processing was done by importing Living Image® files into Aura imaging software by spectral instruments imaging, and then performing region of interest (ROI) measurements to quantify the fluorescence emitted from the mice. The fluorescent light images were collected in the same manner for the harvested organs following the live animal imaging once the mice were sacrificed. The measurement for fluorescence is the mean radiant efficiency within the drawn ROI. Radiant efficiency describes the fluorescent energy emitted from the specimen as a fraction of the excitation fluorescent radiation released by the scanner and incident upon the specimen. Mean radiant efficiency is unitless and is used so that comparisons may be made among mice and harvested organs of different sizes, and consequently slightly differing areas within ROIs. ROIs were drawn as subject ROIs according to the Living Imaging® software user manual (Caliper Life Sciences, 2012).

***Ex vivo* lymphocyte stimulation using immunogenic TSY encapsulated nanoliposomes**

Freshly obtained (cryopreserved) peripheral blood mononuclear cells (PBMC) and lymphocytes from the sentinel immunized nodes (SIN) of 2 patient donors (under IRB protocols, clinical trial Mel41 (NCT00089219; IRB #10464)^[39] were utilized to assess CD4⁺ T cell proliferation after treatment with the anionic TSY (MAGE-3₂₈₁₋₂₉₅ peptide; Table 1) MHP-KDO2 nanoliposome. Firstly, a cell viability study was performed using a live-dead marker and flow cytometry to ensure that cell viability was not impacted by the presence of either the peptides or the liposomes. In this study, SIN lymphocytes from the 2 patient donors (SIN1 and SIN2) were treated with a variety of free peptides and liposome combinations. For the free peptide group, the treatments included: no peptide and GAG peptide as negative controls, a mixture of all 6MHPs, and the single TSY peptide of interest. For the liposome group, the cells were treated with ghost liposomes, liposomes containing KDO2 but no peptide, and TSY containing liposomes both with and without KDO2. A control cell line was used as a viability comparison. Next, in order to assess CD4 T cell proliferation, we split the SIN1 and SIN2 cell lines into five treatment groups. These were: free non-encapsulated TSY, a ghost nanoliposome, a ghost KDO2 nanoliposome, a TSY encapsulated (no KDO2) nanoliposome, and a combinatorial KDO2/TSY nanoliposome (full vaccine). A CFSE dye-dilution proliferation assay was performed to evaluate the donor immune response by flow cytometry. Specimens were thawed and labeled with carboxyfluorescein diacetate (CFSE; Vybrant® CFDA SE Cell Tracer Kit, Invitrogen™, ThermoFisher Scientific) according to the manufacturer's instruction, with a final dye concentration of 1 µM. Two hundred thousand labeled cells were added to flat bottom wells of a 96-well cluster plate (Falcon, ThermoFisher) containing peptides in solution or in nanoparticle form. The final peptide concentration was 2 µg/mL in a final culture volume of 0.2 mL. We also utilized a media-only and

an HIV GAG peptide as negative controls^[40]. To avoid cell starvation from the high PBS content of the nanoliposomes' solvent relative to the necessary culture media nutrient content to sustain the culture during incubation, cells and liposome-containing formulations of peptide (and liposome controls) were first incubated ("pulsed") for 2 h at 37 °C followed by centrifugation to pellet the cells (and absorbed or internalized nanoparticles). The "pulsing" medium supernatant was removed and replaced with a complete culture medium consisting of AIM V (Gibco/Life Technologies, ThermoFisher) supplemented with 5% human AB serum (Gemini Bioproducts). Treatments were incubated for five days. At the end of incubation, cells were collected and labeled with a live/dead fixable dye (Aqua; ThermoFisher), followed by labeling with CD3 v450, CD4 PE, and CD8 PE-Cy7 (BDBiosciences). Cells were acquired on a Canto II flow cytometer (BDBiosciences) maintained by the Carter Immunology Center at the University of Virginia and the data were analyzed using FlowJo software (version 10; BDBiosciences).

RESULTS

Physico-chemical characterization of 6MHP nanoliposomal formulations

We initially incorporated each of the 6 melanoma helper peptides (6MHP) in a neutral liposome formulation containing: (DSPC); (DOPE); (PEG2000PE); KDO2; cholesterol; and a fluorophore in ratios of 4.60:2.14:0.25:0.01:3.00:0.02 respectively [Table 2]. After quantifying initial encapsulation masses, we utilized an iterative approach to improve encapsulation via modifying the charge and lipid ratios of the liposomal formulation as well as the buffer for the peptide. The proportional improvements in encapsulation, as well as the encapsulation efficiencies, are depicted in Table 3.

Using dynamic light scattering (DLS, Malvern Instruments), we demonstrated that all 6 optimized formulations displayed stable, consistent, and homogeneous size distribution, with an overall average size range of 113 ± 8 nm when averaged among all 6 formulations [Figure 1]. Furthermore, Figure 2 shows that all 6 formulations could be mixed together and remain stable in suspension, providing confidence that the charged nanoliposomes are not interacting with each other to cause destabilization or aggregation. The mixed sample gave a Z-average size of 113.5 nm, which is in agreement with our average size distribution of the individual nanoliposomes.

In addition, results of a 5-week long release kinetics study and analysis by LC-MS did not detect any measurable amount of peptides present in the MHP-KDO2-nanoliposome supernatant when stored at 4 °C (data not shown). These data suggest that the nanoliposomes do not have a significant release of encapsulated peptides from their core for at least that length of time, while under typical refrigerated storage conditions. Additionally, the supernatant collected remained clear, providing confidence that the fluorophore was not released from the liposome and DLS analyses still showed good liposome stability. Conversely, at body temperature, greater than 50% of the peptide concentration was released within the first 24 h. DLS data showed that the liposome remained intact, even in 10% bovine serum and the supernatant remained clear of the fluorophore. After one week, the liposomes kept at room and body temperature did appear to begin breaking down, shown by an increased number of peaks in the DLS analyses (data also not shown).

Murine biodistribution studies

A biodistribution study using a mixture of all 6 MHP formulations was performed using an IVIS Spectrum imaging system. Since each liposome formulation contained a different peptide mass, the mixture was prepared to contain equal amounts of each peptide (i.e., different volumes of each liposome solution to maintain equal peptide delivery). For this particular study, the nanoliposome vaccine was prepared using (DiD) fluorophore, as DiD has a far-infrared emission spectrum conducive to live animal imaging via IVIS.

Table 2. Finalized liposome formulations for the neutral, cationic and anionic nanoliposomes developed to encapsulate different peptides based on their residual charge. A dissolution buffer maintaining each peptide's optimal pH range was also used during fabrication, where B1= 1.33 mg/mL sodium bicarbonate (NaHCO₃) in a 1:2 solution of Lactated Ringers solution (LR) and water respectively; B2 = 5 mg/mL NaHCO₃ in water; B3 = 1 mg/mL NaHCO₃ in water; and B4 = 1:9 ratio of 2-(N-morpholino) methanesulfonic acid (MES) buffer and water

Lipid Component	Molar Ratio		
	Neutral (FFL,LLK,RNG)	Cationic (AQN)	Anionic (WNR, TSY)
DSPC	4.60	4.12	3.91
DOPE	2.14	1.90	1.81
PEG(2000)-PE	0.25	0.25	0.25
KDO2	0.01	0.01	0.01
Cholesterol	3.00	3.00	3.00
Rhodamine (or DiD)	0.02	0.02	0.02
DOTAP	-	0.70	-
DHP	-	-	1.00
Buffer	B1	B2	B3 (WNR), B4 (TSY)

DSPC: 1,2-distearoyl-sn-glycero-3-phosphocholine; DOPE: 1,2-dioleoyl-sn-glycero-3-phosphoethanolamine; DOTAP: 1,2-dioleoyl-3-trimethylammonium-propane (chloride salt).

Table 3. Showing both the Initial peptide encapsulation mass within our neutral nanoliposome formulation when the peptides are dissolved in 1 × PBS; compared to the encapsulation efficiencies within our optimized nanoliposome formulations, where each peptide is also dissolved in an aqueous solution that maintains optimal pH, peptide stability, and dissolution. Encapsulation efficiency is based upon initial 500 µg/ml peptide concentration. All peptides were calculated from a full vaccine, which included all lipid components (i.e. adjuvants, PEG, peptides). Each optimized mass encapsulation is based on n = 3 separate experiments, repeated in triplicate

Peptide	Original mass encapsulation using neutral formulation and 1X PBS (µg/mL)		New liposome formulation (Charge and buffer)	pH range	Optimized mass encapsulation (µg/mL)		Encapsulation improvement	Encapsulation efficiency (%)
AQN	0.02	0.005	Cationic (B2)	8.5-9.0	6.25	1.13	312X	1.25
WNR	4.81	0.09	Anionic (B3)	7.0-8.0	7.64	0.99	1.59X	1.53
LLK	34.56	0.69	Neutral (B1)	6.0-8.0	57.26	14.39	1.66X	11.45

TSY	0.17	0.001	Anionic (B4)	5.0-5.5	141.35	2.18	831X	28.27

AQN: AQNILLSNAPLGPQFP; WNR: WNRQLYPEWTEAQRLD; LLK: LLKYRAREPVTKAE; FLL: FLLHHAFFVDSIFEQWLQRHRP; RNG: RNGYRALMDKSLHVGTCALTRR; TSY: TSYVKVLHHMVKISG.

We compared routes of administration, SQ vs. IV. The IVIS images on day zero (immediately after injection) and day 6 (6 days after injection) are shown in [Figure 3](#). The mice injected SQ displayed little bio-distribution on day zero [[Figure 3A](#)], which intensified within a region consistent with liver and spleen on day 6 [[Figure 3C](#)]. In contrast, images of the mice injected IV with nanoliposome vaccines show rapid, systemic biodistribution in both mice on day zero [[Figure 3B](#)], but the tissue fluorescence diminished by day 6 [[Figure 3D](#)] as compared to the fluorescence on day zero. On day 6, the mice were sacrificed and their organs were harvested. Quantitative fluorescence measurements were performed using Aura region of interest (ROI) programming and software (see methods), and these results are shown in [Figure 4](#).

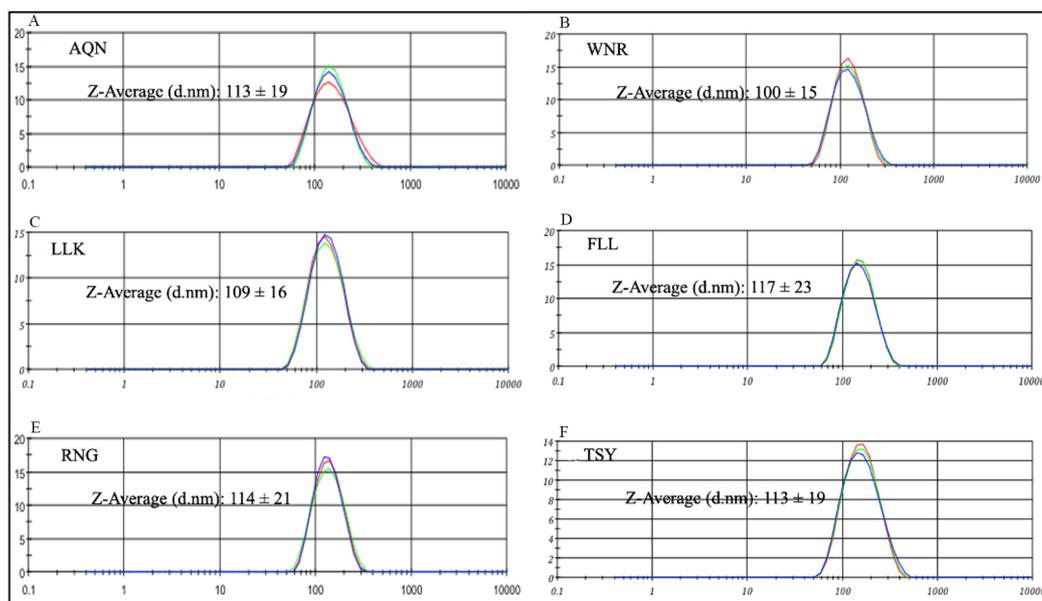

Figure 1. Typical dynamic light scattering (DLS) data attained for each of the 6 melanoma helper peptides. The data shows size distribution by intensity with size, *d* in nanometers along the X-axis and percentage intensity on the Y axis. (A) shows the DLS profile of the AQN peptide; (B) the DLS profile of the WNR peptide; (C) is that of LLK; (D) FLL; (E) RNG; and (F) is the typical profile for the TSY peptide. The graphs show a homogenous size distribution for all 6 peptides. The Z-average size (d.nm) attained from multiple samples is also provided for each peptide. AQN: AQNILLSNAPLGPQFP; WNR: WNRQLYPEWTEAQRLD; LLK: LLKYRAREPVTKAE; FLL: FLLHHAFFVDSIFEQLQRHRP; RNG: RNGYRALMDKSLHVGTCALTRR; TSY: TSYVKVLHHMVKISG.

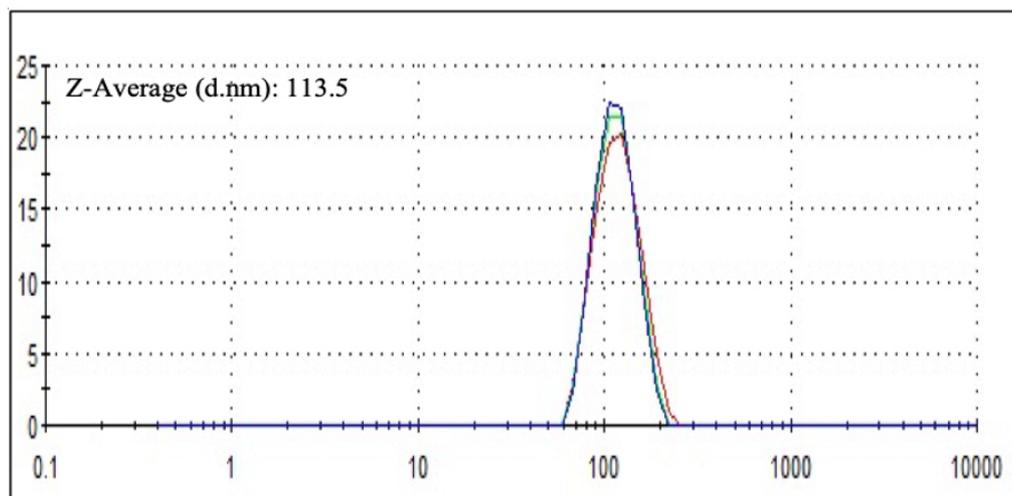

Figure 2. Dynamic light scattering data attained after mixing all 6 peptide nanoliposome formulations together. The data shows size distribution by intensity, with size (*d*) in nanometers along the X-axis and percentage intensity on the Y axis. The graphs show a homogenous size distribution. The Z-average size (d.nm) attained for this data is 113.5 nm.

For all organs, the mice injected SQ displayed a higher concentration of fluorescent liposomes within the harvested organs than the IV-injected group. No overt signs of toxicity (lethargy, loss of appetite, weight loss) were observed in any of the mice over the study. Taken together, these data suggest that both IV and SQ administration of a KDO2-6MHP nanoliposome is safe, and that SQ administration of the KDO2-6MHP nanoliposome offers a robust delivery of cargo to critical secondary lymphoid organs (spleen and lymph nodes), which persists at least 6 days.

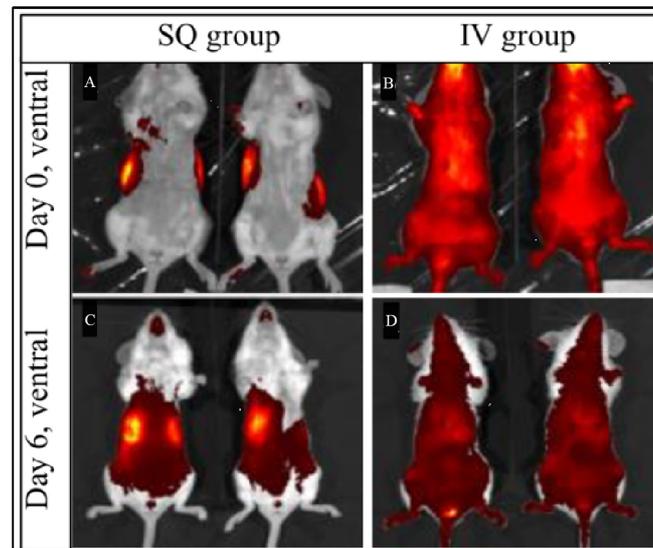

Figure 3. Fluorescent imaging of liposome biodistribution in mice on days 0 and 6. Two mice (SQ group) were injected subcutaneously in either flank and 2 mice (IV group) were injected intravenously.

urinActivation of CD4⁺ T cells from patients by a KDO2-MHP nanoliposome

Using blood samples from melanoma patients who had previously been vaccinated with a 6MHP vaccine on the Mel41 trial and had developed a robust CD4⁺ T cell immune response to the TSY antigen^[39], we analyzed lymphocyte viability and CD4⁺ T cell proliferation to the TSY nano-formulations *ex vivo*. Under IRB guidance, we had previously collected fresh lymphocytes and sentinel immunized nodes (SIN) from these patients during that prior clinical trial. SIN were nodes draining the vaccine site, identified by lymphatic mapping techniques^[39,41] Using a live-dead marker and flow cytometry, we observed no discernable differences in cell viability between each of the patient samples re-treated with free non-encapsulated TSY peptide and the nanoliposomal KDO2/TSY formulation; however, the SIN sample from patient 2 (SIN2) had a decreased viability compared to SIN patient 1 (SIN1, [Figure 5A](#)). Viability was equivalent between a control group of patient samples that were not previously immunized with peptides [[Figure 5A](#)]. Since there was no apparent toxicity to incubation with nanoliposomes, we treated aliquots of each cell preparation with each of the following: (1) an empty ghost liposome; (2) a liposome containing KDO2 but no peptide; (3) Free TSY peptide (no liposome); and (4) TSY encapsulated within a liposome; and v) TSY within an immunogenic (KDO2 containing) liposome. Then the average proliferation of CD4⁺ gated cell populations for various culture treatment conditions was assessed [[Figure 5B](#)] by CFSE dilution over five days. Cell cultures were expanded from the harvested SIN biopsy of each donor, and CD4 T cell proliferation was assessed by CFSE dye dilution. Proliferation is reported as the percentage of CD3⁺ CD4⁺ gated population that have dividing (CFSE-diluted). Compared to all controls, both SIN1 and SIN2 donor cells responded to the combinational therapy. [Figure 5C](#) shows the 2D histograms of the same data against a negative control. Peripheral blood samples from each patient had no significant response to any of the treatments (data not shown). While an expected CD4⁺ T cell proliferation response is observed with free TSY and liposomal TSY, our data suggest an advantage of combining the peptide vaccine with a TLR4 agonist. It is worth noting that neither the liposome alone nor the KDO2-containing liposome alone triggers CD4⁺ proliferation, and thus KDO2 only acts to enhance the response to the peptide of interest. It should also be noted that while the SIN2 patient response is weaker than SIN1 [[Figure 5B](#)], this can be attributed to the slightly lower viability [[Figure 5A](#)] (and hence fewer live cells present) in the SIN2 donor cell population. Taken together, we demonstrate an immunogenic response to the KDO2/MHP nanoliposome *ex vivo*.

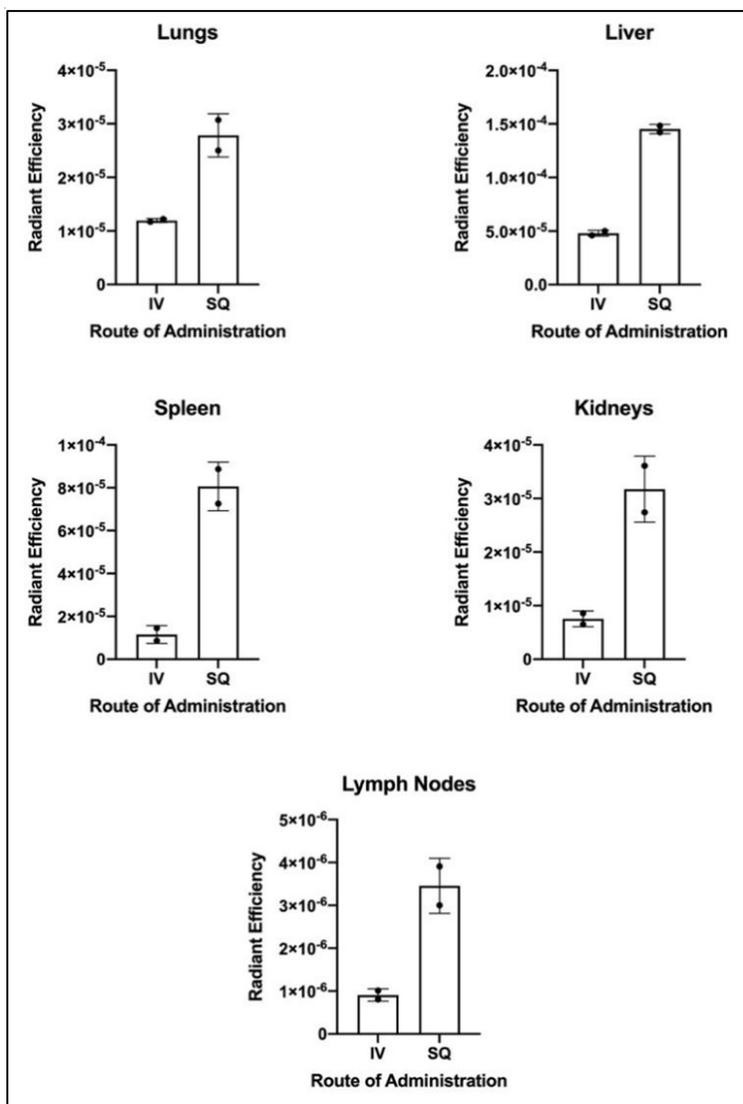

Figure 4. Showing the mean radiant efficiency in the extracted organs of four mice, 2 of which were injected with fluorescent and immunogenic liposomes via intravenous (IV) injection and 2, who were administered the same nanoliposomes via subcutaneous (SQ) injection in either flank.

DISCUSSION

In this study, we have developed nanoliposome formulations to encapsulate a specific panel of 6 melanoma helper peptides as a first step toward clinical application as a new melanoma vaccine strategy. The 6 peptides vary in length, hydrophobicity/hydrophilicity, and isoelectric point, which required creating 3 different nanoliposomal formulations to encompass them. These 6 peptides have previously shown modest immunogenicity and clinical activity as a vaccine when injected in their free form with other immunogenic adjuvants. Our goal was to improve future clinical efficacy through nano-enhancement strategies via simultaneous delivery of all 6MHPs and corresponding immunogenic adjuvants in a single nanoliposomal solution. In these investigations, we incorporated KDO₂, a TLR4 agonist, into the lipid bilayer as our immune-stimulating adjuvant. Our results demonstrate that the individual liposomal formulations remain stable after being mixed together and that they can be simultaneously delivered without apparent toxicity *in vivo*. We show that via SQ injection, these 6MHP-loaded liposomes are capable of diffusing rapidly to

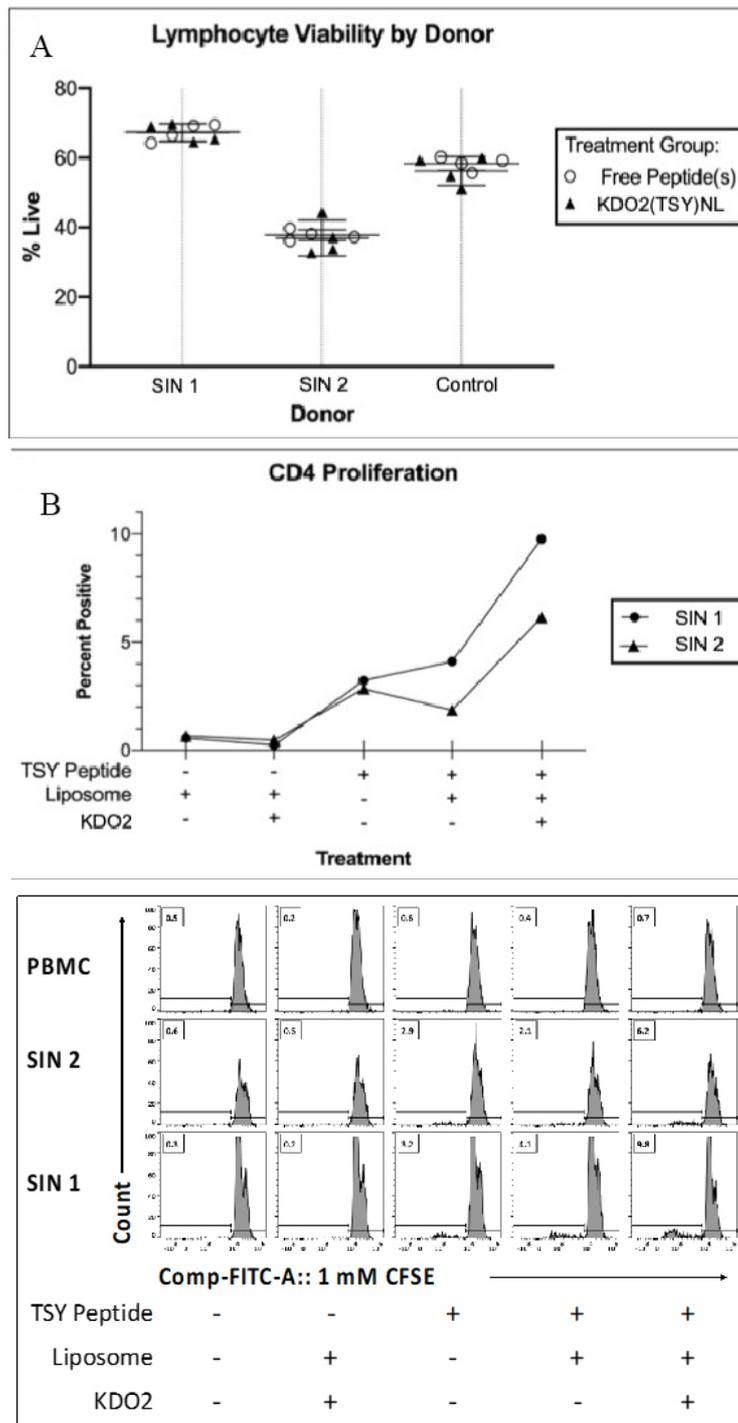

Figure 5. (A) Graph of lymphocyte viabilities of Sentinel Immunized Nodes (SIN) post-treatment. Thick horizontal bars represent mean viability among treatments for a donor; (B) showing a graph of average proliferation of CD4⁺ cell populations after culture treatments with (i) an empty anionic liposome, (ii) an anionic liposome containing KDO2 but no peptide; (iii) Free TSY (no liposome); (iv) TSY encapsulated in an anionic liposome; and (v) an anionic liposome containing TSY and KDO2; and (C) showing the 2D histograms used to calculate the data in 5B. PBMC: Peripheral blood mononuclear cells.

secondary lymphoid organs and appear to remain in circulation for at least 6 days. We also show that these immunogenic liposome formulations significantly enhance immune responses to specific peptides *ex vivo*.

The initial development of our nano-enhanced vaccine was complicated, as we were required to encapsulate and ultimately deliver 6 different peptides simultaneously. We selected a nanoliposome framework because of its versatility. Nanoliposomes can be made with a variety of different lipids to construct the lipid bilayer. They can be made to be neutral or charged, and the exterior surface can be modified chemically for the addition of targeting ligands that enhance liposome delivery; and/or stealth properties that increase biocompatibility and circulation time in the body^[42-44]. Hydrophilic compounds are typically encapsulated within a nanoliposome's aqueous interior, while hydrophobic (or lipophilic) compounds are typically embedded within the lipid bilayer. However, the development and optimization of nanoliposomes is not always a straightforward process, as overall charge, distribution of charge, and size, as well as ionic buffer strength, affect encapsulation efficiency. Each of our peptides had different physical properties, so a single liposome formulation was not optimal for this range of peptides. Instead, we engineered 3 formulations and encapsulated each peptide based upon pH-dependent solubility. While each formulation may have a different surface charge or be formulated with a different buffer system, they still all include a fixed PC/PE ratio that maintains stability, a fixed cholesterol content that prevents leakiness, a fluorophore to facilitate *in vivo* imaging, a reduced PEG brush to help trigger the body's T cell response to these liposomes, and a low concentration of the TLR4-agonist, KDO2, to enhance the adaptive immune response without inducing systemic toxicities. [Figure 6A](#) shows a schematic diagram of our base nanoliposome formulation, and [Figure 6B](#) shows the chemical structure of KDO2-Lipid A.

The new formulations and pH-controlled buffers improved the encapsulation efficiency of most of the peptides compared to the use of a generic neutral nanoliposome formulation. TSY was improved the most. TSY is most stable in pH 5-5.5; thus, PBS did not provide the ideal buffer conditions, while the MES buffer used in our optimized formulations was much more favorable. The anionic liposome formulation also aided in improving the encapsulation of the positively-charged TSY peptide. Similarly, AQN, which had very poor encapsulation in our neutral formulation, also achieved huge encapsulation enhancements when dissolved in a buffer that maintained an alkaline pH and by using a cationic charged nanoliposome to further enhance the encapsulation of the negatively charged peptide. By contrast, encapsulation of WNR, which has a slightly positive charge, was only marginally improved after switching to an anionic liposome and buffer that maintained a pH of 7.0-8.0. LLK, FLL, and RNG achieved reasonable encapsulation values in our neutral formulation, so we did not expect significant improvements with a switch of buffers. However, for LLK and FLL, but not RNG, dissolving the peptides in LR/NaHCO₃ buffer, instead of PBS, slightly improved encapsulation efficiencies. Based on previous clinical studies, where 200 ug of each peptide was delivered to human patients^[39], we estimate that a liposomal loading value of ~50ug/ml should yield an effective immunologic dose. Our studies show that LLK, FLL, and TSY can be reengineered to reach and/or exceed this therapeutic dose. For AQN, WNR, and RNG, we may also attempt pH-dependent active methods of liposomal loading to further enhance encapsulation of these peptides within these nanoformulations. However, based upon previous studies from our group^[22], we might expect that the nanoformulations, in fact, better protect and deliver the peptides, allowing suboptimal encapsulation efficiencies to now reach target therapeutic doses.

In future studies, to further improve liposomal MHP encapsulation, we may also attempt to modify the peptides via techniques such as myristoylation^[45] or palmitoylation^[46]. Both of these methods have been shown to enhance peptide-lipid interactions, allowing for intercalation of the peptides within the lipid bilayer. We chose not to adopt this process initially for several reasons. First, as we already intercalated cholesterol, KDO2, and our fluorophore within the lipid bilayer, we wanted our peptides to sit within the aqueous core of the liposomes in their native form. We were also concerned that incorporation within the lipid bilayer might lower the efficacy of our therapy due to prolonged release kinetics and/or destructive

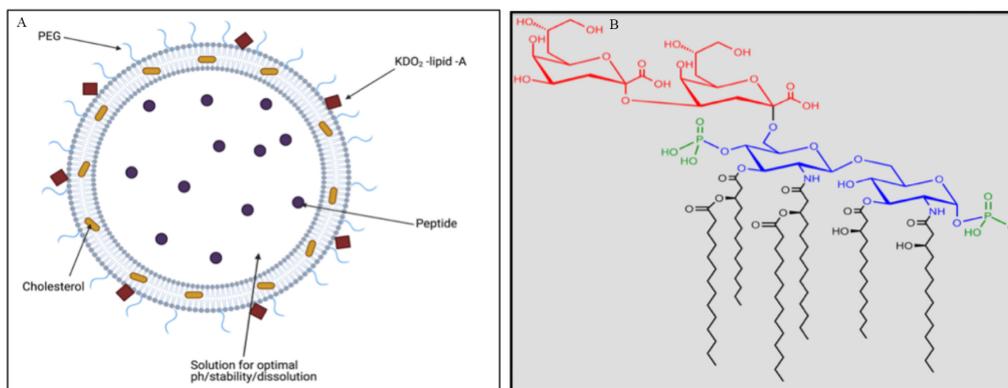

Figure 6. Showing (A) a schematic diagram of the unilamellar nanoliposome with the peptide dissolved within a stabilizing pH controlled buffer within the aqueous liposome core. Cholesterol embeds within the lipid bilayer; and a sparse PEG brush and immunogenic KDO2 lipid head group are arranged around the outer shell of the nanoliposome. The liposome is stored as a suspension in 1X PBS. It should be noted that additional lipid components are added to create either a positive or negative charge in some of the formulations. A fluorophore may also be added, which depending on the fluorophore used, may embed within the bilayer like cholesterol or be attached to a lipid and incorporate within the bilayer like PEG and KDO2. (B) shows the structure of KDO2-lipid A, which has 6 fatty acid chains and a head group on the surface.

interaction/competition with the other adjuvants already in the lipid bilayer. We were also uncertain about how such modifications (and changes in peptide configuration) might affect the immunogenicity of the parent MHP. As part of this ongoing work, we plan to test whether these (and similar) modifications preserve or alter the immunogenicity of the 6MHPs.

A major innovation of our nano-encapsulated approach is the incorporation of the immunogenic KDO2-lipid A into our core nano-liposome formulation. The present study demonstrates the feasibility of creating customized nanoliposomes, containing varying peptides, which can then be mixed for storage and co-administration. These data provide a platform on which to build even more promising nanoliposome strategies. One we propose is to add an antibody that can target the adjuvanted nanoliposomes specifically to dendritic cells. In murine studies, very strong circulating T cell responses, representing about 50% of circulating T cells, have been induced by IV vaccination with peptides plus a TLR agonist and a CD40 antibody that targets antigen-presenting cells (TriVax)^[47-50]. However, comparable systemic dosing of those agents for humans is not likely achievable without unacceptable toxicity. If, on the other hand, these 3 agents could be co-administered in a nanoparticle targeted to dendritic cells (DC), it may prove as effective with a much lower dose. Future versions of our immunogenic liposomes will include bioconjugation strategies (EDC/NHS) for binding CD40 Ab to the surface of the liposomes.

Our biodistribution studies, conducted in healthy murine subjects, suggest that SQ administration could be a preferred method of delivery for our nano-vaccines. Systemic (IV) delivery seems to rapidly distribute the liposomes non-specifically throughout the body immediately after injection, and also appears to then produce a more rapid clearing of them from the body. On the other hand, SQ delivery allows for a slower and more controlled distribution. We acknowledge that a limitation of this present work includes not knowing precisely the extent to which the fluorescent tracer may be released over time *in vivo*. However, as the fluorophore is conjugated to a lipid within the bilayer, we do not expect significant amounts of tracer to be released until the liposomes themselves begin breaking down. Our benchtop studies at body temperature in 10% bovine serum showed that while we observed peptide release after 24 h, the liposomes themselves remained stable for several days. We are confident that the fluorescent distributions imaged immediately after injection on day zero [Figure 3A and C] are representative of liposome distribution at that time. Unlike

IV delivery, SQ delivery does not immediately distribute systemically but does show the rapid appearance of the liposomes within the lymph nodes and spleen. This is encouraging and implies that the nanoliposomes exhibit immunogenicity. It also suggests that even without specific dendritic cell targeting, the nanoliposomes distribute in tissues with high concentrations of dendritic cells, which can be expected to support T cell activation. In future studies, we intend to conduct more detailed benchtop tests to specifically monitor fluoroprobe release over time, as well as increase the frequency of live animal imaging. We also plan to extend this work into a B16 melanoma mouse model. This will require exchanging our humanized antigens with mouse antigens, which may require some alterations to the nanoformulations and thus was beyond the scope of this manuscript. However, this kind of study will allow us to evaluate biodistribution, pharmacokinetics (PK), and immunogenicity of the KDO2-nanoliposomes, as well as determination of pharmacodynamics (PD) for the efficacy of our nanoformulations in a mouse model. We would also like to repeat studies in mice with depletion of dendritic cells to confirm the reliance on those cells.

The goal of the present work was to test whether the 6MHPs could be encapsulated into nanoliposomes with a TLR agonist and whether these would be stable and show preliminary evidence of enhanced immunogenicity. In our preliminary investigations, the TSY peptide consistently achieved the highest liposomal encapsulation values and was also strongly immunogenic in a melanoma patient population^[41]. Our team also had access to 2 patient samples, previously documented to exhibit a strong TSY immunogenic response. Thus, as a proof-of-concept, we evaluated proliferative responses of human CD4⁺ T cells to the TSY peptide *ex vivo* using these 2 patient samples. Our assays showed an enhanced immunogenic response with the peptide encapsulated within a KDO2-nanoliposome, compared to formulations without KDO2 and the free peptide. We expect that this enhancement is mediated by dendritic cell activation and subsequent helper peptide presentations to melanoma-reactive T cells. These results are in line with clinical data demonstrating that simultaneous delivery of a TLR4 agonist with immunogenic peptides enhances T-cell activation^[16]. These initial studies provide a basis for carrying forward this study, first by performing *ex vivo* activation of the five remaining antigens individually, as well as *ex vivo* analysis of the “full vaccine” with a mixture of all 6 peptide nanoliposomes.

Future experiments to support the preclinical development of our nano-formulations include formal PK and toxicological studies by a contract research organization, in addition to the determination of PD for efficacy in a mouse model.

Our results show promise in the use of custom-designed immunogenic (KDO2) nanoliposomes as the delivery vehicle for cancer vaccines. Co-delivery of antigens plus the TLR agonist KDO2 to antigen-presenting cells offer promise to enhance immune responses to melanoma antigens. Prior vaccines in humans commonly induce weak or transient T cell responses: by enhancing those immune responses, this new strategy offers promise to overcome weak antitumor immunity and enable immune-mediated control of melanoma. Moreover, by improving the delivery and efficacy of nano-cancer vaccines, drug resistance to current chemotherapies can also be overcome. Our mouse studies show that a subcutaneous injection may have advantages over IV injection, as it allows the nanoliposome vaccine to concentrate and persist within tissues and organs with high DC populations. This will provide an easier route to immunization that is cost-effective and less invasive for the patients receiving care. Co-administering diverse adjuvants within a nanoliposome are expected to show even further enhanced responses *in vivo*, as it provides a way of targeted delivery, ensuring that all adjuvants are delivered directly and simultaneously to DCs.

Ethical approval and consent to participate

This study included murine *in vivo* studies and experiments using human lymphocytes. The murine studies were approved by the University of Virginia Animal Care and Use Committee (ACUC), as Protocol number 4255. The lymphocytes were isolated from lymph nodes excised as part of a prior clinical trial (Mel41;

NCT00089219), which was approved by the University of Virginia Institutional Review Board for Health

Sciences Research under IRB #10464, and by the U.S. Food and Drug Administration under Initial New

Drug (IND) application #10825. All human participants signed written informed consent for use of their

samples for analysis of immune responses. Participants were assured that they had the right to leave the

study at their convenience. Patients' samples were identified through a code number (VMM#).

Clinicopathological data of patients were confidentially kept, and the electronic information was stored on a

password-protected central server at the University of Virginia.

Abstract

Prostate cancer is the most common cancer and is the second leading cause of cancer-related deaths among men in the United States. Androgen deprivation therapy (ADT) is the standard treatment for advanced-stage prostate cancer; however, this treatment eventually fails, leading to an incurable disease subtype known as metastatic castration-resistant prostate cancer (mCRPC). There are several molecular mechanisms that facilitate the development of mCRPC engaging androgen receptor (AR) growth axis, including AR amplification, gain of function AR mutations, and AR splice variants that are constitutively active and are a foremost factor for mCRPC development. AR-independent mechanisms with exceptionally low or absent AR expression found in cancer cells suppress ADT effectiveness and contribute to aggressive variants, including neuroendocrine differentiation. Several other AR regulatory factors such as epigenetic modification(s), and DNA damage response have been reported during post-ADT exposure and play a crucial role in mCRPC development. Therefore, targeting prostate cancer cells before their progression to mCRPC would improve patient outcomes. This special issue in "Cancer Drug Resistance" focuses on understanding the mechanism(s) and development of mCRPC resistance. This special issue also highlights the therapeutic strategies to combat against resistant subtype. This issue comprehensively reviews the mCRPC and delivers the update in the forum of mCRPC resistance development.

INTRODUCTION

In recent years, studies related to metastatic castration-resistant prostate cancer (mCRPC) have received global attention. mCRPC is an aggressive and advanced form of prostate cancer, having progressed to various organ sites and no longer responding to androgen deprivation therapies that result in lowering of testosterone^[1-2]. Although several treatment options are available for mCRPC patients, the disease remains incurable, with a poor prognosis and low survival rates^[3]. Current systemic treatment options for mCRPC include hormonal therapy, chemotherapy, immunotherapy, radiotherapy, and bone-modifying agents^[4]. There are few recently included novel therapies such as PARP inhibitors and immune checkpoint inhibitors including PD-1/PD-L1 and CTLA4 for a subset of mCRPC patients^[5]. The special issue of “Drug resistance in metastatic castration-resistant prostate cancer” provides insights into the targets and treatment of mCRPC.

ARTICLE DESCRIPTION

In the present special issue, a total of six articles have been qualified and published. The first review published by Yehya *et al.* (2022) shed the light on emerging targeted therapies currently evaluated in clinical trials with promising potential to overcome mCRPC-drug resistance^[6]. This review also provides the updated mechanism of action of mCRPC development. The authors highlight the role of cytochrome P450 enzyme 17 (CYP17) in steroidal biosynthesis, especially androgen synthesis. Implications of altered cellular signaling pathways, kinases, and other factors such as cytokine and enzymes that endorse the mCRPC resistance are described in this review. The authors also highlight the completed and ongoing clinical trials against mCRPC, including PARP inhibitors, immunotherapies, AR degraders, and PI3K signaling inhibitors.

Another original article by Kumar *et al.* (2022) showed the role of extracellular vesicles secretion in paclitaxel resistance of prostate cancer cells^[7]. Treatment of paclitaxel (PTX) resistant prostate cancer cells with GW4869 significantly reduced the release of small EVs (50-100 nm size range) while increasing the release of larger EVs (> 150 nm in size) and inhibited their clonogenicity. Moreover, GW4869 treatment significantly inhibited the survival of PTX-resistant prostate cancer cells in a dose-dependent manner and reduced the tumor weight in an *in vivo* model.

Kushwaha *et al.* (2022) performed a critical review and demonstrated the role of prostate cancer stem-like cells (PCSCs) in the development of antiandrogen resistance^[8]. PCSCs have the ability to differentiate, self-renew, and regenerate tumor heterogeneity. A variety of factors contribute to increasing PCSCs stemness including AR variants, AR mutation, and epigenetic and genetic alterations that lead to changes in the tumor microenvironment, such as adenosine 5'-triphosphate (ATP)-binding cassette (ABC) transporters expression and molecular signaling pathways. This review explored the molecular pathways in the generation of prostate cancer stem-like cells post ADT, various PCSCs markers, and a list of genes, their type and location along with fold change values associated with hematopoiesis pluripotent stem cells. The methods for isolation, identification, and characterization of PCSCs from primary prostate tumors have also been described.

Choi *et al.* (2022) provided a perspective on the transcription factor ONECUT2 which mediates AR-independent cell growth and neuroendocrine differentiation in CRPC^[9]. It is a key factor in NE differentiation between adenocarcinoma to neuroendocrine prostate cancer (NEPC). The perspective specified genes including AR regulatory genes, FOXA1/2, and hepatocyte nuclear factor (Hnf) are the target(s) of ONECUT1 and ONECUT2. Specifically, ONECUT2 regulates the signaling of hypoxia-inducing factors and consequently promotes prostate cancer differentiation and can also serve as a therapeutic target in mCRPC.

Khalil *et al.* (2022) summarize the multifaceted role of Tausled-like kinase 1 (TLK1) in mCRPC progression and development of therapeutic resistance^[10]. The highlight of this review includes that DDR kinase TLK1 mediates an important aspect of adaptation to androgen deprivation and promotes cell cycle progression under unfavorable growth conditions such as ADT and reprograms prostate cancer cells to adapt to androgen-independent growth and resistance development.

The final review article by Biersack *et al.* (2022) demonstrated that epigenetic modification of histone deacetylase (HDAC) plays a significant role in different mechanisms contributing to the development and persistence of CRPC chemoresistance^[11]. The clinical trials on HDAC inhibitors for the treatment of CRPC were reviewed and the major outcomes have been summarized. Several other new HDAC inhibitors and the effect of HDAC inhibitors in combination therapies using anticancer drugs were highlighted.

Altogether, this special issue is a comprehensive review of the mechanism(s) of drug resistance and additional therapeutic opportunities for mCRPC treatment.

Abstract

Resistance to anticancer agents and apoptosis results in cancer relapse and is associated with cancer mortality. Substantial data have provided convincing evidence establishing that human cancers emerge from cancer stem cells (CSCs), which display self-renewal and are resistant to anticancer drugs, radiation, and apoptosis, and express enhanced epithelial to mesenchymal progression. CSCs represent a heterogeneous tumor cell population and lack specific cellular targets, which makes it a great challenge to target and eradicate them. Similarly, their close relationship with the tumor microenvironment creates greater complexity in developing novel treatment strategies targeting CSCs. Several mechanisms participate in the drug and apoptosis resistance phenotype in CSCs in various cancers. These include enhanced expression of ATP-binding cassette membrane transporters, activation of various cytoprotective and survival signaling pathways, dysregulation of stemness signaling pathways, aberrant DNA repair mechanisms, increased quiescence, autophagy, increased immune evasion, deficiency of mitochondrial-mediated apoptosis, upregulation of anti-apoptotic proteins including c-FLIP [cellular FLICE (FADD-like IL-1 β -converting enzyme)-inhibitory protein], Bcl-2 family members, inhibitors of apoptosis proteins, and PI3K/AKT signaling. Studying such mechanisms not only provides mechanistic insights into these cells that are unresponsive to drugs, but may lead to the development of targeted and effective therapeutics to eradicate CSCs. Several studies have identified promising strategies to target CSCs. These emerging strategies may help target CSC-associated drug resistance and metastasis in clinical settings. This article will review the CSCs drug and apoptosis resistance mechanisms and how to target CSCs.

Keywords: Cancer stem cells (CSCs), apoptosis, drug resistance, death receptor pathways, anti-apoptotic proteins, Bcl-2 family, c-FLIP

INTRODUCTION

The cancer stem cell (CSC) paradigm emerged from investigating a subpopulation of less-differentiated CD34⁺/CD38⁻ cells possessing stem cell-like renewal ability and robust malignant-initiating capacity in acute myeloid leukemia (AML)^[1]. Cancer cells from various types of cancers with these characteristics have since been identified in nearly all solid tumors, including cancers of the brain, breast, colon, pancreas, prostate, liver, lung, ovary, head and neck, stomach, thyroid, and melanomas^[2]. The biological importance of activation targets of Nanog, Oct4, SOX-2, and c-Myc in CSCs, which are more frequently overexpressed in poorly differentiated tumors than in well-differentiated tumors, has been shown by correlating signature characteristics of these cells and poor survival^[3]. Interestingly, specific dysregulated signaling pathways maintain CSCs renewal capacity with unique patterns among various tumor types. For instance, CSC maintenance in glioblastoma, colon cancer, gastric cancer, and prostate cancer is regulated by CD133-mediated AKT, leucine-rich G-protein-coupled receptor 5 (LGR5)-mediated Wnt/ β -catenin and speckle-type POZ protein (SPOP)-mediated Nanog pathways^[4-8]. Moreover, Wnt signaling cascades cross-talk with the FGF, Notch, Hedgehog (Hh), and TGF β /BMP signaling pathways and regulate the expression of CSC markers, such as CD44, CD133 (PROM1), EPCAM, and LGR5 (GPR49) in these tumors^[9]. In contrast, regulation of breast cancer CSCs (BCSCs) occurs by CD44 standard splice isoform (CD44s)-activated platelet-derived growth factor receptor b (PDGFRb)/signal transducer and activator of transcription 3 (STAT3), forkhead box C1 (FOXC1)-activated sonic hedgehog (SHH), and sphingosine-1-phosphate (S1P)/S1PR3-activated NOTCH pathways^[10-13]. Therefore, these specific patterns of stemness regulation in various cancers have created significant complexity and specificity in various tumor types, which, in turn, may create a complicated situation with respect to therapeutic interventions aimed at eradicating CSCs from different tumor types.

Substantial data have provided evidence that tumors contain heterogeneous clones of CSCs and these cells are essential for tumor growth and survival^[14]. Based on the CSC model, tumor heterogeneity due to clonal evolution of CSCs^[15,16] is defined as cells with self-renewal capacity which are able to generate a progeny cell population [Figure 1]. As a result, the bulk of the tumor mass is differentiated and expanded progeny capable of rapid proliferation potential and harboring minor populations of various CSCs with particular properties, including their drug resistance phenotype [Figure 2]. Therefore, the major obstacle to curing tumors remains the presence of heterogeneous CSC clones resistant to chemotherapy and apoptosis^[17-22]. Previous reports have proposed that targeting CSC subpopulations may result in tumor eradication and inhibition of tumor relapse^[9,17-19]. However, tumors are curable when the heterogeneous CSC populations, as well as the rest of the tumor mass, including the progenitor cells and differentiated malignant cells, are targeted and eliminated^[9,18,19].

The progression and heterogeneity of tumor cell populations may be explained by the CSC or cancer-initiating cell model^[14-18] or by the clonal evolutionary model^[14]. The CSC model, which is also referred to as the hierarchical model, states that tumors arise from a small percentage of CSCs that are derived from normal stem cells (NSC) that generate the bulk of tumor cell population^[14,15] [Figure 2]. In the clonal evolution model, genetic and epigenetic changes happen over time in individual cells, and these alterations persist and provide a selective advantage; the clonal CSCs will outgrow other clones and result in a heterogeneous tumor population^[14-18]. Interestingly, in the clonal evolutionary model, each cancer cell within the tumor is endowed with the potential to generate tumors having various degrees of drug-resistant

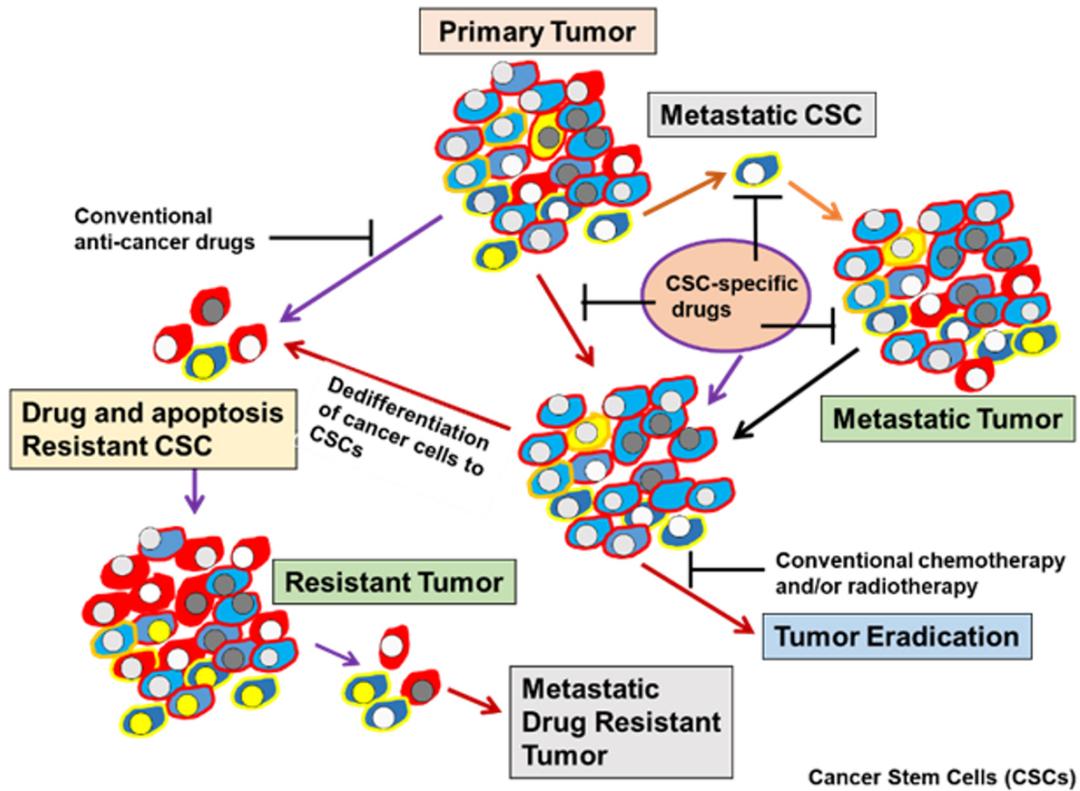

Figure 1. Heterogeneity of CSCs in tumors. Development of drug-resistance phenotype, metastatic tumor formation, and a potential strategy for eradicating tumors using CSC-specific drugs. CSC: Cancer stem cell.

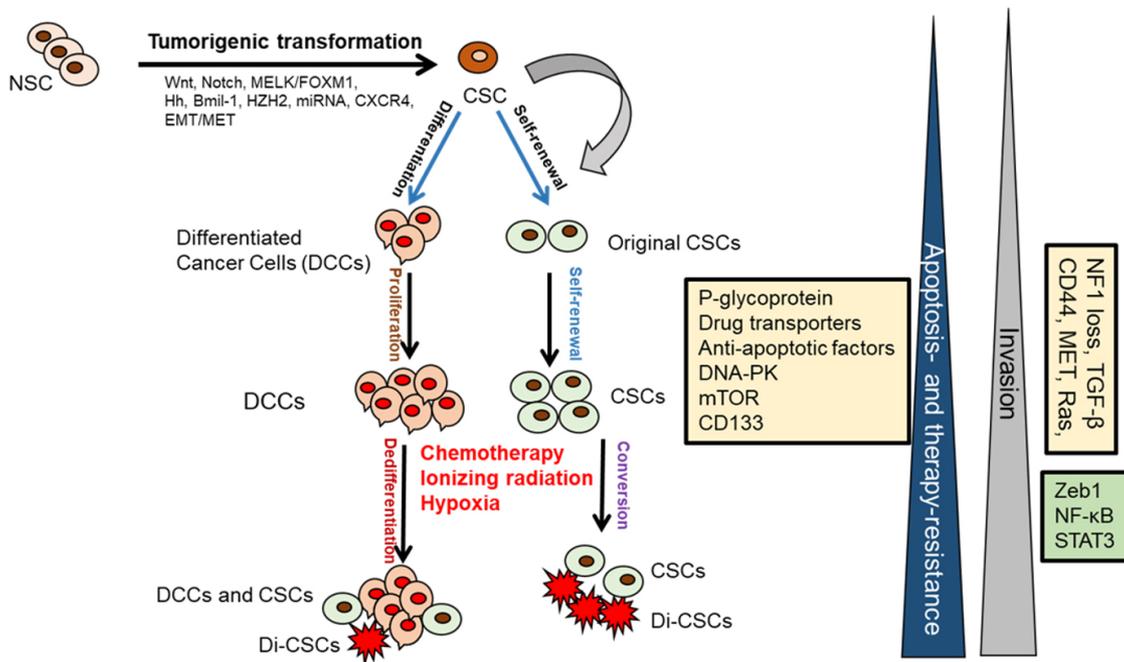

Figure 2. CSCs role in tumor development and progression. CSCs are originated from the NSCs through the tumorigenic transformation of several potential pathways including Hg, epithelial-to-mesenchymal transition (EMT), and the reverse process mesenchymal-to-epithelial transition (MET). CSCs and drug-induced CSCs (Di-CSCs) can be enriched following conventional chemotherapy treatment. CSC: Cancer stem cell; NSCs: normal stem cells.

subpopulations [Figure 1]. Another complexity of cancer treatment is that CSCs can be generated during cancer therapy by epigenetic plasticity due to drug-induced dedifferentiation and conversion of non-CSCs to CSCs^[9,17,18] [Figure 2].

Tumor recurrence due to unresponsiveness to chemotherapy is the major cause of death in patients with incurable cancers and is due to treatment-resistant CSCs in the primary tumor [Figure 1]. CSCs are a low percentage of the cell population within a tumor and express specific molecular markers in a variety of cancers^[14,15,17]. Understanding the molecular network of CSC populations may lead to the identification and development of targeted agents that can trigger CSCs cell death, thus enhancing the opportunity to design more effective treatment strategies to eradicate cancer. CSCs in various types of tumors are responsible for the initiation, progression, metastasis, drug resistance, and recurrence of cancer^[9,14,15,17]. These quiescent and pluripotent cells form CSCs niches, resulting in particular microenvironments that protect CSCs from cell death, chemotherapy, and radiotherapy^[9,18,19]. Additionally, tumors bear a hierarchy of cells initiated from the CSC population. Tumors exhibit stemness (self-renewal and multilineage differentiation) because of CSCs. These cells are capable of recapitulating xenografts similar to the original tumor^[9,18,19]. The CSCs self-renewal and differentiation programming lead to the generation of several cancer cell types within tumors, creating tumor heterogeneity^[9,18,19,23] with gradients of resistance to different therapeutics.

Drug resistance is a major impediment to the successful treatment of tumors with conventional chemotherapeutic agents^[8,18,19]. One major contributor to drug resistance is the heterogeneity of cells with various degrees of sensitivity to drugs within a tumor^[9,23]. A significant amount of data has proven that within solid tumors, there are distinct populations of cancer cells contributing to the complexity of cancer treatment^[9,18,19,24-29]. Additionally, the lack of or refractoriness to apoptosis due to intrinsic resistance to cell death has been another primary limitation in cancer therapy (e.g., pancreatic cancer, colon cancer, glioblastoma, and prostate cancer are typically refractory to cancer chemotherapy mainly due to aberrant apoptotic machinery) along with acquired resistance (e.g., after breast cancer chemotherapy, tumor cells become resistant to multiple drugs)^[18,28]. Based on substantial data, it is now believed that major contributors to intratumoral heterogeneity are CSCs, cellular genotype, genomic instability, cell plasticity epigenetic variation, and stochastic processes^[9,18,19,29]. Additionally, the microenvironmental factors including distinct subpopulations of cancer-associated fibroblasts and cancer-associated macrophages^[9,18,29], regulate various events in cancer cells and contribute to the heterogeneity of the tumor cell population. Therefore, while CSCs participate in drug and apoptosis resistance in tumors, the therapy resistance phenotypes in various cancers are very complex.

Various molecular and biochemical mechanisms participate in triggering resistance to chemotherapeutic drugs in cancer cells, and characterizing these mechanisms is critically important for the development and design of more effective and successful approaches to reverse or circumvent drug resistance in cancer cells and tumors. Upregulation of drug transporter proteins, deregulation of apoptotic signaling pathways, and upregulation of the cytoprotective and survival mechanisms in cancer cells, particularly in CSCs, confer resistance to various drugs in a wide variety of cancers^[28,30-34]. Since several levels of drug resistance phenotype may be present in the bulk of tumor cell population, for effective and successful cancer therapy, it is essential to eliminate the entire CSC population, differentiated cancer cells, and progenitor cells in the entire tumor mass.

Drug resistance in CSCs

Several major signaling pathways have been shown to play essential roles in the regulatory capacity of CSC self-renewal, survival, proliferation, differentiation, and stemness maintenance. These pathways include

Janus-activated kinase/signal transducer and activator of transcription, Hh, Wnt, Notch, phosphatidylinositol 3-kinase/phosphatase and tensin homolog, and NF- κ B signaling pathways^[7-9]. It is also well documented that these critical signaling pathways are also dysregulated in various cancers^[7-9,17,18]. Much evidence suggests that the dysregulation of these signaling pathways may also contribute to the survival and drug resistance of CSCs^[18,19].

It is well documented that CSCs are highly resistant to conventional chemotherapies^[11,26-32] and target specific anticancer agents. **Figure 3** shows that various drug resistance mechanisms have been reported in CSCs including increased anti-apoptotic proteins such as Bcl-2 Bcl-X, and c-FLIP^[11,26], high expression of ATP-binding cassette (ABC) transporter proteins and detoxifying enzymes^[26-28], cell cycle quiescence^[29,30], increased DNA repair ability^[26,27], elevated aldehyde dehydrogenase (ALDH) activity^[31], activation of key prosurvival signaling molecules such as Notch, Wnt/ β -catenin, and NF- κ B^[32-34], increased activities of the phosphatidylinositol 3-kinase (PI3K)/Akt/mammalian target of rapamycin (mTOR), and maternal embryonic leucine zipper kinase (MELK), aberrant stemness signaling pathways, increased quiescence, and increased autophagy^[11,35].

Accumulating data show that CSCs are quiescent, which is the resting stage of the cell cycle, and quiescence is associated with resistance to chemotherapeutic agents since most of these drugs target actively proliferating cells^[36,37]. DNA repair proteins are upregulated in CSCs, and their increased expression correlates with rapid DNA repair, which also triggers drug and radiation resistance^[27,39,40]. Much evidence shows that the cancer microenvironment (niche) critically protects CSCs from cancer therapy^[27,41], and CSCs mutually contribute to the niche in a feedback loop^[32,41]. Furthermore, the extracellular matrix (ECM), a component of the niche, is known to facilitate and maintain CSCs and drug resistance^[42]. Therefore, delineating molecular and biochemical mechanisms of drug resistance as well as understanding the cross-talk between CSCs and their niche is critical for devising strategies to overcome resistance to anticancer drugs and cell death.

This review article discusses the contribution of numerous drug resistance mechanisms and signaling pathways in controlling CSC maintenance and unresponsiveness to drugs and apoptosis. Understanding and delineating these mechanisms are critically important and essential for overcoming drug resistance in these cells^[13-15,23,34]. To appreciate the complex signature network that controls unresponsiveness to drugs, the major mechanisms of chemotherapeutic and apoptotic resistance in CSCs are summarized in **Figure 3**. These mechanisms are interchangeable in controlling resistance to chemotherapy and apoptosis evasion in CSCs.

Signaling pathways in cancer stem cells

Significant evidence has documented that tumors are initiated from CSCs, and these cells maintain patient resistance to therapies^[11,43-49]. Moreover, due to the heterogeneity, high diversity, and plasticity of CSCs, developing efficient and useful therapeutics to target these cells has been difficult. Accumulating data also suggests the possibility of non-CSC reprogramming and dedifferentiation of the progenitor cells or differentiated cancer cells to CSCs [**Figure 1**], resulting in increased complexity and diversity of drug-unresponsive cells with various drug resistance mechanisms in tumors. Therefore, because of this complexity, an ideally potent and effective anticancer drug must eradicate both CSCs and the bulk of the heterogeneous tumor cell population, and avoid triggering tumor cell dedifferentiation of non-CSCs to CSCs or cancer stem-like cells.

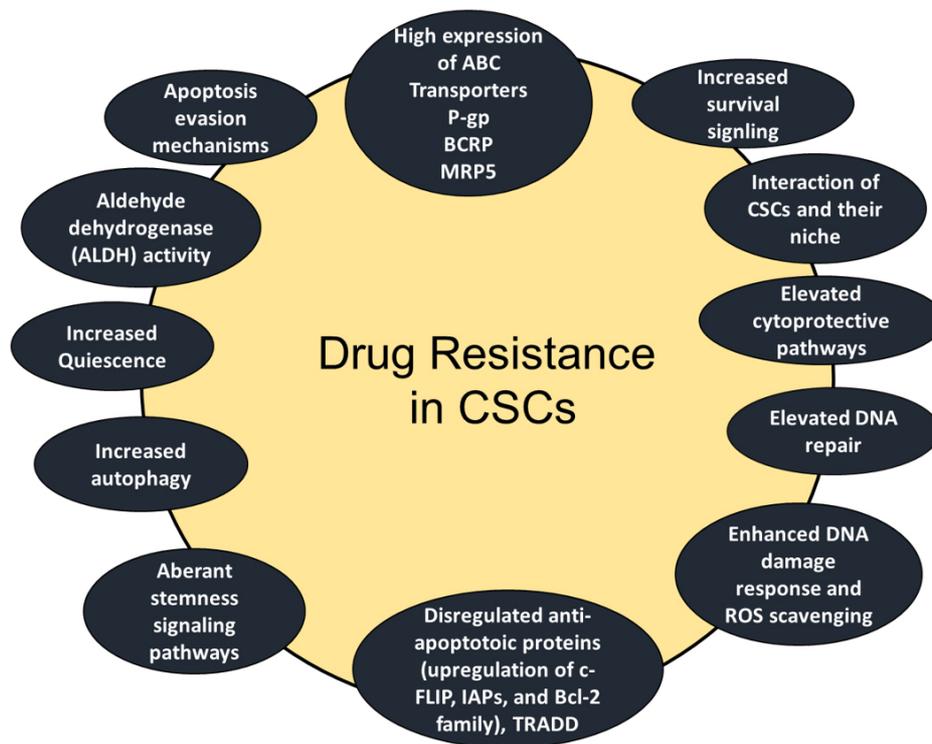

Figure 3. Schematic presentation of CSC-mediated therapy resistance to cancer. Activation of cell survival pathways, quiescence, increased drug efflux, impairment of the apoptotic pathway, increased DNA damage repair, increased detoxifying activity, and increased scavenging of free radicals are possible contributors to the therapy resistance of CSCs. TRADD: Tumor necrosis factor receptor 1 (TNFR1)-associated death domain protein.

A complex signature network including the Notch, Hg, Wnt/ β -catenin, the NF- κ B signaling pathways, PI3K/Akt/mTOR (mTORC1 and mTORC2), MELK, TGF- β , STAT, and Hippo-YAP/TAZ among others are activated and participate in the maintenance, self-renewal, proliferation, and drug resistance characteristics of CSCs^[11,43-50]. These pathways and the cancer stem cell markers including CD133, CD44, Oct4, SOX-2, Nanog, and ALDH1A1 maintain distinct CSC properties^[17,18,28,43-63] [Figure 4].

Accumulating evidence indicates that another important factor, epigenetic modification of CSCs, could result in phenotypic and functional heterogeneity among the cell populations within solid tumors which arise from different tissues of origin^[9, 21, 23]. Emerging data suggest that epigenetic factors regulate CSC properties. For instance, the catalytic subunit of Polycomb repressive complex 2 (PRC2), known as the enhancer of zeste homolog 2 (EZH2), has histone methyltransferase activity, is upregulated in CSCs, and has a critical function in their proliferation and maintenance^[61,64]. Furthermore, histone deacetylases (HDACs) 1, 6, 7, 8 and 6, known to deacetylate transcription factors and other cellular proteins, are overexpressed in CSCs and function in various maintenance activities of these cells^[65,66].

It has been shown that hypoxia plays a crucial role in triggering resistance to chemotherapeutic agents^[67-69]. Hypoxia-driven CSC enrichment results from a dedifferentiation process in breast cancer, and hypoxia-inducible factors (HIFs) are required for chemotherapy resistance in CSCs from various tumors including breast CSCs (BCSCs)^[67], glioblastoma CSCs^[68] and other solid tumors^[57]. Interestingly, the dedifferentiated CSCs display multidrug resistance (MDR) via the PERK (protein kinase R-like endoplasmic reticulum kinase)-Nrf2 signaling pathway^[70]. Moreover, Lee *et al.*^[68] have found that temozolomide (TMZ)-triggered

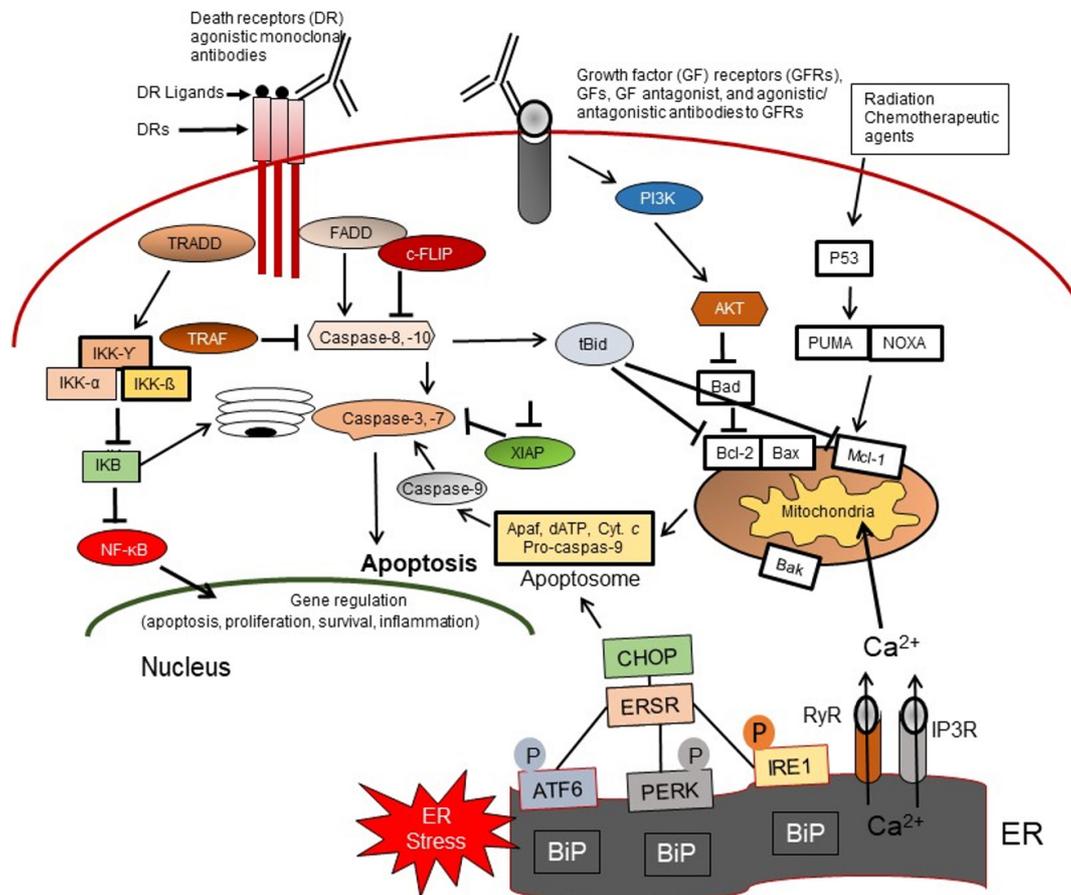

Figure 4. Apoptosis signaling pathways. Overview of the intrinsic (mitochondrial), extrinsic or death receptor (DR), and ER-stress (ERS)-mediated apoptosis pathways in response to the molecular action of anticancer agents, as well as the TRADD/NF- κ B survival pathway, the growth factor (GF) receptors, and PI3K/Akt prosurvival signaling axis in CSCs. FADD: Fas-associated death domain; c-FLIP: cellular FLICE-like inhibitory protein; TRAF: tumor necrosis factor receptor associated factor; NF- κ B: nuclear factor kappa B; I κ B: inhibitor kappa B; IKK: inhibitor kappa B kinase; XIAP: X-linked inhibitor of apoptosis; Apaf-1: apoptotic Protease Activating Factor-1; Cyt. C: cytochrome c; PI3kinase: phosphoinositide 3-kinase; AKT: protein kinase B (PKB); PUMA: p53upregulated modulator of apoptosis; Bcl-2: B cell Lymphoma 2; Bax: Bcl-2-associated X protein; BID: BH3 interacting domain death agonist; Mcl-1: myeloid cell leukemia sequence 1; Bak: BCL-2-anatagonist/killer1; CHOP: C/EBP homologous protein; Noxa: encodes a Bcl-2 homology 3 (BH3) member of the Bcl-2 family of proteins; ATF: activating transcription factor; ER: endoplasmic reticulum; PERK: endoplasmic reticulum stress kinase; IRE1: inositol-requiring enzyme 1; RYR: ryanodine receptors Ca²⁺ release channels; IP3R: inositol 1,4,5-trisphosphate (IP3) regulated channels; BiP: binding immunoglobulin protein.

HIF1 α /HIF2 α upregulation plays a major role in converting non-stem glioma cells to stem-like cells, and that knockdown of HIF1 α /HIF2 α inhibited the conversion of non-stem glioma cells to glioma stem cells (GSCs) post-therapy^[68].

Another critical signaling protein, MELK, a serine/threonine kinase, is upregulated in human cancers and CSCs^[71-73], and evidence suggests that this protein plays a major role in the survival and other known properties of CSCs including drug and apoptosis resistance as well as tumor recurrence. Kim *et al.*^[72] has shown that MELK phosphorylates the oncogenic transcription factor Forkhead Box M1 (FOXM1) and that the MELK/FOXM1 complex targets EZH2, which in turn promotes CSC resistance to drugs and radiation^[18, 61], and that an inhibitor of MELK OTS167 robustly eliminates CSCs from small cell lung cancer (SCLC)^[73, 74].

Resistance to apoptosis in CSCs

While chemotherapeutic agents promote apoptosis in malignant cells and reduce tumor mass, the disease often relapses or progresses due to the repopulation of the cells unresponsive to anticancer therapy^[75-77]. Moreover, cancer cells may acquire more stemness, metastatic properties, and drug resistance during treatment^[78-80]. Therefore, this scenario suggests that therapy itself triggers tumor progression. Such unwanted effects of the therapies may be due to the selective survival of the particular subset of cancer cells having very aggressive mutations, allowing the cells to escape apoptosis^[78], which may trigger tumor aggressiveness. However, this concept is challenged by data indicating a more complex scenario^[81-86]. In fact, cancer tissues treated with cytotoxic agents work by aberrant responses through epigenetic mechanisms, activating signaling pathways directed towards tissue repair and cell repopulation. Such pathways also act by increasing tumor immune escape, metastasis, genetic instability, and acquired resistance to anticancer agents and apoptosis^[87,88]. It is also possible that therapy-induced apoptotic cells produce paracrine signals, promoting proliferation capacity among surviving cells^[89-93]. Therefore, the active role in a compensatory contradicting manner is played by the dying cells, which increase tumor tissue repopulation. In such a scenario, apoptotic cells activate the “Phoenix Rising” pathway to promote wound healing tissue regeneration (the term “Phoenix Rising” means to emerge from a catastrophe stronger and more powerful^[89]).

Unresponsiveness to chemotherapeutic agents, dysregulation of apoptosis pathways, apoptosis resistance, and overexpression of anti-apoptotic proteins are necessary for CSC survival. To discuss the mechanisms of resistance to apoptosis and cancer-related chemotherapeutic drug, apoptosis signaling pathways are first described. Cancer cells and CSCs avoid apoptosis, but apoptosis in these cells is carried out through several signaling pathways in response to chemotherapeutic agents and various apoptotic stimuli^[28,95]. Mutations that occur in normal stem cells (NSCs) lead to the generation of CSCs [Figure 1], enabling them to evade apoptosis and leading to tumor formation^[28,80].

A large amount of data has described three major apoptosis pathways: the extrinsic or cell surface death receptors pathway, the intrinsic or mitochondrion-initiated pathway, and endoplasmic reticulum (ER) stress-mediated pathway control of apoptosis [Figure 4]^[28,96-107]. Extrinsic or the death-receptor mediated apoptotic pathway is initiated by the binding of death receptors (DRs) with their ligands [interaction of Fas/Fas ligand, tumor necrosis factor- α (TNF- α)/TNF receptor 1 (TNFR1), TRAIL (TNF-related apoptosis-inducing ligand)/DR4, or TRAIL/DR5] [Figure 4]. Ligand and DR interaction induces recruitment of Fas-associated protein with death domain (FADD), also called MORT1, and procaspases-8 or -10 to form the death-inducing signaling complex (DISC), which by an autocatalytic process leads to activation of these procaspases to caspases-8 and -10. These initiator caspases subsequently activate the effector caspases-3, -6, and -7. Active forms of these caspases then trigger degradation of the downstream proteins leading to apoptosis. Caspase-8 or -10 cleaves the pro-apoptotic Bcl-2 family member Bid to truncated tBid, thereby linking the extrinsic apoptosis pathway to the intrinsic or mitochondrial pathway and inducing cytochrome *c* release from mitochondria^[28,96,100]. The DR-initiated apoptosis pathway is suppressed by the anti-apoptotic protein cellular FLICE (FADD-like IL-1 β -converting enzyme)-inhibitory protein (c-FLIP), which inhibits DISC formation and activation of caspases-8 and -10 and blocks apoptosis^[34,103,104].

In the intrinsic apoptosis pathway, various apoptotic stimuli (e.g., conventional chemotherapeutic drugs, DNA damaging agents, radiation, and small molecule anticancer compounds) induce mitochondrial outer membrane permeabilization (MOMP). MOMP induction is initiated by the activation of two groups of pro-apoptotic proteins: (1) the Bcl-2 homologous pro-apoptotic proteins (e.g., Bax, Bak, and Bad) and (2) the Bcl-2 homology domain-3 (BH3)-only family of proteins including Bid, Bim, and Puma^[96-102]. Therefore, these proteins provide an interactive protein network with mitochondria, which leads to the release of

apoptosis triggering factors. The apoptosis-inducing factors (AIFs) include certain caspases, Smac/DIABLO, and other factors from the mitochondrial intramembrane space to the cytosol. Following release from mitochondria, cytochrome *c* and dATP bind to apoptotic proteinase-activating factor-1 (Apaf-1) to form the apoptosome, and this complex triggers procaspase-9 autoactivation. The active caspase-9 can activate caspases-2, -3, -6, -7, -8, and -10, leading to degradation of cellular proteins and resulting in apoptosis induction^[28,102,103].

The third main apoptosis pathway is the endoplasmic reticulum (ER)-mediated apoptosis pathway [Figure 4]. One of the functions of the ER is to promote the correct folding of proteins. It also mediates ER-associated degradation of unfolded or misfolded proteins. Dysregulation of ER functions triggers an accumulation of unfolded or misfolded proteins in the ER lumen, resulting in ER stress (ERS), which triggers the unfolded protein response (UPR) or the ERS response (ERSR), leading to restored homeostasis or apoptosis^[105-107].

Another mechanism by which CSCs display resistance to apoptosis is by upregulating the expression of anti-apoptotic proteins including the cellular FLICE-inhibitory protein (c-F1LIP), the Bcl-2 family of proteins, and inhibitor of apoptosis proteins (IAPs)^[28,108,109]. CSCs upregulation of c-FLIP expression regulates resistance to TNF-related apoptosis-inducing ligand (TRAIL)-induced apoptosis^[110]. Overexpression of IAPs also plays a crucial role in resistance to TRAIL and chemotherapeutic agents, as well as unresponsiveness to apoptosis^[28,111].

Mechanisms of CSCs drug resistance

While CSCs are significantly resistant to drugs, there are several characteristics of these cells that may potentially help in the development of anti-CSC therapies. These characteristics include drug transporters, DNA repair machinery, specific cell surface markers, particular networks of transcription factor signaling, aberrant signaling pathways, epigenetic alterations, reprogramming and plasticity, interaction of CSCs with the microenvironment and CSC niche, and using specific metabolic pathways that regulate CSCs^[55,71-73,93-95].

Several mechanisms trigger drug resistance and make CSCs refractory to apoptosis. Characterizing the mechanisms that evade apoptosis and identifying therapeutic targets to increase apoptosis in CSCs are particularly significant for successful cancer therapy. These mechanisms are discussed in detail in the following sections.

Multidrug resistance transporters in CSCs

Several ATP binding cassette protein transporters, including P-glycoprotein (P-gp, MDR1, ABCB1), multidrug resistance protein 1 (MRP1, ABCC1), breast cancer resistance protein (BCRP, ABCG2), and MRP5/ABCC5^[14-120], have been extensively investigated as multidrug resistance transporters in various tumors. Overexpression of these proteins in several solid tumor types, AML, and myeloma leads to ATP-dependent efflux of a wide range of conventional chemotherapeutic agents. Overexpression of these proteins in the multidrug-resistant cells results in lower drug levels in the resistant cells, below the amount required to induce cell death^[112-115]. Consistent with these observations, conclusive evidence shows that CSCs in various solid tumors and hematological malignancies upregulate these ABC transporters, resulting in drug resistance in these cells^[116,117]. For example, Wang *et al.*^[118] reported that Panc-1 pancreatic CSCs displayed resistance to gemcitabine, upregulated expression of CD133/CD44/Oct4/Nestin compared to the parental Panc-1 cells, and overexpressed P-gp and anti-apoptotic proteins. Moreover, in glioblastoma CSCs, epigallocatechin gallate (EGCG) treatment downregulated P-gp overexpression but not that of ABCG2 or O6-methylguanine-DNA methyltransferase (MGMT) and increased the cytotoxic effect of TM^[118]. Additionally, Wilson *et al.*^[116] demonstrated that ABCG5 in melanoma cancer stem cells (MCSCs) maintains

drug resistance and stemness in these cells. Therefore, the ABC multidrug transporter proteins are surface markers for CSC identification as well as their ability to transport drugs and enable CSCs to be resistant to drugs.

PI3K/Akt/mTOR signaling pathway plays a crucial role in CSCs

This is a critical pathway that functions in many important cellular activities and contributes to drug resistance in cancer. Several studies have clearly shown that upregulation of PI3K/Akt/mTOR plays a central role in the maintenance of CSCs^[121-123]. Furthermore, emerging data suggest that this signaling pathway is a rational and promising target for developing anti-CSC drugs^[119-125]. Indeed, some promising compounds targeting this pathway, including salinomycin, metformin, silibinin E1201, rottlerin, and torin, have been shown to be promising anti-CSCs therapeutics^[120]. Additionally, the antidiabetic drug metformin, an inhibitor of PI3K/Akt/mTOR signaling, was shown to effectively reduce temozolomide (TMZ) resistance in CSCs^[123]. Furthermore, the combination of metformin with the RAF inhibitor sorafenib also significantly decreased CSCs oxidative stress and drug efflux pump activity and synergistically killed these cells^[124]. It is well known that CSCs heavily rely on mitochondrial oxidative phosphorylation^[124]. Interestingly, metformin has been shown to use this metabolic weakness and increase CSCs sensitivity to many cancer chemotherapies, modulate drug resistance, and increase treatment efficacy^[125].

Dysregulated anti-apoptotic Bcl-2 family proteins in CSCs

Distinct hallmarks of malignancies are apoptosis evasion due to dysregulation of signaling pathways and apoptotic proteins^[28] and the ability of CSCs to self-replicate, proliferate, and metastasize^[28,126]. While emerging data indicate that in various cancers, several steps within the extrinsic and intrinsic apoptotic pathways in CSCs may be dysregulated^[28,126], the abnormal expression levels, as well as levels and ratios of pro-apoptotic and anti-apoptotic proteins and their contribution to drug resistance in CSCs have not been well described. Bcl-2 family proteins are well characterized and consist of the anti-apoptotic molecules Bcl-2, Bcl-XL, and Mcl-1 and the pro-apoptotic proteins Bax, Bak, Bid, Bim, Bik, Noxa, and Puma^[128,129]. Increased levels of Bcl-2 family proteins were shown in CSCs, and high levels of these proteins have been shown to be associated with the apoptosis and drug resistance of CSCs^[139,131]. This resistance is partly due to the ratio of anti- to pro-apoptotic protein levels, triggering the unresponsiveness of cancer cells to drugs and apoptosis, which enhances cell survival^[28,130,131]. It has been shown that aberrantly overexpressed nuclear factor erythroid 2-related factor 2 (Nrf2), which is the redox-sensing transcription factor, promotes CSC survival by elevating transcription of the genes for drug transporters and the anti-apoptotic Bcl-2 proteins^[132]. Due to the significance of expression of the Bcl-2 family of anti-apoptotic proteins for cell survival and resistance to apoptosis and drugs in CSCs^[28,130-132], therapeutic interventions to eliminate CSCs using inhibitors are potentially an important strategy.

Role of NF- κ B in CSCs resistance to apoptosis and drugs

Cancer cells and CSCs often display constitutively activated NF- κ B expression that promotes levels of apoptosis inhibitory proteins and drug-resistant proteins, resulting in enhanced survival and resistance to therapies in cancer cells^[134-137]. It is documented that the tumor necrosis factor receptor 1 (TNFR1)-associated death domain protein (TRADD) is an adaptor protein in TNFR1 signaling and participates in NF- κ B activation as well as survival signaling in CSCs^[136] downstream of DR4, DR5 [Figure 2]. Moreover, tumor necrosis factor (TNF)-related apoptosis-inducing ligand (TRAIL) promotes the formation of the intracellular Complex II composed of FADD, TRADD, caspases-8 and -10, RIP1, TRAF2 and IKK- γ ^[133]. Upregulated expression of TRADD activates NF- κ B in glioblastoma (GBM) cancer stem cells (GSCs)^[134]. Moreover, cytoplasmic TRADD is significantly associated with worse progression-free survival (PFS) in GBM patients^[134]. Interestingly, knockdown of TRADD by shRNA in GSCs reduced NF- κ B activity and triggered cell death in these cells, revealing that TRADD is required for the maintenance of CSCs

populations^[134]. NF- κ B signaling plays a pivotal role in the maintenance of CSCs^[135] [Figure 4]. In ovarian cancer, NF- κ B signaling supported by the RelB transcription factor directly regulates the CSC-associated enzyme aldehyde dehydrogenase (ALDH)^[135]. Furthermore, the NF- κ B signaling pathway plays a critical role in the drug resistance phenotype of gastric CSCs^[135]. The NF- κ B activity supports CSCs maintenance and reduces sensitivity to NF- κ B inhibitors, indicating that high activity of NF- κ B plays a critical role in the survival and drug resistance of CSCs^[136,137].

Role of the anti-apoptotic IAP family in CSC drug and apoptosis resistance

The IAP family consists of survivin, IAP1, cIAP2, X-linked inhibitors of apoptosis (XIAP), ML-IAP, NAIP, and ILP-2^[138-141]. IAPs suppress the activity of caspases-3, -7, and -9 and help cancer cells evade apoptosis^[138,139]. Upregulation of IAP family proteins has been shown in various tumors and hematological malignancies and causes resistance to apoptosis, anticancer agents, and radiation therapy, as well as causing poor prognoses^[148,139]. These proteins function through interactions of their BIR baculoviral IAP repeat (BiR) protein domains, and these interactions are antagonized by Smac/Diablo, a negative regulator for the inhibitors of IAPs and induction of apoptosis^[138,139]. Intriguingly, survivin plays a role in CD133+ cell resistance of colon CSCs to 5-fluorouracil (5-FU), and a survivin inhibitor can be a potential new targeted agent against CD133+ colon CSCs^[138].

The pivotal role of IAPs in maintaining medulloblastoma (MB) CSCs has been shown^[139,140]. Therefore, the importance of IAP inhibitors with a preference for CD133+ positive MB CSCs has been demonstrated^[139]. Evans *et al.*^[141] has shown that XIAP drove constitutive NF- κ B transcriptional activity in inflammatory breast cancer and maintained CSCs. Furthermore, Ji *et al.*^[142] have found that XIAP has a critical role in maintaining CSCs in nasopharyngeal carcinoma (NPC) stem cells. These authors demonstrated that XIAP regulates SOX-2 stability of the CSC, which is important for the maintenance and self-renewal of NPC CSCs. Furthermore, Janzen *et al.*^[143] showed the important role of IAPs in CSCs by demonstrating that the cIAP inhibitor B (Birinapant) overcomes platinum resistance in CSCs of ovarian cancer *in vivo*, revealing that IAPs may play a significant role in cancer drug resistance and recurrence.

c-FLIP regulates resistance to apoptosis and drugs in CSCs

The master regulator of the death receptor (DR) networks is c-FLIP. Besides its key role as an anti-apoptosis factor, c-FLIP may control necroptosis, pyroptosis, autophagy, nuclear factor κ B (NF- κ B) activation, and tumorigenesis^[143-144]. c-FLIP is a catalytically inactive caspase-8/-10 homolog and a critical anti-apoptotic protein that suppresses cytokine- and chemotherapy-induced apoptosis and causes resistance to these agents^[143]. c-FLIP is expressed as long (c-FLIP_L), short (c-FLIP_S), and c-FLIP_R splice variants, which bind to FADD and/or caspases-8/-10 and TRAIL receptor 5 (DR5) and prevent DISC formation. Moreover, c-FLIP_L and c-FLIP_S are also known to have multifunctional roles in various signaling pathways, as well as activating and/or upregulating several cytoprotective and prosurvival signaling proteins including protein kinase B (PKB) or Akt, extracellular signal-regulated kinase (ERK), and NF- κ B. Furthermore, the upregulation of c-FLIP is also induced by several kinases, including phosphatidylinositol-3 kinase (PI3K)/Akt, mitogen-activated protein kinase (MAPK), and Ca²⁺/calmodulin-dependent protein kinase II (CaMKII)^[34,143]. Several reports have shown that c-FLIP isoforms maintain the survival and resistance of CSCs to apoptosis and anticancer therapeutics^[110,145,146]. CD133, a CSC marker that plays a role in CSC tumorigenesis, metastasis, and chemoresistance, can also upregulate the expression of c-FLIP in CD133+ cells, thus inhibiting apoptosis^[147,148].

Aldehyde dehydrogenase activity

ALDH isoforms detoxify a variety of endogenous and exogenous aldehydes, and high ALDH activity has been frequently used as a selectable marker for CSCs^[149,150]. Much evidence suggests that ALDH may be used

as a marker for CSC self-renewal, proliferation, differentiation, and resistance to drugs^[149-151]. It is well documented that the ALDH protein family is a signature of CSCs and ALDH1A1 is the most studied ALDH isoform^[121-122]. The expression of ALDH1 protein in CSCs is a negative prognostic indicator and predictor of poor clinical outcomes in cancer patients, and high ALDH activity has been attributed to chemoresistant CSCs in different tumor types^[150-152]. In summary, substantial data indicate a critical role of ALDH, particularly ALDH1, in CSC biology and therapy resistance^[149-152]. Therefore, inhibition of ALDH activity may be a rational and potentially useful therapeutic strategy for targeting CSCs with the aim of increasing the efficacy of cancer therapies.

Enhanced DNA damage response and ROS scavenging in CSCs

Much evidence has shown that CSCs are resistant to DNA damaging therapies by regulating the cell cycle, increasing DNA repair capacity, and effectively scavenging reactive oxygen species (ROS)^[155-159]. DNA-damage response (DDR) is considered a significant source of resistance to DNA-damaging treatments and CSCs, and checkpoint inhibitors that sensitize CSCs to DNA-damaging treatments have been developed^[158,159]. Interestingly, DDR appears as a relevant target to sensitize cancer cells and CSCs to conventional radio- and chemotherapies, as well as to overcome resistance^[158,159]. Fang *et al.*^[160] reported that in NSCLC, chemotherapy targeting DNA damage checkpoint (CHK1) signaling in CSCs was p53-independent and caused cell cycle arrest, more efficient DNA damage repair, and enhanced cell survival compared to the bulk of the tumor cell population. Moreover, targeting CHK1 and PARP1 may provide an effective anti-CSC strategy^[157].

Autophagy as a cytoprotective and drug resistance mechanism in CSCs

Autophagy is a catabolic pathway that is characterized by autophagosome formation and triggers tumor cell survival and drug resistance^[160-165]. Autophagy is critical as a survival mechanism in tumors with defects in apoptotic signaling pathways, and CSCs show a high level of autophagy which contributes to their survival and therapy resistance^[131-133]. Autophagy also determines cell fate by targeting the degradation of key transcription factors, including p53 and FoxO3A, or by enforcing quiescent growth arrest^[163]. Apart from promoting resistance to chemotherapy, high levels of autophagy in CSCs maintain their pluripotency, allow them to cope with low nutrients and hypoxia in the tumor microenvironment, regulate CSCs migration and invasion, and help them escape immunosurveillance^[163]. Beclin 1, a Bcl-2 homology 3 (BH3) domain only protein, is an essential initiator of autophagy and a critical determinant of whether cells undergo autophagy or apoptosis^[165]. The BH3 domain of Beclin 1 interacts with Bcl-2 family members. Therefore, the role of Bcl-2 in inhibiting apoptosis and autophagic cell death makes the Bcl-2 protein and autophagy manipulation excellent targets and strategies to inhibit drug, anti-apoptotic, and autophagy-related resistance mechanisms.

CSC dormancy, plasticity and drug resistance

Cellular dormancy refers to the phenomenon that cells are recruited into the G₀-phase of the cell cycle but can enter cell division in response to mitotic stimulation^[166-170]. Emerging data show that CSCs can mediate therapy resistance through dormancy^[169]. Chemotherapy and radiation therapy are mainly effective against proliferating cells. Dormant tumor cells may be comprised of both CSCs and non-CSCs^[170]. It has also been demonstrated that dormant cells express the transcription factor SOX-2, which is essential for their survival and resistance to therapy^[171].

CSCs niche, TME and drug resistance

It is well-documented that the tumor microenvironment (TME) contains several components, including stromal cells, immune cells, cytokines, chemokines and growth factors, hypoxic regions, and ECM^[18,172,173]. Tumor-associated macrophages (TAMs) play major roles in stimulating CSC self-renewal, angiogenesis,

and remodeling immunity, and creating a niche for CSC tumor invasion, metastasis, as well as plasticity and dynamic changes^[174-177]. Additionally, the CSC niche modulates several signaling pathways leading to drug and apoptosis resistance including the Wnt/ β -catenin, Notch, and Hh signaling pathways^[176,177]. Moreover, TAM may control the main transcriptional regulators like Nanog, Oct4, and SOX-2 to maintain CSCs stemness^[177,178].

Current evidence shows the complex interplay between the genes, epigenetic modifications, TME, and the EMT in CSCs plasticity. The CSCs plasticity results in the generation of different subpopulations of CSCs with varying molecular and biochemical traits leading to varied dissemination and drug-resistance phenotypes^[18,179]. Adding to this complexity is the capacity of CSCs to dynamically switch to non-CSCs or to different subsets of CSCs, exhibiting significant metabolic plasticity^[179]. Due to certain microenvironmental stimuli, some cancer cells may exhibit plasticity which results in resuming proliferation^[175]. The CSC niche and reciprocal communications between the CSCs and the TME play a pivotal role in the initiation and development of the tumor^[175]. The TME, in reality, brings together factors to trigger and amplify resistance mechanisms in CSCs. The TME is continuously exposed to nutritional, metabolic, and oxygen deprivation, which promotes CSC adaptation^[44], leading to drug resistance. Drug resistance due to physical barriers to treatment and cell adhesion-associated drug resistance has been associated with the TME and CSC niche^[177]. Novel treatment strategies targeting CSC niche-microenvironmental factors have been developed.

Targeting CSCs to overcome therapy resistance

Due to their drug and apoptosis resistance, as well as tumors and metastasis, CSCs significantly contribute to the unresponsiveness to cancer therapies, relapse, and adverse outcomes in cancer patients^[18]. To reduce or eliminate CSCs and improve the patients' genes and prognosis, new therapies that target key signaling molecules targeting stem-associated proteins, inhibitors of the drug transporters, and transcription factors participating in CSC maintenance have been used or proposed^[179].

Target deregulated CSCs signaling

Much evidence shows that the oncogenic functional role of CSCs is regulated by the dysregulation of several developmental signaling pathways in normal stem cells^[18,46,180,181]. Since these dysregulated pathways participate in self-renewal, metastasis, and resistance to drugs and apoptosis in CSCs, targeting particular proteins in these pathways by small molecule inhibitors offers a novel approach for treating cancers displaying high rates of recurrence and therapy resistance^[28,182]. Among strategies used to target CSCs, there are several compounds that target CSCs specific surface markers, the CSC microenvironment niche, and CSC signaling pathways, which are already undergoing clinical trials [Table 1]. In addition, some new anti-CSC immunotherapeutic approaches, such as chimeric antigen receptor T-cell (CAR-T) therapy, are expected to be an important method of eliminating CSCs^[182]. Emerging data show that novel strategies targeting the CSCs-specific pathways are being pursued^[183]. The small molecule inhibitors of such pathways alone and in combination with different therapeutic agents are in clinical trials^[182-184]. For instance, combined treatment with cisplatin and the PI3K/Akt/mTOR pathway inhibitor BEZ235 compared with cisplatin alone significantly disrupted colony formation ability, triggered higher ROS levels, and induced higher levels of apoptosis in resistant ovarian cancer cells^[185]. Additionally, this combination robustly inhibited the PI3K/Akt/mTOR signaling pathway, reversed EMT, and reduced CSC marker expression^[185]. It has been demonstrated that the inhibition of ALDH activity by all-trans retinoic acid (ATRA) or the specific ALDH inhibitor diethylaminobenzaldehyde in breast CSCs (BCSCs) significantly increases the efficacy of doxorubicin, paclitaxel, and radiotherapy on triple-negative breast cancer (TNBC) cells^[186]. Salinomycin (SLM), an ionophore antibiotic, has been shown to selectively kill BCSCs in various breast cancer subtypes by altering the expression of genes involved in metastasis-free survival, overall survival, decreasing tumorsphere formation, and EMT^[187-190]. The combination of HA (hyaluronic acid)-coated SLM

Table 1. New drugs targeting CSCs in clinical trials^a

CSC targets	Drug	Reference
BCL2	Venetoclax AT101	[202,203]
Notch	MK-0752 RF-03084014 Demiczumab	[204-206]
WNT	PRI-724	[207]
Hedgehog	Glasdegib	[208]
	Vismodegib	[209]
JAK	Roxolitinb	[210]
PI3K	BYL719	[211]
EGFR	Bevacizumab	[212]
CXCR4	Plerixafor	[213]
FAK	Defactinib/VX-6063	[214]
MDR1	Dofequidar/MS-209	[215]
ABCG2		
EpCAM	Catumaxomab	[216]

^aTo locate the clinical trials using these drugs, refer to the reference numbers in this table.

nanoparticles and PTX nanoparticles showed the highest cytotoxicity against CD44+ cells^[187]. Hence, combination therapy using a conventional chemotherapeutic drug and a cancer stem cell inhibitor could be a promising approach to overcoming cancer recurrence due to the resistant cell population^[191]. CD44 has been shown to function as a hyaluronan receptor, and HA has been used to specifically direct drugs to the CSCs^[192]. One study demonstrated that the use of hyaluronan-conjugated liposomes encapsulating gemcitabine significantly enhanced the efficacy of the drug against BCSCs and decreased the systemic toxicity of gemcitabine alone on normal tissue^[194]. Another strategy used against CD44 is using antibodies that block the HA-binding site of CD44^[194].

Dietary polyphenol compounds have been shown to act on self-renewal and survival pathways of CSCs. For instance, we have reported that sulforaphane (SFN) from cruciferous vegetables robustly inhibited the growth of GBM CSCs and was particularly effective in eliminating GSCs, which play a major role in drug resistance and disease recurrence^[195]. SFN also has been shown to be strongly effective against CSCs from other types of cancer^[196]. Other dietary compounds used to target and eliminate CSCs are epigallocatechin-3-gallate, catechin in green tea^[102,103], resveratrol from red grapes and blueberries^[196-198], curcumin^[198], and piperine^[200]. While these compounds and sulforaphane are very effective in eradicating CSCs, they are harmless to normal cells at the concentrations affecting CSCs, indicating that these compounds are appropriate candidates to be used in combination with conventional anticancer agents to robustly eliminate drug-resistant CSCs.

A list of the new drugs targeting CSCs in clinical Trials is shown in [Table 1](#). The FDA has approved three new drugs that can target CSCs. These include (1) vismodegib, a Hg inhibitor that targets a subset of CSCs in basal cell carcinoma^[201] and other solid tumors, such as esophageal cancer^[202]; (2) the BCL-2 inhibitor venetoclax, which selectively eradicates AML stem cells and demonstrated that 60% of patients receiving it with other chemotherapy drugs had complete clinical responses^[202]; and (3) AT101, another pan-Bcl-2 inhibitor [[Table 1](#)], targets CSCs and is effective in esophageal and gastric cancer patients^[203]. Furthermore, in addition to the drugs listed in [Table 1](#)^[202-216], a variety of FDA-approved repurposed drugs, which have

been used for various diseases, also target CSCs and improve treatment with current chemotherapeutic drugs^[217]. These repurposed drugs include ones approved to treat diabetes (metformin and thiazolidinediones), parasitic diseases (chloroquine, niclosamide, mebendazole, and pyrvinium), psychotic disorders (thioridazine, clomipramine, and phenothiazines), alcoholism (disulfiram), lipid disorder (statins), inflammatory diseases (tranilast, auranofin, acetaminophen, and celecoxib), antibiotics (azithromycin), and other disorders. These drugs provide beneficial effects from combined use with conventional cancer therapies^[217].

CONCLUSION

The foregoing discussion clearly demonstrates that CSCs are endowed with the signature properties of malignancy: self-renewal and replicative immortality; resistance to chemotherapeutic agents and apoptosis; EMT; invasiveness; metastasis; and tumor recurrence. The CSCs niche, multiple mechanisms of drug and apoptosis resistance in these cells, intra/inter tumor heterogeneity, and the complex interaction of CSCs with the TME render therapy very ineffective. Therefore, a greater understanding of these factors is needed for the emergence of novel and effective therapies which target CSCs as well as the bulk of tumor cell population. CSC-related drug and apoptosis resistance mechanisms may be important for predicting patient response to therapies and guiding treatment selection with contemporary anticancer drugs targeting CSCs and robustly eliminating the entire tumor mass in various tumors originating from different tissues. While a number of CSC-targeting drugs have been identified for cancer treatment, it is still too soon to determine the true usefulness of these agents in the clinical setting. A challenging task for the development of CSC-specific therapeutics is identifying and detecting specific biomarkers of CSCs, which can be used to analyze their population during tumor treatment. As discussed in detail, CSCs can contribute to tumor resistance to chemotherapeutic agents and apoptosis. However, studying them may provide a better understanding of the molecular mechanisms underlying CSC unresponsiveness to therapies and may lead to the identification of specific targeted therapeutics and novel strategies to increase the sensitivity of CSCs to cancer therapeutics. Such agents may be capable of eradicating CSCs and eliminating the bulk of tumor mass by themselves or in combination with other contemporary anticancer drugs.

DECLARATIONS

Acknowledgments

I would like to thank Dr. Mary D. Kraeszig for her editorial assistance.

Authors' contributions

The author contributed solely to the article.

Availability of data and materials

Not applicable.

Financial support and sponsorship

The work in the author's laboratory on drug resistance and apoptosis signaling pathways was supported by research grants from the National Cancer Institute (CA 080734, CA 90878, and CA 101743), and Department of Defense (DOD) (OC 06095).

Conflicts of interest

The author declared that there are no conflicts of interest.

Ethical approval and consent to participate

Abstract

Human epidermal growth factor receptor 2 (*HER2*) is a major drug target and clinical biomarker in breast cancer treatment. Targeting *HER2* gene amplification is one of the greatest successes in oncology, resulting in the use of a wide array of *HER2*-directed agents in the clinic. The discovery of *HER2*-activating mutations as novel therapeutic targets in breast and other cancers marked a significant advance in the field, which led to the metastatic breast and other solid tumor trials MutHER (NCT01670877), SUMMIT (NCT01953926), and one arm of plasmaMATCH (NCT03182634). These trials reported initial clinical benefit followed by eventual relapse ascribed to either primary or acquired resistance. These resistance mechanisms are mediated by additional secondary genomic alterations within *HER2* itself and via hyperactivation of oncogenic signaling within the downstream signaling axis.

Keywords: Neratinib, *HER2*, *ERBB2*, estrogen receptor, mutation

INTRODUCTION

Human epidermal growth factor receptor 2 (*HER2*)-positive breast cancers have long been treated with targeted therapy, comprising either monoclonal antibodies, such as trastuzumab or pertuzumab, which bind

to the extracellular domain of HER2, or tyrosine kinase inhibitors (TKIs), such as the reversible inhibitors lapatinib and tucatinib and the irreversible inhibitor neratinib^[1]. Genome sequencing efforts have recently identified recurrent somatic mutations in the *HER2* (*ERBB2*) gene in HER2-negative (non-amplified) breast cancer. Recurrent *HER2* mutations have been proven to be oncogenic drivers in both preclinical experiments and clinical trials^[2-9]. Activating *HER2* mutations typically fall into four categories, with distribution dependent on tumor type: single nucleotide variants (SNVs) in the extracellular domain, particularly S310F/Y; SNVs in the transmembrane domain; SNVs in the kinase domain; and small insertions in exon 20^[4,10,11]. *HER2* mutations constitutively activate the tyrosine kinase receptor activity, leading to upregulation of downstream phosphoinositide 3-kinase (PI3K) and mitogen-activated protein kinase (MAPK) signaling^[6,12]. *HER2* mutations are rare in primary cancers, occurring in 2%-12% of solid tumors depending on tumor type and disease stage. In breast cancer, *HER2* mutations vary in frequency from ~2% to 8% depending on disease stage and histology (higher in lobular)^[7,10,11,13,14] and have been associated with poor prognosis^[15,16]. The prevalence of *HER2* mutations is higher in patients with metastatic breast cancer (MBC) that has progressed after primary endocrine therapy (~6%), and these mutations have been causally associated with antiestrogen resistance^[12,13,17]. Furthermore, *HER2* and estrogen receptor 1 gene (*ESR1*) mutations are mutually exclusive in primary breast cancer, suggesting that *HER2* mutations are independent predictive and prognostic markers in estrogen receptor (ER)-positive MBC^[11,12,16].

Neratinib is an orally available, second-generation, pan-HER TKI that irreversibly binds to cysteine residues Cys773 and Cys805 in the ATP pocket of the tyrosine kinase domain of epidermal growth factor receptor (EGFR), HER2, and HER4^[18]. Neratinib inhibits autophosphorylation, downstream signaling, and growth of EGFR- or HER2-dependent cell lines, with cellular half-maximal inhibitory concentration (IC_{50}) < 100 nM^[18]. Neratinib has been approved by the United States Food and Drug Administration for use in patients with adjuvant and metastatic HER2-positive (overexpressed/amplified) breast cancer based on the results of the ExteNET and NALA trials, respectively^[19,20]. Furthermore, neratinib has demonstrated significant anti-tumor activity in preclinical models of HER2-negative/non-amplified breast cancer and other solid tumors with *HER2* mutations^[2,3,5]. In ER-positive, *HER2*-mutant cell lines, ER signaling was suppressed and cells were resistant to endocrine therapy via estrogen deprivation or fulvestrant treatment; sensitivity was restored upon exposure to neratinib^[17]. Dual inhibition with neratinib and fulvestrant was required to inhibit the growth of ER-positive, *HER2*-mutant models^[12], implying a need to inhibit both the ER and HER2 signaling pathways simultaneously.

Clinically, the utility of neratinib, alone or in combination with other agents, in patients with heavily pretreated *HER2*-mutant breast and other cancers was explored in the phase II SUMMIT and MutHER trials^[4,7]. The SUMMIT trial demonstrated clinical benefit from single-agent neratinib in patients with several solid tumor types, including *HER2*-mutant breast cancers^[4]. For patients with *HER2*-mutant, hormone receptor (HR)-positive MBC, both the SUMMIT and MutHER trials were amended to combine neratinib with fulvestrant to suppress both HER2 and HR signaling simultaneously. This dual combination was clinically active in heavily pretreated patients with *HER2*-mutant, HR-positive MBC, including those who had received prior fulvestrant and cyclin-dependent kinase (CDK)4/6 inhibitor therapy. In SUMMIT, the overall response rate (ORR) for neratinib monotherapy in patients with *HER2*-mutant, HR-positive MBC ($n = 23$) was 17.4%, while the ORR for neratinib plus fulvestrant ($n = 47$) was 29.8%, with clinical benefit rates of 30.4% and 46.8%, respectively^[9]. Median progression-free survival (PFS) and duration of response (DOR) were also longer with the combination (3.6-month PFS and 6.5-month DOR for neratinib monotherapy; 5.4-month PFS and 9.2-month DOR for neratinib plus fulvestrant)^[9]. In MutHER, results for neratinib plus fulvestrant ($n = 31$) were clinical benefit rate (CBR) of 30.0%-38.0% and PFS of 5.0-6.0 months^[8,9], consistent with the enhanced inhibition observed preclinically^[12,17]. The independent

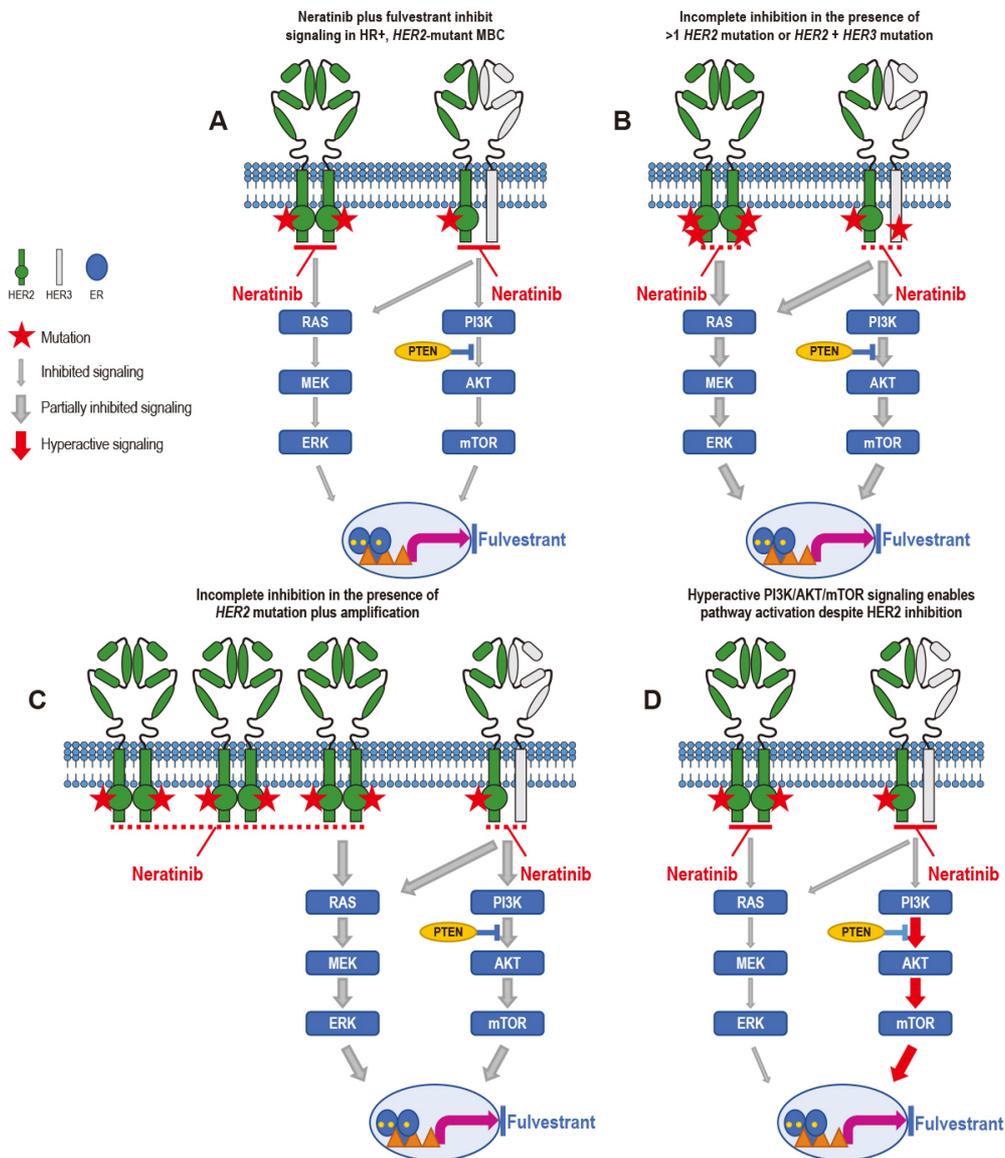

Figure 1. Mechanisms of resistance to neratinib. (A) Neratinib plus fulvestrant inhibit signaling in HR+, HER2-mutant MBC. In patients whose tumors harbor a single somatic activating mutation (red star) in HER2, neratinib strongly inhibits (thin gray arrow) HER2 pathway signaling, whereas fulvestrant inhibits ER signaling, leading to tumor growth inhibition. (B) Neratinib is less effective against/partially inhibits signaling in (thick gray arrow) tumors with more than one HER2 mutation or HER2 mutation plus HER3 mutation or (C) HER2 mutation plus amplification, whether these dual alterations are intrinsic or acquired. (D) Hyperactivation (thick red arrow) of downstream signaling can also preclude the effect of neratinib on mutant HER2. ER: Estrogen receptor; HR: hormone receptor; MBC: metastatic breast cancer.

PlasmaMATCH trial, in which patients with MBC were enrolled based on detection of an activating HER2 mutation in circulating tumor DNA (ctDNA), reported that neratinib as monotherapy or combined with fulvestrant showed comparable clinical activity when patients were selected using this technique versus when the selection was guided by tissue testing, supporting the utility of ctDNA analysis in this patient population^[21].

Unfortunately, patients who initially derived benefit from neratinib or neratinib plus fulvestrant in these studies eventually relapsed with metastatic disease, and a comparison of the genomic landscape of tumor tissue or ctDNA before treatment and upon progression revealed the acquisition of additional genomic aberrations^[8,9,22]. Mechanisms of acquired resistance appeared to occur primarily via the development of secondary *HER2* genomic alterations (mutations or amplification), whereas intrinsic resistance was observed not only in patients whose baseline tumors had more than one *HER2* alteration, but also via alterations in the *HER3*/PI3K/protein kinase B (AKT)/mammalian target of rapamycin (mTOR) and MAPK signaling axis^[8,9,22] [Figure 1].

MECHANISMS OF RESISTANCE

Accumulation of additional *HER2* genomic events

Among patients with heavily pretreated MBC, the presence of more than one *de novo* *HER2*-activating event before treatment trended with a lack of benefit from neratinib alone or in combination with fulvestrant in trials to date. In the SUMMIT trial, six of the seven patients whose pre-treatment tumors harbored more than one *HER2*-activating event (second *HER2* mutation, $n = 2$; copy-number amplification, $n = 3$; or both, $n = 2$) did not derive clinical benefit^[9]. In MutHER, three out of 48 patients had dual *HER2* mutations at enrollment; two of those three patients did not experience clinical benefit^[7,8].

In patients whose treatment-naïve tumors harbored one *HER2* mutation and who initially derived clinical benefit from neratinib-containing treatments, the one consistently observed mechanism of acquired resistance was the accumulation of a second (or further) additional *HER2* alteration^[8,9]. In SUMMIT, three of nine patients with HR-positive, *HER2*-mutant MBC, who were treated with neratinib plus fulvestrant and who had both pre- and post-treatment tumors available for central sequencing, had additional *HER2*-activating events in the post-treatment tumor^[9]. One patient had amplification of the mutant allele, one acquired a gatekeeper mutation, and one had amplification plus two acquired *HER2* hotspot mutations. Secondary *HER2* mutations were also detected in seven of 16 patients with paired pre-treatment and progression ctDNA who derived clinical benefit, including two of the three described above. Among patients in MutHER who had paired ctDNA samples, acquired *HER2* mutations were detected upon progression in three of six patients with clinical benefit following neratinib monotherapy, in four of seven patients with benefit following neratinib plus fulvestrant, and in one who experienced short-term stable disease^[8]. Although several of the tumors acquired gatekeeper mutations (T798I and L785F)^[23,24], the acquisition of additional sensitizing mutations or variants of unknown significance was also reported [Table 1]. Beyond *HER2*, no other acquired genetic event was consistently observed. These findings suggest that *HER2*-mutant MBCs are dependent on *HER2* signaling even upon disease progression.

Aberrant *HER3*/PI3K/mTOR signaling

In preclinical models of HR-positive breast cancer, the recurrent *HER2* L755S and V777L mutations constitutively upregulated *HER3* phosphorylation, particularly upon treatment with fulvestrant, resulting in hyperactivation of the *HER3*/PI3K/AKT/mTOR signaling axis and leading to antiestrogen resistance^[12,22]. Structural modeling of the *HER2* L755S mutation revealed a loss of flexibility in the active state, allowing for increased *HER2*/*HER3* heterodimerization and upregulation of PI3K/AKT/mTOR signaling^[12]. *HER3* mutations have been modeled to stabilize *HER2*/*HER3* dimerization and increase *HER2* signaling^[25,26], and preclinical models showed that dual *HER2*/*HER3* mutations further enhanced oncogenicity and promoted resistance to *HER2*-targeted therapies, including neratinib^[26]. In SUMMIT, pre-existing concurrent activating *HER3* mutations were associated with poor treatment outcomes in patients with *HER2*-mutant MBC^[9]. Further analysis of data from SUMMIT patients with *HER2*-mutant tumors across multiple tumor types revealed that mTOR pathway alterations were associated with a lack of clinical benefit with single-agent neratinib. Preclinically, hyperactivation of mTOR signaling was an actionable acquired mechanism of

resistance to neratinib in *HER2*-mutant cell lines and patient-derived xenograft (PDX) models^[22]. Interestingly, however, *PIK3CA* mutations *per se* were not associated with a lack of clinical benefit with neratinib plus fulvestrant in *HER2*-mutant MBC^[8,9], and no other single gene or mutation in the *HER3/PI3K/AKT/mTOR* signaling axis was clearly associated with acquired neratinib resistance.

Acquisition of somatic *HER2* mutations in *HER2*-positive breast cancer

Although this review focuses specifically on the acquisition of resistance to neratinib in *HER2*-negative, *HER2*-mutant MBC, the acquisition of *HER2* mutations in *HER2*-positive breast cancer also merits consideration. The co-occurrence of *HER2* mutations and amplification has been associated with poor response to trastuzumab and lapatinib, although neratinib has been shown to be effective against *HER2*-positive, *HER2*-mutant preclinical models and in patients whose breast tumors had coincident *HER2* amplification and mutation, suggesting neratinib as monotherapy may be effective in this setting^[27]. In preclinical models of *HER2*-positive breast cancer, *HER2* reactivation in lapatinib-resistant derivatives was driven by the acquisition of a *HER2* L755S mutation, which could be overcome by neratinib or afatinib^[28]. Finally, recent findings from plasmaMATCH demonstrate that the incidence of *HER2* mutations in *HER2*-positive cancers increases with the number of lines of *HER2*-directed therapy^[29]. Regardless of initial *HER2*-positive or *HER2*-mutant status, accumulation of genomic events within *HER2* itself is prevalent upon exposure to *HER2*-targeted agents. Whether or not there is a clinical difference in response depending on which type of alteration is the initial driver remains to be seen.

Taken together, these findings provide a rationale for the combination of multiple HER2 inhibitors or inhibitors of the downstream signaling axis in patients with *HER2*-mutant breast cancer, a therapeutic strategy that has already proven highly effective in HER2-positive breast cancer.

OVERCOMING NERATINIB RESISTANCE IN *HER2* –MUTANT MBC

The following are three possible approaches to overcoming neratinib resistance in *HER2*-mutant MBC: (1) dual HER2 targeting; (2) combination with PI3K, mTOR, MEK, or CDK4/6 inhibitors; and (3) sequential TKI treatment.

Dual HER2 targeting: neratinib plus monoclonal antibody or antibody–drug conjugate

The dual targeting of HER2 either upfront or at disease progression has proven to be effective in patients with *HER2*-mutant MBC. In MutHER, adding trastuzumab after disease progression on neratinib plus fulvestrant led to re-response in four of five patients, with a concomitant decrease in ctDNA^[8]. In SUMMIT, the *HER2*-mutant breast cohorts were recently amended to treat patients upfront with the triple combination of neratinib, fulvestrant, and trastuzumab. This combination, in fact, demonstrated encouraging clinical activity in SUMMIT patients with heavily pretreated HR-positive, HER2-negative, *HER2*-mutant MBC who had previously received a CDK4/6 inhibitor ($n = 33$; ORR of 42.4%, CBR of 51.5%, median DOR of 14.4 months, median PFS of 7.0 months)^[30,31]. Preclinically, neratinib combined with trastuzumab in *HER2*-mutant cancer models yielded more robust inhibition of HER2 signaling and growth than either agent alone^[5,32].

Neratinib induces HER2 receptor ubiquitination and endocytosis^[33]; combining neratinib with a HER2-directed antibody–drug conjugate may therefore enable increased payload internalization. In *HER2*-mutant PDX models, the combination of neratinib and trastuzumab emtansine (T-DM1) or trastuzumab deruxtecan (T-DXd) did, in fact, show synergistic tumor growth inhibition^[34]. Safety and preliminary efficacy of neratinib plus T-DM1 have been demonstrated in patients with HER2-positive breast cancer^[35]; clinical trials of neratinib plus antibody–drug conjugates are similarly warranted in the *HER2*-mutant MBC setting.

Combination with PI3K, mTOR, MEK, or CDK4/6 inhibitors

Combining neratinib with inhibitors of the downstream signaling axis or with CDK4/6 inhibitors may be a second approach to prolonging response to neratinib in patients with *HER2*-mutant MBC. First, preclinical data in *HER2/HER3* double mutant cell lines show that the combination of a PI3K inhibitor (alpelisib) with neratinib overcame neratinib resistance^[26]. Second, the combination of the mTOR inhibitor everolimus with neratinib arrested the growth of neratinib-resistant, ER-positive, *HER2*-mutant organoids and xenografts^[22]. Third, in two HER2-positive breast and colorectal PDX models harboring activating *HER2* mutations (V777L and R678Q) derived from patients who had been treated with HER2-targeted therapies, the combination of neratinib with the MEK inhibitor trametinib, the mTOR inhibitors everolimus or sapanisertib, or the CDK4/6 inhibitor palbociclib synergistically decreased tumor volume to a greater extent than any of the agents alone. These combinations were well tolerated in HER2-positive preclinical PDX models^[36]. A clinical trial to study the safety and tolerability of neratinib combined with trametinib, everolimus, or palbociclib in metastatic solid tumors with HER family alteration or *KRAS* mutation is currently underway (NCT03065387)^[37]. Given the promising efficacy of neratinib-containing regimens post CDK4/6 inhibitor in the SUMMIT trial^[31], first-line treatment with neratinib plus a CDK4/6 inhibitor and endocrine therapy could warrant investigation if the combination is deemed tolerable.

Sequential treatment of neratinib with a second TKI

Sequential TKI treatment has long been standard in *EGFR*-mutant non-small cell lung cancer, and a similar approach could be investigated for *HER2*-mutant MBC. The *HER2* gatekeeper mutation T798I is recurrent in *HER2*-mutant MBC upon clinical progression following neratinib. Preclinically, another second-generation TKI, afatinib, and AZ5104, the metabolite of the third-generation TKI osimertinib, blocked *HER2* T798I mutation-induced cell growth and signaling^[23]. These findings support the clinical investigation of sequencing TKI therapy in *HER2*-mutant cancers that develop gatekeeper mutations.

CONCLUSION

HER2-activating mutations are a targetable alteration in MBC and can be inhibited by neratinib. In heavily pretreated patients with MBC, more than one alteration in the *HER2* signaling pathway, whether in the *HER2* gene itself or downstream in the signaling cascade, may preclude initial response. Furthermore, patients with a single *HER2* mutation who derive initial clinical benefit appear to become resistant via the acquisition of additional *HER2* mutations and/or amplification. Dual *HER2*-targeting via the addition of trastuzumab to neratinib, in combination with fulvestrant for patients with HR-positive MBC, has exhibited strong clinical activity against *HER2*-mutant MBC^[8,30,31]; targeting both *HER2* and *CDK4/6* together may warrant exploration as part of a front-line approach in this setting. Future analysis of plasma samples from patients receiving dual *HER2*-targeting will elucidate whether acquired resistance occurs via the same mechanisms. Combination and/or sequencing of neratinib plus additional agents targeting either *HER2* or downstream or alternative pathway members may be required for more durable clinical benefit. Any combination approach will require diligent clinical management given the gastrointestinal toxicity profile of neratinib, although neratinib dose escalation may help to mitigate adverse events^[38].

Future studies may consider molecularly guided approaches beyond genomics, including but not limited to evaluation of changes in gene or protein expression or protein phosphorylation status, to inform the design of rational drug combinations and lead to improved outcomes for patients with *HER2*-mutant MBC.

DECLARATIONS

Acknowledgments

The authors would like to acknowledge Ron Bose, MD, PhD, and Cynthia Ma, MD, PhD, for providing data from MutHER and for critical review of the manuscript, and Miller Medical Communications for editorial assistance, funding for which was provided by Puma Biotechnology, Inc.

Abstract

HER2 is a pillar biomarker in breast cancer, and it is assessed by immunohistochemistry (IHC) using a three-tier scoring system and reflex *in situ* hybridization (ISH) for IHC score 2+. Novel HER2-directed antibody-drug conjugates have demonstrated significant antitumor activity in breast cancers with low levels of HER2 expression, i.e. IHC score 1+ or ISH-negative IHC score 2+. Both primary and acquired resistance to anti-HER2 therapies remains a challenge in the treatment of breast cancers according to the HER2 positivity *continuum*. Thus, the ability to precisely discriminate among HER2-zero, HER2-low, and HER2-positive breast cancers is no longer a mere academic exercise. HER2 testing criteria, guidelines, and quality controls are re-gaining momentum for this new clinical need. Therefore, all preanalytical and analytical variables that might trouble the sensitivity and reproducibility of this test should be carefully considered to address all possible issues and open all possible therapeutic opportunities for breast cancer patients.

Keywords: Breast cancer, biomarkers, HER2, HER2 low, targeted therapy, antibody-drug conjugates, immunohistochemistry, ISH

INTRODUCTION: THE EXPANDED SPECTRUM OF HER2 POSITIVITY IN BREAST CANCER

HER2 status assessment is considered “the” predictive test in breast cancer pathology because of its

extremely relevant prognostic and predictive values^[1]. Testing for HER2 consists of immunohistochemistry (IHC) using a three-tier scoring system and *in situ* hybridization (ISH) in case of IHC score 2+^[2]. Using this method, patients with HER2+ breast cancer, i.e. IHC score 3+ or ISH-positive IHC score 2+ are eligible for anti-HER2 targeted therapy^[3,4]. Recently, the DESTINY-Breast04 clinical trial demonstrated that targeting HER2 provides significant benefits also for patients with metastatic breast cancer showing low levels of HER2 expression, i.e. IHC score 1+ or ISH-negative IHC score 2+^[5]. Of note, patients with hormone receptor (HR)+ disease had to be refractory/resistant to endocrine therapy (ET). In this randomized clinical study, the antibody-drug conjugate (ADC) trastuzumab deruxtecan (T-DXd) improved median progression-free survival by 4.8 months and median overall survival by 6.6 months, compared with standard single-agent chemotherapy. These data establish a new standard of care for patients with HER2-low breast cancer and a fast-track approval for T-DXd is expected. Indeed, these tumors were previously not eligible for HER2 targeting because they were considered resistant to HER2 inhibitor monoclonal antibodies^[6]. Due to these groundbreaking advances, the capability to precisely discriminate among HER2-zero, HER2-low, and HER2+ breast cancers is no longer a mere academic exercise for pathologists. Instead, HER2 testing criteria, guidelines, and quality controls are re-gaining momentum to embrace this new upcoming clinical need.

THE EVOLUTION OF HER2 TESTING

Historical perspective

The American Society of Clinical Oncology (ASCO)/College of American Pathologists (CAP) Expert Panel has made remarkable efforts to improve the analytical reliability of HER2 testing. Since 2007, they have provided guidelines on HER2 interpretation in breast cancer, including algorithms for defining positive, equivocal, and negative values for both HER2 protein expression and gene amplification. Specifically, a positive HER2 result was IHC staining of 3+ (i.e., uniform, intense membrane staining of > 30% of invasive tumor cells), a fluorescent ISH (FISH) result > 6 HER2 gene copies per nucleus, or a HER2 gene to chromosome 17 signals ratio > 2.2; a negative result was an IHC staining of 0 or 1+, a FISH result of < 4.0 HER2 gene copies per nucleus, or FISH ratio < 1.8^[7]. Subsequently, in 2009, the intra-tumor heterogeneity of HER2 amplification was supplemented to the guideline and defined as HER2/CEP17 signal ratios > 2.2 in 5%-50% of the neoplastic cells^[8,9]. Later, in 2013, to avoid false-negative results, the positivity threshold was decreased to 10% and the HER2/CEP17 ratio to 2^[10]. With these updates, a considerably higher number of patients could be treated with trastuzumab with a reasonable, slight increase of adverse events. In 2018, ASCO/CAP released an integration to the 2013 edition, emphasized the coordination between IHC and ISH results, and mostly addressed specific clinical questions and technical issues related to HER2 equivocal and heterogeneity^[3]. The current IHC algorithm with the expanded spectrum of HER2 reporting category and the reporting results for ISH assays are shown in [Tables 1](#) and [2](#), respectively (Source: Breast Biomarker Reporting, CAP Cancer Protocol Templates, v1.4.1.1, November 2021 update, available at: https://documents.cap.org/protocols/Breast.Bmk_1.4.1.1.REL_CAPCP.pdf).

The evolution of different ISH types has established a proposal of reliable FISH alternatives with faster performance at a lower cost. Silver *in situ* hybridization and chromogenic *in situ* hybridization have demonstrated great reproducibility and have been approved by the U.S. Food and Drug Administration for HER2 testing in breast cancer. The combined technology of dual-color dual-hapten *in situ* hybridization (D-DISH), providing the convenience of light microscopy with an ISH specificity, using chromogenic probes instead of fluorescent ones, also demonstrates a high reproducibility^[11]. Gene protein assays and next-generation sequencing are the newer modalities, which may potentially help to overcome the issue of the tumor heterogeneity, combining the benefits of both IHC and ISH by single-slide HER2 status assessment^[12]. Other promising candidates for the alternative HER2 status assessment are molecular (multiplex ligation-dependent probe amplification) and liquid biopsy assays using circulating tumor cells,

Table 1. Reporting results of HER2 testing by immunohistochemistry and the corresponding expanded spectrum of positivity (ASCO/CAP 2021)

Score	Membrane staining pattern	Tumor cells	Classical category	Expanded spectrum
3+	Intense, complete (circumferential)	> 10%	HER2+	HER2+
2+	Weak-to-moderate, complete (circumferential)	> 10%	HER2+ if ISH+ and HER2- if ISH-	HER2+ if ISH+ and HER2-low if ISH-
	Intense, complete	≤ 10%		
1+	Faint/barely perceptible, incomplete	> 10%	HER2-	HER2-low
0	Faint/barely perceptible, incomplete	≤ 10%	HER2-	HER2 ultra low
	No staining		HER2-	HER2-zero

IHC: Immunohistochemistry; HER2: human epidermal growth factor receptor 2.

Table 2. Reporting results of HER2 testing by in situ hybridization (ASCO/CAP 2021)

Result	Assay	Criteria
Positive	Single probe	CN ≥ 6.0 CN ≥ 4.0 and CN < 6.0 and IHC = 3+ CN ≥ 4.0 and CN < 6.0 and dual ISH ratio ≥ 2.0
	Dual probe	Ratio ≥ 2.0 and CN ≥ 4.0 Ratio ≥ 2.0 and CN < 4.0 and IHC = 3+ Ratio < 2.0 and CN ≥ 6.0 and IHC > 1+ Ratio < 2.0 and 4.0 ≤ CN < 6.0 and IHC = 3+
Negative	Single probe	CN < 4.0 CN ≥ 4.0 and CN < 6.0 and IHC < 3+ CN ≥ 4.0 and CN < 6.0 and dual ISH ratio < 2.0 and CN < 4.0
	Dual probe	Ratio ≥ 2.0 and CN < 4.0 and IHC < 3+ Ratio < 2.0 and CN ≥ 6.0 and IHC < 2+ Ratio < 2.0 and 4.0 ≤ CN < 6.0 and IHC < 3+ Ratio < 2.0 and CN < 4.0

CN: Average HER2 copy number (signals/cell); IHC: immunohistochemical score; ratio: HER2/CEP17 ratio.

cell-free tumor DNA (ctDNA), and extracellular vesicles, which have been tested in IHC/ISH HER2-equivocal breast cancers. Transcriptomic analysis has revealed high *HER2* mRNA levels in HER2-enriched breast cancer subtypes using the PAM50 probe, suggesting another possible subtype signature. Dual HER2-blockade led to positive results in patients with higher *HER2* mRNA levels; thus, it is a newly proposed biomarker for chemotherapy de-escalation^[13-15]. Despite evolving modalities of HER2 testing, they are currently awaiting approval and the IHC-ISH approach remains the “gold standard”^[16].

HER2 targeting and biomarkers of drug resistance in breast cancer

The canonical HER2+ breast cancers account for 15%-20% of all breast malignancies and are characterized by the overexpression/amplification of HER2^[9]. These patients can be treated with a variety of anti-HER2 compounds, including trastuzumab and pertuzumab, in both adjuvant and neoadjuvant settings^[17,18]. Regrettably, the development of primary or acquired resistance is not uncommon in these patients^[19]. Furthermore, despite the success of ET-combined therapy in the metastatic setting, a substantial proportion of initial responders eventually developing resistance and/or recurrence over the time. In this respect, novel predictive biomarkers are warranted. Several mechanisms have been proposed thus far, including phenotype shift through selective pressure^[20-23]. Interestingly, it has been observed that low levels of HER2 expression, both in terms of the percentage of HER2-expressing cells and IHC staining intensity, may impair the binding of traditional anti-HER2 agents to the target^[24]. An additional mechanism of resistance is represented by the activation of the phosphatidylinositol-3-kinase (PI3K)/Akt and the mammalian target of rapamycin (PI3K/AKT/mTOR) and cyclin D1-dependent kinase 4/6 (CDK4/6) pathways^[25-27]. Finally, genetic alterations in HER2 regions responsible for kinase activation can compromise the ability of anti-

HER2 compounds to bind HER2. Specifically, studies have shown that mutations in positions L755S and T798I can cause the highest levels of resistance^[28,29]. In this scenario, an appropriate and reproducible HER2 test able to precisely identify the various types of HER2 expression is essential to put in place the most appropriate HER2-targeted treatment combination.

Challenges and barriers for HER2-low identification

The current evidence on HER2-targeting therapies in HER2-low breast cancer arises from several translational research studies employing various classes of monoclonal antibodies, anti-HER2 vaccines, cellular immunotherapy, ADC, and bispecific antibodies^[22]. In particular, ADC combines the selectivity of anti-HER2-targeted therapy with the cytotoxic potency of chemotherapy while reducing the systemic exposure to the cytotoxic payload^[30-32]. Among this class of drugs, T-DXd is composed of a humanized anti-human HER2 antibody, an enzymatically cleavable peptide-linker, and a proprietary topoisomerase I inhibitor^[30]. After the cleavage of the peptide-based linker by lysosomal cathepsins, the released cytotoxic molecules can affect HER2-low cells neighboring those with higher HER2 expression, reflecting a bystander effect; thus, T-DXd has shown the ability to target tumor cells regardless of their HER2-status^[33,34]. These findings have transformed the traditional dichotomy of HER2 status and have raised the expectations in this field. However, whether HER2-low breast cancer represents a distinct biologic and prognostic subtype is still a matter of controversy. Recently, an analysis of 5,235 patients with HER2-negative invasive breast cancer revealed that HER2-low expression was positively associated with level of ER expression, and ER-low tumors were enriched among HER2-zero tumors^[35]. The Authors of this study suggest that the worse prognosis of ER-low tumors might confound the prognostic analyses of HER2-low expression. Perhaps, re-testing and re-assess HER2 status in these retrospective studies, particularly for HER2-zero tumors would provide additional information. Assessment of data from CAP surveys and from a Yale University-based study of concordance of 18 pathologists reading 170 breast cancer biopsies revealed that the scoring accuracy for HER2 IHC in the low range (0 vs. 1+) was poor^[36]. This inaccuracy might lead to misassignment of many patients for treatment with T-DXd. Further development of HER2-low breast cancer treatment includes combined treatment strategies evaluation, where high expectations rely on the ADC and immune checkpoint inhibitor combination^[37].

Reducing false-negative and false-“low-positive” results

It has been reported that up to 55% of patients with breast cancer have a HER2-low disease^[38-41]. However, up to now, discriminating between IHC score 0 with incomplete and faint staining in $\leq 10\%$ of tumor cells and score 1+, as well as between score 1+ with faint staining and score 2+ with weak-to-moderate staining intensity, was a negligible pathology exercise^[42,43]. In this context, updated guidelines for all the analytical phases are necessary to improve our diagnostic sensitivity for HER2-low breast cancer^[43]. Although the ASCO/CAP continuously updates the guidelines to ensure optimal diagnostic performance, the interpretation of HER2 IHC in HER2-low breast cancer has not yet been formally endorsed^[44]. Accurate and reproducible testing strategies and techniques are the key aspects to identifying patients who may benefit from ADC^[43]. In this regard, to prevent false-negative/positive results and subsequent mistreatment, careful supervision of preanalytical and analytical issues is required^[44]. A range of preanalytical factors such as fixation, antigen retrieval, antibody clones, enzymatic activity, reaction time, temperature, and substrate concentration may influence HER2 staining intensity^[45,46]. Staining methodology, particularly antigen retrieval, the availability of diverse antibody clones with various specificity [i.e., PATHWAY® HER2 (clone 4B5; Ventana Medical Systems Inc., Tucson, AZ, USA), HercepTest™ (Dako Denmark A/S, Glostrup, Denmark), and Oracle® HER2 (clone CB11; Leica Microsystems GmbH, Wetzlar, Germany)] may significantly impact the accuracy and reproducibility of results and complicate the identification of HER2-low expression in terms of false-positive and false-negative results^[46,47]. Test repetition for equivocal results may exclude possible technical problems; however, it does not often result in definitive positive or negative

results. Regarding the post-analytical phase, the lack of consistent epithelial internal positive control for HER2 within non-neoplastic breast tissue, HER2 intratumoral heterogeneity, particularly in HER2-low breast cancer, and the semi-quantitative and subjective mode of HER2 assessment may lead to inter-observer variability affecting the accuracy of the results^[44,48,49]. A larger number of patients with HER2+ metastatic breast cancer might possibly have a long-lasting clinical response with the careful application of more precise and reproducible diagnostic methods^[50]. Thus, rigorous quality control procedures for specimen preparation coupled with well-defined guidelines for the precise assessment of HER2-low cases are required^[51,52].

CONCLUSION

In light of the therapeutic armamentarium broadening based on HER2 patterns of expression, HER2 testing is becoming more complex. To improve sensitivity, specificity, and reproducibility of HER2 status evaluation, pathologists need to be aware of the molecular mechanisms underlying the variable expression of HER2 in different types of breast cancers and even in different cells within the same tumor. In this respect, continuous education, update, quality controls, and multidisciplinary discussions are key elements for optimal patient management.

Abstract

The “seed and soil” concept has reformed paradigms for cancer treatment in the past decade. Accumulating evidence indicates that the intimate crosstalk between cancer cells and stromal cells plays a tremendous role in tumor progression. Cancer-associated fibroblasts (CAFs), the largest population of stroma cells, influence therapeutic effects through diverse mechanisms. Herein, we summarize the recent advances in the versatile functions of CAFs regarding their heterogeneity, and we mainly discuss the pro-tumorigenic functions of CAFs which promote tumorigenesis and confer therapeutic resistance to tumors. Targeting CAFs is emerging as one of the most appealing strategies in anticancer therapies. The endeavors to target or reprogram the specific subtypes of CAFs provide great cancer treatment opportunities, which may provide a better clinical benefit to cancer patients.

Keywords: Cancer-associated fibroblasts (CAFs), heterogeneity, therapeutic resistance, CAFs targeting

INTRODUCTION

Most conventional cancer treatment strategies are based on the special characteristics of tumor cells, such as rapid proliferation rate and oncogenic driver mutations in cancer cells. However, few patients experience complete responses, and the strength and duration of response to treatments vary widely. Intrinsic or acquired resistance developing during the treatment is the central issue in cancer therapies, which often leads to tumor progression. Thus, new therapeutic strategies are urgently needed to bypass or overcome drug resistance in cancer treatment. Before that, a profound understanding of the mechanism of resistance is needed.

The “seed and soil” theory, which Stephen Paget proposed first in 1889, has received widespread attention in recent years. Cancer-associated fibroblasts represent the majority of stromal cell populations in the tumor microenvironment (TME) and are closely linked with clinical outcomes across multiple cancers including colorectal cancer (CRC), pancreatic ductal adenocarcinoma (PDAC), and breast cancer^[1-4]. While numerous studies have revealed that CAFs play pivotal roles in regulating tumor development and progression via various “intermediator messengers” involving extracellular matrix, soluble factors, and metabolites^[5-7], bench-to-bedside translation remains the bottleneck for researchers to properly target CAFs as an efficient antitumor therapy. Thus far, no CAF-specific inhibitors have been approved by the United States Food and Drug Administration (FDA), and this might be, at least partially, ascribed to the high heterogeneity of CAFs.

Heterogeneity of CAFs origin

CAFs can be derived from various cell populations. Tissue-resident fibroblasts are considered one of the most prevalent precursors for CAFs. Soluble factors such as transforming growth factor- β (TGF- β) and platelet-derived growth factor (PDGF) derived from neighboring tumor cells have been implicated in de novo activation of CAFs^[8,9]. Additionally, exosomes (including shuttling cargos such as miRNAs and lncRNAs) have also played essential roles in the transformation of normal fibroblasts (NFs) to CAFs. In some types of cancers, such as pancreatic and liver cancers, stellate cells are recognized as another critical source of CAFs, which have been termed pancreatic stellate cells (PSCs) and hepatic stellate cells (HSCs), respectively. Classic TGF- β , PDGF signaling, and vitamin A deficiency have been found to be involved in PSC activation^[10,11]. Furthermore, a recent work unveiled that stimulation of IGF-1 signaling assisted HSCs in acquiring a fibroblast-like phenotype. Mesenchymal stem cells (MSCs) are also one of the most commonly studied sources of CAFs. Effectors stimulating transdifferentiation of MSCs to CAFs vary across different cancers^[12,13]. For instance, the OPN-MZF1-TGF- β axis was able to mediate MSC-CAF transformation in breast cancer^[14], while TGF- β , as well as CXCL16, participated in the activation of MSCs in prostate cancer. Lastly, other types of cells, including epithelial cells, endothelial cells, hematopoietic stem cells (HSCs), cancer stem cells, adipocytes, and pericytes, have also been reported to possess the potential to transdifferentiate into CAFs. Of note, there is less evidence relating to these origins, which needs further investigation^[15]. Taken together, the origins of CAFs have not been fully elucidated yet. As distinct effectors/signaling pathways contribute to the generation of CAFs, which are related to cancer types or the cell types that the CAFs originated from, it would be meaningful to monitor the dynamic origins of CAFs more precisely during cancer progression by taking advantage of advanced technologies such as lineage tracing and single-cell special analysis.

Functional diversity of CAFs

Similar to the existence of heterogeneity in cellular origins, CAFs exhibit diversity regarding their biological characteristics and function, which was firstly corroborated by David A. Tuveson Group^[16]. By exploiting in vitro 3D co-culture system and in vivo mouse/patient-derived PDAC tissues, they found two distinct subtypes of CAFs present in PDAC. One subpopulation of CAFs, located immediately adjacent to

neoplastic cells, showed elevated expression of α -SMA and low expression of IL-6 (myCAFs), whereas the other, distantly distributed throughout the tumor, had reduced α -SMA expression and elevated production of inflammatory factors including IL-6, thus was termed inflammatory CAFs (iCAFs). Intriguingly, these two subpopulations of CAFs showed distinct transcriptome profiles related to their characteristics and could dynamically change from one state to the other. This study highlighted that various subtypes of CAFs rather than one homologous pro-tumoral CAF population may exist in the TME, which can partially explain the failure encountered in clinical trials by targeting α -SMA+ CAFs^[17,18]. Likewise, the two aforementioned CAF populations with distinct α -SMA expression and transcriptomes have also been reported in CRC, supporting the findings in PDAC^[19]. Moreover, another study from the same group further identified a novel population of CAFs with MHC-II and CD74 expression termed antigen-presenting CAFs (apCAFs). This new subtype of CAFs can directly activate CD4+ T cells in an antigen-specific fashion, confirming the putative immune-modulatory capacity of CAFs^[20]. In accordance, more and more in-depth studies have pointed to the functional diversity of these subpopulations of CAFs. For example, pharmaceutical inhibition or genetic ablation of Shh signaling, which is involved in driving myCAF activation in PDAC, resulted in increased metastasis and decreased animal survival^[21,22]. A similar phenotype was demonstrated in parallel by another group, which also showed depletion of α -SMA+ fibroblasts and led to poorly differentiated tumors and shortened animal survival. More importantly, low myCAF content was found to be associated with worse overall survival in human PDAC tumor sections^[21,23]. Collectively, this evidence strongly supports the tumor-constraining role of myCAFs, which should always be kept in mind when considering whether to target CAFs as anticancer therapy. On the contrary, accumulating evidence uncovers the pro-tumoral properties of iCAFs. This was not very surprising since the key hallmark of iCAFs is secreting inflammatory factors such as IL-6, which have been well-studied for their tumor-promoting capability^[17]. Recent work from our lab showed that IL-6 secreted by CAFs can promote LRG1 expression through STAT3-mediated transactivation, which facilitates epithelial-to-mesenchymal transition (EMT) and ultimately leads to liver metastasis in a xenograft mouse model of CRC. Since many agents that target individual nodes of the IL-6/STAT3/LRG-1 cascade, including IL-6, IL-6R, or JAKs/STAT3, are currently under active investigations as treatments for hematopoietic malignancies and solid tumors, this work opens a new and implementable way to mitigate metastasis by blocking CAF-tumor cell crosstalk in CRC^[24]. Additionally, another seminal study from David A. Tuveson Group revealed the underlying molecular mechanism that promotes the diversity of CAFs. They reported that IL-1 induced LIF expression and downstream JAK/STAT activation to generate iCAFs. Conversely, TGF- β was able to antagonize iCAF generation by downregulating IL-1R expression and promote shifting to myCAFs. Consistently, targeting JAK/STAT signaling reduced the number of iCAFs and increased α -SMA+ myCAFs, indicating a shift from iCAFs to myCAFs. Ultimately, this phenotypic shift within the two subpopulations of CAFs led to a dramatic decrease in tumor volume, confirming the opposite function of the two CAF subtypes. This study raised a promising strategy to tackle cancer by converting pro-tumoral CAFs to tumor-constraining CAFs or selectively depleting tumor-promoting CAFs^[25]. The functional heterogeneity of cancer-associated fibroblasts in distinct tumors is summarized in detail in [Table 1](#).

With advances in single-cell sequencing and multi-omics approaches, more and more novel CAF subsets have been unveiled across different cancers, which have been broadly described elsewhere^[18,26]. Hereafter, to make the content of this review more clinically relevant, we mainly focus on discussing the CAF subpopulations with tumor-promoting properties, thereby possibly being considered as potential targets to overcome therapeutic resistance.

Conventional cytotoxic chemotherapies, targeted therapies, and the emerging innovative immune checkpoint inhibitors (ICIs) are the mainstays in treating cancer patients. Numerous studies have revealed

Table 1. Functional heterogeneity of cancer-associated fibroblasts in distinct tumor types

Cancer types	CAF subtypes	Characteristic markers	Functions	References
BC	CD10+/GPR77+ CAFs	CD10, GPR77	Chemoresistance, proliferation, migration	[34]
	dCAFs	<i>SCRG1, SOX9, SOX10, etc.</i>		[86]

the essential roles of CAFs in conferring therapeutic resistance through diverse mechanisms [Figure 1], such as remodeling of the extracellular matrix (ECM), maintaining the stemness of cancer stem cells (CSCs), and metabolic reprogramming^[5-7,27]. More recently, growing evidence also demonstrates the ability of CAFs to modulate tumor immunity^[15,28].

CAFs promote resistance to chemotherapy

Chemotherapies are still the main first-line treatment strategies for cancer patients. CAFs are one of the most prevalent stromal cell types within the TME across multiple cancers such as CRC and PDAC, and they play pivotal roles in regulating the response to chemotherapy. As the major source of extracellular matrix (ECM) components, CAFs are considered as a physical barrier to influence drug delivery. For instance, depletion of CAFs by inhibition of the Hedgehog cellular signaling pathway or administration of hyaluronan was able to enhance the delivery of chemotherapy (gemcitabine) in a PDAC mouse model^[29,30]. Additionally, by upregulation of lysyl oxidase (LOX) or MMPs, CAFs can alter the abundance and composition of ECM components, especially collagen, ultimately leading to dysregulated ECM homeostasis and resistance to chemotherapy (epirubicin and paclitaxel)^[31,32]. Cancer stem cells (CSCs) are a small cell population within the bulk tumors that possess self-renewing capability and are largely responsible for resistance to chemotherapy. Through the production of cytokines, chemokines, and exosomes (including shuttling cargos such as miRNAs, lncRNAs, or cirRNAs), CAFs play a pivotal role in regulating cancer stemness and are therefore also a route of therapeutic resistance^[33]. A recent study revealed that IL-6 and IL-8 were secreted by a unique subset of CAFs expressing both CD10 and GPR77 against multiple chemotherapeutic interventions (doxorubicin, cyclophosphamide, and paclitaxel and docetaxel and cyclophosphamide) in breast and lung cancers. CD10⁺GPR77⁺ CAFs constantly secrete IL-6 and IL-8 through activating the NF-KB signaling pathway, providing a survival niche for cancer stem cells^[34]. Our

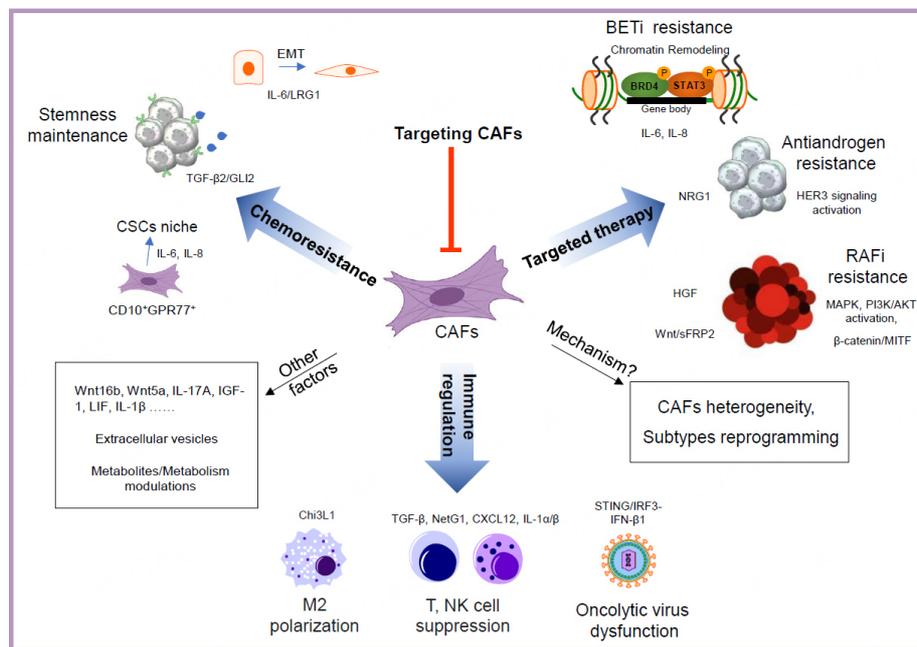

Figure 1. Roles of cancer-associated fibroblasts (CAFs) in cancer drug resistance. CAFs affect almost all cancer treatments, including traditional chemotherapy, targeted therapy, and immunotherapy. There are various mechanisms, such as secretion of growth factors, production of extracellular vesicles, and metabolites, through which CAFs promote drug resistance. Chemoresistance is enhanced by secreted factors from CAFs. Among them, TGF- β 2 and IL-6/IL-8 from CD10⁺GPR77⁺ CAFs induce GLI2 upregulation and NF- κ B activation, respectively, to maintain the stemness of cancers. IL-6 and/or IL-8 from CAFs were also found to induce EMT or chromatin remodeling in cancer cells. Upon stimulation with cytokines, such as IL-6, IL-8, NRG1, and HGF, the response to targeted therapies can be undermined by BRD4 modification, HER3 signaling activation, and MAPK and PI3K/AKT activation. Furthermore, CAFs mitigate tumor immunity by polarizing macrophages into the M2 phenotype, suppressing the function of NK and T cells and oncolytic viruses through Chi3L1, TGF- β , NetG1, CXCL12, IL-1 α/β , and IFN- β 1. Although appealing, targeting CAFs remains a big challenge today. The efforts to define CAF subtypes and further decipher their functions in the microenvironment may shed light on discovering new targeting strategies and provide more benefits to cancer patients. EMT: Epithelial-to-mesenchymal transition; CAF: cancer-associated fibroblast.

recent study also demonstrated that hypoxia-induced HIF1 α and CAF-derived TGF- β 2/Smad signal concurrently transactivate the expression of Hedgehog transcription factor GLI2 in cancer stem cells. Blockade of GLI2 signal induced by HIF1 α and TGF β 2 effectively reverses the CAF-promoted resistance to 5-FU-based chemotherapy in colorectal cancer. Interestingly, a high level of HIF1 α /TGF β 2/GLI2 can predict the high risk of recurrence in patients undergoing chemotherapy. This study proposed a potential biomarker as well as a potential new strategy to overcome chemoresistance by targeting CAFs signaling^[35]. Similarly, by directly transferring exosomes as well as its shuttling cargo-miR-92a-3p to cancer cells, CAFs contributed to cancer stemness by activating the wnt/ β -catenin pathway, which ended in resistance to therapy^[36]. Of note, CAFs displayed a high basal level of autophagy compared to their counterparts in different cancers, such as PDAC, ovarian cancer, and head and neck squamous cell carcinoma (HNSCC), and autophagy could be further induced in response to stimuli from the TME^[37-39]. It is believed that secretory autophagy promotes cancer survival by providing metabolites or other pro-tumoral effectors, including cytokines and growth factors in the harsh tumor milieu. It was also reported that the elevated level of autophagy in CAFs induced epithelial-to-mesenchymal transition and stemness in tumor cells, thus contributing to metastasis and drug resistance. Furthermore, another important role of stress-induced autophagy in CAFs was recently reported to regulate exosome release^[40,41]. Thus, the involvement of autophagy in shaping the TME deserves further attention. Targeting autophagy-related core machinery by small molecules might be an effective alternative to deal with chemoresistance caused by CAFs.

CAFs enhance resistance to targeted therapy

In addition to chemotherapy, the CAF-derived secretome was also found to mitigate the response to targeted therapies. HGF was found to provide an alternative BRAF-independent mechanism for ERK-MAPK activation to mediate resistance to BRAF-targeted therapies in melanoma^[42]. Wnt signaling modulated by CAFs has also been implicated in resistance to vemurafenib by attenuating the response of melanoma cells to DNA damage^[43]. CAF-derived NRG1 confers antiandrogen resistance in prostate cancer by activating HER3 signaling^[44]. In addition, we recently found that the CAF-derived IL-6/8-JAK2 signaling cascade can promote BRD4 phosphorylation^[45], a critical epigenetic regulator in the regulation of cancer cell stemness. BRD4 phosphorylation induces chromatin remodeling, supporting a tumor-promoting transcriptional program and thus leading to BET inhibitor resistance. Given the prominent roles of epigenetic reprogramming in tumorigenesis and tumor progression, the finding paves a new way to more effectively treat CRC by co-targeting epigenetic modulators and CAF-mediated signaling pathways. In the presence of CAFs, tumor cells also displayed resistance to cetuximab, a monoclonal antibody therapy targeting epidermal growth factor receptor (EGFR). A further study ascribed this to increased secretion of EGF from CAFs^[10,46]. Another recent study demonstrated that ECM remodeling and stiffness features were positively correlated with CAFs activation in CRC patients' tissue samples. Mechanistically, key components of the renin-angiotensin system (RAS), such as angiotensin II (ANGII) produced by CAFs, are involved in ECM deposition. More importantly, targeting CAF-derived RAS signaling was able to improve response to antiangiogenic therapy (bevacizumab), which was due to reduced ECM stiffness^[47]. Intriguingly, matrix stiffness can induce autophagy in CAFs by stiffness sensing through the Integrin α V-focal adhesion kinase-AMPK α axis^[48], forming a CAF-ECM positive feedback regulatory loop. Collectively, these studies show an intimate connection between CAFs and resistance to targeted therapy. Blocking CAF-related signaling pathways will be a powerful strategy to tackle this tough issue.

CAFs modulate response to ICI

Immunotherapy, specifically immune checkpoint inhibitors (ICIs), has led to a revolution in cancer treatment paradigms in the past decade. While ICIs have shown effectiveness in multiple cancers such as melanoma and lung cancer, the majority of patients cannot benefit from the treatment, especially those with "cold tumors", such as PDAC and CRC^[49,50]. Based on the underlying mechanism of ICI action, several potential markers are proposed to be related to clinical response, including the PD-L1 expression level, specifically on tumor cells and APC cells, immune composition within the TME, neoantigens, tumor mutation burden, *etc.* Recent evidence shows that CAFs are linked to the resistance of ICIs^[15]. CAFs can modulate the recruitment and activity of immune cells mainly through regulating ECM remodeling, the expression of immune checkpoints, and cytokines/chemokines, thereby skewing the TME to immunosuppressive status. For example, CAF-modified ECM is involved in the exclusion of cytotoxic T cells (CTLs) from the proximity of tumor cells. The secretion of matrix proteins and the production of matrix metalloproteinases (MMPs) by CAFs increased matrix stiffness, which not only promotes the migration and invasion of cancer cells but also serves as the physical barrier for immune cell infiltration^[51,52]. Depletion of FAP+ CAFs, which exhibited upregulation of proinflammatory factors similar to iCAFs, can decrease tumor volumes in a CD4+ T cell- and CD8+ T cell-dependent manner in a KPC mice model^[53,54]. Treating the FAP+ CAF-depleted mice with ICIs targeting PD-L1/CTLA-4 dramatically reduced tumor volumes. Furthermore, FAP+ CAFs are considered the principal source of CXCL12 and IL-6, which have been implicated in the prevention of T cell accumulation/activity in the tumor. Combined treatment with inhibitor targeting the CXCL12-CXCR4 axis or IL-6 antibody and anti-PD-L1 elicited synergistic efficiency in a PDAC mouse model^[55-57]. apCAFs, which present antigens to CD4+ T cells through expressing MHCII molecules, were speculated to deactivate CD4+ T cells by inducing either anergy or differentiation into Tregs and dampen antitumor immunity^[20,58]. Interestingly, an analog to apCAFs was reported to kill CD8+ T cells in an antigen-dependent manner via PD-L2 and FASL^[59]. Thus, targeting

apCAFs might enhance antitumor immunity by restricting immune checkpoint activation. Another newly published work unraveled that CAF-derived wnt2 suppressed dendritic cell (DC) differentiation as well as DC-mediated antitumor T cell response. Targeting wnt2+ CAFs via monoantibody was able to significantly restore antitumor T cell response and enhance response to anti-PD-1 in both esophageal squamous cell carcinoma (OSCC) and a CRC mouse model^[60]. Additionally, numerous studies have demonstrated that the expression of immune checkpoints such as PD-L1, PD-L2, and B7-H3 on CAFs can directly induce T cell exhaustion and deactivation^[59,61,62]. Moreover, CAFs were reported to induce PD-L1, PD-1, cytotoxic lymphocyte-associated antigen-4 (CTLA-4), lymphocyte-activation gene-3 (LAG-3), and mucin-domain containing-3 (TIM-3) on the surface of immune cells or tumor cells, which dampen the proliferation and activity of immune cells, especially cytotoxic T cells^[63-66]. By regulating the expression of those immune checkpoint molecules, CAFs also possibly potentiate the effect of ICIs. Enhanced recruitment of immunosuppressive cells, such as tumor-associated macrophages (TAMs) and myeloid-derived suppressor cells (MDSCs), was also shown to reduce the sensitivity of immunotherapy^[67-69]. For instance, overexpression of proline isomerase (PIN1) in CAFs was correlated with more infiltration of TAMs and fewer infiltrated CD8+ T cells in human PDAC tissue samples. Targeting pin1 rendered PDAC tumors more sensitive to anti-PD-1 treatment by disrupting the immunosuppressive TME^[70]. CAF-derived soluble effectors such as CCL2 and CSF1 were critical for the recruitment of MDSCs. Depletion of MDSCs by targeting CSF1 was shown to significantly improve response to ICIs such as anti-CTLA4^[63,67,71,72]. By taking advantage of single-cell analysis, a recently published seminal work has revealed a positive feedback loop between specific CAF-S1 clusters and Tregs in breast cancer, which subsequently contributed to resistance to immunotherapy^[73]. In addition, a recently identified subtype of CAFs, termed NetG1+ CAFs, possessed intrinsic immunosuppressive properties and inhibited NK cell activity in PDAC^[74]. Cardiotrophin-like cytokine factor 1 (CLCF1) derived from CAFs was able to promote infiltration and polarization of neutrophils in HCC^[75]. Taken together, these studies suggest that co-targeting CAFs or CAF-derived signaling pathways might be one of the most attractive options to improve the efficiency of ICIs by reshaping the tumor immune microenvironment.

Challenges and Perspectives to target CAFs

Although tremendous efforts have been made to either directly or indirectly target CAFs [Figure 2], many strategies have failed to show promising clinical outcomes. The breadth of CAF functions and the interconvertibility of different subtypes pose a challenge for the field. In addition to their oncogenic functions, it has been revealed that CAFs can also play important roles in restraining tumors^[21,23]. In several clinical or preclinical studies, targeting CAFs by some approaches did not lead to sufficient therapeutic efficacy or even promoted disease progression^[76-78]. For example, depletion of α -SMA+ CAFs resulted in unexpected immunosuppression and aggressive tumor. Analogously, targeting the Sonic hedgehog (SHH) -smoothened (SMO) signaling that is involved in the activation of myCAFs also did not present therapeutic efficiency or, in some contexts, even shortened patient survival in clinical trials. Further studies indicated that this might be due to the aforementioned heterogeneity of CAFs present in the tumor milieu, and myCAFs tended to play a tumor-restraining role. On the contrary, depletion of FAP+ CAFs or interference with its derived CXCL12-CXCR4 axis restored antitumor immunity in PDAC. This prompted an ongoing phase II clinical trial involving patients with pancreatic cancer (NCT02826486). Thus, more efforts should be addressed to define CAF subtypes and further decipher their functions when interacting with other components in the microenvironment. In addition to direct depletion of CAFs, modulation of CAF activity would be another way to target CAFs. An important study described above found that the IL-1/JAK/STAT signaling cascade was mainly responsible for the generation of iCAF, which displayed tumor-promoting properties across multiple cancers. Targeting IL-1 or JAK was considered as an appealing approach to converting pro-tumoral CAFs into a tumor-restraining subpopulation. The preclinical data have encouraged an early phase I clinical trial to combine standard chemotherapy and IL-1 receptor antagonist

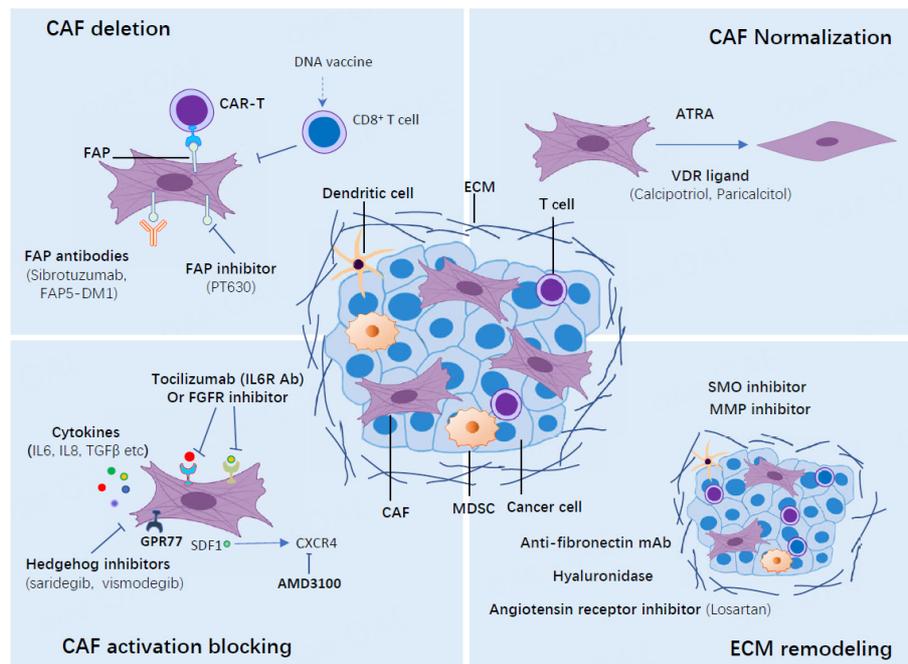

Figure 2. Targeting cancer-associated fibroblasts (CAFs) in cancer. Four main strategies targeting cancer-associated fibroblasts (CAFs) as cancer treatment are discussed. CAFs can be depleted by several treatments targeting CAF-specific markers, such as FAP and α -SMA. The normalization of CAFs from a pro-tumorigenic status to a quiescent or tumor-suppressive state can also be used for cancer treatment with small molecules such as ATRA or VDR ligands. The crucial signalings for CAF tumor-promoting function, such as cytokines and growth factors signalings, can be targeted to inactivate CAFs. Finally, CAF-derived extracellular matrix (ECM) proteins or related signalings can be targeted to induce ECM remodeling. MDSC: Myeloid-derived suppressor cell; FAP: fibroblast activation protein; CAR: chimeric antigen receptor; ATRA: all-trans retinoic acid; VDR: vitamin D receptor; FGFR: fibroblast growth factor receptor; SMO: smoothened; MMP: matrix metalloproteinase.

Anakinra in PDAC (NCT02021422). All-trans retinoic acid (ATRA) may normalize the CAFs to an inactive state in pancreatic ductal adenocarcinoma (PDAC)^[79] (NCT03307148, NCT00001509). Pharmacological stimulation of the vitamin D receptor (VDR) with its ligand calcipotriol can induce stromal reprogramming, ultimately reversing chemotherapeutic resistance induced by CAFs in the PDAC models^[80]. Targeting the crucial signalings for CAFs' tumor-promoting function, such as tocilizumab targeting IL-6 receptor^[81] (NCT02767557) or an FGFR inhibitor^[82] (NCT02699606, NCT01962532, NCT01703481, NCT02421185), can also be exploited to counteract the pro-tumoral effects of CAFs. Finally, CAF-derived extracellular matrix (ECM) proteins or related signalings can be targeted to induce ECM remodeling, which ultimately alleviates therapeutic resistance caused by CAFs. For example, losartan, an angiotensin inhibitor, can reduce hyaluronan production by CAFs, thereby improving vascular perfusion and drug delivery in breast and pancreatic cancers^[83] (NCT04106856). The above-mentioned clinical trials targeting CAFs are summarized in [Table 2](#).

The rapid development of single-cell RNA sequencing provides great opportunities to define subtypes and interpret the roles of CAFs. Although the high heterogeneity and diverse potential functions of CAFs have been revealed in many types of cancer utilizing scRNA-seq^[20,84-88], there are still many details to be elucidated: (1) The precise roles of various CAF subtypes in therapeutic resistance remain largely undefined. The precise identification and characterization of CAFs' role in promoting or restraining tumors might pave new ways to target CAFs; (2) the mechanism of how the homeostasis between fibroblasts [including CAF subtypes and normal fibroblasts (NFs)] is maintained requires further investigation. For example, fibroblasts play different roles in tumors by secreting different cytokines^[85]. The interconversion between

Angiotensin receptor	Losartan	Breast cancer, Pancreatic cancers	Reduces hyaluronan production by CAFs	Phase III	NCT04106856, NCT03900793, NCT01805453

PDAC: Pancreatic ductal adenocarcinoma; CAF: cancer-associated fibroblasts.

CAF subtypes might change the tumor's behavior. Furthermore, NFs can be educated to be tumor-promoting by tumor cells or CAFs^[5,89]. Epigenetic and chromatin remodeling could be a potential mechanism to interpret these conversions. (3) The effect of therapeutic approaches on CAFs is another direction to be investigated. Many therapeutic paradigms such as chemotherapy could profoundly affect the CAFs' status and the tumor microenvironment in which they reside, ultimately changing the response of the tumors to treatments. With advances in technologies, the studies of multi-omics such as transcriptomics, proteomics, epigenomics, and metabonomics, improve our understanding of cancer biology in an unprecedented way. A comprehensive analysis and precise functional studies in CAFs are

required to integrate these multi-omics data using multiple model systems, especially at single-cell resolution. Next, super-resolved spatial omics studies may offer systematic approaches to understand the interplay between CAFs and other cells in tumors. In conclusion, these comprehensive investigations may warrant both preclinical and clinical studies targeting CAFs to achieve better clinical benefits for patients.

DECLARATIONS

Authors' contributions

Writing, review, and/or revision of the manuscript: Wang W, Cheng B, Yu Q

Conception and design of the perspective: Wang W, Cheng B, Yu Q

Abstract

Aim: The main goal of this study was to elucidate at the transcript level the tyrosine kinase expression profiles of primary leukemia cells from mixed lineage leukemia 1 gene rearranged (KMT2A/MLL-R⁺) acute myeloid leukemia (AML) and acute lymphoblastic leukemia (ALL) patients.

Methods: We evaluated protein tyrosine kinase (PTK) gene expression profiles of primary leukemic cells in KMT2A/MLL-R⁺ AML and ALL patients using publicly available archived datasets.

Results: Our studies provided unprecedented evidence that the genetic signatures of KMT2A/MLL-R⁺ AML and ALL cells are characterized by transcript-level overexpression of specific PTK. In infants, children and adults with KMT2A/MLL-R⁺ ALL, as well as pediatric patients with KMT2A/MLL-R⁺ AML, the gene expression levels for FLT3, BTK, SYK, JAK2/JAK3, as well as several SRC family PTK were differentially amplified. In adults with KMT2A/MLL-R⁺ AML, the gene expression levels for SYK, JAK family kinase TYK2, and the SRC family kinases FGR and HCK were differentially amplified.

Conclusion: These results provide new insights regarding the clinical potential of small molecule inhibitors of these PTK, many of which are already FDA/EMA-approved for other indications, as components of innovative multi-modality treatment platforms against KMT2A/MLL-R⁺ acute leukemias.

INTRODUCTION

The lysine [K]-methyltransferase 2A (KMT2A)/mixed-lineage leukemia 1 (KMT2A/MLL) gene on chromosome 11 encodes a 431-kDa protein involved in the regulation of transcription^[1]. Rearrangements (r) of the KMT2A/MLL gene have been reported in acute myeloid leukemia (AML) and acute lymphoblastic leukemia (ALL)^[2-14]. AML and ALL patients with KMT2A/MLL-R⁺ leukemia have a poor prognosis with disappointing event-free survival (EFS) and overall survival (OS) outcomes on contemporary treatment regimens due to relapses caused by cancer drug-resistant clones^[1-19]. Therefore, more effective frontline as well as salvage treatments for MLL-R⁺ acute leukemias are urgently needed.

The main goal of the present study was to evaluate the protein tyrosine kinase (PTK) profiles of primary leukemic cells in patients with KMT2A/MLL-R⁺ AML and ALL as potential therapeutic targets to overcome cancer drug resistance. We compared the transcriptomes of primary leukemic cells from KMT2A/MLL-R⁺ vs. KMT2A/MLL-R⁻ AML and ALL patients with an emphasis on the relative gene expression levels of for 21 PTK, including ERBB1, FGR, FLT3, FYN, HCK, JAK2, LCK, LYN, MERTK, SRC, BLK, BMX, BTK, ERBB2, ERBB3, JAK1, JAK3, PTK2, SYK, TEC, TYK2. Our studies provided unprecedented evidence that the genetic signatures of KMT2A/MLL-R⁺ AML and ALL cells are characterized by transcript-level overexpression of specific PTK. In infants, children and adults with KMT2A/MLL-R⁺ ALL, as well as pediatric patients with KMT2A/MLL-R⁺ AML, the gene expression levels for FLT3, BTK, SYK, JAK2/JAK3, as well as several SRC family PTK were differentially amplified. In adults with KMT2A/MLL-R⁺ AML, the gene expression levels for SYK, JAK family member TYK2, and the SRC family PTK HCK and FGR were differentially amplified. These results provide new insights regarding the clinical potential of small molecule inhibitors of these PTK, many of which are already FDA/EMA-approved for other indications, as components of innovative multi-modality treatment platforms against KMT2A/MLL-R⁺ acute leukemias.

METHODS

Statistical methods for gene chip normalization for ALL and AML samples

A recently published working database, including data on primary leukemia cells from 201 adult patients with B-ALL (GSE13159), 119 pediatric patients with B-ALL (GSE11877 and GSE13351) and 97 infants with B-ALL (GSE68720), as well as 74 normal/non-leukemic control bone marrow samples (GSE13159), was built with previously archived datasets from the NCBI repository and used in our comparative gene expression analyses, as previously described in detail^[20]. We also used a working database derived from archived datasets including data on primary leukemia cells from 542 adult patients with AML (GSE13159), and 279 pediatric patients with AML (GSE19577, GSE17855) along with the 74 normal/non-leukemic control bone marrow samples (GSE13159) in our comparative gene expression analyses, as described^[20]. Probeset level normalization procedures were used as previously reported^[20].

We also compared the gene expression profiles of primary leukemia cells from FLT3-ITD⁺ pediatric AML patients ($N = 48$ from GSE17855) with those of primary leukemia cells from 189 FLT3-ITD⁻ pediatric AML patients (GSE17855) as well as normal hematopoietic cells from 74 non-leukemic control bone marrow samples (GSE13159). Forty-seven patients from the KMT2A/MLL-R⁻ “other” group of pediatric AML patients were FLT3-ITD⁺, including 18 patients with cytogenetically normal AML, one patient with inv^[16] AML, 12 patients with t(15;17) AML, 3 patients with t(8;21), 9 patients with AML and other cytogenetic features, and 4 patients who had AML with unknown cytogenetic features. One pediatric patient with KMT2A/MLL-R⁺ AML was FLT3-ITD⁺. This double mutant (FLT3-ITD/MLL-R) case was removed from

the analysis of FLT3-ITD⁺ ($N = 47$; GSE17855) versus KMT2A/MLL-R⁺ pediatric AML patients ($N = 88$; GSE17855, $N = 46$; GSE19577, $N = 42$).

No pediatric patients with KMT2A/MLL-R⁺ AML harbored *NPM1* or *CEBPA* mutations. Within the KMT2A/MLL-R⁺ (“other”) group of KMT2A/MLL-R⁺ AML pediatric AML patients, 17 harbored *NPM1* mutations (*NPM1*⁺) and 16 patients had *CEBPA* mutations (*CEBPA*⁺) (GSE17855). We investigated the gene expression profiles from primary leukemia cells from 71 KMT2A/MLL-R⁺ pediatric AML patients who were FLT3-ITD⁺, *NPM1*⁺ or *CEBPA*⁺ (GSE17855; only *NPM1*⁺ $N = 10$, only *CEBPA*⁺ $N = 14$, only FLT3-ITD⁺ $N = 38$; 9 cases harbored one or more of the *NPM1*, *CEBPA* or *FLT3-ITD* mutations) versus 88 cases of KMT2A/MLL-R⁺ [GSE17855 ($N = 46$); GSE19577 ($N = 42$)]. One patient with both FLT3-ITD and MLL-R was removed from this comparison.

Statistical methods for differential gene expression

Our analyses for ALL and AML focused on the expression levels (interrogated with 64 probesets) of the following 21 PTK genes: *ERBB1*, *FGR*, *FLT3*, *FYN*, *HCK*, *JAK2*, *LCK*, *LYN*, *MERTK*, *SRC*, *BLK*, *BMX*, *BTK*, *ERBB2*, *ERBB3*, *JAK1*, *JAK3*, *PTK2*, *SYK*, *TEC* and *TYK2*. Standard statistical methods, including mixed model ANOVAs, and hierarchical clustering method were employed, as reported^[20-24].

RESULTS

Differentially amplified expression of PTK genes in primary leukemic cells from KMT2A/MLL-R⁺ B-ALL patients

We first examined PTK gene expression profiles of primary leukemic cells from infants ($N = 80$), children ($N = 25$) and adults ($N = 70$) with KMT2A/MLL-R⁺ B-ALL vs. normal hematopoietic cells from healthy volunteers ($N = 74$). Notably, FMS-like tyrosine kinase 3(FLT3) expression in infant KMT2A/MLL-R⁺ ALL cases was 16.09-fold higher than in normal hematopoietic cells in non-leukemic control bone marrow samples (P -value $< 1 \times 10^{-8}$) [Supplementary Figure 1; Supplementary Table 1]. The genes for several additional PTK showed augmented expression in KMT2A/MLL-R⁺ infant ALL cells, including *TEC*, *SRC*, *BLK*, *JAK2*, *BTK*, *PTK* (3 probesets), *SYK* and *JAK1* (2 probesets) [Supplementary Figure 1; Supplementary Table 1]. As the second most upregulated gene, the gene for *BLK* was expressed at a 6.77-fold higher level in infant KMT2A/MLL-R⁺ ALL cells than in normal hematopoietic cells (P -value $< 1 \times 10^{-8}$) [Supplementary Table 1]. Similarly, *FLT3* was expressed at a 22.38-fold higher level in pediatric KMT2A/MLL-R⁺ ALL cells than in normal hematopoietic cells (P -value $< 1 \times 10^{-8}$) [Supplementary Figure 2; Supplementary Table 2]. As in infant leukemia cells, *BLK* was the second most upregulated gene in pediatric KMT2A/MLL-R⁺ ALL cells showing a 4.38-fold higher expression level than in normal hematopoietic cells (P -value $< 1 \times 10^{-8}$). The genes for several additional PTK showed augmented expression in pediatric KMT2A/MLL-R⁺ ALL cells, including *PTK2*, *TEC*, *BTK*, and *SYK* [Supplementary Figure 2; Supplementary Table 2]. Similarly, *FLT3* and *BLK* expression in leukemic cells from adult patients with KMT2A/MLL-R⁺ ALL were 21.00-fold (P -value $< 1 \times 10^{-8}$) and 21.79-fold (P -value $< 1 \times 10^{-8}$), respectively, higher than in normal hematopoietic cells [Supplementary Figure 3; Supplementary Table 3].

We next compared the PTK gene expression profiles of leukemic cells from each KMT2A/MLL-R⁺ subset to the *PTK* gene expression profiles of leukemic cells without KMT2A/MLL rearrangements from the corresponding control ALL patients in the “other” categories (Infants, $N = 17$; Children, $N = 94$; Adults, $N = 131$). In infants [Figure 1; Supplementary Table 4], children [Figure 2; Supplementary Table 5] and adults [Figure 3; Supplementary Table 6] with KMT2A/MLL-R⁺ ALL, the gene expression levels for *FLT3*, *BTK*, *SYK*, *JAK2/JAK1*, as well as several *SRC* family PTK, including *BLK*, were differentially and significantly amplified. In KMT2A/MLL-R⁺ infant ALL cells, *FLT3_206674_at* was the most significantly

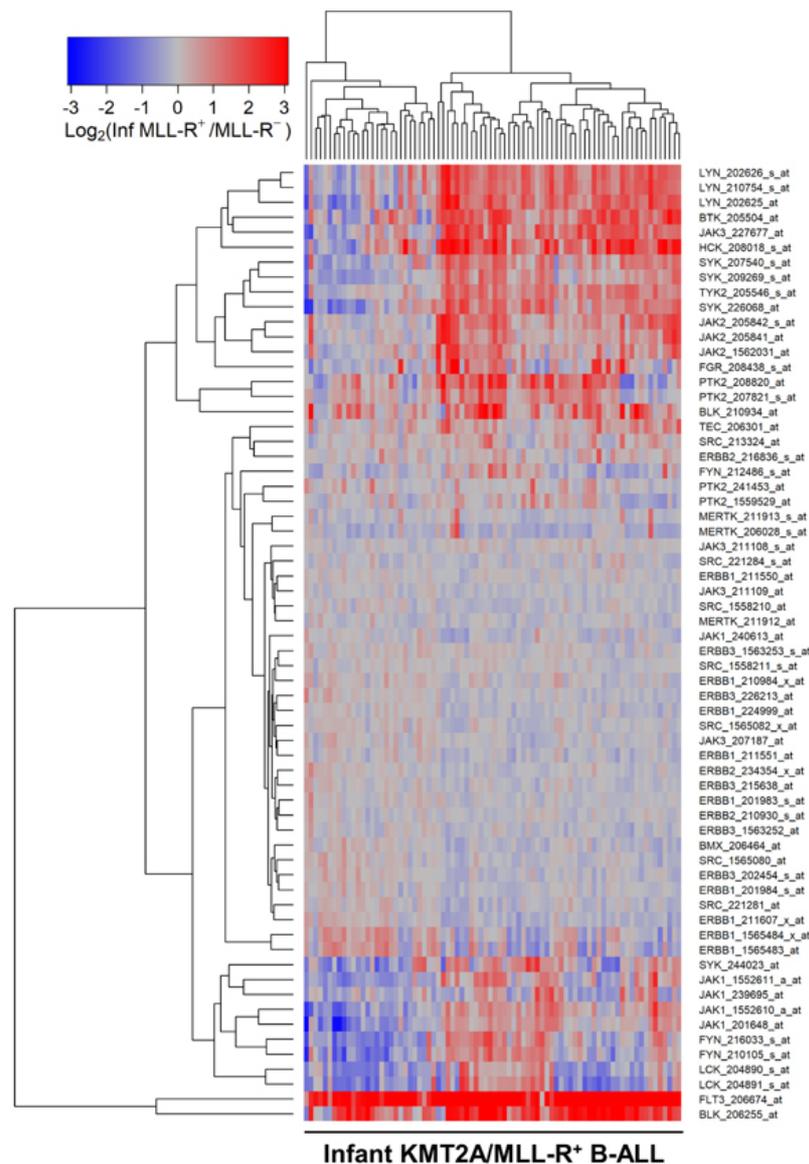

Figure 1. Gene Expression Levels for Tyrosine Kinases in Leukemic Cells from infants with KMT2A/MLL-R⁺ B-ALL vs. Other Types of B-ALL without KMT2A/MLL Rearrangements. Probeset level normalized, robust multi-array analysis (RMA) signal values from the archived data for infant ALL (GSE68720) were examined in these comparisons. Infant KMT2A/MLL-R⁺ B-ALL gene partners for KMT2A were AF4 (N = 48), ENL (N = 16), AF9 (N = 6), ASAH3 (N = 1), EPS15 (N = 3), Unknown (N = 6) (GSE68720; Total N = 80). The cluster figure displays the expression levels in KMT2A/MLL-R⁺ ALL cells mean centered to the reference group [KMT2A/MLL germline/WT gene (KMT2A/MLL-R-)] represented by log₂-transformed fold change values (blue to red color indicates under-expression to over-expression respectively in KMT2A/MLL-R⁺ samples). Co-regulated probesets are organized and depicted by dendrograms for both probesets (rows) and patients (columns). The log₂-transformed RMA values for leukemic cells from 80 infants with KMT2A/MLL-R⁺ B-ALL compared to that from leukemia cells obtained from 17 infants with MLL-germline/WT ALL (MLL-R negative) showed 19 probesets that were upregulated in KMT2A/MLL-R⁺ infant ALL cells. FLT3_206674_at was the most significantly upregulated probeset (Fold Change = 11.23; P-value < 10⁻⁸) followed by BLK_206255_at (Fold Change = 3.98; P-value < 10⁻⁸) and HCK_208018_s_at (Fold Change = 2.46; P-value < 10⁻⁸) [Supplementary Table 4]. Cluster visualization of the mean centered expression values suggested co-regulation of LYN (3 probesets), BTK, JAK3, HCK, SYK (3 probesets), TYK2, JAK2 (3 probesets), FGR, PTK2 (2 probesets) and BLK (2 probesets).

upregulated probeset (Fold Change = 11.23; < 10⁻⁸) followed by BLK_206255_at (Fold Change = 3.98; < 10⁻⁸) when compared to infant ALL cells with germline/wildtype KMT2A/MLL gene [Figure 1;

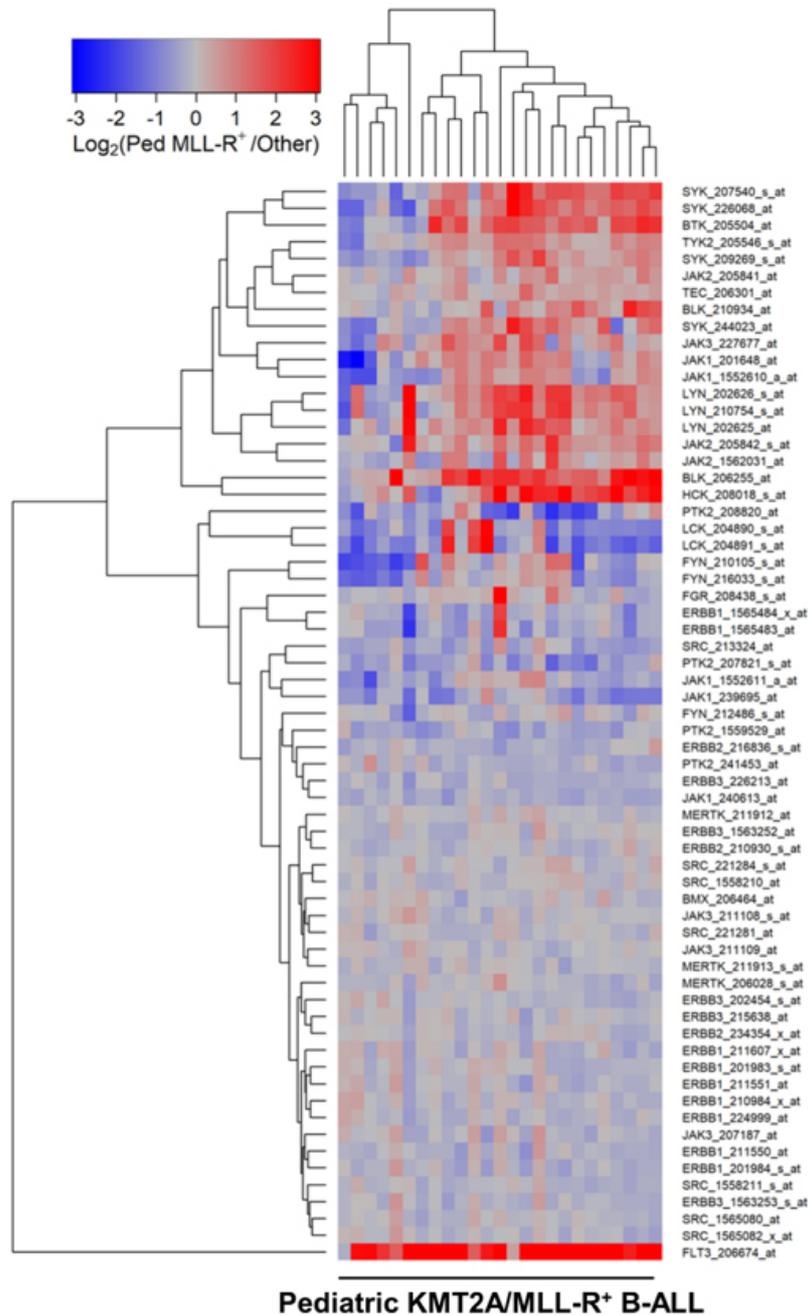

Figure 2. Gene Expression Levels for Tyrosine Kinases in Leukemic Cells from Pediatric Patients with KMT2A/MLL-R⁺ B-ALL vs. Other Types of B-ALL without KMT2A/MLL Rearrangements. Probeset level normalized signal values from the archived data sets GSE11877 and GSE13351 were examined in these comparisons. The cluster figure displays the expression levels in KMT2A/MLL-R⁺ ALL cells mean centered to the reference group (other subsets of ALL without KMT2A/MLL rearrangements) represented by \log_2 -transformed fold change values (blue to red color indicates under-expression to over-expression respectively in KMT2A/MLL-R⁺ samples). Co-regulated probesets are organized and depicted by dendrograms for both probesets (rows) and patients (columns). Depicted are the differential gene expression changes of \log_2 -transformed, robust multi-array analysis (RMA) normalized values for 25 pediatric ALL KMT2A/MLL-R⁺ cases (GSE11877 and GSE13351) compared to 94 non-MLL-R⁺ other samples (GSE11877 and GSE13351) exhibiting 20 dysregulated probesets, of which 14 were upregulated in KMT2A/MLL-R⁺ subset of cases. FLT3_206674_at was the most significantly upregulated probeset (Fold Change = 8.65; P -value < 10^{-8}) followed by BLK_206255_at (Fold Change = 3.11; P -value < 10^{-8}) and HCK_208018_s_at (Fold Change = 2.64; P -value < 10^{-8}) [Supplementary Table 5].

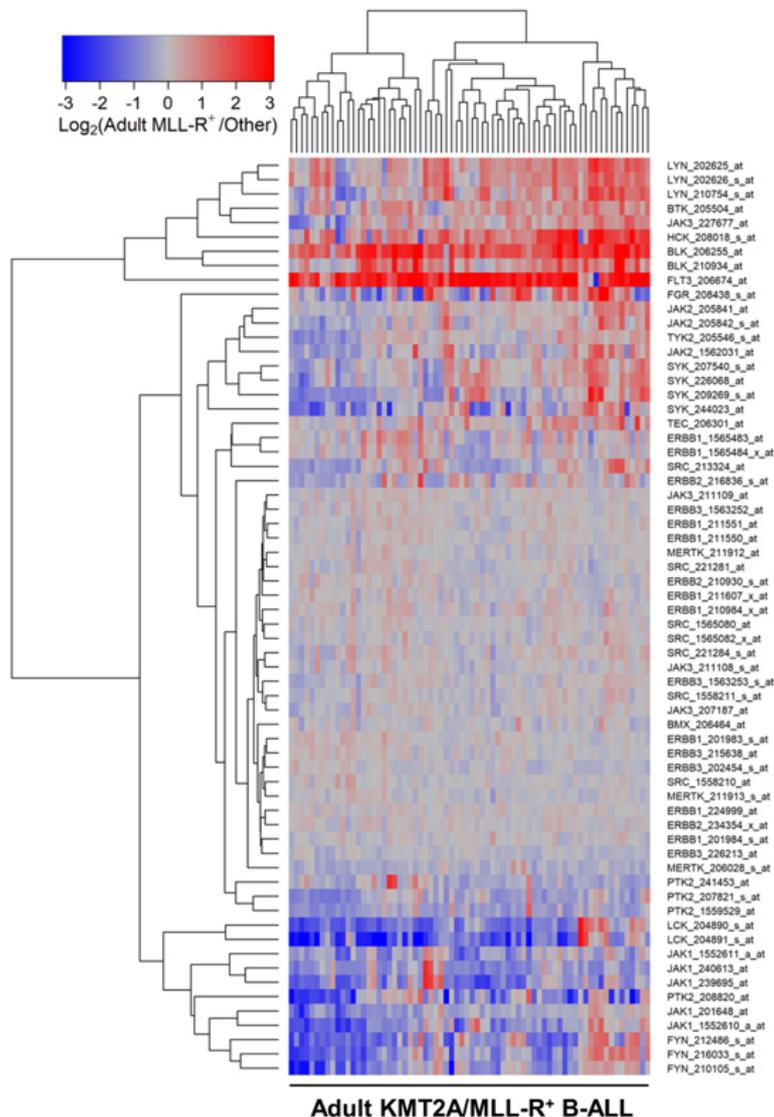

Figure 3. Gene Expression Levels for Tyrosine Kinases in Leukemic Cells from Adult Patients with KMT2A/MLL-R⁺ B-ALL vs. Other Types of B-ALL without KMT2A/MLL Rearrangements. Probeset level normalized signal values from the archived data set GSE13159 were examined in these comparisons. The cluster figure displays the expression levels in KMT2A/MLL-R⁺ ALL cells mean centered to the reference group (other types of ALL without KMT2A/MLL Rearrangements) represented by log₂-transformed fold change values (blue to red color indicates under-expression to over-expression respectively in KMT2A/MLL-R⁺ samples). Co-regulated probesets are organized and depicted by dendrograms for both probesets (rows) and patients (columns). The comparison of the log₂-transformed RMA values for leukemic cells from 70 adult patients with KMT2A/MLL-R⁺ ALL with the RMA values for leukemic cells from 131 adult patients with other forms of ALL resulted in 25 probesets that were significantly dysregulated, of which 10 were upregulated in KMT2A/MLL-R⁺ subset of cases. FLT3_206674_at was the most significantly upregulated probeset (Fold Change = 5.69; *P*-value < 10⁻⁸) followed by BLK_206255_at (Fold Change = 3.95; *P*-value < 10⁻⁸) and HCK_208018_s_at (Fold Change = 2.21; *P*-value < 10⁻⁸) [Supplementary Table 6]. FLT3 was co-regulated with BLK (2 probesets), HCK and LYN (3 probesets).

Supplementary Table 4]. Likewise, in KMT2A/MLL-R⁺ pediatric ALL cells, FLT3_206674_at was the most significantly upregulated probeset (Fold Change = 8.65; *P*-value < 1 × 10⁻⁸) followed by BLK_206255_at (Fold Change = 3.11; *P*-value < 10⁻⁸) when compared to pediatric ALL cells without KMT2A/MLL rearrangements [Figure 2; Supplementary Table 5]. Similarly, in KMT2A/MLL-R⁺ adult ALL cells, FLT3_206674_at was the most significantly upregulated probeset (Fold Change = 5.69; *P*-value < 10⁻⁸) followed by BLK_206255_at (Fold Change = 3.95; *P*-value < 10⁻⁸) when compared to leukemic cells from

adult ALL patients without KMT2A/MLL rearrangements [Figure 3; Supplementary Table 6].

Differentially amplified expression of PTK genes in primary leukemic blasts from KMT2A/MLL-R⁺ AML patients

We examined the PTK gene expression profiles of primary leukemic blasts from 89 children and 38 adults with KMT2A/MLL-R⁺ AML vs. normal hematopoietic cells from healthy volunteers ($N = 74$). In comparison to normal hematopoietic cells, KMT2A/MLL-R⁺ pediatric as well as adult AML cells were characterized by amplified expression of FLT3 gene. FLT3_206674_at was the most significantly upregulated probeset (Fold Change in pediatric KMT2A/MLL-R⁺ AML cells = 7.54; P -value $< 1 \times 10^{-8}$; Fold Change in adult KMT2A/MLL-R⁺ AML cells = 8.28; P -value $< 1 \times 10^{-8}$) followed by TEC_206301_at (Fold Change in pediatric KMT2A/MLL-R⁺ AML cells = 2.2; P -value $< 1 \times 10^{-8}$; Fold Change in adult KMT2A/MLL-R⁺ AML cells = 1.73; P -value $< 1 \times 10^{-8}$) [Supplementary Figures 4 and 5; Supplementary Tables 7 and 8].

We next compared the PTK gene expression profiles of leukemic cells from pediatric and adult KMT2A/MLL-R⁺ AML cells to the PTK gene expression profiles of AML cells without KMT2A/MLL rearrangements from the corresponding control AML patients in the “other” categories (Children, $N = 190$; Adults, $N = 504$). In pediatric patients with KMT2A/MLL-R⁺ AML, the gene expression levels for FLT3, BTK, SYK, JAK2/JAK3, as well as several SRC family PTK were differentially amplified [Figure 4; Supplementary Table 9]. In adults with KMT2A/MLL-R⁺ AML, the gene expression levels for SYK, JAK family kinase TYK2, and the SRC family kinases FGR and HCK were differentially amplified [Figure 5; Supplementary Table 10].

The FLT3-ITD⁺ subset ($N = 48$) among the pediatric AML patients exhibited upregulated FLT3 expression when compared to non-leukemic control samples ($N = 74$) [Supplementary Figure 6; Supplementary Table 11] as well as FLT3-ITD⁻ pediatric AML cases ($N = 189$) [Supplementary Figure 7; Supplementary Table 12]. Comparing 189 cases of FLT3-ITD⁻ samples with 48 cases of FLT3-ITD⁺ pediatric AML samples (GSE17855) exhibited 13 differentially expressed probesets, of which four probesets were significantly upregulated in pediatric FLT3-ITD⁺ cases. FLT3_206674_at was the most significantly upregulated probeset (Fold Change = 1.96; P -value $< 10^{-8}$) followed by BTK_205504_at (Fold Change = 1.25; P -value = 9.8×10^{-4}) and TEC_206301_at (Fold Change = 1.23; P -value = 0.0025) [Supplementary Figure 7; Supplementary Table 12].

A comparison of the 88 KMT2A/MLL-R⁺ pediatric AML cases with 47 FLT3-ITD⁺ pediatric AML cases showed 31 differentially expressed probesets, of which 24 probesets were significantly upregulated in pediatric KMT2A/MLL-R⁺ cases. FGR_208438_s_at was the most significantly upregulated transcript (Fold Change = 4.40; P -value $< 10^{-8}$) followed by SYK_207540_s_at (Fold Change = 3.81; P -value $< 10^{-8}$) and JAK1_1552611_a_at (Fold Change = 2.78; P -value $< 10^{-8}$). ERBB1_1565483_at was the most significantly downregulated transcript in KMT2A/MLL-R⁺ cases (Fold Change = 0.56; P -value $< 10^{-8}$) followed by ERBB1_1565484_x_at (Fold Change = 0.57; P -value = 2.5×10^{-8}) and MERTK_211912_at (Fold Change = 0.73; P -value = 0.0016) [Supplementary Figure 8; Supplementary Table 13].

A comparison of the 88 KMT2A/MLL-R⁺ pediatric AML cases with 71 cases of FLT3-ITD⁺/NPM1⁺/CEBPA⁺ pediatric AML cases exhibited 34 differentially expressed probesets, of which 26 probesets were significantly upregulated in the KMT2A/MLL-R⁺ subset. FGR_208438_s_at was the most significantly upregulated probeset (Fold Change = 4.31; P -value $< 10^{-8}$) followed by SYK_207540_s_at (Fold Change = 3.92; P -value $< 10^{-8}$) and HCK_208018_s_at (Fold Change = 2.86; P -value $< 10^{-8}$). ERBB1_1565483_at was the most significantly downregulated transcript in KMT2A/MLL-R⁺ cases (Fold Change = 0.55; P -value $< 10^{-8}$)

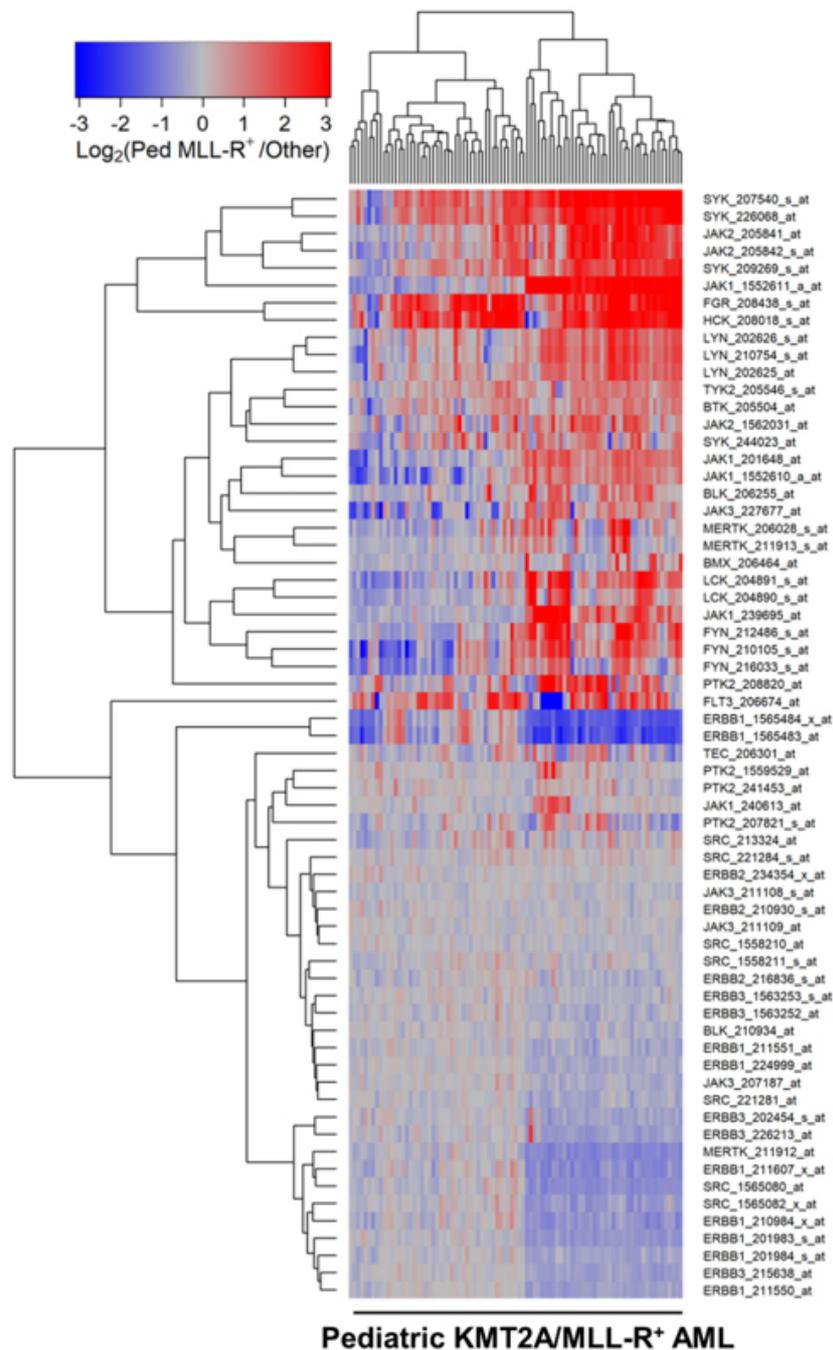

Figure 4. Gene Expression Levels for Tyrosine Kinases in Leukemic Cells from Pediatric Patients with KMT2A/MLL-R⁺ AML vs. Other subsets of AML without KMT2A/MLL rearrangements. Probeset level normalized signal values from the archived data sets GSE17855 and GSE19577 were examined in these comparisons. The cluster figure displays the expression levels in KMT2A/MLL-R⁺ AML cells mean centered to the reference group (non-KMT2A/MLL-R⁺ other AML subsets) for log₂-transformed fold change values (blue to red color indicates under-expression to over-expression respectively in KMT2A/MLL-R⁺ samples). Co-regulated probesets are organized and depicted by dendrograms for both probesets (rows) and patients (columns). Comparing 190 cases of non-KMT2A/MLL-R⁺ other samples (GSE17855) with 89 cases of KMT2A/MLL-R⁺ pediatric AML samples [GSE17855 (N = 47) and GSE19577 (N = 42)] exhibited 38 differentially expressed probesets, of which 25 probesets were significantly upregulated in pediatric KMT2A/MLL-R⁺ subset of cases. FGR_208438_s_at was the most significantly upregulated transcript (Fold Change = 4.31 P-value < 10⁻⁸) followed by SYK_207540_s_at (Fold Change = 4.01; P-value < 10⁻⁸) and HCK_208018_s_at (Fold Change = 3.97; P-value < 10⁻⁸) [Supplementary Table 9]. SYK (3 probesets), JAK2 (2 probesets), JAK1, FGR and HCK formed a cluster of patients with significantly higher expression levels in KMT2A/MLL-R⁺ cases.

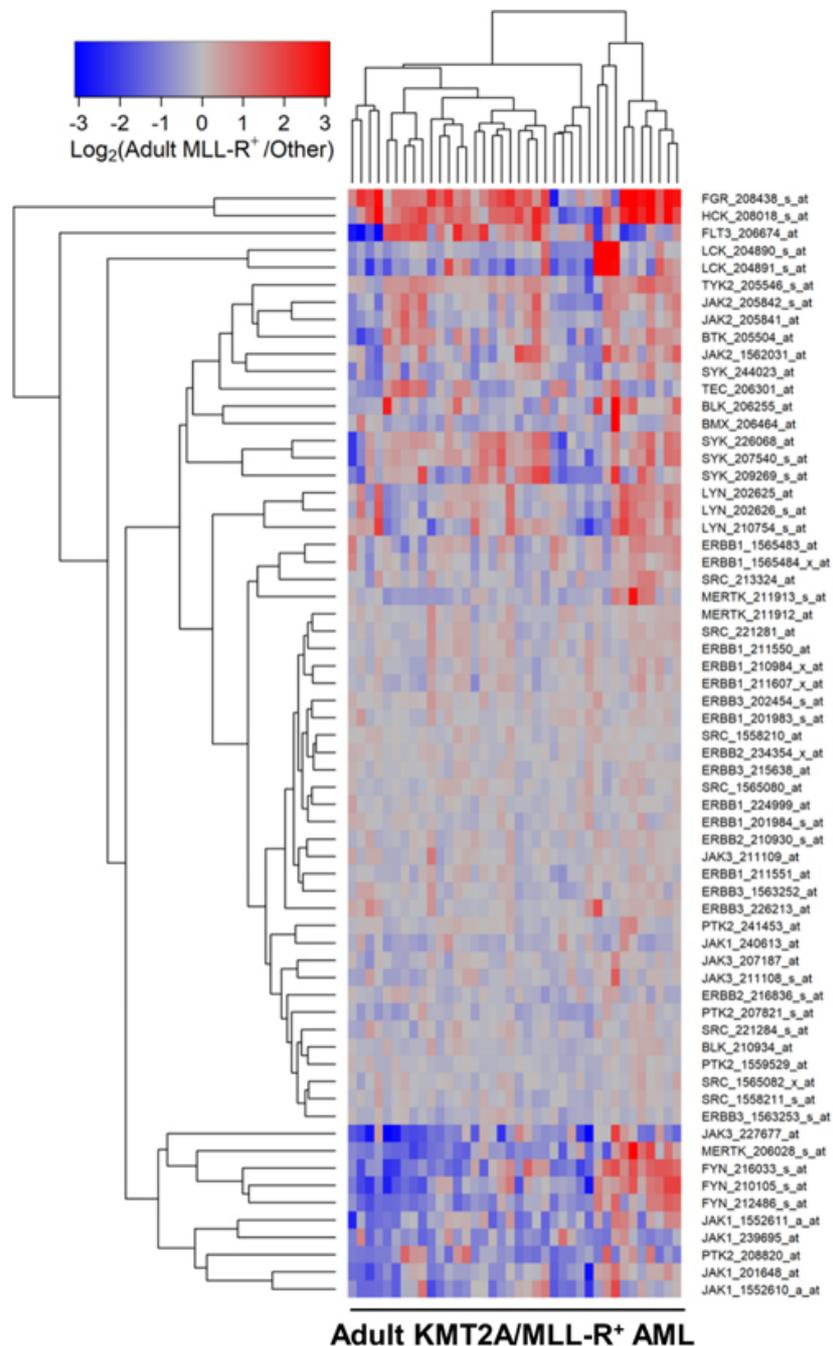

Figure 5. Gene Expression Levels for Tyrosine Kinases in Leukemic Cells from Adult Patients with KMT2A/MLL-R⁺ AML vs. Other subsets of AML without KMT2A/MLL rearrangements. Probeset level normalized signal values from the archived data set GSE13159 were examined in these comparisons. The cluster figure displays the expression levels in KMT2A/MLL-R⁺ AML cells mean centered to the reference group (other AML subsets without KMT2A/MLL rearrangements) for log₂-transformed fold change values (blue to red color indicates under-expression to over-expression respectively in KMT2A/MLL-R⁺ samples). Co-regulated probesets are organized and depicted by dendrograms for both probesets (rows) and patients (columns). Side-by-side comparison of 38 adult MLL-R⁺ AML cases with 504 other non-MLL-R⁺ adult AML cases resulted in 15 dysregulated probesets, of which 6 were upregulated in the adult KMT2A/MLL-R⁺ subset of cases. FGR_208438_s_at was the most significantly upregulated probeset (Fold Change = 2.46; *P*-value < 10⁻⁸) followed by HCK_208018_s_at (Fold Change = 2.1; *P*-value < 10⁻⁸) and TYK2_205546_s_at (Fold Change = 1.29; *P*-value = 0.0012) [Supplementary Table 10]. Cluster visualization of the mean centered expression values suggested co-regulation of CD33 with BTK, TYK2 and SYK (3 probesets).

followed by ERBB1_1565484_x_at (Fold Change = 0.56; P -value < 10^{-8}) and MERTK_211912_at (Fold Change = 0.72; P -value = 1.5×10^{-4}) [Supplementary Figure 9; Supplementary Table 14].

DISCUSSION

The outcome of KMT2A/MLL-R⁺ AML and B-ALL patients, especially those with relapsed or refractory leukemia, is disappointingly poor after contemporary treatments^[3,5-8,10-14]. New treatment strategies are urgently needed for both KMT2A/MLL-R⁺ AML and KMT2A/MLL-R⁺ ALL. Therefore, a large panel of drugs are being evaluated as potential therapeutic agents against KMT2A/MLL-R⁺ AML and ALL, including inhibitors of Menin-MLL1 interaction^[25-28]. The present study demonstrates that PTK inhibitors (PTKi), especially inhibitors of FLT3, may have clinical impact potential as therapeutic agents against KMT2A/MLL-R⁺ B-ALL as well as AML. Further, inhibitors of SRC family PTK may be clinically useful against KMT2A/MLL-R⁺ B-ALL and inhibitors of BTK, SYK, and JAK family PTK may be clinically useful against KMT2A/MLL-R⁺ AML. If our observations in this small series are confirmed in a larger series of leukemia patients, preferably with corresponding proteomics/phosphoproteomics data, proof-of-concept studies with FDA-approved PTKi would be warranted to further evaluate the clinical potential of PTK targeting in KMT2A/MLL-R⁺ ALL and AML.

PTK play a critical role in normal lymphohematopoiesis, and they have also been implicated as leukemogenic oncoproteins in the development of acute and chronic leukemias^[29-31]. The incorporation of PTKi into the standard of care has caused a paradigm shift in the treatment of CML (PTKi: ABL1 and SRC inhibitors), CLL (PTKi: BTK inhibitors), Ph⁺ B-ALL (PTKi: ABL1 and SRC inhibitors), and AML with *FLT3* mutations (PTKi: FLT3 inhibitors)^[29,30]. There is growing consensus regarding their evolving role in Ph-like B-ALL (PTKi: ABL1, SRC, TRK, FLT3 and JAK inhibitors) and pre-B ALL with t(1;19) (PTKi: BTK and SRC inhibitors)^[30-53] [Table 1]. Notably, Ph⁺ B-ALL was associated with a very poor outcome in both children and adults, with less than 20% long-term survival until the introduction of PTKi capable of inhibiting the oncogenic BCR-ABL tyrosine kinase^[36-48] [Table 1]. Due to very high rates of deep complete remissions and markedly improved long-term EFS and OS achieved with combinations of PTKi and standard chemo- or biotherapy, patients with Ph⁺ B-ALL are no longer considered to have a poor prognosis. The standard of care is being optimized by developing novel combinations of PTKi such as dasatinib and ponatinib with bispecific antibodies such as blinatumomab, CAR-T cells, and antibody-drug conjugates and using less toxic chemotherapy regimens^[36-48]. Likewise, FLT3 inhibitors have contributed to improved outcomes in AML patients with a *FLT3* mutation^[49]. FLT3 is a receptor tyrosine kinase that plays an important role in normal lymphohematopoiesis^[50]. Leukemic cells from AML patients abundantly express FLT3 and many AML patients have activating mutations of FLT3, including internal tandem duplication mutations (FLT3-ITD) and kinase domain activation loop mutations (FLT3-ALM)^[50,51]. *FLT3* mutations are rare in ALL, but a high-level expression of FLT3 was also reported in MLL-AF4 positive ALL patients and showed poor prognostic value^[52,53]. Our study significantly expands the knowledge regarding FLT3 expression in ALL as well as AML by demonstrating amplified expression levels in infants, children, and adults with KMT2A/MLL-R⁺ B-ALL and children with KMT2A/MLL-R⁺ AML. Several PTKi have been approved for the treatment of AML with *FLT3* mutations, including midostaurin and gilteritinib [Table 1]. Our results suggest that FLT3 inhibitors may have clinical potential as therapeutic agents against KMT2A/MLL-R⁺ ALL. It is noteworthy that Dovitinib, a multi-functional PTKI with FLT3 inhibitory activity, was reported to exhibit nanomolar in vitro activity against KMT2A/MLL-R⁺ ALL cells^[54].

One of the intriguing findings of our study relates to the amplified expression of the gene for FLT3 in KMT2A/MLL-R⁺ pediatric AML cells. Except for GSE17855, the archived datasets used in the present study did not contain information about the FLT3 status of the respective leukemia cases. Additional

Table 1. FDA-approved Inhibitors of FLT3, ABL1, SRC, BTK/TEC, KIT, SYK, and JAK1-3

Target kinase	Drug	Brand
ABL1, SRC	Bosutinib	Bosulif, SKI-606
ABL1, SRC, FGR, CKIT	Dasatinib	BMS- 354825, Sprycell
ABL1, CKIT, PDGFR	Imatinib	STI571, Gleevec
ABL1	Nilotinib	AMN107, Tassigna
ABL1	Olverembatinib	HQP1351
ABL1, SRC, FGR	Ponatinib	Iclusig
BTK/TEC	Ibrutinib	PCI-32765, Imbruvica
BTK	Zanubrutinib	BGB3111, Brukinsa
BTK	Acalabrutinib	Calquence
FLT3	Midostaurin	CPG 41251, Rydapt
FLT3	Gilteritinib	ASP2215, Xospata
JAK1	Upadacitinib	ABT-494, Rinvoq
JAK1/2	Baricitinib	Olumiant, LY 3009104
JAK1/2/3, Tyk	Ruxolitinib	Jakafi
JAK2	Fedratinib	TG101348, Inrebic
JAK3	Tofacitinib	Xeljanz
KIT/PDGFR	Ripretinib	DCC- 2618, Qinlock
SYK	Fostamatinib	R788, Tavalisse
TRKA/B/C	Larotrectinib	LOXO-101, Vitrakvi
TRKA/B/C, ROS1	Entrectinib	RXDX-101, Ignyta, Rozlytrek
VEGFR2, FLT3, CKIT	Sunitinib	Sutent

KMT2A/MLL-R⁺ patients whose leukemia cells do not have amplified FLT3 gene expression but an activating *FLT3* mutation like FLT3-ITD may also benefit from the use of FLT3 inhibitors. Analysis of the GSE17855 contributed to our finding that in pediatric patients with KMT2A/MLL-R⁺ AML, the gene expression level for FLT3 is differentially amplified. It is noteworthy that only one patient with KMT2A/MLL-R⁺ AML had FLT3-ITD whereas 47 patients from the KMT2A/MLL-R negative “other” group of pediatric AML patients were FLT3-ITD⁺, including patients with cytogenetically normal AML ($N = 18$); AML with inv^{t(16)} ($N = 1$); AML with t(15;17) ($N = 12$); AML with t(8;21) ($N = 3$); AML with other cytogenetic features ($N = 9$); and AML with unknown cytogenetic features ($N = 4$). Therefore, our results should not be interpreted to suggest that FLT3 inhibitors would be preferentially active in pediatric AML patients with KMT2A/MLL rearrangements, as many cases without KMT2A/MLL rearrangements whose leukemia cells are FLT3-ITD⁺ may also benefit from FLT3 inhibitors. Some PTK, such as FLT3, participate in immune suppression mediated by leukemia cells, which may promote the immune escape of leukemic clones^[55]. Therefore, their inhibition with PTKi may partially contribute to favorable treatment outcomes by lifting the immune suppression. For example, the PTKi sorafenib has been shown to abrogate the transcriptional downregulation of interferon regulatory factor 7 (IRF7), which resulted in an augmented CD8⁺CD107a⁺IFN- γ ⁺ T cell response in mouse models of FLT-ITD⁺ AML^[55]. Mathew *et al.* proposed that sorafenib may therefore exhibit immune-mediated anti-leukemic activity in FLT3-ITD mutant AML^[55].

The SRC kinase family includes several cytoplasmic PTK, including BLK, HCK, FGR, LYN, FYN, and LCK, which have important regulatory functions for signal transduction pathways related to survival, proliferation, and apoptosis of leukemic cells^[29-31]. FDA-approved SRC kinase inhibitors have become part of the standard of care in the treatment of CML as well as Ph⁺ ALL^[36-48] [Table 1]. In the current study, we discovered the amplified expression of the genes for BLK, HCK, FGR as well as LYN in primary leukemic cells from infants, children as well as adults with KMT2A/MLL-R⁺ B-ALL. The gene for BLK was expressed

at a 6.77-fold higher level in infant KMT2A/MLL-R⁺ ALL cells, 4.38-fold higher level in pediatric KMT2A/MLL-R⁺ ALL cells, and 21.79-fold higher level in adult KMT2A/MLL-R⁺ ALL cells than in normal hematopoietic cells. Notably, the expression of the genes for BLK, HCK and LYN in primary leukemic cells from KMT2A/MLL-R⁺ ALL patients was differentially and significantly amplified regardless of the age group compared to the expression levels in leukemic cells from B-ALL patients without KMT2A/MLL gene rearrangements. Likewise, the genes of several SRC family PTK were differentially upregulated in pediatric and adult KMT2A/MLL-R⁺ AML cells. The availability of FDA-approved potent inhibitors of SRC family PTK such as ponatinib, bosutinib, and dasatinib [Table 1] provides an opportunity to evaluate their clinical impact potential for KMT2A/MLL-R⁺ leukemias in proof-of-concept clinical trials. The insights and lessons learned in the clinical development of these PTKi as precision medicines against Ph⁺ ALL should facilitate their development as potential precision medicines against KMT2A/MLL-R⁺ ALL as well.

Additional insights from the present study relate to the upregulation of SYK and JAK expression in pediatric and adult KMT2A/MLL-R⁺ acute leukemias. These results extend our earlier studies regarding upregulation of the JAK-STAT pathways in infant B-ALL^[56,57] and upregulation of SYK expression in pediatric B-ALL^[58-62]. The availability of FDA-approved potent inhibitors of SYK and JAK provides the opportunity to evaluate their clinical efficacy in KMT2A/MLL-R⁺ acute leukemias with overexpression of their respective targets. A significant portion of high-risk acute leukemia patients, especially those with KMT2A/MLL-R⁺ ALL or AML relapse after being treated on contemporary chemotherapy protocols due to cancer drug resistance of their leukemic clones, and the survival outcome of available salvage regimens is disappointing due to the short nature and poor quality of second remissions. We previously reported that the JAK/STAT signaling pathway is constitutively active in infant pro-B ALL cells and treatment with a JAK3 inhibitor or a pan-JAK kinase inhibitor effectively triggered their apoptosis^[56,57]. JAK targeting with a small molecule inhibitor may be a viable strategy to overcome cancer drug resistance in KMT2A/MLL-R⁺ B-ALL cells. Constitutively active JAK2-STAT5 signaling has been shown to be associated with increased surface PD-L1 expression due to amplified PD-L1 promoter activity in myeloproliferative neoplasms, which may facilitate PD-L1-mediated immune escape^[63,64]. JAK2 inhibition reduces the PD-L1 expression levels and may therefore mitigate this risk.

SYK has been discovered to regulate the cancer drug resistance-related anti-apoptotic STAT3, NF- κ B as well as PI-3K-AKT-mTOR pathways^[60-62]. Our earlier studies have identified high-level SYK expression as a likely contributor to cancer drug resistance and relapse in B-ALL^[60,61]. Upregulation of SYK expression was associated with significant upregulation of at least one of the STAT3 target genes^[60]. Inhibition of SYK caused apoptotic death in primary leukemia cells from B-ALL patients that are resistant to chemotherapy^[61]. Notably, a nanomedicine candidate containing the SYK-inhibiting small molecule compound 1,4-bis(9-O-dihydroquinidyl) phthalazine/hydroquinidine 1,4-phthalazinediyl diether (C61) was capable of destroying > 99.9% of clonogenic B-ALL cells in vivo and thereby improved the event-free survival outcome of SCID mice challenged with otherwise invariably fatal doses of human leukemic B-cell precursors in each of three different xenograft models of chemotherapy-resistant human B-ALL^[62]. Taken together with these earlier observations, the amplified expression of SYK in the poor prognosis KMT2A/MLL-R⁺ ALL patients prompts the hypothesis that SYKi may help overcome the cancer drug resistance of relapse clones and thereby provide the foundation for more effective multi-modality treatment regimens for KMT2A/MLL-R⁺ acute leukemias.

DECLARATIONS

Authors' contributions

Designed the evaluations reported in this paper, directed the data compilation and analysis, and prepared the initial draft of the manuscript: Uckun FM

Performed statistical and bioinformatic analyses: Qazi S
Analyzed, validated data and reviewed and revised the manuscript, and provided final approval for submission of the final version: Uckun FM, Qazi S

Availability of data and materials

All data are presented in the manuscript and the Supplemental Material. The publicly available archived databases that were used to generate the data have been provided in Materials and Methods. Specifically, raw Affymetrix .CEL data files on gene expression profiles of AML cells analyzed in the current study were obtained from 3 publicly available datasets deposited in the NCBI repository (GSE13159, GSE19577, and GSE17855). Raw Affymetrix .CEL data files on gene expression profiles of ALL cells analyzed in the current study were obtained from 8 publicly available datasets deposited in the NCBI repository (GSE11877, GSE13159, GSE13351, GSE18497, GSE28460, GSE7440, GSE68720, and GSE32962).

Financial support and sponsorship

This study received funding from Ares Pharmaceuticals.

Conflicts of interest

All authors declared that there are no conflicts of interest.

Ethical approval and consent to participate

IRB approval was not required as the analysis of de-identified, publicly available data does not constitute human subjects research as defined at 45 CFR 46.102.

Consent for publication

Not applicable.

Abstract

Tumor heterogeneity can contribute to the development of therapeutic resistance in cancer, including advanced breast cancers. The object of the Halifax project was to identify new treatments that would address mechanisms of therapeutic resistance through tumor heterogeneity by uncovering combinations of therapeutics that could target the hallmarks of cancer rather than focusing on individual gene products. A taskforce of 180 cancer researchers, used molecular profiling to highlight key targets responsible for each of the hallmarks of cancer and then find existing therapeutic agents that could be used to reach those targets with limited toxicity. In many cases, natural health products and re-purposed pharmaceuticals were identified as potential agents. Hence, by combining the molecular profiling of tumors with therapeutics that target the hallmark features of cancer, the heterogeneity of advanced-stage breast cancers can be addressed.

Keywords: Breast cancer, chemoresistance, drug resistance, targeted therapy

Breast cancer is a consequence of complex epigenetic and genetic alterations. The heterogeneity and

evolution within breast cancers underpin tumor progression, as well as therapeutic resistance^[1-3]. In recent years, significant efforts have focused on addressing therapeutic options that can address tumor heterogeneity in breast cancer^[4-6]. This is particularly important in triple-negative breast cancers and metastatic breast cancers because many patients with advanced breast cancers will succumb to their disease as tumor heterogeneity gives rise to therapeutic resistance^[7-9] [Figure 1].

To address the challenge of therapeutic resistance and tumor heterogeneity, a group of 180 cancer researchers collaborated in “The Halifax Project” to consider combinations of agents that might be employed^[10]. In this effort, twelve teams of researchers were organized around the Hallmarks of Cancer^[11] and tasked to identify high-priority targets along with corresponding therapeutic agents that could reach those targets with limited toxicity. The hallmarks used are attributes ultimately found in most cancers (i.e., genomic instability, sustained proliferative signaling, tumor-promoting inflammation, evasion of anti-growth signaling, resistance to apoptosis, replicative immortality, dysregulated metabolism, immune system evasion, angiogenesis, tissue invasion and metastasis, and an accommodating tumor micro-environment). The overarching goal was to identify a significant number of agents that have limited to no toxicity, that might be combined to reach a multitude of key targets simultaneously.

Cancer is caused by an array of mutations and genomic events that coordinate to activate aberrant pathways. To address this complexity, we used the Hallmarks of Cancer as an organizing framework. We then focused on the development of a “broad-spectrum” methodology and therapeutic agents that could be combined using this approach. In particular, we focused on identifying natural health products (NHPs) and re-purposed pharmaceuticals, because both are readily available, often well tolerated, and broadly applicable to many cancers^[10,12-22]. A detailed rationale for the methodology was provided and it was determined that it should be feasible from a safety standpoint and relatively inexpensive to implement^[23].

In the table below [Table 1] we have provided a sampling of NHP with updated references to show how these agents act on key mechanisms and pathways across the hallmarks of cancer^[10-22].

Some NHPs, such as curcumin and resveratrol, target multiple signaling networks and pathways simultaneously which is attractive molecular promiscuity^[68,69]. The appropriate selection of NHPs can also offer synergies for chemotherapy and radiation therapy treatment. For example, curcumin, resveratrol, tocotrienol, garcinol and quercetin have a mechanism of action that increases chemosensitivity^[70,71] and can reduce chemoresistance. While other NHPs, such as ellagic acid, diindolylmethane, and berberine, can increase radiation sensitivity^[72-74].

Other NHPs, such as gingerol and curcumin can also protect normal (healthy) cells from adverse toxicity from cytotoxic agents^[75,76]. Thus, NHPs have many features that may designate them particularly suited as agents that might be used in situations where tumor heterogeneity has resulted in chemoresistance.

In particular, for breast cancer, the presence of subpopulations of cancer stem cells (CSCs) is known to be one cause of chemo-resistance and ultimately contributes to therapeutic relapse^[77]. Notably, there are specific NHPs such as sulforaphane, curcumin, genistein, resveratrol, lycopene, and epigallocatechin-3-gallate that have been shown to promote cell cycle arrest and apoptosis in triple-negative breast cancer cells and which have also been shown to inhibit important CSC pathways, such as NF- κ B, PI3K/Akt/mTOR, Notch 1, Wnt/ β -catenin, and YAP^[78].

Table 1. Aligning targets with the hallmarks of cancer

Cancer hallmark	Examples of potential agents	Key mechanism or pathway
Genomic instability	Allyl Isothiocyanate ^[24] Chrysin ^[25] Plumbagin ^[26]	DNA damage and condensation DNA double-strand break repair DNA damage
Sustained proliferative signaling	Resveratrol ^[27] Perillyl alcohol ^[28] Artemisinin ^[29]	Cell cycle Cell cycle Cell cycle
Tumor-promoting Inflammation	Rosmarinic acid ^[30] Berberine ^[31] Curcumin ^[32] Punica granatum L ^[33]	NF3 kappaB-p53-caspase-3 pathways NLRP3 Inflammasome pathway Nuclear factor-κB (NF-κB) miRNA-27a and miRNA-155
Evasion of anti-growth signaling	Deguelin ^[34] Luteolin ^[35] Withaferin A ^[36,37] Curcumin ^[38]	EGFR-p-AKT/c-Met p-ERK AKT/mTOR pathway Notch2 SLC1A5-mediated ferroptosis
Resistance to apoptosis	EGCG ^[39] Gossypol ^[40] Triptolide ^[41] Kaempferol ^[42] Berberine ^[43,44]	P53/Bcl-2 pathway miRNA expression of many apoptosis related genes p38/Erk/mTOR Bcl2 Bcl2 (and many other pathways)
Replicative immortality	Curcumin ^[45,46] Silibinin ^[46] Coumestrol ^[47] Diosmin ^[48]	Telomerase expression Telomerase expression Protein kinase CKII Senescence

FAK: Focal adhesion kinase; EGCG: epigallocatechin gallate; VEGF: vascular endothelial growth factor.

In addition to NHPs, there are also many existing pharmaceuticals that could provide additional targeting options. Numerous commonly prescribed non-oncology drugs possess multi-targeted anti-cancer effects. Pharmaceuticals already on the market have significant safety records and robust drug-drug interaction data compared to natural products and several researchers have looked at the effects of existing pharmaceuticals as it relates to relapse. Retsky (2012, 2020), for example, observed that the perioperative use of the NSAID analgesic ketorolac appears to reduce early relapse following mastectomy in breast cancer^[79,80]. Hence, the use of both NHPs and repurposed pharmaceuticals to reach a broad-spectrum of molecular targets could be useful in developing personalized treatment protocols^[81] [Figure 2].

Although our proposed approach has many potential advantages, there are challenges to conducting validating clinical studies. First, there is a shortage of funding for this type of initiative due to lack of patentability, manufacturing difficulties, contamination, and lack of product consistency^[82]. Second, the use of NHPs among cancer patients is quite common. In fact, many patients who use them do not share the details with their physicians because they feel their physicians are not knowledgeable or will be indifferent

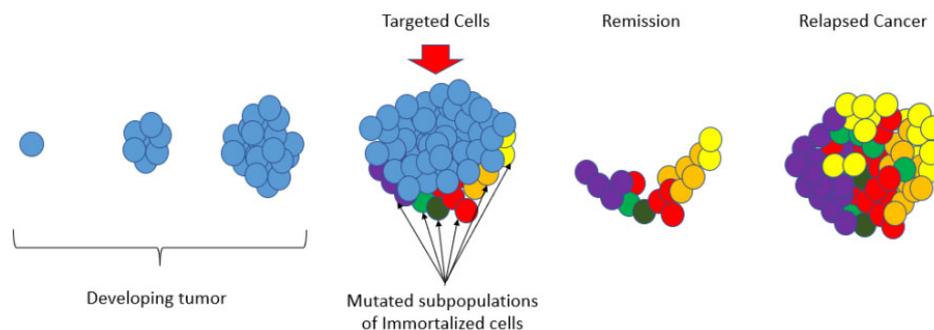

Figure 1. Therapeutic resistance - Developing tumors begin with a single immortalized cell that may have a single therapeutic target that can act to stop those cells from replication. For example, Tamoxifen (TAM) is the most common therapy used for the treatment of estrogen receptor-positive (ER+) breast cancer and it is used successfully in many cases. However, there are advanced-stage breast cancers that are plagued with mutated subpopulations of immortalized cells and cancer stem cells that play a key role in breast cancer progression, and metastasis. In these cancers, a single targeted therapy may produce a remission by successfully arresting some of the immortalized cells that have been targeted. However, if the remaining subpopulations of cells are driven by different mechanisms and prove to be chemoresistant, they will persist during remission and ultimately produce a relapsed cancer that is fully refractory to the initial treatment or combination of treatments.

Combinations of NHPs and repurposed pharmaceuticals

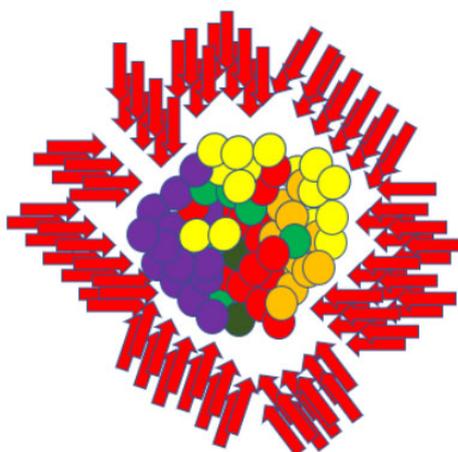

Figure 2. A broad-spectrum approach - In a broad-spectrum approach, heterogeneous subpopulations of chemoresistant immortalized cells are not targeted using a single targeted therapy or even a combination of 2-3 chemotherapy agents. Instead, a significant number of low toxicity agents are aimed at a multitude of key pathways/mechanisms simultaneously. Since most immortalized cells are driven by the pathways/mechanisms described in the Hallmarks of Cancer framework^[11], this approach increases the chance that a significant number of synergistic effects will be produced (i.e., since each affected cell will potentially be acted on in a multitude of ways).

or negative toward their use^[83,84]. Finally, NHPs have yet to be approved by the FDA and although many NHPs are available as supplements and generally well-tolerated over an extended duration, the clinical evidence for these agents is often weak or non-existent.

One example of how NHPs can be used to improve the treatment of breast cancer is that NHPs have been shown to combine with Tamoxifen synergistically in inhibition of tumor cell growth, improved Tamoxifen sensitivity and reduction of Tamoxifen side effects^[85]. However, some NHPs showed estrogen-like activity, which could reduce the effect of Tamoxifen, underscoring the need for a detailed analysis of any protocol that combines a multitude of agents^[85]. They did find that some NHPs (e.g., morin, silybin, epigallocatechin gallate, myricetin, baicalein, curcumin, kaempferol, and quercetin) helped to increase the bioavailability of

Tamoxifen *in vivo*. These promising observations suggest that NHPs with Tamoxifen are worthy of clinical studies.

Some NHPs are used to support cancer therapy by clinicians who practice integrative oncology; however, these physicians are typically less familiar with the molecular mechanisms of cancer signaling^[86]. Instead, integrative oncology mainly focuses on the treatment of cancer-related symptoms such as acupuncture for nausea, exercise for sleep, and anxiety^[86]. Indeed, a survey of clinics in Washington State showed that more than 72 oral or topical, nutritional, botanical, fungal and bacterial-based medicines had been used during the first year of care of the female breast cancer patients studied ($n = 324$)^[87]. Since most of these agents are not aimed at the molecular mechanisms of cancer, the use of NHPs for these purposes would typically not include the type of analysis that would be needed to target tumor heterogeneity.

We highlight this approach as an important avenue that should be investigated further because the idea of reaching many key targets simultaneously makes sense given what is now known about the biology of cancer. Importantly, this is not something that has been attempted previously. Clinical trials of NHPs that have been undertaken typically involve single agents or limited combinations of agents at best. We speculate the use of combinations of NHPs that are able to hit multiple targets is most likely to be clinically effective.

The goal should be to provide a clinical treatment protocol that makes a rational utilization of the evidence base. If this approach is to work, future efforts utilizing NHPs and repurposed pharmaceuticals will require clinical studies involving unique combinations of dozens of agents in protocols that are tailored/personalized for each patient. The agents that are used will therefore need to be carefully considered for potential interactions, and some of these agents may have shown limited or no activity when used individually. Until there is clinical research that fully explores the synergies that can be produced when a significant number of pathways are targeted simultaneously, the true potential of combining these actions all at once will simply not be known.

Finally, we acknowledge that what we are proposing would require a change from phased clinical trials. A case series or a cohort study might be a more appropriate means to document the results of experimental efforts of this nature^[88], since each patient will require an individualized protocol. We do believe that such an approach may be able to help address the challenges of therapeutic resistance that emerge in many breast cancers.

Abstract

Purpose/Objective(s): Discovery of genetic drivers of radioresistance is critical for developing novel therapeutic strategies to combine with radiotherapy of radioresistant PDAC. In this study, we used genome-wide RNA-seq to identify genes upregulated in generated radioresistant PDAC cell lines and discovered the Inhibitor of DNA Binding 1 (ID1) gene as a potential regulator of radioresistance in PDAC.

Materials/Methods: Radioresistant clones of the PDAC cell lines MIA PaCa-2 and PANC-1 were generated by delivering daily ionizing irradiation (IR) (2 Gy/day) *in vitro* over two weeks (total 20 Gy) followed by standard clonogenic assays following one week from the end of IR. The generated RR and parental cell lines were submitted for RNA-seq analysis to identify differentially expressed genes. The Limma R package was used to calculate differential expression among genes. Log₂ fold change values were calculated for each sample compared to the control. Genes with an absolute fold change > 1 were considered significant. RNA sequencing expression data from the Cancer Genome Atlas (TCGA) database was analyzed through the online databases GEPIA, cBioPortal, and the Human Protein Atlas.

Results: Following exposure to two weeks of 2 Gy daily IR *in vitro*, the two PDAC cell lines showed significantly greater clonogenic cell survival than their parental cell lines, indicating enhanced RR in these cells. RNA-seq analysis comparing parental and RR cell lines found upregulated seven genes (TNS4, ZDHHC8P1, APLNR, AQP3, SPP1, ID1, ID2) and seven genes downregulated (PTX3, ITGB2, EPS8L1, ALDH1L2, KCNT2, ARHGAP9, IFI16) in both RR cell lines. Western blotting confirmed increased expression of the ID1 protein in the RR cell lines compared to their parental cell lines. We found that ID1 mRNA was significantly higher in PDAC tumors compared to matched normal and high ID1 expression correlated with significantly worse disease-free survival (DFS) in PDAC patients (HR = 2.2, log rank $P = 0.009$). ID1 mRNA expression was also strongly correlated in tumors with TP53 mutation, a known driver of radioresistance.

Conclusion: Our analysis indicates a novel role of ID1 in PDAC radioresistance. ID1 expression is higher in tumor tissue compared to normal, and high expression correlates with both worse DFS and association with the TP53 mutation, suggesting that targeting ID1 prior to IR is an attractive strategy for overcoming radioresistance in PDAC.

Keywords: Pancreatic cancer, radiation resistance, ID1, RNA-seq

INTRODUCTION

Pancreatic Ductal Adenocarcinoma (PDAC) is one of the most lethal solid tumors with a rapid progression course and poor prognosis, contributing to a 10% of five-year survival rate for all stages^[1]. By the year 2040, the incidence of PDAC is expected to increase from 56,000 to 96,000 cases, a 66% increase. Pancreatic cancer is projected to become the second leading cause of cancer-related death, killing ~46,000 patients yearly in the U.S. alone^[2]. The only hope for long-term survival in patients with localized PDAC is surgical resection of the tumor. However, upwards of 60% of the patients with potentially curable localized PDAC do not present with frank eligibility for surgical resection^[3], and therefore require an aggressive therapy regimen to reduce tumor burden enough to elicit removal. The standard course includes 3-6 months of multi-regimen genotoxic chemotherapies and, commonly, an additional 3-6 weeks of radiation therapy (RT). For most locally advanced PDAC patients, curative surgery will not be achieved despite these aggressive therapies due to the poor response of the tumor and thus remain unresectable. The rate of conversion from unresectable to resectable disease remains at a dismal ~15%^[4]. Unresected patients have nearly the same dismal survival rates as metastatic disease, with a prognosis of roughly 15-16 months and a poor quality of life^[5]. Why PDAC responds so poorly to typically effective strategies in other cancers is not entirely clear. It is speculated that the natural prevalence of robust DNA repair mechanisms in PDAC underlies resistance to genotoxic therapy^[6]. Therefore, understanding the biological underpinnings of radioresistant systems in PDAC is critical for uncovering vulnerabilities in the resistant phenotype.

In this study, we generated radiation-resistant (RR) PDAC cell lines *in vitro* by treating them with daily doses of ionizing radiation and allowing the cells to recover, followed by an analysis of the changes in gene expression. Through next-generation RNA sequencing (RNA-seq), we discovered several novel genes differentially expressed after RR, including the inhibitor of DNA binding-1 (ID1). The ID1 gene has been previously shown to be upregulated in pancreatic cancer cells following nicotine stimulation via a Src kinase-dependent fashion leading to chemoresistance to gemcitabine treatment. Furthermore, elevated ID1 was shown to correlate with worse overall survival in resected pancreatic cancer patients^[7]. Another study in pancreatic cancer showed ID1 uncouples TGF β -induced EMT from apoptosis leading to enhanced cell survival^[8]. The current study validates ID1 as a marker for radiation resistance in PDAC cells for the first time.

METHODS

Cell culture and materials

The human pancreatic adenocarcinoma cell lines MIA PaCa-2 and PANC1 were obtained from American Type Culture Collection (Manassas, VA) and maintained at 37 °C in 5% CO₂ in DMEM media and supplemented with 10% fetal bovine serum (Hyclone, Logan, UT) and penicillin/streptomycin (Life Technologies, Grand Island, NY).

Generation of radioresistant PDAC cell lines

Cells were subjected to 2 Gray (Gy) radiation daily for 5 days, and then allowed to recover for two weeks, followed by a second course of radiation of 2 Gy daily for 5 days for a total of 20 Gy. Throughout the irradiation process and recovery time, cells were kept at 40%-70% confluency to ensure the potential for exponential growth. After completion of the second week of radiation, cells were collected for protein lysates, plated as single cells for clonogenic assays, or submitted for whole genome sequencing. Radioresistance of the cell lines was verified by comparing the radiosensitivity of the radiation-selected cells (after a recovery period) with their respective parental cell lines by the clonogenic assay as described below.

Immunoblotting

Cell lysates were prepared using RIPA buffer (ThermoFisher, Waltham MA) supplemented with 1x protease (Complete, Roche, Indianapolis, IN) and phosphatase inhibitors (PhosSTOP, Roche, Indianapolis, IN, Roche), followed by protein quantification by the Dc protein assay kit (Bio-Rad, Hercules, CA). Equal amounts of protein were loaded and resolved by SDS/PAGE and transferred to nitrocellulose membranes. The ID1 (Santa Cruz sc-133104) and GAPDH (Cell Signaling D16H11) primary antibodies were allowed to bind overnight at 4 °C and used at a dilution of 1:100-1000. After washing in TBS-Tween, membranes were incubated with StarBright Goat Anti-Mouse/Rabbit IgG secondary antibodies (Bio-Rad) diluted 1:2500-1:5000 for 1 h. Membranes were washed with TBS-Tween and then imaged on the ChemiDoc MP Imaging System (Bio-Rad).

Radiation clonogenic assays

Cells were trypsinized to generate single cell suspensions and seeded onto 60 mm tissue culture plates in triplicate. Cells were then irradiated with various doses (0-8 Gy). Ten to 14 days after seeding, colonies were fixed with Methanol/Acetic Acid and stained with 0.5% crystal violet, and the numbers of colonies or colony forming units (CFU) containing at least 50 cells were counted using a dissecting microscope (Leica Microsystems, Inc. Buffalo Grove, IL) and surviving fractions calculated. Experiments were repeated multiple, independent times.

Experimental radiation

Irradiation was performed with the X-ray at 160 kV, 25 mA at a dose rate of approximately 113 cGy/min using an X-RAD 320 Biological Irradiator (Precision X-Ray Inc.).

RNA library construction and sequencing

Total RNA was isolated with the TRIzol Reagent protocol (ThermoFisher, Waltham, MA) from the parental and RR cell lines. RNA quality and concentration were estimated with Bioanalyzer 2100 and RNA 6000 Nano Kit (Agilent Technologies, Waldbronn, Germany). RNA-Seq libraries were prepared with Illumina TruSeq Stranded mRNA LT Sample Preparation Kit (Illumina, San Diego, CA) using 1 µg of total RNA according to the manufacturer's protocol. Sequencing was performed by the genomics core at UAMS on the NovaSeq 6000 platform (Illumina).

RNA-seq analysis

RNA-seq reads were quality-checked, trimmed, and aligned to the hg38 reference genome (accession: GCA_000001405.15) using the Nextflow RNAseq pipeline, nf-core/rnaseq (version 3.4) available at DOI 10.5281/zenodo.1400710. The resulting gene counts were transformed to log₂ counts per million (CPM)^[9]. Lowly expressed genes were filtered out and libraries were normalized by the trimmed mean of M-values^[10]. The Limma R package was used to calculate differential expression among genes^[11]. Log₂ fold change values were calculated for each sample compared to the control. Genes with an absolute fold change > 1 were considered significant.

Human patient data

The following websites were utilized to query for tumor and normal expression and clinical data for patients with PDAC in the TCGA: <https://cbioportal.org/>^[12], <http://gepia.cancer-pku.cn/>^[13], and <https://www.proteinatlas.org/>^[14].

Statistical analysis

For *in vitro* experiments, data are presented as the mean ± SEM for clonogenic survival. Statistical comparisons were made between the control and experimental conditions using the two-sided two-group *t*-tests with significance assessed at $P < 0.05$.

RESULTS

Generation of radioresistant cell lines

To generate RR cell lines, we delivered 10 Gy of IR (2 Gy/day) to PDAC MIA PACA-2 and PANC-1 cells *in vitro* over five days, followed by a recovery time of 2 weeks followed by a second course of 10 Gy in 2 Gy per day fractions followed by an additional two weeks of recovery [Figure 1]. In parallel, we cultured the parental cells and exposed them to 10 daily doses of sham radiation. Following the generation of RR cells, we performed radiation clonogenic assays comparing the parental and RR cells. In addition, we performed whole-genome sequencing on the parental controls and RR cells in triplicate using the next-generation NovaSeq 6000 RNA sequencer.

In both the PDAC cell lines, the generated RR cells showed increased clonogenic survival after exposure to increasing doses of radiation *in vitro* [Figure 2]. For example, at doses of 4 and 6 Gy, the RR cells displayed roughly 50% more clonogenic survival than the parental controls. These clonogenic assay results confirm the increased RR potential of our newly generated PDAC cell lines.

RNA-seq reveals changes in gene expression following RR

RNA-seq analysis comparing global expression levels in the RR cells to parental cells revealed notable differential expression profiles. In the MIA PACA-2 cell line, there was a total of 65 genes found to be upregulated in the RR cells and 136 genes downregulated (adj $P < 0.05$) [Figure 3A]. In the PANC-1 cells, there were a total of 222 genes upregulated in the RR cells and 156 genes downregulated (adj $P < 0.05$) [Figure 3B]. We found a total of 14 genes that were differentially expressed (adj $P < 0.05$) commonly between both the RR cell lines, including seven genes (TNS4, ZDHHC8P1, APLNR, AQP3, SPP1, ID1, ID2) upregulated, and seven genes (PTX3, ITGB2, EPS8L1, ALDH1L2, KCNT2, ARHGAP9, IFI16) that were downregulated.

The full list of genes differentially expressed in both cell lines, function, mutational rate in PDAC, and prior studies examining radiation sensitivity is displayed in Table 1. Most of these genes have some implications for radiation sensitivity, and the gene with multiple studies relating to RR was the ID1 gene. We next analyzed the publicly available cancer cell encyclopedia (CCLE) database, which has IC₅₀ treatment response

Table 1. Significantly upregulated genes in both radiation resistant pancreatic cell lines

Gene ID	Gene name	Cellular function*	Significantly upregulated genes	
			Mutational frequency in pancreatic cancer [^]	Association with radiation
APLNR	Apelin receptor	A member of the G protein-coupled receptor gene family. The encoded protein is related to the angiotensin receptor	5.5%	None
AQP3	Aquaporin 3	The water channel protein aquaporin 3. Aquaporin 3 is localized at the basal lateral membranes of collecting duct cells in the kidney	4.6%	AQP3 expression is downregulated by UVA irradiation ^[15]
ID1	Inhibitor Of DNA binding 1	A helix-loop-helix (HLH) protein that can form heterodimers with members of the basic HLH family of transcription factors. The encoded protein has no DNA binding activity and therefore can inhibit the DNA binding and transcriptional activation ability of basic HLH proteins with which it interacts	3.7%	1) In Glioblastoma, PGE2-mediated induction of ID1 is required for optimal tumor cell self-renewal and radiation resistance ^[16] . 2) ID1 overexpression in GBM cells increased radioresistance ^[17] . 3) Id1 and Id3 co-expression seems associated with a poor clinical outcome in patients with locally advanced NSCLC treated with definitive chemoradiotherapy ^[18] . 4) In GBM, a significant correlation ($P < 0.001$) was found between radiotherapy efficacy and ID1 expression levels with respect to overall survival and knockdown of ID1 increased radiosensitivity <i>in vitro</i> ^[19]
ID2	Inhibitor Of DNA binding 2	A helix-loop-helix (HLH) protein that can form heterodimers with members of the basic HLH family of transcription factors. The encoded protein has no DNA binding activity and therefore can inhibit the DNA binding and transcriptional activation ability of basic HLH proteins with which it interacts	0.9%	ID2 is induced in response to γ -irradiation ^[20]
SPP1	Secreted phosphoprotein 1	Involved in the attachment of osteoclasts to the mineralized bone matrix	1.8%	SPP1 regulates radiotherapy sensitivity of gastric adenocarcinoma via the Wnt/Beta-Catenin pathway ^[21]
TNS4	Tensin 4	Involved in protein localization. Located in focal adhesion	1.4%	None
ZDHHC8P1	ZDHHC8 pseudogene 1	Pseudogene	NA	None

data for the DNA damaging agent 5-Fluorouracil (5-FU) from 600 cancer cell lines including 27 PDAC cell lines. We compared the mRNA expression in the CCLE from each of the significant genes found in our RNA-seq experiment [Supplementary Figures 1 and 2]. We plotted mRNA expression against the IC₅₀ value for 5-FU. We found ID1 expression had the highest correlation and strongest *P*-values with higher treatment resistance to 5-FU using Spearman and Pearson correlation tests. These results strengthen our findings that ID1 is a marker for resistance to DNA damaging agents in PDAC. Therefore, we further characterized the ID1 gene as a potential mediator of RR in PDAC patients.

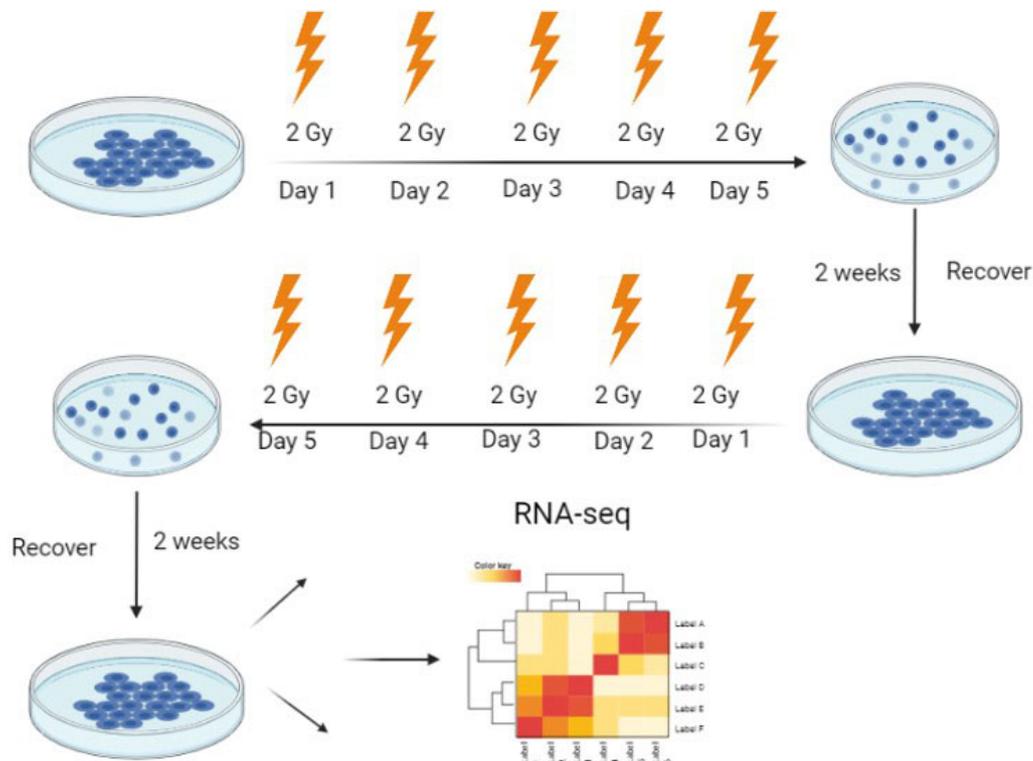

Figure 1. Generation of radioresistant (RR) PDAC cell lines. Schematic of the generation of RR sublines. Cell lines were exposed to 5 fractions of 2 Gy irradiation over one week and then allowed to recover for two weeks, followed by a second course of 5 fractions of 2 Gy over one week and an additional 2-week recovery period. Subsequently, RR cells were collected for RNA-seq analysis, western blotting, and sensitivity to radiation using the clonogenic assay to compare the parental and RR sublines and created with BioRender.com.

ID1 expression is increased following RT resistance

Following the generation of RR cell lines, we collected the protein lysates of the control and RR cell lines to test the expression of the ID1 protein. Western blotting revealed that ID1 protein expression was increased in the PANC-1 and MIA PACA-2 RR cells compared with parental PANC-1 and MIA PACA-2 cells [Figure 4A and B]. These results confirm the RNA-seq data showing increased ID1 levels in both RR cell lines compared to the parents. We next sought to address the mechanism of ID1 and radiation resistance. We knocked down the expression of the ID1 protein through siRNA transfection of both the parent and RR PANC-1 cells. After 48 h of siRNA treatment, good knockdown was shown in both cell lines [Figure 4C]. We next performed clonogenic experiments comparing radiation sensitivity in the parent and RR cells following siControl or siID1 pre-treatment. We again show that RR cells display radioresistance compared to the parental cells. We found that siID1 transfection of the RR cells reverted the sensitivity to radiation of the RR cells compared to the siControl parental cells. There was no impact on the radiation sensitivity of the parental cells following siID1 transfection [Figure 4D]. These results suggest that ID1 is activated in the radiation resistance population, and targeting ID1 could be a strategy to increase sensitivity to radiation.

ID1 is a potential biomarker in PDAC patients

To evaluate the expression profile of ID1 in PDAC, we analyzed the available tissue sample data from both IHC and RNA-seq data from PDAC patients in the TCGA project and normal samples in the GTEx project using the human protein atlas website. As shown in Figure 5A, ID1 high or medium protein expression was

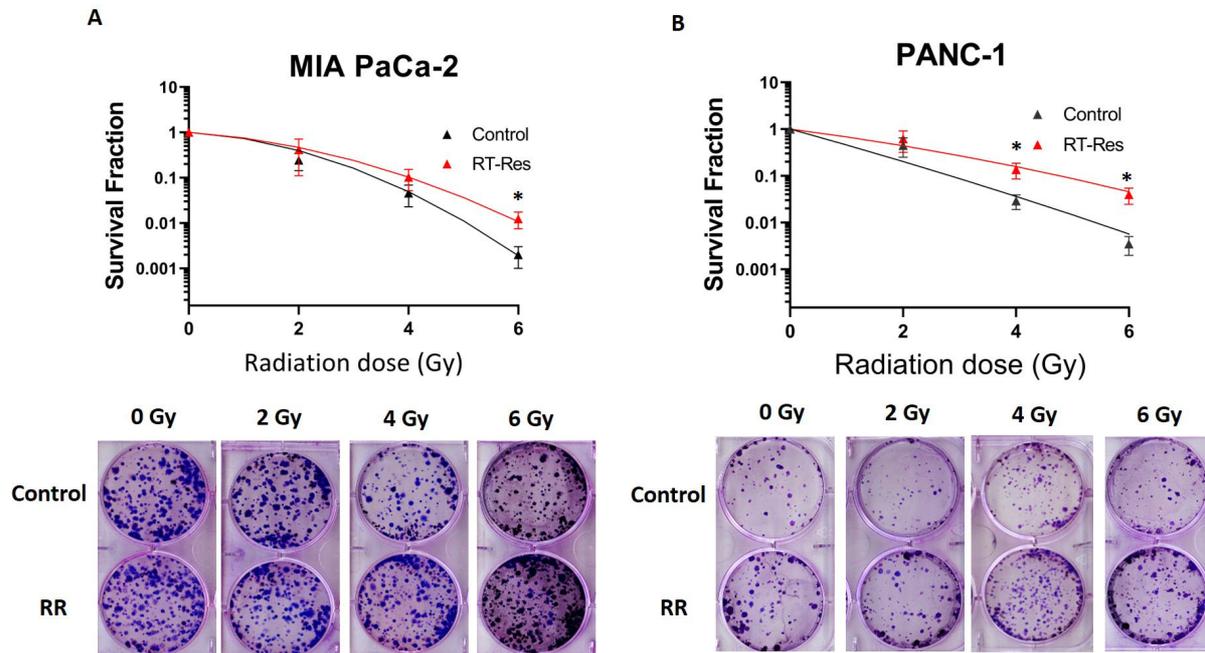

Figure 2. RR PDAC sublines display increased resistance to radiation. Colony formation assay of (A) MIA PACA-2 RR vs. MIA PACA-2 and (B) PANC-1 RR vs. PANC-1. Representative images of colony formation following increasing doses of IR are displayed below the curves. * $P < 0.05$; RR: radioresistant.

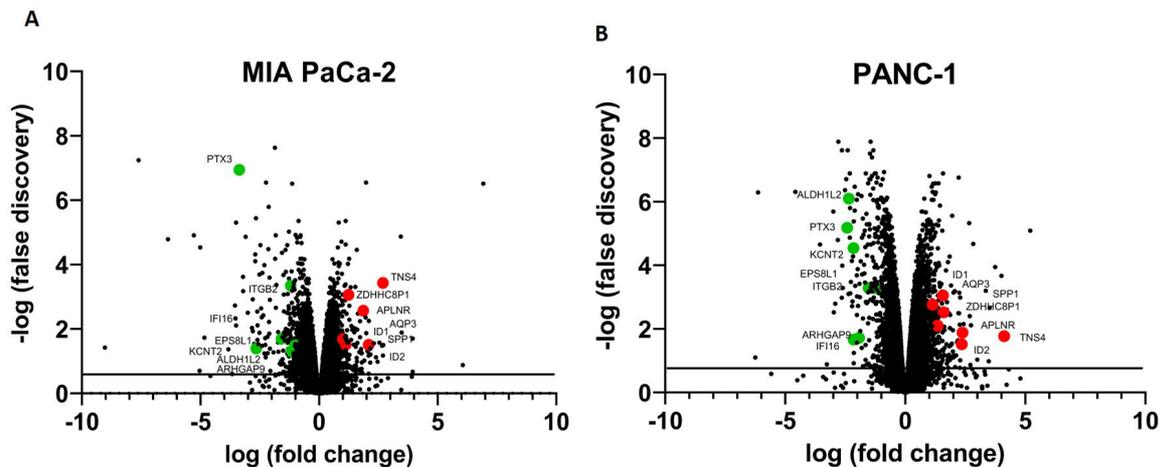

Figure 3. RNA-seq analysis reveals gene expression differences between radioresistant cells and parental cells. Volcano plot representation of differential expression analysis of genes in the parental cells versus RR cells for the MIA PaCa-2 (A) and PANC-1 (B) cells. Red and green points mark the genes with significantly increased or decreased expression in both MIA PaCa-2 and PANC-1 cell lines (FDR < 0.05). The x-axis shows log fold changes in expression, and the y-axis is the negative log of the false discovery value.

found in 75% of pancreatic cancer patients, and PDAC was the second-highest ID1 expressing cancer behind only thyroid cancer. In the normal tissue samples from the GTEx RNA-seq dataset, the normal pancreas had relatively low expression compared to other tissues. The pancreas was the 4th lowest normal tissue expression [Figure 5A]. The direct comparison of ID1 mRNA expression in PDAC tissue vs. normal pancreas tissue showed significantly higher ID1 expression in the tumor samples compared to normal tissues ($P < 0.05$) [Figure 5B].

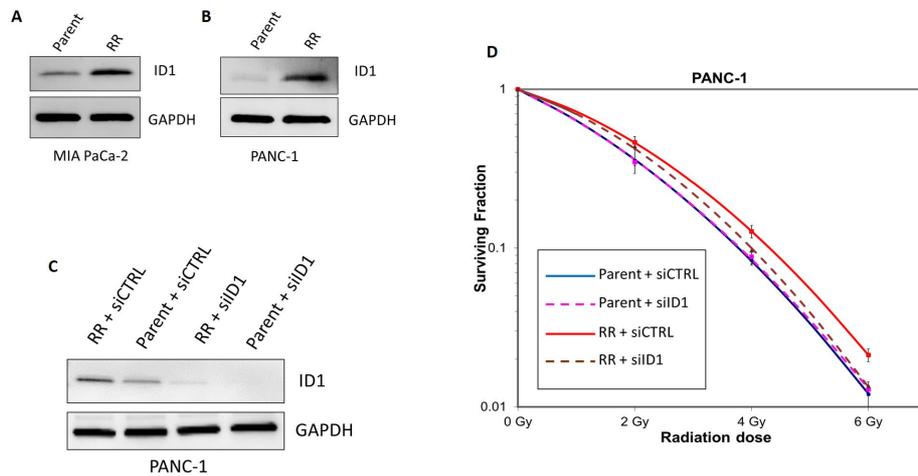

Figure 4. ID1 expression is increased in radioresistant cells. Western blotting confirmed increased protein expression of the ID1 gene in RR cells compared to the parental controls in both (A) MIA PaCa-2 and (B) PANC-1 PDAC cell lines. (C) Western blotting of ID1 and GAPDH 48 h following siRNA transfection of either control or ID1 in parental or RR PANC-1 cells. (D) Clonogenic curves following siControl or siID1 transfection of parent and RR PANC-1 cells. RR: Radioresistant; GAPDH: glyceraldehyde-3-phosphate dehydrogenase.

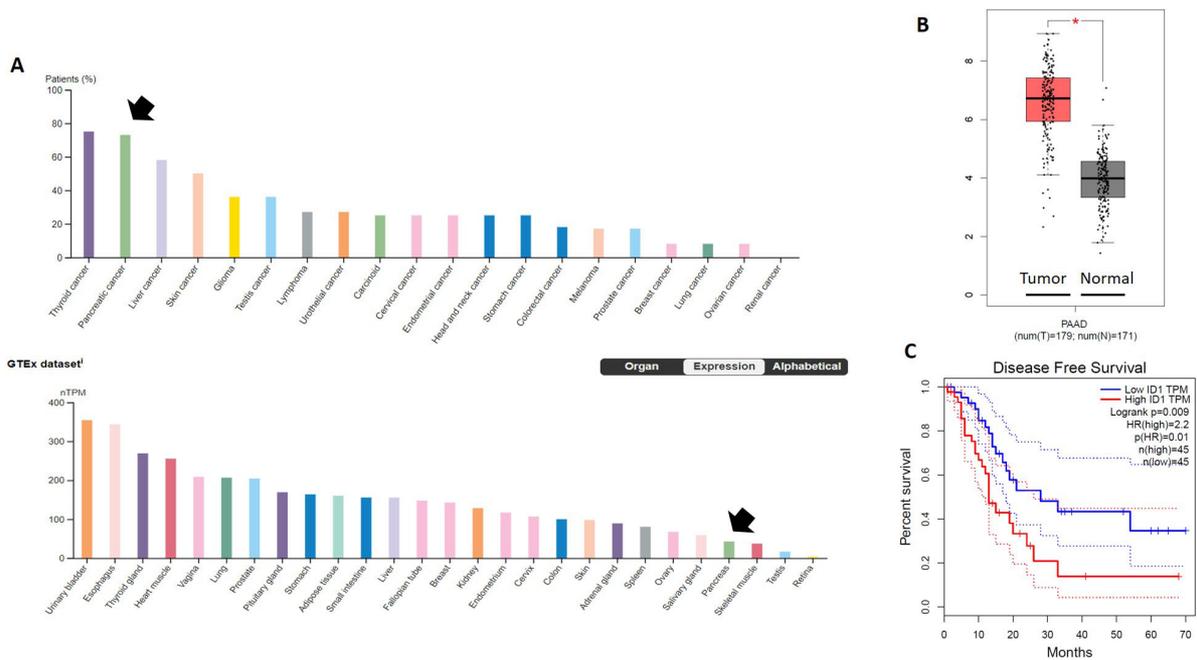

Figure 5. ID1 expression is high in PDAC tissue compared to normal samples and correlates with worse disease survival. (A) The percent of tumor samples with either high or medium expression of ID1 on immunohistochemistry (IHC) was rank-ordered. The mRNA expression of ID1 in normal tissue was rank-ordered in normal tissue samples from the GTEx RNA-seq dataset. Arrow points to PDAC and pancreas tissue. (B) Direct comparison of mRNA expression data from PDAC tumors in the TCGA and normal pancreatic tissue from GETx. * $P < 0.05$. (C) PDAC patients in the TCGA dataset were grouped based on mRNA expression of ID1 split on the median value. High ID1 tumor expression predicted worse disease-free survival, $P = 0.009$ HR = 2.2.

We next investigated the association between ID1 expression and disease-free survival (DFS) from the TCGA database. Survival analysis using Kaplan-Meier and log-rank test divided at the median value revealed lower DFS in PDAC patients with high ID1 expression compared to patients with low ID1

expression [hazard ratio (HR) = 2.2, $P = 0.009$] [Figure 5C].

The p53 gene is a known regulator of cellular response to radiation therapy^[22]. Patients with mutated p53 in multiple cancer types, including PDAC, have worse RT response rates than p53 wildtype patients^[23]. From our analysis of the TCGA PDAC cohort, p53 mutant patients had lower DFS than p53 wildtype patients (log rank $P = 2.9e-3$) [Figure 6A]. We next sought to determine if there was a correlation between p53 mutation and ID1 expression. In the TCGA tumor dataset, we found that p53 mutant PDAC patients had significantly higher ID1 mRNA expression than p53 wildtype patients ($P = 0.03$) [Figure 6B].

Together, our data showed that expression of ID1 is upregulated in PDAC and is associated with poor survival and p53 mutation, supporting ID1 as a potential mediator in PDAC RR.

DISCUSSION

Although the development of metastatic disease dominates the natural history of PDAC, local tumor progression contributes significantly to morbidity and mortality. Conventional RT (cRT) with small 1.8-2 Gy/fraction doses has shown low long-term tumor control rates or survival benefits. Over the past decade, dose-escalation strategies (otherwise termed ablative RT, or aRT (3-4 Gy/fraction)), have shown promising results^[24-27]. The aRT technique requires a highly specialized team of Radiation Oncologists and Physicists in addition to state-of-the-art technologies such as daily adaptive MR linear accelerators, only available in a handful of centers in the U.S.A. Outside of large tertiary cancer centers, delivery of aRT while safely avoiding normal tissue dosing is possible for a minority of PDAC patients where tumors are far enough away from the luminal gastrointestinal (GI) tract. Therefore, novel strategies to improve radiosensitivity to standard lower doses of RT are critical. To enhance radiosensitivity, genetic drivers of RR are crucial to be discovered to develop novel targeted therapeutics to combine with RT.

Two previous studies have studied gene regulation of radiation resistance using engineered radioresistance PDAC cell lines. Soucek *et al.*^[28] and Ogawa *et al.*^[29] used the cDNA microarray method to identify gene changes following radioresistance. The Soucek study found the cholesterol pathway to be significantly upregulated in radioresistance cells, including genes: FDPS, ACAT2, AG2, CLDN7, DHCR7, ELFN2, FASN, SC4MOL, SIX6, SLC12A2, and SQLE. The Ogawa study found upregulated pathways related to growth factors, cell cycle checkpoint, and angiogenesis, including genes: AREG, MAPKAPK2, RGN, ANG-2. Our study generated RR PDAC cells and utilized the RNA-seq to further increase the current understanding of gene expression changes in radioresistant PDAC cell populations. The novelty of our study is that we used a clinically relevant dose fractionation of 2 Gy/day to generate our RR cell lines compared to a single 10 Gy dose in the Ogawa study. The Soucek study also used this clinically relevant dose fractionation, but in contrast to our study, it only utilized one cell line. In this study, two different PDAC cell lines were generated, and genes that were upregulated in both were analyzed further, increasing the robustness of the current study.

Other studies have examined intrinsic radiation sensitivities in various PDAC cell lines to study potential therapeutic vulnerabilities. Wiechmann *et al.* screened 38 PDAC cell lines and pulled out two radiation sensitive and two resistant cell lines to study the phosphoproteomes in response to 8 Gy of radiation^[30]. They found increased actin dynamics and FAK activity in the resistant cell lines and FAK inhibition radiosensitized radioresistant cell lines more than the radiosensitive cell lines. Schröter *et al.* examined the role of high dose radiation and changes in cell surface expression of immunomodulatory molecules^[31]. Interestingly, they found that only high radiation doses of > 5 Gy increased surface expression of PD-L1 and CD73. These results have implications for the potential use of immunotherapy combinations with radiation

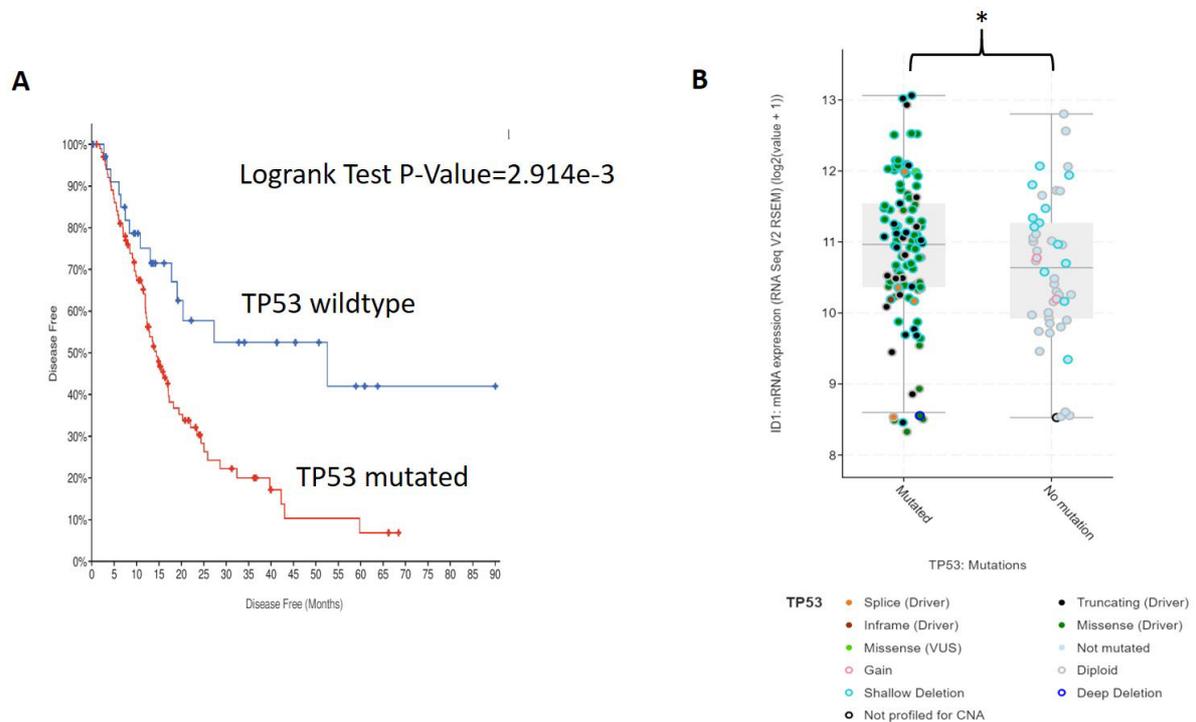

Figure 6. TP53 mutation is a poor prognostic factor and correlates with higher ID1 expression. (A) PDAC patients in the TCGA dataset with tumor p53 mutation (63%) were compared to p53 wildtype for disease free-survival (DFS). Patients with p53 mutations had significantly worse DFS than p53 wildtype, $P = 0.003$. (B) ID1 mRNA expression was compared in p53 mutated tumors vs. p53 wildtype tumors from the TCGA PDAC dataset. ID1 expression was higher in the p53 mutated patients $*P < 0.05$.

such as stereotactic body radiotherapy (SBRT) which utilizes high doses per fraction of radiation.

In our study, we generated new RR PDAC cell lines and then further characterized the changes in gene expression using next-generation-based RNA-Seq. The new cell lines displayed higher survival levels after radiation *in vitro*, and we discovered 14 genes that had significant changes in expression in the RR cell lines compared to the parental. Of these genes, we explored one gene, ID1, that has multiple prior published reports in other cancer types related to RR.

ID1 is a helix-loop-helix (HLH) protein that can form heterodimers with members of the basic HLH family of transcription factors. The encoded protein has no DNA binding activity and, therefore, can inhibit the DNA binding and transcriptional activation ability of essential HLH proteins with which it interacts^[32]. Maruyama *et al.* reported that PDAC cells expressed high levels of the ID genes and that ID1 expression was increased compared to normal controls. The authors concluded that increased ID1 expression might be associated with the enhanced proliferative potential of pancreatic cancer cells^[33]. In our analysis of the TCGA database, we found that ID1 expression was highly expressed in pancreatic tumor samples compared to normal pancreas tissue [Figure 5].

There have been several prior published publications examining the role of ID1 in radiation resistance, reviewed in Table 1. Cook *et al.* showed that PGE2 signaling regulated radiation resistance in mouse glioblastoma (GBM) primary cultures in an ID1-dependent manner^[16]. In GBM, ID1 overexpression increased radioresistance^[17], and ID1 expression levels predicted poor overall survival and knockdown of ID1 increased radiosensitivity *in vitro*^[18]. One of the other genes from our RNA-seq data shown to regulate

radiation sensitivity was SPP1 in gastric adenocarcinoma^[21].

To explain the potential role of ID1 in associating with RR in PDAC cells, we found that patients with p53 mutation had significantly higher expression of ID1 mRNA than p53 wildtype patients. Qian and Chen reported that ID1 expression was downregulated following DNA damage in a p53-dependent manner. They found that ID1 overexpression promoted cell proliferation and inhibited DNA damage-induced cell senescence. They concluded that ID1 was a critical p53-dependent DNA damage response pathway^[34].

Looking into the future, ID1 may serve as a therapeutic target to increase the radiosensitivity of PDAC tumors and improve the outcomes in PDAC. Further studies developing strategies to target ID1 are warranted.

DECLARATIONS

Authors' contributions

Made substantial contributions to conception and design of the study and performed data analysis and interpretation: Zuniga O, Byrum S, Wolfe AR

Performed data acquisition, as well as provided administrative, technical, and material support: Wolfe AR

Availability of data and materials

Abstract

The current therapeutic protocols and prognosis of gliomas still depend on clinicopathologic and radiographic characteristics. For high-grade gliomas, the standard of care is resection followed by radiotherapy plus temozolomide chemotherapy. However, treatment resistance develops due to different mechanisms, among which is the dynamic interplay between the tumor and its microenvironment. Different signaling pathways cause the proliferation of so-called glioma stem cells, a minor cancer cell population with stem cell-like characteristics and aggressive phenotype. In the last decades, numerous studies have indicated that Notch is a crucial pathway that maintains the characteristics of resistant glioma stem cells. Data obtained from preclinical models indicate that downregulation of the Notch pathway could induce multifaceted drug sensitivity, acting on the expression of drug-transporter proteins, inducing epithelial–mesenchymal transition, and shaping the tumor microenvironment. This review provides a brief overview of the published data supporting the roles of Notch in drug resistance and demonstrates how potential novel strategies targeting Notch could become an efficacious action to improve the therapy of high-grade glioma to overcome drug resistance.

INTRODUCTION

The most frequent malignant primary brain tumor in adults is glioma. Low-grade glioma (LGG) includes WHO grades 1-2, while high-grade glioma (HGG) includes WHO grades 3-4. Glioblastoma (GBM), one of the most lethal and most prone to recurrence of malignant solid tumors, represents the majority of WHO grade 4. GBM accounts for more than 50% of all gliomas and primary malignant brain tumors^[1]. Current molecular diagnostic techniques allow alternative classification based on molecular abnormalities and signaling pathways involved in glioma genesis. Isocitrate dehydrogenase (IDH) is a basic biomarker for subtyping and prognosis of gliomas. Tumors that are IDH-mutant have a better prognosis than their counterparts with similar histologic grade and IDH-wildtype phenotype^[2]. Furthermore, methylation of the O6-methylguanine DNA methyltransferase (MGMT) promoter is related to a better response to chemotherapy with temozolomide (TMZ) and longer overall survival^[3]. However, the combination of multiple tumorigenic events, such as highly deregulated tumor genome with hyper-activation of oncogenes, causes and sustains the pathogenesis of glioma and resistance to various therapies^[4]. For instance, oncogenic activation of receptor tyrosine kinases (RTKs) is a crucial signaling mechanism for maintaining glioma oncogenicity. Among all the RTK alterations, epidermal growth factor receptor (EGFR) gene amplification is the most common variation (approximately 40%) in GBM, although EGFR inhibitors (e.g., gefinitib and erlotinib) have not caused clinical effects in patients with GBMs in clinical trials^[5]. Increased expression of platelet-derived growth factor receptors (PDGFR) and PDGF has been evidenced in astrocytic cancers of different grades and is associated with poor prognosis^[6]. Although GBM patients present sporadic RAS alterations, RAS and AKT mediate fundamental pathways in different models of GBM^[7]. In addition, Sonic Hedgehog homolog (SHH), which mediates molecular signals to the embryonic cells required for normal development and Notch, plays a crucial role as an important factor influencing neural progenitor behavior and is dysregulated in glioblastoma stem cells (GSCs)^[8]. In the next sections, we recapitulate the state of our knowledge regarding the functional role of the Notch signaling pathway, focusing on GBM disease progression and therapy resistance and suggesting novel treatments to overcome drug resistance for effective therapeutic protocols of brain malignancies.

NOTCH SIGNALING

The Notch receptor mediates a highly conserved signaling pathway that is crucial in central nervous system development and malignant transformation^[9,10]. Four Notch receptors (Notch1 to Notch4) interact with different canonical activators such as delta/serrate/lag-2 (DSL) ligands Jagged1 and Jagged2 and delta-like (Dll) 1, Dll3, and Dll4 of the Notch pathway^[11]. Notch1 and Notch2 are extensively expressed in numerous tissues during embryonic development and in adult mammals^[12]. Vascular smooth muscle and pericytes express elevated Notch3, while Notch4 is much more abundant in the endothelium^[13,14]. Notch receptors, located on the cell membrane^[15], are characterized by N-terminal EGF repeats that compose the extracellular portion and by a juxtamembrane negative regulatory region (NRR). The intracellular region is formed by a transcriptional activation domain and a C-terminal degron domain rich in the amino acids proline, glutamate, serine, and threonine (PEST)^[13,16]. Notch signaling is initiated by the contact of DSL ligands from sending cells and Notch receptors existing on proximal cells. After this occurrence, the Notch protein undergoes additional proteolytic cleavage determined by the γ -secretase enzyme complex, originating in the Notch intracellular domain (NICD) which translocates into the nucleus. NICD binds to DNA/chromatin-specific sequences, displaces a repression complex, interacts with the DNA binding protein recombination signal binding protein for immunoglobulin kappa j region (RBPJ), and recruits the co-activator mastermind-like1 (MAML1)^[17]. Next, the ternary complex recruits the histone

acetyltransferases P300/CBP-associated factor (PCAF), a key regulator of transcription which is expressed in GBM cells^[18]. Lastly, these protein complexes induce the expression of Notch-regulated genes, for example, hairy enhancer of split (Hes) and HES-related proteins (Hey), both important in lineage-commitment choices. In addition, cell cycle regulators such as p21/Waf1, CYCLIN D1 (CD1) and CD3, and an important regulator of stem cell biology (c-Myc), an EGFR-related gene found to be amplified in human breast cancer cell lines such as the human epidermal growth factor receptor 2 (HER2), as well as nuclear factor kappa B (NF- κ B), insulin-like growth factor 1-receptor (IGF1-R), survivin, snail homolog 2 (SLUG), SOX2, and paired box (PAX) 5^[19,20], all directly associated with tumorigenesis, are described as Notch target genes^[20,21]. The Notch-dependent transcriptional activity concludes with NICD degradation. Cyclin-dependent kinase 8 (CDK8), which binds to and/or phosphorylates several transcription factors, causes the phosphorylation of a degron within the PEST domain of NICD and is targeted for proteasome-mediated degradation by E3 ubiquitin ligases SEL10 (FBW7)^[15]. The Notch pathway may be regulated through post-translational modification^[22], which changes the affinity of the Notch receptor for DSL. The stability of NICD and the extent of signaling are also influenced by phosphorylation of Notch proteins induced by glycogen synthase kinase 3 β (GSK3 β), largely expressed throughout the brain with an additional expression on endothelial cells in mice^[23]. Beyond the established signaling stimulation, distinct proteins missing the DSL domain have been described^[24], such as membrane-integral proteins delta/Notch-like epidermal growth factor-related receptor (DNER), a glycosylphosphatidylinositol (GPI)-linked membrane (e.g., NB3/Contactin6), or secreted proteins^[25]. For instance, NICD physically cooperates with a major component of canonical WNT signaling, β -catenin^[26], Smad tumor suppressor proteins^[27], and the key regulators of cellular response to changes in oxygen concentration, such as hypoxia-inducible factor 1 alpha (HIF-1 α)^[28], thus obtaining direct crosstalk between Notch and the wingless/integrated (WNT), transforming growth factor-beta (TGF- β), and hypoxia-dependent signaling pathways.

NOTCH SIGNALING IN CANCER

Given the outstanding position of Notch in regulating cellular behavior, it is well recognized that Notch signaling is altered in a wide range of diseases, including human malignancies. Unbiased genome-scale sequencing data indicate mutations in Notch genes in various types of cancers. Interestingly, the positions, identities, and effects of these mutations represent varied roles for Notch in different types of cancers^[29], such as breast cancer^[30], prostate cancer^[31], lung cancer^[32], glioblastoma^[33], and other malignancies^[34]. Definitely, functional studies consider Notch signaling one of the hallmarks of cancer, although several data suggest both oncogenic and tumor suppressive functions, depending on the cancer type.

Three separate patterns of Notch gene mutations have been highlighted in several malignant tumors: (1) strong gain-of-function mutations that disrupt the NRR, with or without PEST degron domain deletions, as evidenced in T cell acute lymphoblastic leukaemia (T-ALL) and triple-negative breast cancer (TNBC); (2) PEST degron domain deletions only, as shown in B cell tumors; and (3) disruptive nonsense, frameshift, or point substitutions in the N-terminal portions of Notch receptors, which probably lead to loss of Notch function, as seen in squamous cell carcinoma, small cell lung carcinoma, bladder carcinoma, and certain low-grade gliomas^[16]. A recent study focused on the frequent RBPJ copy number loss and diminished RBPJ protein expression in a significant minority of several types of carcinoma, mainly breast carcinomas^[35]. Nevertheless, the connection between changed RBPJ gene dosage and tumorigenesis is multifaceted and may diverge depending on the tumor type.

The diverse mutational patterns of Notch receptor genes in specific cancers suggest that Notch can function as oncogenic signaling as well as a tumor suppressor in other situations^[13]. The initial demonstration of an onco-suppressor action of Notch comes from results obtained in keratinocytes from mice and humans^[36].

More recent data from whole-genome sequencing analysis describe Notch-inactivating mutations in patients with head and neck squamous cell carcinoma^[37]. Thus, Notch signaling mediates both oncogenic and onco-suppressive action in similar tissue, as demonstrated in the hematopoietic system. Such a dual role is related to the action exerted by Notch in the modulation of cell fate decisions in immune cell expansion.

In addition, experimental data establish that the Notch signal has a fundamental part in cancer patient survival. For example, high expression of Jagged1 or Notch1 correlates with poorer overall survival when compared with low levels of both. Jagged1 was also found to be highly expressed in metastatic prostate cancer compared to localized prostate cancer or benign prostatic tissues^[38,39]. High levels of Jagged1 and Notch1 have been detected in breast cancers and were related to poor prognosis^[38]. Shi *et al.* similarly reported that the Notch expression profile in papillary bladder transitional cell carcinoma appears dissimilar to the matched invasive phenotype. Consequently, Notch1 and Jagged1 may be used as additional markers for the prognosis of papillary bladder transitional cell carcinoma patients^[40]. Cervical carcinomas patients positive for nuclear Notch3 expression showed shorter overall survival when compared with Notch3-negative patients; thus, Notch3 is a possible prognostic marker in cervical carcinomas^[41,42]. Taken together, these data fuel additional scientific interest regarding the investigation of the Notch family as diagnostic and prognostic markers in human cancer.

NOTCH SIGNALING IS ABERRANTLY ACTIVATED IN BRAIN TUMORS

In recent years, large-scale genomic sequencing on brain tumors provided a unique understanding of the genomic aberrations and cellular signaling mechanisms that control brain tumor initiation and progression^[43]. Among the different pathways, aberrant Notch signaling was found in brain tumors, even though its members are infrequently altered^[43]. Elevated Dll1, Notch1, Notch3, Notch4, and HEY1 levels were associated with advanced glioma grade and poor prognosis^[44,45], strongly suggesting that Notch signaling influences an undifferentiated and aggressive brain cancer phenotype. mRNA and protein levels of Notch1, Notch4, Dll1, Dll4, Jagged1, HEY1, HEY2, and HES1 are increased in brain tumors and associated with upregulation of vascular endothelial growth factor (VEGF) and phospho-AKT, together with a reduction of the tumor suppressor phosphatase and tensin homolog (PTEN)^[33,46]. However, data suggest a controversial role of Notch1 in glioma genesis^[47]. Specifically, Notch1 levels are increased in patients with a survival of > 1 year compared to < 1 year^[48]. Thus, outstanding questions remain to be addressed. A very recent study suggested the Notch canonical ligand, Dll3, as a key therapeutic target and/or prognostic marker in LGG. The authors demonstrated that Dll3 promoter methylation and decreased mRNA expression influenced the patient's prognosis in LGG but not in GBM. This is a crucial discovery that identified subsets of LGG with different immune microenvironments which depend on Dll3 mRNA expression^[49].

Notch signaling in glioblastoma drives GSCs phenotype

GBM harbors various cellular categories, several with amplified aggressiveness and stemness of GSCs, which are responsible for tumor relapse and therapy resistance^[50,51]. GSCs are regulated by genetic, epigenetic, and metabolic factors, in addition to extrinsic factors, the immune system, and the tumor microenvironment (TME)^[52]. Indeed, vascular cells, microglia, peripheral immune cells, and neural precursor cells that populate the TME control the course of the disease^[53]. Specifically, the multiple molecular interactions of bulk glioma cells and GSCs with the TME exert a pathological impact influencing tumor progression and response to different treatments^[53]. These observations suggest targeted therapeutic approaches that are effective against heterogeneous GBM cell populations^[54].

The potent tumorigenic activity of GSCs has been associated with the expression of Nestin, glial fibrillary acidic protein (GFAP), β -III tubulin, and CD133 stem cell markers^[55]. Among the different aberrant signaling pathways, the Notch pathway, co-opted in GBM, stimulates astrocytes to assume a stem-like state through different mechanisms (as summarized in [Figure 1](#)), which can be accompanied by increased proliferation^[56]. The dependence of GSCs on Notch signaling is further supported by experiments demonstrating depletion of GSCs by treatment with γ -secretase inhibitors^[57]. Interestingly, cell fate determinant Numb4 controls the expression of stem cell markers in GSCs, which function as regulators of Notch signaling. Overexpression of Numb4 decreased EGFR expression due to Numb-mediated endocytosis^[58].

Active Notch signaling is essential for maintaining the tumorigenic potential of GSCs and drug resistance under hypoxic conditions. Accordingly, stimulation of the Notch pathway by HIF-1 α in GSCs is crucial for hypoxia-mediated effects. Indeed, reduction of HIF-1 α or inhibition of Notch signaling partially prevents the hypoxia-mediated maintenance of GSC^[59].

Notch effects are also evident in terms of metabolic reprogramming, which is mainly influenced by mitochondrial respiration. Reverse electron transfer (RET), which influences ROS levels under a variety of metabolic conditions, many of which are associated with pathology, is particularly active in GSCs. Notch modulates RET through the interaction with specific respiratory chain complex I (RC-I) proteins. The authors demonstrated that genetic and pharmacological interference of Notch and RET inhibited GSC proliferation in mouse models. These results demonstrate the crucial role of Notch as a regulator of metabolic reprogramming of brain tumors, suggesting novel therapeutic purposes^[60] targeting the metabolic regulation of GBM cells. Besides, further data support the multifaceted role of Notch. On the one hand, Notch2 expression levels are associated with Nestin and SOX2 stemness markers, together with vimentin and GFAP, as well as anti-apoptotic proteins, but they are also inversely associated with pro-apoptotic proteins in GBM tissue^[33]. On the other hand, several groups have reported dissimilar expressions of Notch1, Notch2, MAML1, and pPCAF300 in human glioma, with controversial results regarding tumor progression and prognosis^[47].

Notch Signaling drives drug resistance and disease progression dependent on GSCs

In GBM, innate and acquired mechanisms of treatment resistance could depend on the blood - brain barrier, tumoral heterogeneity, and TME. In addition, GSCs are actually retained to support GBM progression and resistance to different drugs^[61]. Different mechanisms have been described, and, more recently, a live-imaging study of GSCs acquired from the infiltrative area and putative relapse-driving area showed that GSCs are interconnected and able to transfer mitochondria via thin membranous open-ended channels, connecting distant cells. The authors concluded that this novel mechanism might have a potentially relevant role in therapy resistance; however, the increased stem cell population, DNA repair activity, expression of multidrug transporters, and redundant signaling pathways such as Notch^[62] are better established and investigated mechanisms of resistance (as summarized in [Figure 2](#)). Data from different experimental models suggest that anticancer drugs such as TMZ^[63], bevacizumab^[64], and oxaliplatin^[65,66] frequently induce Notch, which in turn controls the factors implicated in drug efflux, metabolic reprogramming, regulation of GSCs and TME, etc. that lead to acquired resistance. Loss of serine/threonine-protein kinase polo-like kinase 2 (PLK2), a key regulator of centriole duplication, was found to be strongly related to acquired resistance to TMZ via stimulation of the Notch pathway in GBM. Particularly, the authors suggested that loss of PLK2 induced the Notch pathway, mediated by the transcriptional inhibition of HES1^[63].

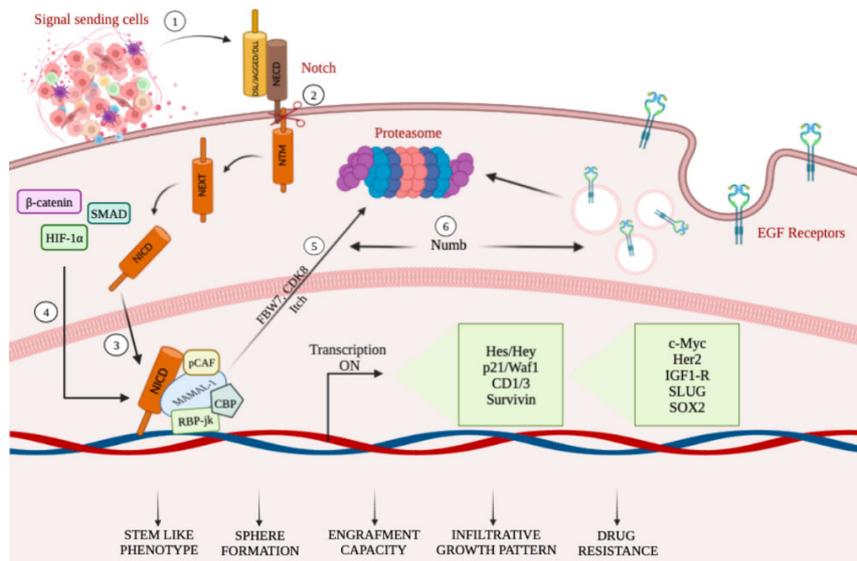

Figure 1. A schematic summary illustrating mechanisms targeting Notch in GCSs (see the text for details). (1–3) TME cell populations, secreting a number of factors including Notch ligands, stimulate the transcriptional activity of Notch receptors, thus influencing tumor biology. (4) NICD physically cooperates with β -catenin, Smad proteins, and HIF-1 α , thus obtaining the crosstalk among Notch, Wnt, TGF- β , and hypoxia-dependent signaling pathways. (5) Notch-mediated transcriptional activation achieves the NICD degradation through phosphorylation of NICD, mediated by CDK8 and targeted for proteasome-mediated degradation. (6) Decrease of EGFR expression due to Numb-mediated endocytosis.

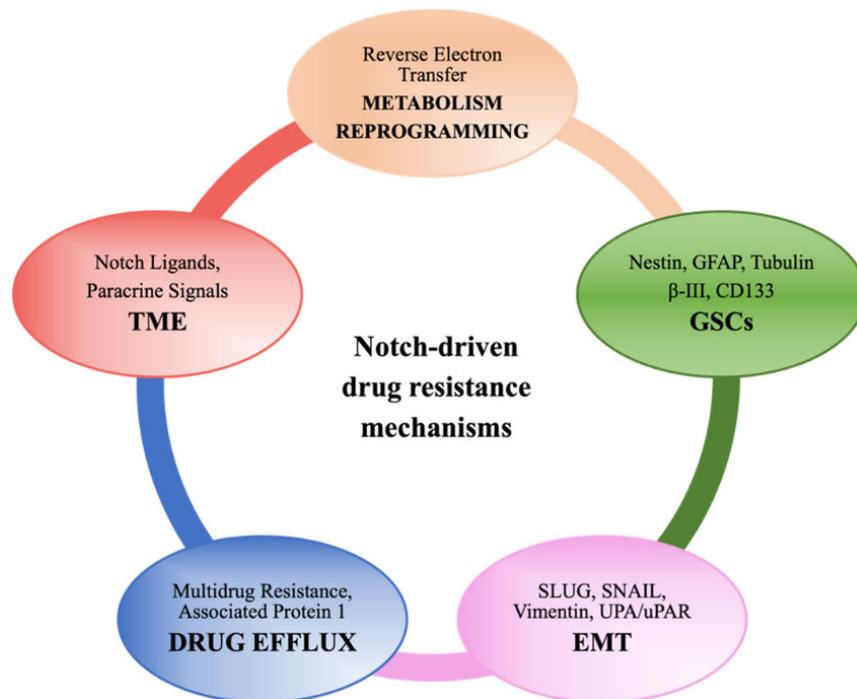

Figure 2. A schematic illustration showing Notch-driven drug resistance mechanisms (see the text for details).

Several fundamental mechanisms have been described; for example, Notch1 regulates the expression of multidrug resistance-associated protein 1 (MRP1), which plays an intrinsic role in the chemoresistance of GBM tumor cells^[67]; thus, Notch is an encouraging target for the improvement of the current glioma

therapeutic portfolio. Blocking Notch signaling or RBPJ reduced clonogenic potential in tumor-sphere assays and engraftment capacity in GBM xenograft models^[68]. Accordingly, NICD overexpression could induce cell survival due to radioresistance and side population phenotype in glioma cells^[69]. Moreover, the extracellular matrix glycoprotein Tenascin-C and Jagged1 strengthen the expression of each other, promoting brain tumor-initiating cell (BTIC) growth. These cells from human GBM patients exhibit increased resistance to radiation and chemotherapy^[70].

GSC population enrichment and its increasing resistance to treatment are favored by the brain TME, secreting a number of factors including Notch ligands which influence tumor biology. For instance, endothelial cells provide ligands, bind the Notch receptors, and are expressed by GSCs. Paracrine signals from mesenchymal stem cells (MSCs) induce chemosensitization to TMZ in heterogeneous GSCs that lack EGFR amplification through the downregulation of Notch1 and SOX2 and the upregulation of vimentin^[71].

The poor prognosis of GBM patients and the high levels of radio- and chemoresistance are strictly associated with the highly infiltrative capacities of these tumors. Primary GBM comprises both proneural and mesenchymal GSCs, but the treatment causes proneural to mesenchymal transition, determining the prevalence of mesenchymal GSCs in resistant tumors^[72]. The mechanisms are analogous to those underlying the epithelial–mesenchymal transition (EMT). SLUG expression, which is linked to the mesenchymal profile, is regulated by the Notch1 pathway and has been implicated in radioresistance^[73]. An elegant study demonstrated that GBM-derived neurosphere cultures with elevated Notch levels were prone to form intracranial tumors with major infiltrative characteristics. In this scenario, elevated Notch1 expression confers a more invasive phenotype to neurosphere cultures once matched to the low Notch1 experimental condition^[74]. Downregulation of urokinase-type plasminogen activator/urokinase-type plasminogen activator receptor (uPA/uPAR), a multifunctional system playing a critical role in GBM invasion, inhibited the cleavage of the Notch receptor, thus inhibiting Notch signaling-induced AKT, NF- κ B, and extracellular signal-regulated kinases (ERK) pathways^[75].

TARGETING NOTCH SIGNALING IN THE EMERGENCE OF RESISTANCE TO CURRENT GLIOBLASTOMA THERAPIES

The existence of the GSC population within the tumor is an important limiting factor for achieving therapeutic success for GBM patients. These GSCs possess increased resistance to chemo- and radiotherapy compared to bulk cancer cells, although they appear to be sensitive to treatment targeting Notch^[57,76]. However, additional difficulties limit the therapeutic response of GBM patients, such as insufficient drug delivery across the blood–brain barrier, abundant intra- and intertumoral heterogeneity, and an immunosuppressive microenvironment. The therapeutic resistance in GBM is particularly complicated by the interplay between GSCs and the TME, which is crucially orchestrated by the Notch pathway^[77], suggesting that the novel therapeutic approach targeting Notch could overcome drug resistance. In the subsequent sections, we review the state of our knowledge regarding the functional role of Notch signaling pathway in drug resistance and several approaches that are potentially valuable to overcome drug resistance for the efficacious treatment of gliomas.

Direct and alternative targeting of Notch signaling

Starting from the molecular structure of Notch receptors, Notch ligands, and Notch activators, several studies have aimed to target the Notch pathway pharmacologically. The majority of identified compounds revealed anticancer activity in several preclinical studies^[78,79]. Moreover, the combined effects of several inhibitors with components of the current therapeutic portfolio are still under investigation in different clinical trials. Since the stimulation of Notch depends mainly on γ -secretase complex activity^[80], γ -secretase

inhibitors, inhibiting NICD from Notch receptors, are the most promising in different solid cancers including GBM^[81]. The inhibition of the second cleavage of the Notch receptor is possible through α -secretase inhibitors, which block members of the disintegrin and metalloproteinase (ADAM) family^[82]. Additionally, novel promising therapeutic tools that directly or indirectly target Notch signaling have been developed to overcome therapy resistance.

Gamma secretase inhibitors

Several forms of γ -secretase inhibitors have been tested for anti-tumor effects, and DAPT is the first γ -secretase inhibitor tested in brain tumor experimental models^[83,84]. DAPT stimulus in medulloblastoma xenografts induced apoptosis in cancer cells^[85]. The positive effects of DAPT fortified the progress of γ -secretase inhibitors such as RO4929097, MRK-003, and L-685,458 (here indicated as GSIs)^[86].

GSIs have been utilized in clinical and experimental studies in many tumors. Most of these studies have assumed that GSIs, except for potency, are biologic equivalents. However, the biology of GSIs is more complex, and the general assumption of pharmacological and functional equivalency of GSIs needs to be investigated further. Different studies designate several GSIs as the most clinically relevant anti-Notch treatments^[87], even though the overall success in clinical trials shows limitations due to off-target complications^[88]. These drugs have been analyzed on several subcutaneous brain tumor models, indicating the inhibition of neurosphere tumor growth by GSI-18. In established glial tumor models, Notch signaling downregulation using a single compound had partial effects, but it improved the efficacy of DNA-interfering agents. Accordingly, DAPT has been shown to improve the efficiency of TMZ^[89]. Furthermore, DAPT has been shown to improve the efficiency of TMZ *in vivo*, as a single agent and in combination. Further studies in glial tumor models evaluated the GSI RO4929097 activity *in vitro*. Cotreatment with RO4929097 and chemotherapeutic agent improved TMZ properties and potentiated the cytotoxicity of etoposide and cisplatin in glial tumor models. RO4929097 enhanced irradiation effects in GBM xenografts and decreased tumor growth in advanced-stage GBM xenografts. The authors concluded that the described preclinical data are necessary for the clinical development of Notch inhibitors in glial tumors^[90]. Combined therapy with GSI RO4929097, radiation, and TMZ increased the survival of orthotopic GBM mouse models. The triple combination is more active than radio- and chemotherapy or GSI alone^[91]. Similarly, DAPT intensifies the effects of radiation and decreases GSC growth and the number of endothelial cells disrupting the perivascular niche^[92]. DAPT, tested in combination with an EGFR inhibitor, reduced endothelial cell sprouting and downregulated VEGF secretion. Therefore, the concomitant targeting of Notch and EGFR enhances the inhibitory effects on GBM angiogenesis and cell viability, suggesting a supplementary valuation of this targeting approach in clinical settings^[93]. Similar to DAPT, other compounds, such as benzyloxycarbonyl-leu-leu-Nle-CHO (LLNle), induce GSC death and proteolytic stress and reduce NICD amount^[94].

Furthermore, *in vivo* studies have shown that in the absence of supplementary therapies, less invasive tumors are generated from neurospheres isolated by xenografts previously treated with MRK003^[95]. Similarly, a tripeptide with γ -secretase inhibitor activity may target CD133+ cells at a low concentration to serve as a radiosensitizer for GBM patients.

Some clinical trials have been directed to estimate the tumor-suppressive effects of a limited number of Notch inhibitors in recurrent invasive gliomas^[88]. However, the lack of activity by RO4929097 and a marked reduction of steady-state drug levels have been described^[96]. The cause for the absence of activity needs to be clarified. A possible mechanism could be the auto-induction of RO4929097 metabolism. A phase 0/I study evidenced the effect of chemo-radiotherapy in combination with RO4929097 in newly diagnosed GBMs. It

found the reduction of cells expressing CD133, a putative GSC marker. The authors concluded that, although evidence of target modulation was observed, recurrence occurred, associated with alterations in angiogenesis signaling pathways and variable blood–brain barrier penetration^[79]. In a phase I/II trial, the combination of RO4929097 with bevacizumab targeting VEGF in patients with progressive or recurrent malignant glioma was tested. The drug combination was well-tolerated, and GBM patients indicated complete or partial remission after radiography^[97].

α -secretase inhibitors

Notch is first cleaved by α -secretase outside the plasma membrane, via ADAM-10 and -17. A potent α -secretase inhibitor tested in GBM decreased cell proliferation and tumor size and prolonged survival *in vivo*. Furthermore, combination with DAPT reduced HES1 and HEY1 levels as well as leukemia inhibitor factor (LIF) and chitinase 3-like 1 (YsKL-40) levels, two new key players in GBM pathogenesis^[82].

Antibodies

In addition to the secretase inhibitors, other molecules have been used to block Notch signaling in GBM, in order to overcome the drug resistance which drives disease progression. Blocking antibodies targeting specific isoforms of Notch receptors and engaged in contrast to the NRR, as well as blocking the receptor folding permitting ADAM cleavage, has been employed in preclinical and *in vitro* studies^[98]. The specific antibodies, such as the anti-Notch1, proposed for GBM patients show the advantage of fewer side effects than GSIs. Another group of antibodies blocks Notch receptor - ligand interactions by hampering the EGF repeats essential for binding^[99]. The first-in-human tested humanized anti-Notch1 blocking antibody treatment in a collection of GSC models with elevated Notch1 expression counteracted the transcription of Notch pathway target genes and caused significant impairment of cellular invasion under chemotherapy. However, the authors concluded that the observed phenotype could be due in part to Notch1 blockage as well as the activation of off-target signals^[100]. Further pharmacological models were directed to Notch ligands such as for anti-Dll4 treatment. A rise in vessel density and reduced tumor dimension were observed after the administration of recombinant Dll4-Fc or anti-Dll4 polyclonal antibody in a bevacizumab-resistant human fibrosarcoma tumor model^[101]. Similar findings were obtained in the human GBM cell line U87, subcutaneously implanted in nude mice. The authors showed that the overexpression of dominant negative soluble Dll4ECD-Fc enhanced the number of blood vessels and reduced tumor growth *in vivo*^[102]. Anti-Dll4 antibodies are now being used in clinical trials.

Natural agents

The empirical screening of thousands of molecules permits identifying compounds with potential antineoplastic effects within the available GBM preclinical experimental models. The Notch signaling pathway is the target of several natural compounds, and although the exerted molecular mechanisms are not completely understood, they have been tested for therapeutic aims. Resveratrol (RSV), a well-known polyphenol^[103,104], may reverse multidrug resistance, and several reports demonstrate that it can act as a sensitizer in different types of tumor cells to standard therapeutic agents^[105]. Resveratrol inhibited HEY1 levels and NCID in GBM cells. Moreover, we found that low doses of RSV and GSI cotreatment resulted in the induction of GBM cell apoptosis and the concomitant block of the autophagic flux. We showed a prolonged rise of microtubule-associated protein light chain 3 (LC3-II) and p62 expression levels, related to a marked decrease of cyclin-dependent kinase 4 (CDK4), an important regulator of lysosomal function. The activation of autophagy after RSV and GSI stimulus, when the cells have impaired lysosomal function, caused the collapse of the system and thereafter apoptosis. The current studies addressed how the Notch inhibitor and RSV combination could be prospectively implemented in a novel therapeutic strategy for GBM treatment^[81]. In A172 and T98G GBM cell lines with a heterozygous p53 mutation, RSV restored wild-type p53 expression, and these effects were mediated by the stimulation of Notch1 levels in a time-

dependent manner. Inhibition of AKT and B-cell lymphoma 2 (BCL-2), increase of BCL2-associated X (BAX) expression, and cleavage of caspase 3 were observed, indicating the great pro-apoptotic effect of RSV^[106]. Some *in vitro* and *in vivo* studies have shown that alpinetin, a natural chalcone distributed in a wide range of plants, can suppress the proliferation and invasiveness of GSCs by suppressing Notch signaling^[107]. Diosgenin, a natural steroidal sapogenin, induces the differentiation of GBM cells, as shown by the increase of GFAP protein levels and decrease of N-MYC, telomerase reverse transcriptase (TERT), and Notch1^[108]. Additionally, faltarindiol, a cytotoxic and anti-inflammatory polyacetylenic oxylipin, has anticancer properties against GBM cells by evoking the differentiation of GSCs, as well as triggering the apoptosis pathway. Conversely, the authors showed that faltarindiol has detrimental effects by disrupting the maintenance of normal neural stem cells and changing the balance between self-renewal and differentiation by suppressing forkhead transcription factor family O (FoxO), which preserves the adult stem cell population through the Notch axis^[109].

Other agents

Antihelmintic niclosamide is a previously unrecognized candidate for clinical development. Niclosamide led to cytostatic, cytotoxic, and antimigratory effects, strongly reducing the frequencies of multipotent/self-renewing cells *in vitro* and *in vivo*. Mechanism of action analysis revealed that niclosamide simultaneously inhibited intracellular signaling, including Notch, mTOR, and NF- κ B signaling cascades. Additionally, deletion of the nuclear factor kappa-b inhibitor alpha (NFKBIA) locus, encoding the inhibitor of the NF- κ B and EGFR signaling pathway, could be a biomarker that predicts the synergistic activity of niclosamide with TMZ for GBM therapy^[110]. Several studies consider the idea of peptides inhibiting intracellular Notch signaling. A peptide that mimics MAML1 binding to NICD-RBPJ has been shown to disrupt the ternary transcription complex and pass through the cell membrane^[111].

CONCLUSIONS AND FUTURE DIRECTIONS

This review highlights the compelling body of evidence that demonstrates the pivotal role of Notch signaling in coordinating mechanisms of therapy resistance in high-grade brain tumors. The molecular basis of therapeutic resistance in GBM is complex and multifaceted due to the dynamic interplay between the tumor cells, GSCs, TME, and different aberrant signaling, including Notch signalling. Recent studies have evidenced that Notch signaling exerts a dynamic action sustaining the complex interaction among different cell types composing TME, thereby driving GBM recurrence and therapy resistance. Furthermore, redundant signaling pathways converging on Notch signaling can determine increased stem cell population, expression of multidrug transporters, and alteration of DNA repair activity, which control the emergence of disease progression. Besides, the worse prognosis of GBMs and the high levels of radio- and chemoresistance are strictly connected with the highly infiltrative capacities of these tumors, which are partially Notch pathway-dependent. Therefore, the successful treatment of GBM may rely on combinations of therapies, acting on multiple specific targets, converging on Notch inhibition, which could overcome drug resistance. The design of drug dosing schedules and delivery methods to improve brain penetration, together with a better understanding of GBM heterogeneity and Notch orchestrated signaling network, would assure the best possible performance when the treatments are used in combination therapy settings. However, further studies are necessary to ascertain the role of Notch as a predictive biomarker of acquired chemoresistance to be implemented in molecular screening strategies that would be crucial for identifying patients who might benefit from specific treatment combinations.

DECLARATIONS

Acknowledgments

Our special thanks to Miss Anna De Amicis for the English language review of the manuscript.

Authors' contributions

Conceptualization: De Amicis F

Preparing the manuscript: De Amicis F, D'Amico M

Collecting data: De Amicis F, D'Amico M

Writing, and editing: De Amicis F

Preparing figures: De Amicis F, D'Amico M

Authors have read and agreed to the published version of the manuscript.

Abstract

Cancer is one of the most harmful diseases in the world, which causes huge numbers of deaths every year. Many drugs have been developed to treat tumors. However, drug resistance usually develops after a period of time, which greatly weakens the therapeutic effect. Tumor drug resistance is characterized by blocking the action of anticancer drugs, resisting apoptosis and DNA repair, and evading immune recognition. To tackle tumor drug resistance, many engineered drug delivery systems (DDS) have been developed. Metal-organic frameworks (MOFs) are one kind of emerging and promising nanocarriers for DDS with high surface area and abundant active sites that make the functionalization simpler and more efficient. These features enable MOFs to achieve advantages easily towards other materials. In this review, we highlight the main mechanisms of tumor drug resistance and the characteristics of MOFs. The applications and opportunities of MOF-based DDS to overcome tumor drug resistance are also discussed, shedding light on the future development of MOFs to address tumor drug resistance.

Keywords: Metal-organic framework, drug resistance, drug delivery, cancer therapy, nanosystem

INTRODUCTION

Cancer ranks as the second leading cause of death worldwide among various diseases. According to

statistics and estimates by the World Health Organization (WHO), there are 19.3 million new cancer cases and nearly 10 million deaths worldwide in 2020^[1]. The global cancer burden is expected to be 28.4 million cases in 2040, although cancer treatment technologies including surgery, chemotherapy^[2-5], radiation therapy^[6], chemodynamic therapy (CDT)^[7,8], gene therapy^[9-11], photothermal therapy (PTT)^[12], and immunotherapy^[13-15] have shown great progress in prolonging survival of cancer patients. However, the multidrug resistance (MDR) of anticancer drugs seriously affects the therapeutic effect, leading to tumor recurrence and metastasis, which has become one of the main obstacles in tumor treatment^[16,17].

With the rapid progress of nanotechnology, multifunctional nanoparticles (NPs) enable selective delivery of therapeutic and/or diagnostic drugs to target tumor sites, making precision therapy possible. To date, many organic/inorganic nanomaterials^[18-20], including polysaccharides^[21,22], proteins^[23,24], polymers^[25], metals and metal oxides^[26,27], mesoporous silica^[28], engineering macrophages^[29], nucleic acid nanodevices^[30-32], and metal-organic frameworks (MOFs)^[33,34], have been extensively designed to address physicochemical issues associated with free drugs, tumor drug resistance, and biological barriers during delivery. Among them, MOFs, as an emerging class of nanomaterials, have gained the broad interest of many researchers owing to their high specific surface area, tunable porous structure, satisfactory stability, and biocompatibility. In particular, MOFs have shown great potential and advantages as nanocarriers for drug delivery and protection, such as encapsulation of drugs, direct assembly of drug molecules as organic ligands^[35], post synthesis^[33], and surface modification^[36]. Up to now, the MOF-based drug delivery system (DDS) has been employed to deliver drugs such as cisplatin^[37], doxorubicin (DOX)^[38-40], biomolecular agents^[2,41-43], and immunosuppressants^[44,45]. Both single and multiple drug delivery using MOF-based DDS is available^[36,46], and combined therapeutic approaches with multiple mechanisms are also commonly performed^[47]. In this regard, MOFs, as the carrier in the nanosystem, could protect the drug from degradation, controllably release the drug at the tumor site, inhibit the expression of drug-resistant proteins and genes, and modify the physiological state of the tumor microenvironment, which could enhance the therapeutic effect and mediate the immune behavior against the drug-resistant behavior of cancer cells^[44].

To achieve better outcomes in MOF-based nanotechnology for cancer therapy, it is an urgent need to gain a deeper understanding of the mechanisms of tumor resistance and evaluate the potential as well as the challenges of MOF-based DDS in tumor resistance.

MECHANISMS OF TUMOR RESISTANCE

MDR in tumors is complex and multifactorial, including biological barrier formed by the tumor microenvironment (TME)^[48-53] and overexpression of drug efflux transporter resulting in the inability to accumulate drugs intracellularly^[40,54-57], the drug inactivation due to the specific environment of gene control and metabolism, the resistance to apoptosis and deoxyribonucleic acid (DNA) damage repair^[58-63], and immune evasion^[64-71], as shown in [Figure 1](#).

Biological barriers

The biological barrier formed by the extracellular matrix (ECM) of the dense tumor site makes it difficult for drugs to reach the target site and is the main reason for human pancreatic ductal adenocarcinoma (PDAC) being one of the least curable and most malignant cancers. PDAC is characterized by the presence of a rich matrix. Pancreatic stellate cells secrete an excess of ECM proteins comprising the matrix with collagen, fibronectin, laminin, and glycoprotein as the main components^[51], following the activation by pro-fibrotic mediators including transforming growth factor β (TGF- β). The high density of matrix binds to a large number of stromal cells to form a biological barrier, and the two matrices work together to prevent drug penetration into the cancer cells. Recently, some researchers have developed new strategies to

(D) Immune evasion^[69]. Reproduced with permission from ref^[69]. Copyright 2020 Science.

overcome the barrier. For example, Han *et al.* utilized metformin to disrupt the dense matrix by activating adenosine phosphate-activated kinase pathway, thereby promoting the penetration and therapeutic effect of the DDS [Figure 1A]^[48]. Lv *et al.* showed that PDAC cells utilized gasdermin E to mediate resistance to digestive juices in the pancreatic microenvironment^[72].

Dense ECM is a distinctive feature of PDAC, but overexpression of drug efflux pumps is more prevalent in more cancer cells. The overexpression of drug efflux pumps is one of the essential mechanisms of MDR in cancer cells^[50,52], as various adenosine triphosphate (ATP)-binding cassette transporter family proteins are expressed on the cell membrane. Most of these proteins are ATP-driven multidrug efflux pumps such as MDR protein and P-glycoprotein (P-gp). After the intracellular drug binds to the transporter on the cell membrane, ATP hydrolysis drives a conformational change and pushes the drug out of the cell, resulting in the inability of the intracellular drug to accumulate in sufficient quantities to kill the cells^[73]. Ruan *et al.* used nanocarriers to reverse drug resistance induced by overexpression of the drug efflux pumps by inhibiting mitochondrial ATP synthesis^[52]. The cyclin-dependent kinase 6-phosphoinositide 3-kinase (CDK6-PI3K) signaling axis is an effective target for attenuating ATP binding cassette subfamily B member 1/P-gp-mediated MDR in cancer cells^[11,74,75].

Drug inactivation

The cancer cells are continuously subjected to intense metabolic activity and exhibit hypoxia, high lactate content, and slightly acidic TME. Thereinto, lactate has been shown to be involved in downregulating the expression of the drug efflux pumps P-gp and reducing drug resistance^[40], while hypoxia causes the failure of many kinetic treatments that rely on oxygen for oxidative stress. In the drug-induced adverse factors, cancer cells will activate metabolic adaptations to eliminate the adverse factors and evade anticancer treatment [Figure 1B]. Activated metabolic adaptation consists of two major cellular pathways, mitochondrial oxidative phosphorylation (OXPHOS) to glycolytic ATP production and autophagy to recycle harmful substances within the cells^[54]. To keep a higher level of metabolism, cancer cells maintain a stable antioxidant defense system internally with a relative balance between glutathione (GSH) and reactive oxygen species (ROS)^[55]. Drugs entering the cells are often depleted by GSH and cannot increase ROS content to generate oxidative stress, which leads to the failure of dynamic therapy. Resistance based on GSH and ROS mechanisms has led to the inefficiency or even failure of most chemotherapeutic and kinetic

treatments that rely on stimulating oxidative stress^[3,56,57,76].

Wang *et al.* demonstrated that nitric oxide (NO) could be used to reduce oxygen consumption by inhibiting cancer cell respiration, thereby eliminating hypoxia-induced chemoresistance of DOX^[56]. Jiang *et al.* synthesized photosynthetic microcapsules to successfully complete sustained photosynthetic oxygenation in cancer cells, inducing lipid peroxidation and iron death processes to kill cancer cells^[76].

The emergence of secondary drug resistance has exacerbated the difficulty of treating cancer with some drugs. Secondary drug resistance indicates that, after being treated with one drug, cancer cells become resistant to another specific drug that was not previously used^[77]; that is, its development is the dynamic clonal evolution of primary resistance to the drugs used. Aldonza *et al.* found that cancer cells with primary acquired resistance to the microtubule-stabilizing drug paclitaxel also tended to exhibit resistance to epidermal growth factor receptor-tyrosine kinase inhibitors (EGFR-TKIs), even though the cancer cells had never been exposed to this drug before^[77].

Resistance to apoptosis and DNA damage repair

Cancer cells, which are generated from gene mutations in normal cells, can autonomously control the apoptotic program and enter an endless cell cycle. To induce DNA damage in cancer cells to cause cell necrosis and apoptosis is an overwhelming chemotherapeutic idea to destroy cancer cells. The chemotherapeutic drug cisplatin interacts with DNA to inhibit DNA replication and induce apoptosis killing cells. The chemotherapeutic drug DOX, a topoisomerase II (TOP2) inhibitor, inhibits DNA remodeling by inserting into double-stranded DNA and suppressing TOP2 activity. However, DNA damage repair (DDR) plays an important role in resistance to apoptosis mediated by anticancer drugs, including base excision repair, base mismatch repair, nucleotide excision repair, and DNA double-strand break repair^[78]. Proactively enhanced DDR produces resistance of cancer cells to DNA damage-based therapies. Recently, Wu *et al.* observed that the products of glycolysis and exogenous pyruvate in cancer cells could enhance H2A variant H2AX serine (S) 139 (γ H2AX) loading on chromatin, thereby promoting DNA repair [Figure 1C]^[61]. Chen *et al.* employed a hypoxia-activated chemotherapeutic in cancer cells to downregulate the DNA repair protein, xeroderma pigmentosum group F, whose overexpression triggered resistance to cisplatin treatment^[3].

Cancer cells could prevent apoptosis through immune checkpoint blockade and autophagy^[58,60,79]. Among them, immune checkpoint blockade tends to target extracellular immune cells for killing, while apoptosis is evaded intracellularly by autophagy and regulation of partial protein expression^[50]. Cancer cells can suppress apoptosis by the overexpression of anti-apoptotic proteins (e.g., B-cell lymphoma-2 (BCL-2), BCL-XL, and myeloid cell leukemia-1 (MCL-1)) to downregulate or inactivate pro-apoptotic proteins (BCL-2-associated X, BCL-2-associated K, and BCL-2-related ovarian killer)^[59]. Chen *et al.* used synthetic NPs to destabilize microtubules and prevent the formation of spindles in normal mitosis, leading to abnormal cell division and eventually apoptosis^[62]. Wang *et al.* found that acetaldehyde dehydrogenase (ALDH2) gene was involved in mediating the RAF/MAPK signaling pathway, which is engaged in the regulation of apoptosis and drug sensitivity^[74].

Immune evasion

Cancer immunotherapy has achieved clinical success and the use of T cells to kill cancer cells is a highly effective therapeutic mechanism. However, cunning cancer cells can evade the immune response by shaping immunosuppressive TME and immune checkpoint blockade. Joung *et al.* revealed that four genes, programmed death-ligand 1 (PD-L1), MCL-1, JunB proto-oncogene (*JUNB*), and β 1,3-N-acetylglucosaminyltransferases (*B3GNT2*), affect the interaction of cancer cells with T cells, conferring

resistance to T cell cytotoxicity^[64]. Programmed cell death protein 1 (PD-1) on the T cells interacts with PD-L1 on the cancer cells to inhibit activation of T cells^[67]. To address this problem, Topalian *et al.* proposed neoadjuvant PD-(L)1 blockade therapy to enhance systemic immunity against tumors and prevent recurrence [Figure 1D]^[69]. In addition, Huang *et al.* summarized that multiple checkpoint blockades, including PD-1 and cytotoxic T lymphocyte antigen-4 (CTLA-4), developed an immunosuppressive TME in melanoma tumors^[65]. Recently, Saha *et al.* revealed that cancer cells can interact with platelets entering TME to produce chemoresistance^[80]. The platelet has been increasingly found to work as an important activator to induce epithelial-mesenchymal transition (EMT), while EMT is the primary and key event in promoting the distant spreading of metastatic tumor cells^[81]. In another study, indoleamine 2,3-dioxygenase (IDO) in TEM was found to catalyze the metabolism of L-tryptophan to L-kynurenine, thus inhibiting the increase of effector T cells and promoting the growth of regulatory T (Treg) cells^[70].

METAL-ORGANIC FRAMEWORK NANOSYSTEM

Synthesis of MOFs and drug loading methods

MOFs are a class of crystalline porous materials with periodic network structures constructed by metal (cluster) nodes and organic ligands through coordination self-assembly^[82]. Benefiting from the abundant species of metal (cluster) nodes and organic ligands, and the diverse coordination patterns between them, tens of thousands of MOFs have been reported. The research on MOFs in therapy has exhibited rapid growth in recent years [Figure 2].

Various synthetic methods provide flexibility in the synthesis of MOFs. Solvothermal and non-solvothermal methods are common approaches for the fabrication of MOFs. Solvothermal synthesis is typically performed at high temperatures or high pressure to dissolve the reagents and facilitate the synthesis. Non-solvothermal synthesis is performed at temperatures that are lower than the boiling point of the solvent and favorable for nucleation. Non-traditional synthetic approaches for drug delivery include microwave, sonication, mechanical milling, or electrochemical synthesis^[83].

The key challenge for the application of MOFs in the biomedical field lies not only in the precise control of their synthesis but also in the effect of surface affinity on their application behavior. Remarkably, the attractiveness of MOFs as drug delivery vehicles is mainly due to their special drug-carrying capacity. The drug loading efficiency is determined by the physical properties of the MOF (e.g., pore size, surface area, and spatial structures). The loading methods are essential to maximize loading and attain the ideal release. There are three common drug loading techniques for MOFs: one-pot synthesis^[84], biomimetic mineralization^[85], and post-synthesis loading^[86] [Figure 3].

One-pot synthesis is the co-precipitation of therapeutic molecules with MOFs during synthesis, resulting in a uniform distribution of drug agents in the pores of the MOF. One-pot synthesis is beneficial for the controlled release of drugs in the MOF, provided that the pore size of the MOF is small enough to limit the rapid diffusion of drugs through the MOF structure [Figure 3A]^[84]. Biomimetic mineralization is valuable for loading biological agents such as protein and nucleic acid. Unlike one-pot synthesis, biomimetic mineralization utilizes bioagents as nucleation sites for MOF crystallization [Figure 3B]^[85]. Specifically, the biomolecule partially interacts with the MOF building blocks, thereby promoting nucleation. Thus, the encapsulated biological molecules determine the sizes, morphologies, and crystallinities of the MOFs. Such an efficient encapsulation mechanism has been proved to protect bioagents from harsh chemical environments, heat, and degrading enzymes. Since the therapeutic drugs are integrated into the MOF, their release is dependent on the degradation of the MOF, which may lead to the sustained release and delayed activity of the encapsulated drugs. Post-synthesis loading involves the encapsulation of medicaments into

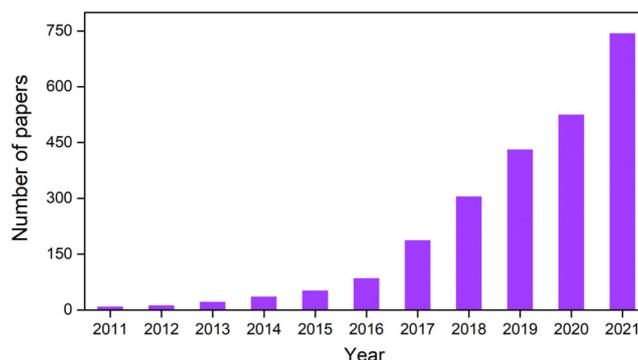

Figure 2. The number of publications in the last decade on the topic of therapy using MOFs according to Web of Science search.

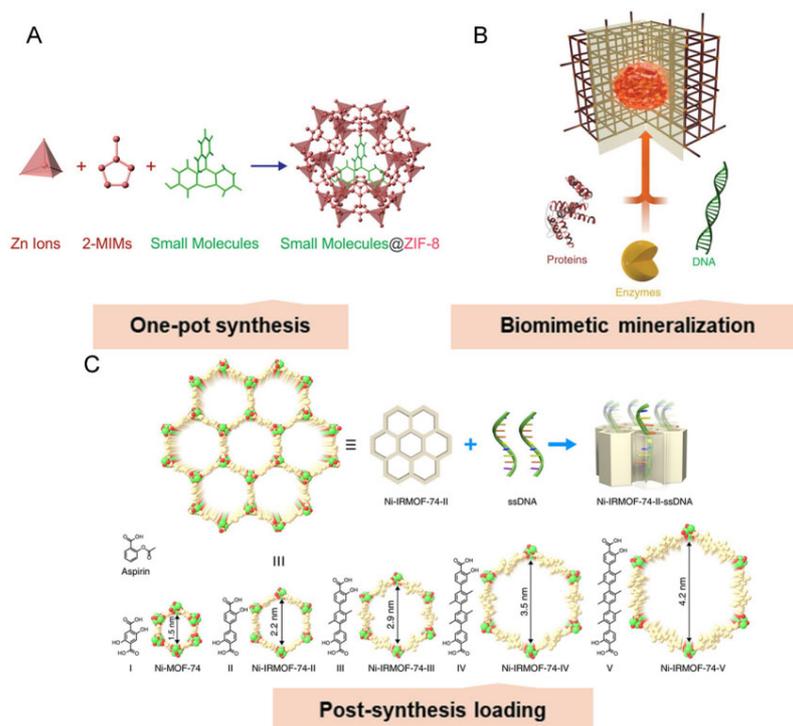

Figure 3. The common drug loading methods on the MOFs. (A) One-pot synthesis^[84]. Reproduced with permission from ref^[84]. Copyright 2014 American Chemical Society. Copyright 2018 the authors.

the pores or the surface of the MOF after synthesis [Figure 3C]. This could be obtained commonly by mixing the MOF and medicaments in a solvent, followed by evaporation to remove the solvent^[86,87]. Surface loading is typically dominated by unsaturated metal site interactions and electrostatic interactions and could also be implemented by attaching the drugs to the polymer-coated surface^[88]. Unfortunately, surface loading normally leads to reduced drug loading in contrast to other approaches. Overall, the high porosity of the MOF provides space for the loading of guest molecules. The well-defined structure of MOFs has a clear relationship to their properties, which provides guidance for future modifications. Regardless of the encapsulation method employed, MOFs protect bioagents from degradation and expand potential avenues for clinical drug delivery.

Advantages of MOFs

MOFs have not only excellent porous properties (e.g., high specific surface area and high porosity) but also many advantages such as structure design and function adjustment, so they have been widely applied in gas adsorption and separation^[89,90], chemical sensing^[91,92], heterogeneous phase catalysis, biological diagnosis^[93,94], and cancer therapy. In view of the flexibility in the design and synthesis of MOF materials, it is convenient to introduce primitives into MOFs through metal nodes, ligands, and guests to endow such materials with unique activities, thereby constructing multifunctional MOFs. Different from the simple loading of primitives by traditional heterogeneous porous materials, the structure of MOFs is ordered and observable, which is conducive to understanding the distribution of primitives in the framework and their interactions at the microscopic scale. Therefore, the structure-activity relationship between spatial structure and performance could be better understood. Furthermore, MOFs are tunable in structure and easily modified. It is easy to adjust the structure of MOFs and introduce various functional groups through crystal engineering and to exert a synergistic effect among the active centers through a specific spatial arrangement in MOFs, thereby regulating chemical interactions between multiple components within the framework. In addition, the rich and diverse pore structures of MOFs are not only conducive to material transport, but also can mimic the function of enzymes. Their unique cavities can generate a "spatial confinement effect" on the guest molecules, thereby influencing the behavior between the host and the guest from a kinetic aspect. Therefore, MOFs, as a class of excellent nanocarriers, are characterized by porosity, heterogeneous properties, and biocompatibility, which endow them with unique advantages in the fields of enzyme-like catalysis, disease diagnosis^[95], therapy^[96,97], and bioimaging.

Potential biomedical application of MOFs

Drug delivery

To overcome the inherent limitations of therapeutic drugs and achieve targeted delivery and controllable release of drugs, the development of drug nanocarriers has become a research hotspot. One of the most essential considerations for drug nanocarriers is that the drugs must be released at a certain rate until the target site is reached, achieving the appropriate dose in a given time. The biological metal-organic framework (BioMOF), connecting MOF chemistry with bioscience, has become a drug delivery vehicle due to its high drug loading capacity and excellent biodegradability^[98,99]. Recently, Ni *et al.* synthesized MIL-100 NPs loaded with chemotherapeutic drug mitoxantrone and hyaluronic acid (HA) [Figure 4A]^[93]. The NPs targeted cancer cells with recognition of cluster of differentiation 44 (CD44) by HA, while co-injected anti-OX40 antibody (α OX40) reversed the immunosuppressive effect, allowing NPs to enter cancer cells favorably and release drug for chemotherapy. A bimetallic MOF for intracellular drug synthesis and self-sufficient therapy was designed [Figure 4B]^[42]. Copper ions that were liberated from MOFs could catalyze the drug synthesis, killing tumors on site to minimize side effects on normal cells.

Biological imaging

The rapid development of bioimaging technology has contributed significantly to exploring the pathological characteristics and metabolic functions of biological tissues by providing vital equipment, which has greatly facilitated the diagnosis of diseases. More recently, MOF-based nanocomposites have been widely used in fluorescence imaging (FL), computed tomography (CT), and magnetic resonance imaging (MRI), as well as other fields, due to their simple functionalization, diverse structures and compositions, and large porosity^[100,101]. Cheng *et al.* prepared a bimetallic Cu/Zn-MOF, further hollowed the multivalent ($\text{Cu}^{+2+}/\text{Mn}^{2+/4+}$) structure after heating in manganese(II) acetylacetonate, and finally loaded indocyanine green (ICG). This MOF nanocarrier released Mn^{2+} for achieving MRI via a Fenton-like reaction and ICG for turn-on FL^[101]. Li *et al.* synthesized a covalent organic framework cladding MOF (MOF@COF) encapsulated with Bi^{3+} , Mn^{2+} , and meso-Tetra (4-carboxyphenyl) porphyrin (TCPP) [Figure 4C]^[102]. Upon reaching the tumor site, the nanocapsules degraded and Bi could be used for CT while TCPP was used for FL, ensuring

extremely high imaging performance.

Biomimetic catalysis

An enzyme is a robust macromolecular biocatalyst that accelerates chemical reactions with unparalleled efficiency and specific selectivity under mild conditions. Thus, biomimetic catalysis for tumor therapeutic application is a highly attractive field with broad prospects for efficient catalysis^[103]. The construction of functional systems that mimic natural enzymes is a remarkably popular goal. Especially, metalloporphyrins and their derivatives have been attracting attention as the catalytic centers of certain enzyme families. Feng *et al.* reviewed the precise synthesis of various MOFs using robust and multifunctional porphyrins as ligands and evaluated the efficient enzyme-like catalytic ability of porphyrin MOFs exhibited in oxidation catalysis, Lewis acid catalysis, electrocatalysis, and photocatalysis, providing ideas for the future synthesis of specific functional porphyrin MOFs and the development of their enzyme-like catalytic function^[104]. Zr-MOF-based single substitution toward high-performance catalysis was proposed, achieving the molecular-level control of the chemical environment around the catalytic center [Figure 4D]^[105]. Zhao *et al.* demonstrated the synthesis of Corrole-based MOF exhibits more efficient heterogeneous catalytic action than the porphyrin-based MOFs^[106].

THERAPEUTIC APPLICATIONS OF MOF NANOSYSTEM TO OVERCOME TUMOR RESISTANCE

Improving delivery

Normally, some drugs are consumed in the blood circulation by autoimmune system before they come to the tumor. The barriers from TME and cancer cells could work together to prevent drugs from entering the cells and even excrete drugs that have entered cells due to the overexpression of the drug efflux pump,

making it difficult for the drugs to accumulate effectively in the cell. MOF-based NPs are allowed to accumulate in the tumor through enhanced permeability and retention effects (EPR)^[107]. For example, Chen *et al.* developed an HA-coated Zr(IV)-based porphyrinic MOF DDS loaded with α -cyano-4-hydroxycinnamate (CHC)^[35]. This DDS was delivered to cancer cells with CD44 overexpression owing to the targeting ability of HA towards CD44, and then released Zr(IV)-based porphyrinic MOF and CHC for enhanced photodynamic therapy (PDT) effect. Du *et al.* synthesized DOX@NH₂-MIL-88B-COD@CS NPs, which were loaded with cholesterol oxidase (COD), DOX, and chondroitin sulfate (CS) gel shell^[39]. The COD catalyzed the degradation of cholesterol on the cell membrane to weaken the bio-barrier of cell membrane, thus facilitating the delivery of NPs into the cell. Meanwhile, H₂O₂ generated from the cholesterol degradation was catalyzed by the nanoenzyme, NH₂-MIL-88B (MIL, Materials of Institute Lavoisier), to produce •OH to kill cancer cells. An erythrocyte membrane camouflaged iron-based MOF was developed for the multidrug delivery platform [Figure 5A]^[55]. Erythrocyte membrane prolonged the circulation cycle of the multidrug platform in the blood as well as provided targeting. After endocytosis and catabolism, the multidrug platform released iron and multiple drugs, triggering the ferroptosis process and chemotherapeutic effect towards tumors. In addition, Cheng *et al.* utilized cell membrane artefacts from human breast cancer MDA-MB-231 and MOF to protect gelonin from catabolism^[108]. The gelonin@ZIF-8/MDA-MB-231 (ZIF, zeolitic imidazolate framework) cell membrane was 11-fold more effective than free gelatin in cancer treatment. The biomimetic cascade MOF nanoreactor loaded with glucose oxidase (GOD) and DOX for starvation-amplified chemotherapy combination therapy demonstrated powerful anticancer efficacy^[109].

The efflux of intracellular drugs has been a difficult obstacle in the fight against MDR due to the overexpression of ATP-binding cassette transporter family proteins P-gp on cancer cell membranes. MOF-based NPs could enter the cell by endocytosis and ensure their release in the perinuclear region, bypassing membrane transporters. Innovating upon this evidence, Wang *et al.* showed a biohybrid bioreactor through the integration of DOX-loaded MIL-101 and a *Shewanella oneidensis* (SO) bacterium^[40]. After injection, the bioreactor migrated to the tumor site with high lactic acid content. The metabolism of lactic acid in TME led to the degradation of MIL-101, the release of DOX, and the downregulation of P-gp, which was related to the tumor multidrug resistance, improving the therapeutic efficiency.

Overcoming obstacles

The specific TME is resistant to the delivery and action of drugs^[48,110,111]. PDAC has the highest mortality rate among various types of cancers owing to the high density of matrix which prevents drug penetration into the cancer cells^[48]. Not only hypoxic environments but antioxidant defense systems mediate the resistance of PDT^[110]. Some signaling, such as S100A9-CXCL12, creates a TME, rendering cancers insensitive to immunotherapy^[111]. Even under high metabolic intensity, cancer cells tend to adopt the metabolism of glycolysis that consumed large amounts of oxygen and produced large amounts of lactate, resulting in a hypoxic state. The metabolite lactate promotes the development of drug resistance [Figure 5B]^[40]. The hypoxic also greatly reduces the efficacy of kinetic therapies which rely on the conversion of ROS to stimulate oxidative stress. Intracellular autophagy and high levels of GSH lead to rapid degradation of drugs or resist the process of drug-induced cell death. Researchers have reversed resistance to enhanced therapy by increasing oxygen or ROS levels and depleting GSH. Since the drugs are susceptible to degradation, their activities could be maintained for a long time by the protection of a biocompatible and chemically stable MOF. We summarize the recent MOF-based materials to overcome cancer drug resistance in Table 1. For example, Lian *et al.* used PCN-333(Al) (PCN, porous coordination network) as the nanocarrier to load tyrosinase (TYR) for synthesizing an enzyme-MOF nanoreactor, converting the non-toxic prodrug paracetamol (APAP) to 4-acetamido-o-benzoquinone (AOBQ) *in vivo*^[33]. They demonstrated that AOBQ induced the depletion of GSH and oxidative stress, attracting ROS-generated CDT to poison cancer cells.

ZIF-8	DOX, GOD	Starvation therapy, chemotherapy	TME adjustment, drug intracellular activation, precise target	Cheng <i>et al.</i> ^[109]
ZnMOF	DOX, quercetin	Chemotherapy	Efficient intracellular drug accumulation	Sun <i>et al.</i> ^[38]
Zr(IV)-based porphyrinic MOF	CHC	PDT	Reduced cellular O ₂ consumption, relieve hypoxia	Chen <i>et al.</i> ^[35]

DOX: doxorubicin; PDT: photodynamic therapy; CDT: chemodynamic therapy; GSH: glutathione; ROS: reactive oxygen species; AOBQ: 4-acetamido-o-benzoquinone.

The cytotoxicity of enzyme from the enzyme-MOF nanoreactor was still observed after three days, while the free enzyme without MOF protection was completely inactive within a few hours. Pan *et al.* proposed a copper(II) nano-MOF loaded with disulfiram prodrug (DQ) and conjugated with GOD, displaying cascade oxidation and Fenton-like reaction^[7]. The nano-MOF was first metabolized by GOD-catalyzed glucose to produce H₂O₂, which triggered the activation of the prodrug DQ to produce highly cytotoxic copper (II) diethyldithiocarbamate (Cu(DTC)₂) *in situ* and Fenton-like reaction to generate •OH against cancer.

Polypharmacy and combination therapy

Single drugs and simple single-mechanism therapeutic effects are more likely to produce resistance in MDR. Researchers have found that unexpected efficacy can be achieved when a combination of multiple drugs acts simultaneously in the tumor^[112,113]. Combination therapies with multi-drug synergistic effects or different mechanisms in tandem are becoming an effective way to improve tumor therapy. MOFs also show good applicability in constructing multidrug nanosystems. For example, Hu *et al.* synthesized hybrid NPs by employing porous UiO-66-NH₂ (UiO, University of Oslo) as the nanocarrier and polymer as the shell to encapsulate cisplatin in MOF pores and DOX in the polymer shell, which showed high multidrug loading capacity and good biocompatibility [Figure 5C]^[36]. The negatively charged shell was degraded in acidic TME and the positively charged MOF was then exposed to interact with the negatively charged cell membrane to promote drug intracellularization, lysosomal escape, and nuclear localization. This drug co-loaded hybrid nanosystem showed excellent anti-tumor effects and higher biosafety than the free drugs *in vivo*. In addition, Ling *et al.* synthesized a dual drug-loaded nanosystem in MOF with DOX and 5-fluorouracil,

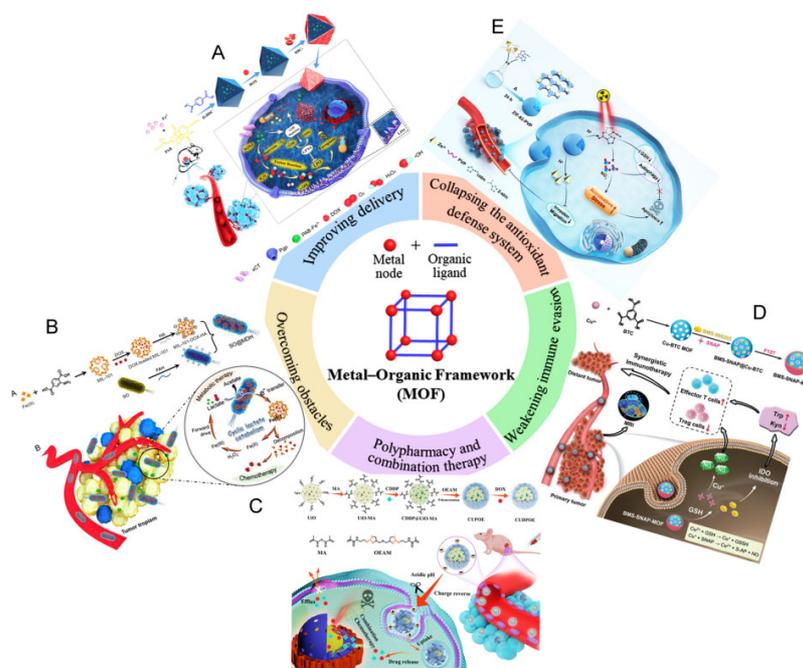

Figure 5. Summary of the therapeutic application of MOFs to overcome tumor resistance. (A) Improving delivery^[55]. Reproduced with permission from ref^[55]. Copyright 2021 the authors. (E) Collapsing the antioxidant defense system^[118]. Reproduced with permission from ref^[118]. Copyright 2021 Wiley-VCH.

achieving good results in both anticancer therapy and bioimaging^[114]. Jiang *et al.* synthesized a DOX-loaded MOF with porphyrin derivatives as organic ligands, combining chemotherapy with PDT^[4]. DOX was shown to enhance the efficacy of PDT, causing more severe mitochondrial membrane potential damage and enhanced inhibition of P-gp.

Weakening immune evasion

Immunotherapy is based on the patients immune systems^[115,116]. By weakening the immune evasion of cancer cells, immunotherapy helps the immune system recognize tumors in the body and activate the immune program to clear cancer cells^[117]. Immunotherapy has always been the most effective way to treat cancer with few side effects.

IDO plays a key role in mediating the immune evasion of cancer cells. The amino acid L-tryptophan (Trp) can be degraded to L-kynurenine (Kyn) catalyzed by IDO, which has a suppressive effect on cytotoxic T lymphocytes (CTL) as well as activates Treg cells to protect cancer cells. Du *et al.* synthesized a Cu-MOF to load with NO donor s-nitrosothiol groups (SNAP) and IDO inhibitor [Figure 5D]^[44]. The abundant GSH triggered a cascade reaction to release drugs and produced NO *in situ*. These two substrates synergistically modulated the immunosuppressive TME accompanied with increasing CD8⁺ T cells, decreasing Treg cells, and weakening the immune evasion of the tumor. This immunotherapy showed significant anticancer effects. Safe, biocompatible, and physiologically stable MOFs show great potential as carriers of genetic material. For example, Chen *et al.* synthesized MIL-101(Fe) encapsulated with specific small interfering ribonucleic acids (siRNAs) and modified with selenium (Se)/ruthenium (Ru) NPs to protect siRNAs from nuclease degradation during targeted delivery into cancer cells^[62]. The developed NPs promote cellular uptake and lysosomal escape of siRNA to silence the MDR gene. Previous kinetic therapies mainly killed

cancer cells by elevating intracellular ROS to trigger oxidative stress and collapse the antioxidant defense system, as shown in [Figure 5](#). The hypoxic environment is highly resistant to kinetic treatments such as PDT and CDT. However, hypoxia is ineffective against reactive nitrogen species (RNS) mechanisms as it does not require ROS involvement. Therefore, Li *et al.* utilized 2-nitroimidazole (2-nIm) and 1H-imidazole-4-cyano as ligands and Zn²⁺ as a metal node to synthesize a MOF. 2-nIm produced RNS to damage cancer cells under X-ray by exploiting the RNS mechanism, bypassing the resistance of the hypoxic environment [[Figure 5E](#)]^[118].

FUTURE PERSPECTIVES

MOFs, formed by the coordination between metal ions or metal clusters and organic ligands, have become high-profile nanomaterials in medical research due to their controllable, regular structure, a large number of active sites, tumor microenvironment responsiveness, high biocompatibility, and physiological stability. Many researchers have devoted themselves to developing MOF-based DDS as nanocarriers of anticancer drugs. Although great progress has been made in related research, there are still many difficulties and challenges in the continuous development and translation of this emerging technology into clinical practice. First, the weak interactions between MOFs and drugs limit their development. Using MOFs as a nanocarrier to encapsulate or load anticancer drugs requires strong interactions between MOFs and anticancer drugs, such as the binding of special functional groups (carboxyl groups, aldehyde groups, etc.) and electrostatic adsorption caused by opposite charges. The weak interactions of MOF may result in drug leakage with reduced therapeutic efficiency. Second, the approaches to drug encapsulation into MOFs are limited. At present, there are three methods for the encapsulation of drugs and MOFs: one-pot synthesis, *in situ* encapsulation, and post-synthesis loading. *In situ* encapsulation is drug encapsulation during the synthesis of MOFs, which requires milder MOF synthesis conditions. However, not all MOF synthesis conditions allow *in situ* encapsulation, which limits the choice of carriers and drugs for DDS. Third, biocompatibility and safety issues of MOFs *in vivo* are uncertain. Although the biocompatibility of MOFs has been verified, a comprehensive evaluation of the *in vivo* toxicity of the DDS throughout the treatment process is still required before human therapy. Moreover, in fact, the function of MOFs as a nanocarrier is often to protect and release the drug in MOF-based DDS, while the functions such as targeting the tumor still need to rely on specific modifications.

In future studies, the development and practical application of MOF-based DDS need to overcome the above difficulties, design multifunctional MOFs, design mild synthesis conditions, construct novel MOFs with strong interrelationships between drugs, and evaluate the effects of DDS on organisms throughout the therapeutic process.

CONCLUSION

The research progress of MOF-based anticancer DDS to overcome tumor drug resistance is summarized and reviewed. Among the tumor drug resistance features, biological barrier, drug inactivation, anti-apoptosis, DNA repair, and immune evasion, the tumor microenvironment with multiple resistance mechanisms cannot be ignored, which has a great impact on the drug resistance of tumors. Next, the synthesis and drug loading method of MOFs are described, which is crucial for the excellent drug loading and protection ability of MOFs. The advantages of MOFs and their application potential in drug delivery, bioimaging, and biomimetic catalysis are also demonstrated. Finally, the application of MOF-based DDS in chemotherapy, radiotherapy, immunotherapy, gene therapy, and starvation therapy, as well as combination therapy with various mechanisms, is systematically reviewed from multiple perspectives. The approaches of MOFs to protect drugs, overcome drug resistance, and improve the effectiveness of cancer treatment are expounded from four perspectives: improving drug entry into cancer cells, overcoming drug resistance

barriers, multidrug loading and combination therapy, and reactivating immunotherapy. Compared with other nanocarriers, the tunable structure of MOFs provides great convenience for loading different drugs. The responsiveness of the tumor microenvironment provides a guarantee for drug protection and controlled release, which improves the efficiency of drug utilization. Using MOFs as nanocarriers to load drugs and overcome tumor resistance will become an emerging and achievable technology.

Benefiting from the controllable structure and high porosity of MOFs, based on the known drug resistance mechanisms, we can utilize biological and chemical techniques to load drugs on MOFs, and then modify them to synthesize composites for suppressing drug resistance of cancer cells and improving the efficacy of cancer therapy. Although there is still a certain gap from the actual human treatment and more intensive research is needed, we believe that MOFs will eventually overcome tumor drug resistance and show their great potential to benefit human cancer therapy.

DECLARATIONS

Authors' contributions

Made substantial contributions to conception and design of the study: Wang H, Wei T

Review the literature: Wang H, Li S, Yang Y, Zhang L, Zhang Y

Wrote the manuscript: Wang H, Li S, Wei T

Finalized the manuscript: Wang H, Wei T

Supervised the manuscript: Wei T

Availability of data and materials

Not applicable.

Financial support and sponsorship

This work was supported by the National Natural Science Foundation of China for the project (22074064).

Conflicts of interest

All authors declared that there are no conflicts of interest.

Abstract

Loss of HER2 in previously HER2-positive breast tumors is not rare, occurring in up to 50% of breast cancers; however, clinical research and practice underestimate this issue. Many studies have reported the loss of HER2 after neoadjuvant therapy and at metastatic relapse and identified clinicopathological variables more frequently associated with this event. Nevertheless, the biological mechanisms underlying HER2 loss are still poorly understood. HER2 downregulation, intratumoral heterogeneity, clonal selection, and true subtype switch have been suggested as potential causes of HER2 loss, but translational studies specifically investigating the biology behind HER2 loss are virtually absent. On the other side, technical pitfalls may justify HER2 loss in some of these samples. The best treatment strategy for patients with HER2 loss is currently unknown. Considering the prevalence of this phenomenon and its apparent correlation with worse outcomes, we believe that correlative studies specifically addressing HER2 loss are warranted.

INTRODUCTION

Human epidermal growth factor receptor-2 (HER2)-positive breast cancer (BC) accounts for 15%-20% of breast carcinomas^[1]. Although originally associated with a poor prognosis, the advent of anti-HER2 agents has dramatically changed the natural history of HER2-positive BC. Most patients with early-stage disease are now cured following (neo)adjuvant therapy^[2,3], and many patients with advanced disease live many years after diagnosis^[4,5]. This unprecedented success is due to the development of numerous highly effective HER2-targeting agents capable of inhibiting the HER2 signaling pathway, which is the main driver of cancer cell proliferation and progression for this breast cancer subtype^[6]. Indeed, HER2 status is not only a prognostic biomarker but also a strong predictor of response to HER2-targeted therapies^[6,7].

According to 2018 American Society of Clinical Oncology (ASCO)/College of American Pathologists (CAP) guidelines, HER2 status is assessed by both immunohistochemistry (IHC) and *in situ* hybridization (ISH)^[8]. The former describes the expression level of the HER2 protein on the tumor cell membrane, while the latter reflects the amplification of the *ERBB2* gene at the nuclear level. The results of IHC and ISH are consistent in most BCs. However, some cases may instead be “borderline” or equivocal, and they are codified in specific groups by ASCO/CAP guidelines^[8].

Discordance between HER2 status in paired samples has been described previously in both early and advanced setting^[9,10]. Specifically, the loss of HER2 is defined as a negative HER2 status in a previously HER2-positive tumor (i.e., a change from a 3+ IHC score or 2+/ISH-amplified to an IHC 0-1+ or 2+/ISH-negative), implying that the residual tumor no longer has HER2 overexpression or amplification at surgery, after neoadjuvant treatment^[11]. This phenomenon is of particular interest in the landscape of breast cancer care because of its potential impact on treatment choice and prognosis. Although it has been reported in many studies, the reasons behind HER2 loss are still unclear. Both true biological changes and technical pitfalls have been assumed as potential causes of this phenomenon^[12] [Figure 1].

BIOLOGICAL MECHANISMS DRIVING HER2 LOSS

Several biological mechanisms may be potentially responsible for HER2 loss, including HER2 downregulation, subtype switching, and clonal selection.

HER2 downregulation

HER2 downregulation - defined as a reduction in HER2 expression at the proteomic level while retaining the *ERBB2* gene amplification - can be induced by anti-HER2 agents acting on the HER2 pathway itself^[14]. In untreated HER2-positive tumors, cancer growth is driven by *HER2* gene amplification, which increases transmembrane HER2 tyrosine kinase (TK) receptor expression by up to 100-fold^[15]. HER2 overexpression thus induces both homo- and hetero-dimerization of HER receptors, i.e., HER1, HER2, HER3, and HER4; phosphorylation of the kinase domains; and consequent activation of a downstream signaling pathway involving both the MAPK and PI3K/AKT/mTOR cascades^[16].

Anti-HER2 drugs targeting the extracellular domain of HER2 have been shown to induce HER2 internalization by downregulating HER2 membrane expression in cells that retain HER2 amplification^[14]. This phenomenon was first described in the early 2000s in cell cultures exposed to trastuzumab^[2,3], although

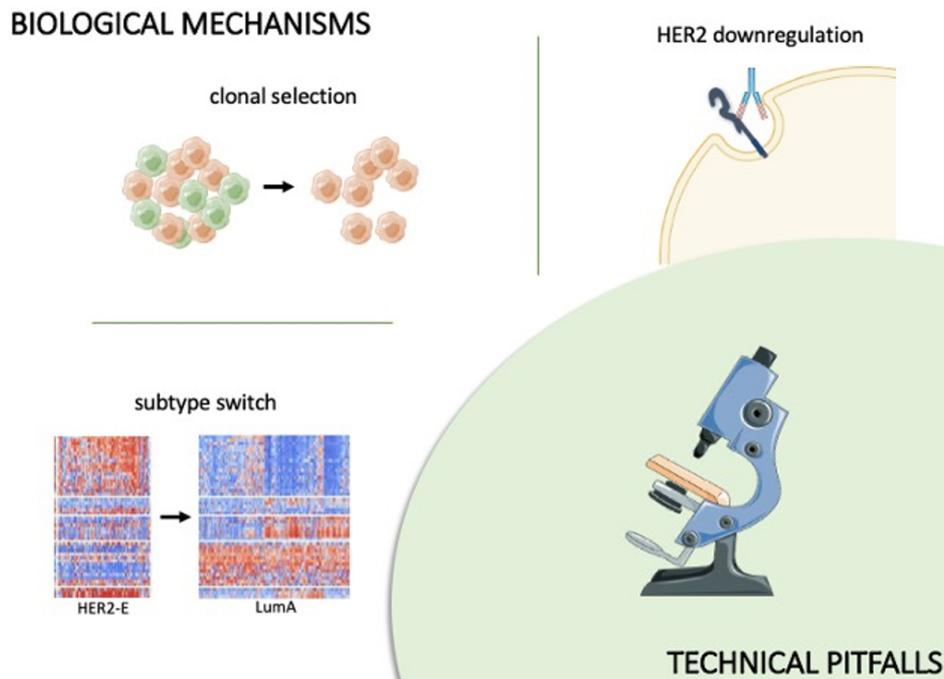

Figure 1. HER2 downregulation, subtype switch, and clonal selection are biological mechanisms potentially responsible for HER2 loss. In parallel, technical pitfalls can cause false-negative results. Figure partly generated using Servier Medical Art, provided by Servier, licensed under a Creative Commons Attribution 3.0 unported license and adapted from Mathews et al.^[13] (<http://creativecommons.org/licenses/by/4.0/>). HER2: Human epidermal growth factor receptor-2.

it has not been confirmed by other studies^[14,17]. To date, there is no clear explanation for these contradictory results. Some authors have suggested that immune cells may play a crucial role, since HER2-downregulation seems to occur only when trastuzumab is actively engaged with immune cells^[18]. For instance, Shi and colleague observed HER2 downregulation only in co-cultures of cancer cell lines with immune cells and not in culture of cancer cells with trastuzumab only^[18]. In particular, they detected an increased level of interferon gamma (IFN- γ) production by immune cells, which in turn activated the signal transducer and activator of transcription 1 (STAT1) that has been assumed to be responsible for HER2 transcriptional downregulation^[18,19]. Indeed, the authors found an increased level of STAT1 in cancer cells with HER2 downregulation, whereas inhibition of STAT1 with fludarabine blocked the immune-related HER2 downregulation^[18].

More recently, Bon and colleagues reported an even higher HER2 downregulation with the dual blockade by trastuzumab-pertuzumab combination^[20]. The authors first observed a reduction in HER2 expression in cell lines after treatment with dual blockade and then demonstrated this *in vivo* by assessing HER2 in four patients with paired biopsies collected before and after exposure to trastuzumab-pertuzumab. HER2 downregulation at the membrane level was observed in all patients, although gene amplification by fluorescence in situ hybridization (FISH) was preserved in two of them^[20]. Similarly, HER2-downregulation was observed after treatment with trastuzumab emtansine (T-DM1)^[21-23] and has been hypothesized as a potential mechanism of primary or secondary resistance to other anti-HER2 antibody-drug conjugates (ADCs)^[22,24]. Of note, the recently presented correlative analysis from the DAISY study, which investigated trastuzumab deruxtecan in patients with HER2-positive, HER2-low (1+ or 2+/FISH-negative) and HER2 0 at IHC, showed a decrease of HER2 expression at progression in 65% of patients^[25].

In contrast, TK inhibitors (TKIs), which act at the intracellular level, do not induce HER2 internalization but instead may increase HER2 expression by inhibiting HER2 phosphorylation and preventing receptor ubiquitination and internalization^[17]. Indeed, treatment with TKIs might actually result in a marked accumulation of inactive receptors at the cell surface^[17]. This phenomenon explains the rationale for combining TKIs with anti-HER2 antibodies, as their antitumoral activity is stronger in combination therapies rather than when single agents are administered^[17,26,27].

Intratumor HER2 heterogeneity and clonal selection

Breast cancer is a highly heterogeneous disease, with differences in biology, gene expression profiles, and treatment sensitivity often coexisting in the same tumor area^[1]. The exposure to anti-cancer drugs affects these cells differently, killing some cell populations and clonally selecting others.

HER2 heterogeneity can thus result in HER2 loss due to treatment exposure, with HER2-positive subpopulations killed by treatment and resistant HER2-negative cells surviving. Many studies have characterized HER2 heterogeneity in breast cancer using various techniques, but very few of them have examined the correlation with HER2 loss^[1,28-30].

In 2009, the ASCO/CAP guidelines defined HER2 heterogeneity as the presence of $\geq 5\%$ to $< 50\%$ tumor cells with a ratio ≥ 2.2 when using dual probes or ≥ 6 HER2 signals/cell when using single probes^[31]. Two to 4 representative areas of the invasive tumor should be selected and assessed after scanning the entire slide to look for heterogeneity. In 2013, this definition was updated by changing the cut-off value from 5% to 10% and the ratio from 2.2 to 2.0, in line with the updated definition for HER2-positivity^[32]. Filho and colleagues applied the first definition to assess HER2 heterogeneity in two different areas of pretreatment biopsies of a cohort of 164 patients enrolled in a single-arm neoadjuvant trial administering T-DM1 plus pertuzumab and its impact on outcomes^[28]. Of note, 16 out of 157 evaluable samples were classified as heterogeneous (10%), and none of them achieved a pathologic complete response (pCR) compared to 55% of non-heterogeneous tumors that achieved pCR^[28]. Most of the heterogeneous cases were 2+ at IHC (75%) and ER-positive (81%). The authors also assessed heterogeneity as a fraction of the proportion of HER2 amplified cells defined by single-cell FISH and found an even higher correlation with non-pCR. Unfortunately, HER2 status on surgical samples and dynamics of heterogeneity were not reported^[28].

Caswell-Jin and co-workers instead applied a whole-exome sequencing approach to evaluate HER2 heterogeneity in pretreatment samples and in different regions of surgical specimens after neoadjuvant anti-HER2 therapy in 5 patients^[33]. By comparing the frequency of mutations across spatially distinct regions, they observed clonal replacement in two of five tumors, with mutations detected in surgical specimen that were absent in the pretreatment core biopsy. This suggests selection of resistant cells by neoadjuvant treatment in heterogeneous tumors, although it was not investigated whether this finding correlates with a different receptor profile across heterogeneous areas and HER2 loss was not investigated^[33].

Subtype switch

According to gene expression profiles, breast tumors are classified into four major subtypes: luminal A, luminal B, HER2-enriched (HER2-E), and basal type^[34-36]. Approximately 50%-60% of HER2-positive breast cancer are classified as HER2-E, with the remaining half distributed among luminal A (15%-20%), luminal B (10%-15%), and basal-like (5%-10%)^[37]. HER2-E tumors are characterized by high expression of growth factor receptor-related genes (*ERBB2*, *EGFR*, and/or *FGFR4*) and cell cycle-related genes and low expression of estrogen-related and basal-related genes^[38]. These tumor subtypes were initially characterized using microarray analysis evaluating more than 400 genes^[35,39], although the PAM50 classifier is currently applied for tumor subtyping in most correlative studies^[34].

In a number of studies, platforms for gene expression profiling have been used to assess the tumor intrinsic subtypes of HER2+ BC both before and after neoadjuvant treatment^[40-43] [Table 1]. Of note, a subtype switch was observed in a substantial proportion of patients across different drug regimens, with the HER2-E to luminal A switch being the most frequent^[40-43]. This finding could be attributed to a decreased expression of genes involved in cell proliferation after treatment exposure. Of note, gene expression analyses cannot distinguish among intra-tumor heterogeneity, stromal alterations, or a true treatment effect, so that stromal contamination might have a role in subtyping after treatment exposure. Interestingly, Brasó-Maristany and colleagues observed that this subtype switch can be reversible after anti-HER2 therapy discontinuation^[41].

To our knowledge, none of these correlative studies performed in the context of neoadjuvant clinical trials correlated the subtype switch with HER2 loss on surgery specimens. These data were reported only by Pernas *et al.* in a retrospective study examining the PAM50 subtype in a cohort of 26 HER2-positive BC with paired samples and residual disease (RD) at surgery^[44]. In this cohort, most HER2-E tumors (81.8%) converted to non-HER2-enriched, and a conversion to HER2-negative in residual disease was observed in 7/26 patients^[44].

TECHNICAL PITFALLS

HER2 status assessment by IHC and ISH represents the standard of care for clinical decision making^[8]. Thus far, these are the only two assays that proved to predict response to anti-HER2 therapy in several randomized clinical trials, therefore having solid clinical utility. IHC uses an antibody to assess HER2 protein expression, whereas ISH determines *HER2* copy number using a single probe for copies calculation or a dual probe that includes chromosome 17 centromere probe (CEP17) hybridization to determine the *HER2*/CEP17 ratio^[45]. Different categories of ISH-based assays are available, including FISH or bright field-based techniques such as silver (SISH) or chromogenic in situ hybridization (CISH). Although FISH is considered the gold standard and is more used worldwide, SISH and CISH have shown very good concordance with FISH and can be considered as an alternative^[8].

Both IHC and ISH have shown a good concordance in assessing HER2 status, but standardization of laboratory testing - including accuracy, reproducibility, and precision - is needed, as technical variabilities can account for both false-negative and -positive results. In particular, ICH is highly dependent on tissue fixation methods, so that variable fixation time and different antibody clones and antigen retrieval methods can lead to incorrect IHC results. Conversely, ISH is less dependent on tissue fixation methods and more reproducible^[46,47], although other pitfalls can cause false results such as intratumoral heterogeneity, accidental assessment of in situ rather than invasive lesions, or suboptimal resolution (nonuniform signals, high autofluorescence, poor nuclear resolution, or high background-obscuring signal resolution)^[48]. Additionally, ISH assessment on unstained sections stored for prolonged periods can be falsely read as negative. ASCO/CAP guidelines strongly recommend that laboratories performing HER2 testing should participate in regular laboratory inspections and biannual proficiency testing, such as the program offered by CAP^[8,32].

The technical variability of these assays accounts for the limited reproducibility of HER2 status across laboratories. Discrepancies in HER2-status between local and central testing have thus been demonstrated in many studies^[49-52]. For instance, an analysis of the N9831 intergroup adjuvant trial identified a discordance rate of 18% and 12% for ICH and FISH, respectively, when comparing local and central laboratories, although a high degree of concordance was observed between central and reference laboratories^[53]. The meta-analysis by Schrijver *et al.* evaluated instead receptor conversion from primary tumors to distant metastasis and showed a higher rate of discrepancy when HER2 was assessed with IHC

Table 1. Neoadjuvant trials evaluating subtype switch during or after anti-HER2-based therapy

Clinical trial	Patients (n)	Treatment	Paired samples (n)	Subtype switch

H: Trastuzumab; P: pertuzumab; D: docetaxel; T: paclitaxel; *considering only patients with residual disease and paired analysis.

(20.8%) instead of FISH (16.3%)^[10].

In 2018, the new ASCO/CAP guidelines introduced a 5-group classification for dual-probe ISH results to address specific scenarios of non-univocal interpretation, identifying for all these groups what additional work-up should be performed to obtain the most accurate classification of HER2 status. Groups 1 (HER2/CEP17 ratio ≥ 2 , HER2 copy number > 4) and 5 (HER2/CEP17 ratio < 2 , HER2 copy number < 4) identify the most frequent and straightforward categories of HER2-positive and -negative samples, respectively, whereas Groups 2-4 include the 5% of cases with a doubtful attribution. These cases frequently stain 2+ by IHC and are referred for a second opinion from a blinded pathologist.

Amplification of *CEP17* represents one of the potential pitfalls causing dual-probe ISH test to fall into these groups. Specifically, cells with co-amplification of *CEP17* and *HER2* are usually characterized by a HER2/CEP17 ratio < 2.0 and an average HER2 signals/cell ≥ 6.0 , falling into Group 3. According to the 2018 ASCO/CAP guidelines, these samples should be reported as HER2-positive if IHC 2+/3+ is detected, although it was acknowledged that data on response to anti-HER2 therapy are limited. *CEP17* gains or losses without involvement of the *HER2* gene have also been reported, which lead to an under- or overestimation of HER2 amplification^[54]. Of note, multiple gene amplifications on chromosome 17 may potentially involve further telomeric genes alteration (*TOP2*, *RARA*, *GRB7*, and *STARD3*), and this demands careful evaluation of the *HER2* amplicon along with the potentially co-amplified neighboring genes, as well as possibly additional IHC assays for HER2^[55].

Further bias in HER2 assessment may result from sampling errors^[56]. In the case of metastatic recurrence, guidelines recommend repeating HER2 testing in a metastatic site, if tissue sample is available, although a new biopsy cannot always be feasible^[8]. Additionally, false-negative results can be caused by technical pitfalls, as frequently occurs in bone lesions, or by sampling bias due to intratumor heterogeneity^[57].

To improve diagnostic precision, some authors recommend also performing ISH in HER2-positive scored as 3+ or 0/1+ at IHC to confirm HER2 status^[58]. The repeat biopsy, however, is not recommended for receptor re-evaluation, as it does not improve diagnostic accuracy^[49].

More recently, HER2 assessment on liquid biopsies has emerged as potential alternative to tissue sampling. Possible sources of HER2 status assessment are circulating tumor cells, cell-free tumor DNA (ctDNA), and extracellular vesicles. The advantage of the method is low invasiveness, albeit copy number assessment is complicated due to the vast background of healthy material, tumor heterogeneity, and high signal-to-noise

ratio. Thus, HER2 assessment on liquid biopsies remains investigational and should not be recommended for clinical decision making^[57].

CONCLUSION

Loss of HER2 is not a rare phenomenon, being detected in up to 50% of breast tumors in different settings. Several mechanisms may contribute to this finding, including intratumor heterogeneity, clonal selection, and true biological modifications such as HER2 downregulation or subtype switch. Nevertheless, these associations are mainly speculative, as no study has specifically linked these phenomena to HER2 loss in tissue specimens. On the other side, analytical pitfalls may be responsible for some false-negative results, and some authors have suggested that technical issues are responsible for most cases of HER2 loss. The limited reproducibility of HER2 retesting across laboratories is well-known and can exemplify the technical variability behind these tests^[49], especially in immunohistochemical evaluation. In contrast, assessment of gene amplification by ISH is less dependent on technical variables. The ESMO Clinical Practice Guidelines for diagnosis, treatment, and follow-up of primary breast cancer suggest that HER2 gene amplification status may be determined directly from all invasive tumors using any type of in situ hybridization (fluorescent, chromogenic, or silver), completely replacing IHC or only for tumors with an ambiguous (2+) IHC score (II, B)^[59].

Many studies investigated receptor conversion both in the neoadjuvant setting and at metastatic relapse^[9,11,60,61]. Nevertheless, most of them were small, retrospective, included patients receiving different drug regimens, and applied distinct definitions of HER2-positivity, thus leading to many biases and low statistical power. Additionally, most studies were conducted before the approval of trastuzumab in the (neo)adjuvant settings, so most patients did not receive anti-HER2 therapy^[62]. Notably, none of these studies performed correlative analyses to understand the biology behind HER2 loss, but some of them investigated whether analytical problems may have been responsible for some of these cases. When also adding FISH analysis in IHC 0 or 1+ cases, some authors disproved cases of HER2 loss^[20,61-64]. This is particularly relevant after administration of trastuzumab or other agents targeting the HER2 extracellular domain, due to the potential downregulation of membrane expression with persisting gene amplification^[14,20]. Interestingly, this phenomenon may be reversible, so that HER2 loss may be falsely detected if samples are collected during targeted therapy^[41,65]. Although it is not possible to distinguish reversible from definitive HER2 loss, it might be argued that patients retaining HER2 amplification at ISH are more prone to restore HER2 expression after stopping anti-HER2 therapy. Unfortunately, timing of HER2 re-overexpression for cases with transient HER2 loss is unknown. To minimize the chance of false-negative results, we believe ISH testing should be performed in all cases of HER2 loss, even in tumors scored as 0 or 1+ at IHC. Indeed, ISH can detect gene amplifications not only in cases of HER2 downregulation but also when technical artifacts lead to a false negative result^[49]. Given the efficacy of new anti-HER2 therapies, determination of HER2 addition/targetability is crucial and may open important therapeutic options with potential impact on survival.

In conclusion, many studies have described HER2 loss in various settings, but correlative studies specifically addressing this phenomenon, i.e., studies collecting and analyzing samples from patients with HER2 loss at different timepoints (before, during, and after therapy), are lacking, and the extent to which technical pitfalls contribute to HER2 loss is unknown.

We believe translational studies that match clinicopathological and biologic features are warranted, to both shed light on this phenomenon and provide guidance on which drugs and strategies may be more effective for patients with HER2 loss.

Abstract

Immunotherapy is an emerging form of cancer therapy that is associated with promising outcomes. However, most cancer patients either do not respond to immunotherapy or develop resistance to treatment. The resistance to immunotherapy is poorly understood compared to chemotherapy and radiotherapy. Since immunotherapy targets cells within the tumor microenvironment, understanding the behavior and interactions of different cells within that environment is essential to adequately understand both therapy options and therapy resistance. This review focuses on reviewing and analyzing the special features of cancer stem cells (CSCs), which we believe may contribute to cancer resistance to immunotherapy. The mechanisms are classified into three main categories: mechanisms related to surface markers which are differentially expressed on CSCs and help CSCs escape from immune surveillance and immune cells killing; mechanisms related to CSC-released cytokines which can recruit immune cells and tame hostile immune responses; and mechanisms related to CSC metabolites which modulate the activities of infiltrated immune cells in the tumor microenvironment. This review also discusses progress made in targeting CSCs with immunotherapy and the prospect of developing novel cancer therapies.

Keywords: Immunotherapy, cancer stem cells, immunotherapy resistance, tumor microenvironment

INTRODUCTION

Cancer heterogeneity at the cellular level has recently shifted cancer research from exclusive investigations

of events affecting specific cell types to investigations of events governing all types of cells in the tumor microenvironment^[1,2]. Tumor heterogeneity is the concept of morphological and phenotypical variation in cancer cells and, therefore, different proliferation potential. Cancer stem cell theory is a confirmed theory derived from this topic, which characterizes subpopulations of tumor cells that can proliferate extensively^[3]. These cells are comparable to normal adult stem cells in that they both undergo self-renewal to maintain the stem cell population. The purpose of this feature is to enable the continuous replacement of cells needed in tissues due to everyday damage, age, *etc.* In cancer stem cells, however, self-renewal has been observed to be the driving force for tumorigenicity and metastasis. Furthermore, there is evidence that cancer stem cell population growth is promoted by oncogenic events induced by chemotherapy, radiation therapy, hypoxia, *etc.*, which are generally thought to reduce tumor growth but, on the contrary, increase the risk of cancer recurrence. Cancer stem cells are observed in all cancers^[3]. While cancer stem cells were shown to have the ability to differentiate into distinct types of cancer cells within the tumor^[4-6], several types of immune cells were shown to control cancer growth in different ways, from directly targeting and killing cancer cells to suppressing the immune attack by modulating other immune cells^[7]. While this paradoxical effect of immune cells on cancer growth is critical to developing adequate immunotherapy regimens, the presence of cancer stem cells in the tumor microenvironment is another factor that could affect the response of cancer to immunotherapy and subsequently lead to therapy resistance. This review discusses the distinctive characteristics of cancer stem cells that we believe may contribute to immunotherapy resistance. Along the same lines, we suggest new areas of focus in the field of immunotherapy research, which may help bypass the therapy resistance caused by cancer stem cells.

CANCER STEM CELLS

The presence of stem cells in tumors has shifted laboratory and clinical approaches to cancer research and has given insight into mechanisms contributing to the therapeutic resistance of many cancers^[8-12]. Cancer stem cells (CSCs) are the “seed” of the tumor with self-renewal and differentiation properties. They are believed to be present in all cancers. Although there is debate regarding CSC generation, hypotheses include evolving from the de-differentiation of differentiated cells, the division of existent tissue stem cells, and a combination of both rationales^[13]. More importantly, CSCs have been observed to resist chemotherapy by at least five main mechanisms: (i) being in a quiescent proliferative state rendering the cells less sensitive to any form of therapy; (ii) activating drug efflux mechanisms; (iii) overexpressing DNA repair mechanisms; (iv) overexpressing anti-apoptotic genes; and (v) releasing cytokines and chemokines rendering other tumor cells resistant to therapy^[14]. As the mechanisms by which CSCs affect the development of chemotherapy resistance have been extensively reviewed, we focus on the characteristics of CSCs that may contribute to resistance to immunotherapy and consider recent findings related to cancer immunotherapy and the cancer microenvironment.

THE INTERACTION BETWEEN IMMUNE CELLS AND CANCER STEM CELLS

Current research aims to understand the immune system’s role in cancer as it is evident that the immune system does not target cancer cells in the same way that it targets other types of self-altered cells. Cancer can escape from immunosurveillance through a well-described procedure termed “cancer immunoediting”, which comprises three main sequential events, namely elimination, equilibrium, and escape, eventually leading to cancer growth^[15]. A tumor microenvironment is an ideal place for starting an investigation of factors contributing to therapy resistance because it is a diverse environment in which a variety of cells grow and interact with one another. It has been shown that the tumor microenvironment (TME) is rich with factors that suppress immune cells by inhibiting their growth.

This interaction in TME can involve both innate and adaptive immune systems. Innate immune cells integral for tumor recognition include natural killer (NK) cells, dendritic cells (DC), macrophages, and myeloid-derived suppressor cells (MDSC). Adaptive immune cells include T cells and B cells. The unique properties of CSCs may make them more susceptible or resistant to immune cells. For example, CSCs have been observed to be more susceptible to being killed by NK cells because of their typical presentation of no/low levels of MHC class I^[16]. Additionally, CSC-secreted factors can actively modulate the function of immune cells to generate an immune-suppressive environment. Tumor-associated macrophages (TAMs) can be differentiated into an M1 or M2 phenotype via exposure to specific cytokines and metabolites in the TME. M1 macrophages are characterized by phagocytic activity promoting tumor-killing properties, whereas M2 macrophages are characterized by cytokine production promoting an anti-inflammatory response in the TME, thus promoting tumor growth. CSCs have been observed to release many cytokines, chemokines, and soluble proteins to attract macrophages into the TME and polarize them into M2 TAMs^[17]. Furthermore, CSC-induced secretion of the immunosuppressive cytokine IL-10 increased the differentiation of CD4⁺CD25⁺FoxP3⁺ regulatory T cells^[18]. Regulatory T cells are a type of CD4⁺ T cell that function as an immunosuppressant to prevent inappropriate immune system activation. These immunosuppressive cells can interact with cancer cells in various ways ranging from direct ligand-receptor interactions to systemic regulation^[19,20]. While systemic regulation is beyond the scope of our discussion in this review paper, it is essential to mention that altered hematopoiesis in cancer is a growing field of research^[21,22] that may contribute to immunotherapy resistance.

CSCs and resistance to immunotherapy

The mechanisms that govern the resistance of cancer to any form of therapy are complicated and numerous. No single mechanism has been shown to fully govern the resistance of a tumor to shrinkage in response to therapy. Instead, a combination of alterations related to surface receptors, secreted factors, and metabolism have been noted in therapy-resistant cells^[23]. Therefore, understanding the behavior of all cells in the TME is crucial to fully understanding therapy resistance. As mentioned above, CSCs can contribute to chemotherapy resistance by either modifying their own behavior or by inducing a therapy-resistant phenotype in surrounding cancer cells. It is also important to mention that the mechanisms governing resistance to immunotherapy may differ from those governing resistance to chemotherapy.

Cancer immunotherapy is briefly divided into two main types of interventions: passive and active^[24]. Passive immunotherapy strategies aim to compensate for missing or deficient immune functions by directly administering tumor-specific antibodies, recombinant cytokines, or the adoptive transfer of immune cells. Active immunotherapy strategies are designed to stimulate effector functions *in vivo*, e.g., vaccination strategies with tumor peptides^[25] or allogeneic whole cells^[26], inhibition of immune checkpoints with antibodies, and induction of immune responses with oncolytic viruses. Unlike chemotherapeutic drugs, which directly target cancer cells, the success of immunotherapy relies on the dynamic interaction between cancer and immune cells. Increasing evidence indicates that non-genetic, intrinsic cancer cell alterations play a key role in resistance to immunotherapies and immune evasion. Therefore, understanding therapy resistance in particular requires understanding the interactions among immune cells, cancer cells, and CSCs and the behavior of CSCs in response to immunotherapy, as CSCs are considered the root of cancer.

CSCs were first identified from leukemia cells as a subpopulation of cancer cells that displayed increased tumorigenicity using serial limiting dilution transplantation assays with severe combined immunodeficient (SCID) mice^[27]. Thereafter, CSCs in many solid tumors were identified using nonobese diabetic (NOD)/SCID mice^[6]. Most of these experiments, using partially immunocompromised mice, demonstrated that a small subset of cancer cells can initiate tumor development. It is still being debated whether the increased tumorigenicity of CSCs attributes to the “stemness” or adaptation ability of CSCs to new

microenvironments^[28,29]. Indeed, it has been reported that tumor-initiating cells in human melanoma were not a rare population when transplanted into more highly immunocompromised NOD/SCID IL-2 receptor gamma chain null (NSG) mice^[30]. Xenotransplantation of non-CSCs into NSG mice also resulted in tumor formation. However, in tumor tissues developed from non-stem melanoma cells transplanted into NSG mice, the expressions of melanoma markers were no longer retained, suggesting the failure of self-renewal. Moreover, these non-stem cancer cells also failed to pass in NSG mice, whereas CSCs were successively propagated and, more importantly, mirrored the heterogeneity of the parental melanoma^[29]. Similar findings have been reported in other models^[31]. The current view is that the rarity of cancer cells exhibiting tumor-initiating properties may not be so important for CSC definition^[32]. Instead, tumor immune evasion may be a more important characteristic of CSCs. Consistently, tumor tissues exposed to an immune challenge *in vivo* exhibited a CSC-like gene expression profile with increased CSC properties, including tumor initiation ability^[33]. Cancer stem cells have characteristics such as slow rates of division, heightened activation of DNA repair mechanisms, cellular plasticity, and microenvironment characteristics including hypoxia and acidosis, which are due to the expression of specific surface markers and secreted and/or enzymatic proteins. Many of these factors may also contribute to the resistance of CSCs to immunotherapy. These mechanisms can be organized into three main categories: (i) mechanisms related to cellular surface proteins; (ii) mechanisms related to released cytokines; and (iii) mechanisms related to metabolic alteration.

Mechanisms related to cellular surface proteins

CSCs are known to express a wide variety of cellular markers that can be used to differentiate them from other tumor cells^[34,35]. In addition to “stemness” markers, CSCs also express membrane proteins that play roles in tumorigenesis and/or therapy resistance^[36]. This review discusses the markers that are vital in the context of cancer immunology and resistance to immunotherapy.

Immune recognition molecules

One of the mechanisms used by CSCs to evade immune response is the downregulation of major histocompatibility complex class I (MHC I) molecules. This protects them from recognition by CD8⁺ T cells. For example, enriched cells with stem-related markers isolated from patients with locally advanced head and neck squamous cell carcinoma (HNSCC) showed decreased expression of human leucocyte antigen I (HLA-I) molecule after chemotherapy treatment^[37]. Similarly, CSCs isolated from primary melanoma, glioblastoma multiforme (GBM) and lung cancer cell lines displayed lower MHC-I levels than their differentiated counterparts^[18,38-40]. Downregulating MHC-I may make CSCs more susceptible to being killed by NK cells. However, CSCs from acute myeloid leukemia (AML)^[41], GBM^[42], and breast cancer (BC)^[43] were found to escape NK cell-mediated killing by the downregulation of activating NKG2D ligands. Lastly, the upregulation of the “don’t eat me” signal, CD47, is another way for CSCs to evade immune control^[44]. The blocking of CD47 was shown to enable macrophage-mediated phagocytosis of CSCs from pancreatic ductal adenocarcinoma (PDAC), AML, and hepatocellular carcinoma (HCC), and thus it promotes their elimination^[45-47].

Immune checkpoint proteins

PD-L1/PD-1 has been well established as an immune checkpoint to control T cell function. CSCs isolated from GBM, BC, CRC, and HNSCC can evade immune surveillance by increasing the expression of the immune checkpoint ligand PD-L1^[48], which binds to its receptor, PD-1, expressed on T-cell surfaces, thus inducing their exhaustion^[48]. Another immune “brake” is represented by T cell immunoglobulin mucin-3 (TIM-3), a specific surface molecule found on leukemic stem cells^[49]. This receptor was described as responsible for T-cell suppression and MDSC expansion. Similarly, it was observed that B7-H4 promotes brain CSC tumorigenicity while negatively regulating T cell-mediated immunity^[50].

Immuno-stimulatory molecules

CD80 is a co-stimulatory molecule known for its role in T-cell activation. It is primarily expressed by immune cells but has been shown to be expressed in cancer cells including melanoma, colorectal cancer, and some tumor-initiating stem cells^[51,52]. CD80 is an important cellular surface protein that has been shown to contribute to stem cell resistance to immunotherapy^[52]. In one study conducted on a model of epidermal squamous cell carcinoma, CD80 in CSCs was shown to be indispensable for CSC resistance to adoptive cytotoxic T cell transfer therapy (ACT)^[52]. Interestingly, CD80 was also observed to interact with cytotoxic T lymphocyte antigen-4 (CTLA-4), which is known to suppress T cell function^[53]. Upon engaging CTLA-4, CD80-expressing CSCs directly dampen cytotoxic T-cell activity, which provides evidence for the importance of CD80 in immunotherapy resistance. The mechanism of action, however, needs to be confirmed by future research. In the same study, the authors selected CSCs that displayed sensitivity to TGFβ and studied the resistance of those CSCs to adoptive cell transfer (ACT) therapy. TGFβ responding CSCs were shown to be resistant to ACT, and, interestingly, CD80 expression was observed to be indispensable for resistance. However, interactions between these two proteins have not been studied^[52]. Future research is required to understand the possible overlap in the mechanisms governing TGFβ sensitivity and CD80 in these resistant cells. Moreover, the clinical feasibility of specifically targeting CSCs' CD80 while sparing CD80 expressed by other immune cells is also not well understood. In a more recent study, both *in vitro* and *in vivo* deactivation of CD80 were associated with higher immunogenicity manifested by the activation of immune cells^[54]. This immunogenicity was antagonized by blocking CTLA-4^[54]. Although the aforementioned study does not specifically target CSCs, it confirms two important concepts governing the mode of action of CD80 (shown in the previously mentioned study to be highly expressed by TGFβ sensitive CSCs): (i) CD80 has an anti-immunogenic role in at least some types of cancer; and (ii) CD80 exerts its anti-immunogenic functions, at least in part, through CTLA-4.

Apart from the above-mentioned mechanisms, CSCs further interact with immune cells in order to create a suitable microenvironment for its survival and self-renewal. Studies have shown the importance of TAMs in maintaining tumor homeostasis and immune suppression. One such interaction involves the myeloid cell marker CD11b on TAMs and CD90 on cancer stem cells, accompanied by EphA4 and epinephrine leading to the release of several other immunosuppressive cytokines that help maintain cancer stemness and survival^[55]. CSCs can also interact with CD66⁺ neutrophils to prevent their maturation into N2 neutrophils alongside blocking T cell IFNγ-mediated killing of cancer cells^[56,57]. Another study showed the importance of CSCs surface marker CD133, which prevents DC maturation and thus downregulates T cell-mediated response^[58].

Mechanisms related to released cytokines

The release of cytokines has been observed to have paradoxical effects on immunotherapy resistance. While proinflammatory cytokines are required for adequate function of T cells in ACT and in CTLA-4/PD-1 targeting therapies, they can induce stemness of CSCs, promoting therapy resistance^[36]. Many cytokines have dual roles in promotion of CSC self-renewal and immune evasion and immune suppression. In this context, two main therapy options arise: (i) moderating the proinflammatory environment in a way that can induce/maintain stemness; and (ii) antagonizing the proinflammatory environment in a way that can block stemness, at least partially, yet create an immunosuppressive environment that may not be favorable for immunotherapy.

Tumor microenvironments in solid tumors are rich in many cytokines, including IL-1, IL-6, IL-4, IL-8, granulocyte-CSF, MF inhibitory cytokine-1 (MIC-1), and TGF-β, which can impair the anti-tumor immune responses and shield them from T-cell infiltration^[59]. IL-1β is responsible for the infiltration of myeloid cells, primarily MDSCs, CD11b⁺Gr-1⁺ granulocytes, and CD11b⁺F4/80⁺Gr-1^{-/low} TAMs in the tumor

microenvironment, thereby promoting tumor growth, progression, and poor prognosis^[60,61]. IL-6 produced in the tumor microenvironment by CSCs has been shown to enhance the neoplastic progression of tumors. STAT3 activation by IL-6 in TAMs and MDSCs induces the expression of VEGF and bFGF in a positive feedback mechanism promoting angiogenesis^[62]. Apart from regulating the TAMs and MDSCs, IL-6 has also been shown to interfere with the antigen presentation of DCs that are primarily important for the activation and priming of CD8⁺ T cells (cytotoxic T cells)^[62]. Furthermore, IL-6 signaling also induces the polarization of immature myeloid cells to macrophages or MDSCs instead of antigen-presenting DCs, which in turn contributes to tumor progression. IL-8, for example, has been shown to recruit and activate the differentiation of immature neutrophils into pro-tumor neutrophils in the tumor microenvironment, thereby helping tumor progression and angiogenesis^[63]. These pro-tumor neutrophils can suppress the adaptive immune response by secreting arginase 1, which cleaves the arginase required by the cytotoxic T cells to function^[64,65]. CSCs were shown to promote the polarization of macrophages toward an M2 phenotype by the production of TGF- β , granulocyte-macrophage colony-stimulating factor (GM-CSF), and macrophage colony-stimulating factor (M-CSF)^[66] and via the cyclooxygenase (COX)-2/PGE2 pathway^[67]. In turn, M2 TAMs support the expansion and drug resistance of CSCs by producing the cytokine IL-6^[68]. Administration of TGF- β inhibitors eliminates TGF-mediated immunosuppressive effects on the immune system, thereby enhancing immunotherapy efficiency^[69].

Apart from their role in immune suppression, many cytokines, including TNF α ^[70], IL-17^[71], IL-1^[72], and IL-8^[64], are known to activate CSC formation and renewal. For example, a recent study showed that IL-17 could activate the autophagy of CSCs through one of its receptors, IL-17RB, in a gastric cancer model^[73,74]. While autophagy is a cell death mechanism, it may be indispensable for the self-renewal of CSCs and can be considered as a homeostatic mechanism through which the tumor's pool of CSC is replenished.

Mechanisms related to metabolic alteration

Although poorly studied, metabolic alterations in CSCs might be vital for the adequate understanding of many aspects of the tumor microenvironment^[75,76]. Metabolic alterations in CSCs have been shown to govern cancer-related mechanisms that may serve purposes beyond energy production^[76]. In other words, metabolic alterations might go hand in hand with alterations in both stemness and growth potential. For example, the overproduction of lactate has always been thought of as a demonstration of the tumor's adaptation to hypoxia and is now known to have roles in the self-renewal of CSCs. We focus our discussion on CSC metabolic plasticity, which may govern resistance to immunotherapy and be a potential therapy target^[77].

Excessive lactate production

Although studies have shown that CSCs can undergo oxidative phosphorylation, the glycolysis/lactate production rate has been shown to be significantly higher in CSCs than in non-CSCs of a tumor^[78]. Moreover, CSCs were also shown to be activated by lactate^[79]. One recent study showed that lactate, produced by differentiated cancer cells from a colorectal cancer patient, was shown to promote the self-renewal of CSCs in organoids^[80]. Therefore, lactate represents an important metabolite that is secreted by CSCs and responded to by CSCs. Lactate can induce the accumulation of MDSCs through granulocyte-macrophage colony-stimulating factor (GM-CSF) and IL-6 and enhance the immunosuppressive phenotype of MDSC through the G-protein-coupled receptor 81 (GPR81)/mTOR/HIF-1 α /STAT3 pathway^[81,82]. In addition, lactate-induced HIF-1 α activates the CCL20/CCR6 axis by inducing myeloid trigger receptor-1 (TREM-1) expression in TAMs, attracting aggregation and initiating immunosuppressive effects of Treg. A recent study showed that lactate-derived lactylation of histone lysine residues serves as a new epigenetic modification that directly stimulates gene transcription from chromatin^[83]. Histone lysine lactylation has been shown to promote M2 activation, but the exact mechanism is not well understood^[83]. Besides, lactate

inhibits the expression of activated receptor Nkp46 in NK cells^[81]. What is yet to be determined, however, is whether targeting lactate metabolism would affect the response of tumor cells to immunotherapy by antagonizing the stemness in CSCs.

Lactic acid accumulation in the tumor microenvironment is a well-established immunosuppressive strategy employed by CSCs. Studies have shown that the increased accumulation and production of lactate can hinder tumor infiltration of NK cells and T cells^[84] as well as inhibit proliferation and the production of cytokines by T cells^[85]. A very recent article also discusses the role of lactate in the tumor microenvironment regulating T-cell redox functions and suppressing T-cell proliferation, wherein the authors showed that inhibiting lactate production by cancer cells can improve T-cell functions in adaptive T-cell therapy and overcome immunotherapeutic resistance^[86]. The acidic microenvironment also impairs IL-2 and IFN γ production by T cells, thus reducing the cytotoxic effects of effector T cells^[87].

Retinoic acid metabolism in CSCs

ALDH1 is a putative CSC marker in a variety of solid cancers including pancreatic cancer, ovarian cancer, uterine cancer, and breast cancer^[88]. Several isoforms (ALDH1A1, ALDH1A2, and ALDH1A3) play a role in retinoic acid (RA) formation through oxidation of all-trans-retinal and 9-cis-retinal that are involved in retinoid signaling, which has been related to the stemness of CSCs. Although it has been observed that RA has anti-tumor and anti-CSC capabilities, there is evidence that its role is manipulated by TME and associated with the ALDH1A3 receptor to promote CSC stemness^[89]. Sullivan *et al.* observed that RA metabolism via the ALDH1A3 receptor transcriptionally upregulated tissue transglutaminase in mesenchymal glioma CSCs, an enzyme associated with aggressive tumors and upregulation of CD44⁺ glioma CSCs^[90]. They further noted that glioma CSCs regulated this mechanism by promoting the transcription of RA-inducible genes. Marcatò *et al.* found a similar correlation regarding the promotion of RA-induced genes in aggressive and/or triple-negative breast cancer cell lines upon ALDH1A3 and RA interaction^[91].

This interaction may be a potential factor in immunotherapeutic resistance. Terzuoli *et al.* found that ALDH3A1 overexpression in both melanoma and non-small-cell lung carcinoma transcriptionally modified the cells to CSC phenotype with upregulation of PDL-1 and EMT markers and an increase in proinflammatory immunosuppressive factors including NF κ B, prostaglandin E₂, IL-6, IL-13, and COX-2^[92]. Additionally, Devalaraja *et al.* uncovered that TME-induced tumor-derived RA induced by IL-13 in sarcoma cells supported immunosuppression via inhibiting monocyte differentiation of antigen-presenting dendritic cells (DCs) and, instead, promoted differentiation of M2 TAMs^[93]. It is likely that CSCs contribute to this interaction as studies have observed their involvement in both inhibiting DC maturation and promoting M2 TAM differentiation from monocytes^[94].

Altered metabolic pathways in TAM

Solid tumors are known to have special metabolic characteristics that would allow them to face challenges related to hypoxia and/or shortage of nutrients^[77,95]. It has been shown that hypoxia in the tumor microenvironment preferentially upregulates OXPHOS and FAO metabolic pathways in the M2 TAMs. This causes the accumulation of metabolic byproducts such as glutamine, α -ketoglutarate, and succinate, resulting in activation of the HIF-1 α -mediated cell-self-renewal signaling pathway. Furthermore, tumor-associated macrophages undergo “M2 polarization” by secreting IL-6 to promote PI3K/AKT phosphorylation. This promotes protein kinase 1 (PDK1)-mediated phosphoglycerate kinase 1 (PGK1)-catalyzed glycolysis of macrophages^[96]. Interestingly, IL-6, as discussed in a previous section, can enhance the stemness of CSCs and CSC-dependent chemoresistance through STAT3 transcription factor activation. Other studies have shown a mutually symbiotic relationship between CSCs and M2 TAMs, in that CSCs

were considered to play an active role in M2 polarization, resulting in inhibition of antigen presentation and anti-tumor cytotoxic CD8⁺ T-cell responses^[17]

Immunotherapeutic strategies to target CSCs

To achieve complete regression of tumors, CSCs have to be targeted for therapy. Compared to differentiated counterparts, CSCs are known to express a different set of genes that can potentially serve as tumor antigens. Although all over-expressed antigens might not be strong immunotherapeutic targets, certain other types of overexpressed antigens have been studied, such as ALDH1A1 and hTERT in CD44⁺ breast cancer CSCs^[97], HER2 proto-oncogene in glioma CSCs^[98], and CEP55 and COA-1^[99] in colon CSCs. These overexpressed antigens could be novel targets for the development of CSC-associated immunotherapeutic strategies. Dendritic cells (DCs) are antigen-presenting cells in the immune system that induce primary immune system responses. In the creation of DC-based vaccines, DCs are primed with tumor antigens, such as fusion with tumor lysates and transfection of certain peptide sequences to induce T-cell activation upon vaccination^[100]. Examples of recent vaccines being studied targeting CSCs include DCs primed with CSC lysate, Panc-1 CSC lysate, NANOG peptide, and ALDH^{high} CSCs^[101]. In a study conducted by Yin *et al.*, DCs were primed with pancreatic CSC lysates identified via culturing Panc-1 cells with a non-adherent sphere culture system due to the heterogeneity of surface markers. Upon co-culturing with lymphocytes, proliferation and significant activation of lymphocytes were observed along with the secretion of tumor-killing cytokines INF- γ and IL-2. Significant cytotoxic effects induced by the primed DCs were also observed^[102].

Oncolytic virotherapy utilizes viruses engineered to replicate within tumor cells via the cytolytic pathway. The virus is selected regarding the type of cancer and its known receptors to increase infectivity of the tumor cells^[103]. Examples of viruses used include the herpes simplex virus, adenovirus, vaccinia virus, and measles virus^[101]. Sato-Dahlman *et al.* conducted a study designing and testing a form of oncolytic virotherapy for colorectal cancer with an adenovirus. The adenovirus was selected in particular because of its capability for efficient transduction in cells with its receptor to combine with the engineered specificity for the CD133 receptor known to be upregulated in colorectal cancer, among other types of cancer. The transmembrane receptor CD133 has been highly studied as a cancer stem cell marker, and its upregulation has been associated with the maintenance of self-renewal and metastasis. The results support increased infectivity and lysis of CD133⁺ cells *in vitro* and *in vivo*^[104].

Some CSC-specific surface markers can be used as specific targets for chimeric antigen receptor T cell (CAR-T) therapy to eliminate CSCs. In addition, the expression of MHC molecules on the surface of CSCs is low, which causes MHC restriction when immunotherapy is used to target CSCs^[39]. However, in CAR-T therapy, CAR-T cells can recognize the target antigen with no MHC restrictions, which endows some advantages for the application of CAR-T therapy to eliminate CSCs. Recently, the clinical application of CAR-T therapy has made an unprecedented breakthrough in the treatment of hematological diseases^[105]. The safety and feasibility of CAR-T therapy in the treatment of solid tumors have also been confirmed^[106]. The discovery of surface markers of CSCs provides specific therapeutic targets for the treatment of CSCs. Many previous experiments have identified the expression of CD133, CD90, ALDH, and EpCAM in CSCs of many types of cancer^[107-109]. These markers can be used as an important molecular target for CAR-T cells to kill CSCs in order to achieve the therapeutic effect of eliminating CSCs and inhibiting tumor recurrence and metastasis. In addition, certain molecular markers expressed in common tumor cells, such as epidermal growth factor receptor variant III (EGFRvIII), chondroitin sulphate proteoglycan 4 (CSPG4), human epidermal growth factor receptor 2 (HER2), NKG2D ligands (NKG2DLs), *etc.*, are also expressed on the surface of tumor stem cells^[110]. The construction of CAR-T cells with molecular markers of CSCs as targets has a certain theoretical effect on the elimination of CSCs.

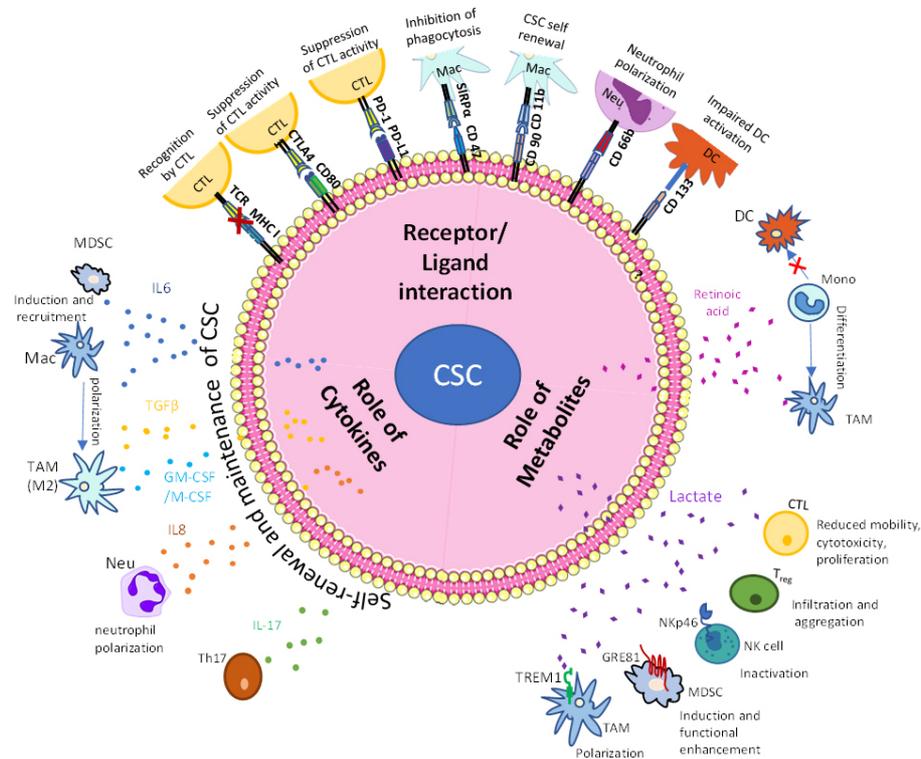

Figure 1. CSC-mediated immune escape and self-renewal. The tumor microenvironment is home to a lot of immune cells, which contribute to cancer cell survival and proliferation. The CSCs can self-renew themselves due to their stem-like properties and are also aided by different cytokines in the TME. Metabolic products from the CSCs, such as retinoic acid and lactate, are also involved in their self-renewal. Other immune cells in the TME, such as MDSCs, immature neutrophils, and TAMs, are also involved in tumor proliferation by dampening the cytotoxic effects of killer T cells and promoting regulatory T cells. CSCs: Cancer stem cells; TME: tumor microenvironment; TAMs: tumor-associated macrophages; CTL: cytotoxic T lymphocyte; Mac: macrophage; Mono: monocyte; Neu: neutrophil; DC: dendritic cells; Treg: regulatory T cell.

TIL follows the same methodology, but it isolates T cells with tumor-specific epitopes to target antigens rather than the CAR receptor. Chen *et al.* employed this strategy in their observation of the synergistic effect between $\gamma\delta$ T cells and $CD8^+$ T cells in killing CSCs. This was achieved because $\gamma\delta$ T cells secrete interferon gamma ($IFN-\gamma$), resulting in the upregulation of MHC class I and $CD54/ICAM-1$ in CSCs and, thereby, allowing CSCs to become more susceptible to $CD8^+$ T cell-mediated cytotoxicity^[111].

While low expression of MHC-I may limit $CD8$ T-cell recognition and response to CSCs, the lack of MHC-I molecules should, in turn, promote NK cell activation, representing an alternate immunotherapeutic target^[112]. In regard to adoptive immunotherapy of NK cells, NK cells have been identified to contain activating and cytotoxic receptors that can bind with tumor-specific stress-induced ligands, thereby increasing antigen recognition^[113]. There is evidence that NK cells may preferentially target CSCs because of both this and their ability to identify the lower expression of MHC class I molecules that provide CSCs their non-proliferative properties. This was supported in the study conducted by Ames *et al.* in their identification of CSC markers $CD24^+/CD44^+$, $CD133^+$, and aldehyde dehydrogenase bright present on NK cells *in vitro* and *ex vivo*^[114]. CSC ligands MICA/B, Fas, and DR5, involved in NK activation, were also noted to be upregulated. The mechanism for this observation was further investigated by studying the NKG2D pathway that is important for the binding of MHC class proteins during cellular stress for increased cytotoxicity. Significant *in vivo* studies have found reduced CSC population and tumor size in NSG mice with human pancreatic tumors^[114].

CONCLUSION AND FUTURE PERSPECTIVES

Many studies performed in the past decade confirm the importance of the whole microenvironment in driving cancer growth and resistance to therapy. As immunotherapy targets a very fundamental aspect of the tumor microenvironment, namely the interaction between immune cells and cancer cells, investigating the tumor microenvironment is critical for an adequate understanding of therapy options and therapy resistance. This review focuses on CSC characteristics that we think might govern the resistance of cancer to immunotherapy [Figure 1]. While the focus is on the expression of cellular markers/release and response to cytokines/metabolic reprogramming, other mechanisms might govern CSCs' ability to bypass or help cancer cells bypass immunotherapy. In addition to answering the questions raised in this review paper, future research needs to focus on other aspects that might govern resistance. These include the systemic control of the hematopoiesis characteristic of cancer and the common markers between CSCs and embryonic stem cells, which might allow for escaping immune surveillance and, therefore, escaping immunotherapy.

DECLARATIONS

Acknowledgments

We thank Zachary Ferris for proofreading the manuscript.

Abstract

Recent evidence suggests that genetic and epigenetic mechanisms might be associated with acquired resistance to cancer therapies. The aim of this study was to assess the association of genome-wide genetic and epigenetic alterations with the response to anti-HER2 agents in HER2-positive breast cancer patients. PubMed was screened for articles published until March 2021 on observational studies investigating the association of genome-wide genetic and epigenetic alterations, measured in breast cancer tissues or blood, with the response to targeted treatment in HER2-positive breast cancer patients. Sixteen studies were included in the review along with ours, in which we compared the genome-wide DNA methylation pattern in breast tumor tissues of patients who acquired

© The Author(s) 2022. **Open Access** This article is licensed under a Creative Commons Attribution 4.0 International License (<https://creativecommons.org/licenses/by/4.0/>), which permits unrestricted use, sharing, adaptation, distribution and reproduction in any medium or format, for any purpose, even commercially, as long as you give appropriate credit to the original author(s) and the source, provide a link to the Creative Commons license, and indicate if changes were made.

resistance to treatment (case group, $n = 6$) to that of patients who did not develop resistance (control group, $n = 6$). Among genes identified as differentially methylated between the breast cancer tissue of cases and controls, one of them, *PRKACA*, was also reported as differentially expressed in two studies included in the review. Although included studies were heterogeneous in terms of methodology and study population, our review suggests that genes of the PI3K pathway may play an important role in developing resistance to anti-HER2 agents in breast cancer patients. Genome-wide genetic and epigenetic alterations measured in breast cancer tissue or blood might be promising markers of resistance to anti-HER2 agents in HER2-positive breast cancer patients. Further studies are needed to confirm these data.

Keywords: Breast neoplasms, epigenetics, genetics, HER2 inhibitors, treatment response, biomarkers

INTRODUCTION

The human epidermal growth factor receptor 2 (HER2) is a transmembrane tyrosine kinase receptor and belongs to the epidermal growth factor receptor (EGFR) family^[1]. It comprises an extracellular domain (ECD), a transmembrane segment, and an intracellular region^[2]. *HER2* gene amplification and receptor overexpression, which occur in approximately 15%-20% of breast cancer patients, are important markers for poor prognosis, including a more aggressive disease and shorter survival^[3]. In addition, HER2-positive status is considered a predictive marker of response to HER2-targeted drugs^[4]. Detection of receptor overexpression via immunohistochemistry (IHC) and/or *HER2* gene amplification using *in situ* hybridization (ISH) techniques in breast cancer tissue, including fluorescent ISH (FISH), determines patients' eligibility to receive anti-HER2 therapies^[5]. Food and Drug Administration (FDA)-approved anti-HER2 agents currently used in clinical settings in combination with chemotherapy comprises recombinant monoclonal antibodies that bind the ECD of HER2, such as trastuzumab (Herceptin[®]), pertuzumab (Perjeta[®]) and trastuzumab emtansine (T-DM1, Kadcyla[®]), and small molecule tyrosine kinase inhibitors, like lapatinib (TYKERB[®]), that inhibit enzyme function of the intracellular catalytic domain of HER2 and other EGFR members^[6,7].

Although targeted treatment with anti-HER2 agents has significantly improved the disease-free and overall survival rates of metastatic and early-stage HER2-positive breast cancer patients^[8-11], resistance to anti-HER2 therapy, both primary and acquired, has emerged as a major clinical problem in the treatment of HER2-positive breast cancer patients^[12-14]. Even though several molecular mechanisms of resistance to anti-HER2 agents have been proposed in preclinical models, no clinically applicable strategy to overcome resistance to these targeted treatments has been identified yet^[15]. Therefore, there is an urgent need to identify reliable predictive molecular markers of treatment failure with the ultimate goal of developing targeted drugs that can overcome resistance.

Studies indicate that genetic factors, including single nucleotide polymorphisms (SNPs), copy number variations (CNVs), *HER2* mutations, and HER2 splice variants, might influence treatment effectiveness toward targeted therapies in HER2-positive breast cancer patients or HER2-positive breast cancer cell lines^[16-28]. Recent evidence suggests that epigenetic regulatory mechanisms, including DNA methylation and microRNAs (miRNAs), might play a role in acquiring resistance to cancer therapies^[29-32]. DNA methylation occurs through the covalent attachment of a methyl group on cytosine residues in CpG dinucleotides and contributes to transcriptional regulations^[33]. While DNA methylation in the immediate vicinity of the transcriptional start site (TSS) generally represses gene expression, methylation in the gene body (far from annotated TSS) may stimulate elongation and is, therefore, positively associated with gene expression^[34,35]. miRNA are approximately 22 nucleotides long non-coding RNAs that regulate gene expression in a sequence-specific manner^[36].

The aim of this pilot study was to analyze the association between DNA methylation patterns in breast cancer specimens and response to trastuzumab in a cohort of 12 trastuzumab-treated, non-metastatic HER2-positive breast cancer patients. Additionally, a systematic review that combines these findings with all available published results on the association of genome-wide genetic and epigenetic alterations in breast cancer tissue or blood with response to anti-HER2 treatment in HER2-positive breast cancer patients is also reported.

MATERIAL AND METHODS

Pilot study of new findings

Study population and data collection

The study population consisted of 12 women (six cases and six controls) selected among 106 trastuzumab-treated patients with non-metastatic, HER2-positive breast cancer diagnosed between July 1, 2005 and December 31, 2010 at the Centre des Maladies du Sein, a specialized breast center in Quebec City, Canada. Information on tumor characteristics and prognostic factors at the time of diagnosis (baseline) and follow-up information were collected from medical records. The clinical endpoint in this study was disease-free survival (DFS). All breast cancer recurrences (locoregional, contralateral breast, and distant) were considered as events, whereas death (from any cause) before recurrence and loss to follow-up were considered as censoring events.

Over a mean follow-up period of 6.22 years, 22 patients out of 106 experienced recurrence. Eight cases were randomly selected among all patients who developed recurrence during follow-up and six had a sufficient amount of primary breast cancer tissue available for DNA extraction (see below). Of note, baseline characteristics of the six selected cases were comparable to the total population of cases ($n = 22$) for all characteristics except tumor grade (the proportion of grade III tumors among the selected cases was 67% vs. 41% for the total population of cases) [Supplementary Table 1]. For each case, one control was selected from the 84 patients who had not developed recurrence and were alive at the date of the case's recurrence. Controls were matched to cases for the following factors: age at diagnosis (with 5-year age categories), estrogen receptor (ER) status, year of diagnosis (with 2-year categories), and menopausal status. The number of samples used was determined upon the availability of samples and not evaluated using a statistical sample size calculation. All patients provided written informed consent. Ethical approval of the study was obtained from the Research Ethics Committee of the Centre de Recherche du CHU de Québec (# 2016-2802).

Gene methylation assessment

To ensure that DNA methylation was analyzed to the greatest possible extent in breast cancer tissue and to reduce contamination with other cell types (lymphocytes, adipocytes, fibroblasts), tissue microarray (TMA) blocks containing formalin-fixed, paraffin-embedded (FFPE) breast cancer tissue cores (1 mm in diameter) were constructed for each patient, as previously described^[37]. From each TMA block, one section was stained with hematoxylin and eosin (H&E) to verify the cellular composition of the cores. Cores were removed from TMA blocks if they contained abnormal tissue or if epithelial tumor tissue occupied < 70% of the core area before proceeding to DNA extraction. H&E sections were prepared from different levels of the TMA blocks: at the beginning, at regular intervals (every tenth 10- μ m-thick serial section), and after the last section. DNA was extracted from tissue cores using GeneJET FFPE DNA Purification kit (ThermoScientific, Ottawa, Canada) with minor modifications to the manufacturer's instructions in which samples were incubated with Digestion buffer for six minutes and incubated with Proteinase K solution for 180 minutes.

DNA samples were sent to Génome Québec Innovation Center (Montreal, Canada). Methylation was measured with the Illumina HumanMethylation450 BeadChip array (Illumina Inc., San Diego, CA, USA) following the manufacturer's instructions for the bisulfite treatment, Infinium FFPE quality control (Illumina FFPE QC kit, Illumina, Inc., CA, USA), and DNA restoration. This BeadChip interrogates 482,421 CpG sites, 3091 non-CpG sites, 65 random SNPs, and covers 21,231 RefSeq genes. It uses two distinct oligonucleotide probes (Infinium I and Infinium II) to assess methylation levels^[38].

Statistical analysis

Raw β -values, defined as the ratio of the methylated probe intensity to the overall intensity (sum of the methylated and unmethylated probe intensities)^[39], were imported into the R statistical programming environment (version 3.2.2). Since M-values [\log_2 transformed β -values, calculated as $M = \log_2\left(\frac{\beta}{1-\beta}\right)$] are considered more reliable in the detection rate and true positive rate for both highly methylated and unmethylated CpG sites compared to β -values^[39], M-values were used for statistical analyses.

Quality control was performed with the qcReport function from the minfi package, and none of the 12 samples were excluded due to bad quality control. The Dasen method from the WateRmelon package, also known as data-driven separate normalization, was used to background correct and quantile normalize data based on methylated and unmethylated intensities, separately, by probe types (Infinium I and II)^[40]. A probe filtration step was performed to remove CpG sites corresponding to probes that could affect our analysis, including probes with bad detection (detection P -value > 0.01); unique probes having a common single nucleotide polymorphism (SNP) in European individuals at the interrogated CpG loci or the single-base extension according to the list published by Chen *et al.*^[41]; probes that can hybridize to multiple loci also listed by Chen *et al.*^[41]; and probes located on X and Y chromosomes. A total of 76,161 unique probes were removed, leaving 406,260 autosomal probes for the analysis. Data were verified for confounding batch effects due to separate chips^[42], and none were observed. All samples passed quality-control tests and were therefore retained in the analysis.

Baseline characteristics between cases and controls were compared using Fisher's exact test for categorical variables, Student's t -test for follow-up time and Wilcoxon-Mann-Whitney test for the other continuous variables. The difference in global methylation levels between median M-values of cases and controls was assessed using a Wilcoxon signed-rank test for paired samples. Differentially methylated probes (DMPs) were identified using LIMMA (robust linear regression method), taking into account the matching factors between cases and controls (i.e., age at diagnosis, ER status, year of diagnosis, and menopausal status). Multiple testing correction was performed using false discovery rate (FDR) estimation (cut-off < 5%). In addition, we used a \log_2 -fold change $|\log_2\text{FC}|$ (i.e., the difference between mean M-values measured in breast cancer tissues of resistant patients and controls) > 2.0 as a cut-off to identify probes that were strongly differentially methylated between cases and controls.

Systematic review of published findings

A systematic review was conducted and reported according to the 2020 Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines^[43].

Eligibility criteria

Population: We included studies of HER2-positive breast cancer patients treated with any type of anti-HER2 agent (trastuzumab [Herceptin®], lapatinib [TYKERB®], pertuzumab [Perjeta®], trastuzumab emtansine [trastuzumab-DM1, Kadcyla®], erlotinib [Traceva®], gefitinib [Iressa®]) regardless of age, stage, and menopausal status.

Exposure: To be included, a study had to measure response-specific survival using including pathologic complete response (pCR), disease-free survival (DFS), progression-free survival (PFS), or event-free survival (EFS).

Outcome: We considered all assessments of genetic and epigenetic alterations at the genome-wide level in breast cancer tissue or blood, whatever the measurement method.

Types of studies: Any observational or randomized controlled study that assessed the association between genome-wide genetic and epigenetic alterations in breast cancer specimens or blood and the response to anti-HER2 agents in HER2-positive breast cancer patients was eligible. Case reports were excluded.

Only full available articles in English were included.

Information sources

Dragic D searched the PubMed biomedical database from inception to the search date of March 25, 2021, to identify eligible studies.

Search strategy

The search strategy was developed by Dragic D and Furrer D, approved by Diorio C, using controlled vocabulary search terms and free-text words related to HER2-positive breast cancer, genome-wide genetic and epigenetic alterations and treatment outcome [[Supplementary Table 2](#)]. No restrictions regarding language were applied.

Selection process

The references identified by the search strategy were selected according to the predefined eligibility criteria in a two-step process: titles and abstracts were screened by one author (Dragic D), and full texts of retained articles were examined by two authors (Dragic D and Furrer D). Disagreements between the two authors were discussed until a consensus was reached, and whenever required, a third review author (Diorio C) was consulted.

Data collection process

We designed a data extraction form for this review. Data were extracted by two authors (Furrer D and Dragic D) for half of the included studies. A third author (Diorio C) was consulted when discrepancies between both authors could not be resolved. For the remaining studies, the extraction was done by one author (Dragic D), and when needed, a second author (Diorio C) was involved. Additionally, the authors of studies of interest that lacked data to evaluate eligibility ($n = 1$) or other measures needed for this review ($n = 3$) were contacted to obtain the necessary information.

Data items

For all selected articles, study characteristics (study design and sample size), patient's characteristics (age, stage, ER and PR status, menopausal status, and treatment received), assessment of genetic and epigenetic alterations (tissue processing, DNA, RNA or miRNA extraction method, assessment method, and parameters used), as well as statistical methods and study results, were collected. The study's definition of response to targeted treatment was recorded.

Risk of bias assessment

Studies included in the review were assessed for risk of bias using the “Risk Of Bias in Non-randomized Studies of Interventions (ROBINS-I) tool^[44]. The following domains were assessed: selection of participants in the study, exposure measurement, outcome measurement, potential confounding factors, missing data, and selective reporting.

Assessment of the risk of bias was done by two authors (Furrer D and Dragic D) for half of the included studies. Inconsistencies were discussed to reach a consensus. For the remaining studies, the assessment was done by one author (Dragic D), and when required, a second reviewer (Furrer D) was consulted.

Assessment of heterogeneity

Differences between studies, including study design, patient characteristics (age, menopausal status, ethnicity, and treatment received), tumor characteristics (stage, ER status), assessment of genome-wide genetic and epigenetic alterations (tissue processing, extraction method, and measurement method), and different levels of risk of bias were considered for exploring possible sources of heterogeneity.

Synthesis methods

Considering that high heterogeneity between studies was expected, quantitative data synthesis was not considered appropriate. Instead, we adopted a qualitative systematic review approach to investigate the relationship between epigenetic and genetic alterations and response to HER2-targeted therapies in HER2-positive breast cancer patients. The selection process was detailed using the PRISMA 2020 flow diagram. Extracted data were first reported in a table gathering summary characteristics of all included studies. Additional information specific to the epigenetic or genetic method used was detailed in several tables. Results and genes identified by several studies were also highlighted in a table. If pathway analysis was not presented, we performed pathway analysis using the list of the differentially expressed genes reported by the study authors and the PANTHER online software (Protein Analysis Through Evolutionary Relationships). *P*-values < 0.05 were considered significant.

RESULTS

Pilot study of new findings

Genome-wide DNA methylation data in 12 breast cancer specimens were obtained from six trastuzumab-treated HER2-positive breast cancer patients who experienced recurrence during follow-up (cases) and six individually matched patients who had not developed recurrence and were alive at the date of the case's recurrence (controls). Baseline characteristics of cases and controls are summarized in [Table 1](#). Baseline characteristics for both groups were comparable in clinicopathological characteristics (tumor grade, lymph node status, and tumor size) and treatment received. Compared to controls, a higher proportion of cases (50%) had a body mass index > 25 kg/m², although not statistically significant.

Global methylation levels between cases and controls were not statistically different: the median M-values of cases were 0.487, and the median M-values of controls were 0.504 (*P*-value: 0.844). At probe methylation levels, we identified 2,009 CpGs (1,382 genes) that were differentially methylated between cases and controls: 1,200 DMPs (885 genes) were significantly hypermethylated and 809 DMPs (497 genes) were significantly hypomethylated in tumor tissues of cases compared to those of controls after multiple testing correction (FDR < 0.05).

Fifteen genes had a $|\log_2FC| > 2.0$: ten genes (*SIX2*, *PLEC1*, *ZNF833*, *RAI1*, *ZNF598*, *USP4*, *DOCK1*, *UNC84A*, *KLF16*, *PRKACA*) were significantly hypermethylated, and five genes [*STK33*, *TBXT* (alias *T*),

KCNH7, *ADAMTS2*, *FAM19A5*] were significantly hypomethylated in breast cancer tissues of cases compared to controls. Results are reported in [Table 2](#).

Systematic review of published findings

Study selection

Of the 758 references retrieved by electronic search in PubMed, we reviewed 52 full-text documents, and fifteen met the eligibility criteria [[Figure 1](#)]. This review also included our pilot study that assessed the association between DNA methylation patterns in breast cancer specimens and response to trastuzumab in a cohort of 12 HER2-positive breast cancer patients.

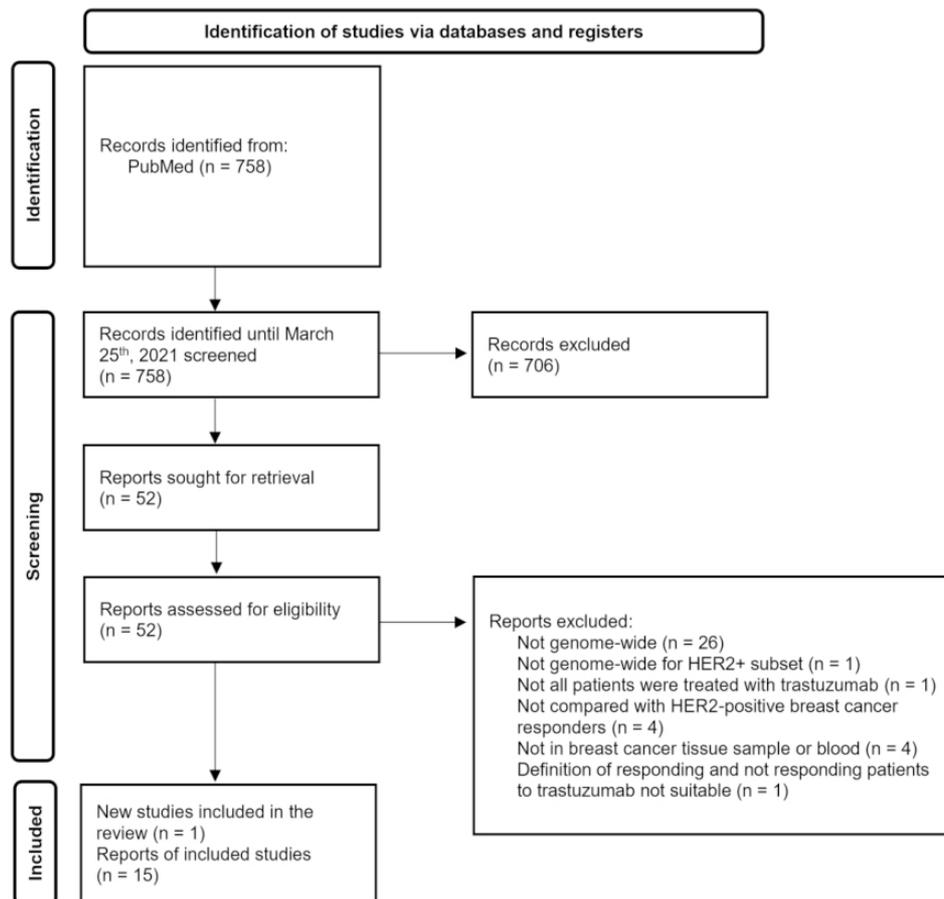

Study characteristics

In all selected studies, epigenetic and genetic patterns were measured genome-wide in breast cancer tissues or blood. DNA methylation patterns were evaluated in one study (our pilot study), gene expression profile in nine studies^[45-53], miRNA expression in two studies^[54,55], long intergenic non-coding RNA (lincRNA) profile in one study^[50], copy number alteration (CNA) profile in two studies^[48,56], protein expression in one study^[57] and mutations in two studies^[58,59]. One study reported both genome-wide gene expression and

**Figure 1.** Process flow for article selection (PRISMA 2020 flow diagram).

genome-wide CNA patterns^[48], and one reported both genome-wide gene and genome-wide lincRNA expression profiles^[50]. The majority of studies were retrospective ($n = 10$)^[46,47,49-51,54-57] including ours, and six studies were prospective^[45,48,52,53,58,59] [Table 3].

DFS was reported in four studies including ours^[46,52,54], RFS in two studies^[49,53], and pCR in ten studies^[45,47,48,50,51,55-59]. DFS was defined as the time between the diagnosis and recurrence (locoregional recurrence, recurrence in the contralateral breast, and distant breast cancer recurrence) or death; RFS was defined as the time from the start of trastuzumab treatment to the first local, regional or distant recurrence event; and pCR as the absence of invasive breast cancer in the breast and axillary lymph nodes at the time of surgery. Besides ours, the other fifteen included studies were published between 2007 and 2020 and involved between 9 and 849 HER2-positive, anti-HER2 therapy-treated breast cancer patients [Table 3].

Studies of genome-wide DNA methylation and response to targeted treatment

Characteristics of the study (our new findings) that evaluated the association between genome-wide DNA methylation patterns measured in breast cancer tissues and response to targeted treatment in HER2-positive, trastuzumab-treated breast cancer patients are presented in [Supplementary Table 3](#). The study was retrospective. The mean age of included HER2-positive breast cancer patients was 51.3 years. The proportion of ER-positive breast cancer patients was 67%, and the proportion of positive lymph node status was 92%. Sixty-seven percent of HER2-positive breast cancer patients were postmenopausal. DNA methylation was assessed using Infinium HumanMethylation450 BeadChip array. Breast cancer patients were treated with adjuvant chemotherapy and trastuzumab. The study reported DFS. HER2-positive breast cancer patients were of Caucasian ethnicity. Tumor cell fraction was $\geq 70\%$.

Studies of genome-wide gene expression profile and response to targeted treatment

Characteristics of the nine studies that examined the association between genome-wide gene expression profiles measured in breast cancer tissues and response to HER2-targeted therapies in HER2-positive breast cancer patients are presented in [Supplementary Table 4](#). Five studies were retrospective^[46,47,49-51], and four studies were prospective^[45,48,52,53]. The median age of HER2-positive breast cancer patients was not reported in four studies^[46,48,50,51] and varied from 52 to 58 years in two studies^[47,49]. The mean age was 55.2 years in one study^[52], 60.9% of participants were < 45 years in another^[45], and 48.3% of participants were < 50 years in one other study^[53]. The proportion of ER-positive breast cancer patients was reported in three studies and varied between 43.4% and 69.6%^[45,47,49]. In eight studies, patients received trastuzumab^[45-47,49-53], and in the remaining study, patients were treated with trastuzumab, lapatinib or both^[48]. pCR was reported in five studies^[45,47,48,50,51], RFS in two studies^[49,53], and DFS in two studies^[46,52]. Gene expression profile was evaluated in fresh frozen tissue in five studies^[45,46,48,50,51] and in FFPE tissues in four studies^[47,49,52,53]. Gene expression profile was assessed using HumanHT-12 v3 BeadChip^[46], HumanHT-12 v4 BeadChip^[49], Affymetrix Human Genome U219 array^[47], Affymetrix GeneChip 3' IVT Express kit^[48], Illumina HiSeq 2500 platform^[50], Illumina HiSeq 3000^[52], GeneChip U133 Plus 2.0 Gene Array^[45], DASL technology^[53] and Agilent UNC Perou Lab Homo sapiens 1X44K Custom Array/Illumina HumanHT-12 WG-DASL V4.0 R2 expression BeadChip/Affymetrix technology using the HG-U133 Plus 2.0 GeneChip array^[51]. Tumor cell fraction was not reported in five studies^[47,48,50,51,53], and was at least 70% in three studies^[46,49,52]. In the remaining study, breast cancer samples of each patient contained at least 500 breast cancer cells^[45] [Supplementary Table 4].

Study of genome-wide miRNA expression profile and response to targeted treatment

Characteristics of the two studies that examined the association between genome-wide miRNA expression profile and response to targeted treatment in HER2-positive trastuzumab-treated breast cancer patients are presented in [Supplementary Table 5](#). Both studies had a retrospective design^[54,55]. miRNA expression was

measured genome-wide in FFPE breast cancer tissues using Agilent miRNA assay^[54] or Agilent SurePrint G3 Human miRNA microarray^[55] in cohorts of 14 and 40 HER2-positive breast cancer patients. Patients were treated with trastuzumab. DFS^[54] and pCR^[55] were reported. Tumor cell fraction was not reported in one study^[54] and was at least 80% in the other^[55].

Study of genome-wide lincRNA expression profile and response to targeted treatment

Characteristics of the single study that examined the association between genome-wide lincRNA expression profile and response to targeted treatment in HER2-positive trastuzumab-treated breast cancer patients are presented in [Supplementary Table 6](#). The study had a retrospective design. lincRNA expression was measured genome-wide in fresh frozen breast cancer tissues using the Illumina HiSeq 2500 platform in a cohort of 13 HER2-positive breast cancer patients. Patients were treated with trastuzumab and pCR was reported. Tumor cell fraction was not reported.

Study of genome-wide CNA profile and response to targeted treatment

Characteristics of the two studies that examined the association between genome-wide CNA profile and response to HER2-targeted therapies in HER2-positive breast cancer patients are presented in [Supplementary Table 7](#). The studies had a prospective design^[48,56]. CNA profile was assessed genome-wide in fresh frozen breast cancer tissues using Affymetrix Genome-wide Human SNP array^[48] or Illumina HiSeq^[56] in cohorts of 68 and 11 HER2-positive breast cancer patients. Patients were treated with trastuzumab, lapatinib or both in one study^[48] and trastuzumab in the other^[56]. pCR was reported. Tumor cell fraction was not reported.

Study of genome-wide protein expression profile and response to targeted treatment

Characteristics of the only study that examined the association between genome-wide protein expression profile and response to targeted treatment in HER2-positive trastuzumab-treated breast cancer patients are presented in [Supplementary Table 8](#). The study had a retrospective design^[57]. The protein expression profile was assessed genome-widely in blood using TMT-6 plex Isobaric Label Reagent Set in a cohort of 6 HER2-positive breast cancer patients. Patients were treated with trastuzumab. pCR was reported.

Study of genome-wide mutation profile and response to targeted treatment

Characteristics of the two studies that examined the association between genome-wide somatic or germline mutation profile and response to targeted treatment in HER2-positive breast cancer patients are presented in [Supplementary Table 9](#). The studies had a prospective design^[58,59]. Somatic mutation profile was assessed genome-wide in fresh frozen breast cancer tissues for the two studies. Germline mutation profile was assessed genome-widely in blood using Illumina HiSeq 2000^[59], and whole genome sequencing (WGS) and whole exome sequencing (WES) + Illumina HiSeq 2000 platform^[58] in cohorts of 48 and 203 HER2-positive breast cancer patients. Patients were treated with trastuzumab. pCR was reported. Tumor cell fraction was not reported in one study^[58] and was at least 10% in the other study^[59].

Risk of bias in studies

Overall, studies ranged on average from low to critical risk of bias [low ($n = 2$)^[53,59], moderate ($n = 4$, including our study)^[47,49,57], serious ($n = 1$)^[54], and critical ($n = 9$)^[45,46,48,50-52,55,56,58], most commonly due to confounding. The bias evaluation of each included study is presented in [Supplementary Table 10](#).

Results of individual studies*Genome-wide gene expression profile in breast cancer tissues and response to anti-HER2 agents in HER2-positive breast cancer patients*

The genes reported to be differentially expressed in breast cancer tissues of cases compared to controls for each identified study are presented in [Supplementary Table 11](#). Higher expression of the following genes was consistently observed in two different studies: *ESR1*^[49,50], *RBP1*, *SLP1*^[46,50], *EPS8L1*^[50,52], *MEP1B*, *UTP15*, *RRAS2*, *GRB10*, *FAM98A*, *RBMS2*, *RPL9*, *RPAIN*, *MORF4L1*, *LLPH*, *MTMR1*, *FRYL*, *FLCN*, *CLINT1*, *ERICH1*^[47,52], *ZNF281*, *ANKRD52*, *PIAS3*, *BRD1*, *RNF146*, *CLDN12*, *PROM2*, *COMM5*, *VMP1*, *DEDD*, *ZNF439*, *CRIP2*, *PRSS16*, *GUK1*, *RRN3*, *PLEKHG3*, *JUN*, *BCL9*, *SLC25A37*, *CRYZ*, *RNF24*, *PSMG3*, *PAQR7*, *ABT1*, *WNT7B*, *SLC35B2*, *SYTL4*, *NUPR1*, *DPY19L1*, *DAZAP1*, *EEF1D*, *SGPP1*, *GALNT2*, *SPA17*, *RAD51*, *MBD6*, *KIF1C*, *C1QTNF3*, *BLOC1S2*, *SLC2A10*, *ZNF740*, *ADCK2*, *SLC41A1*, *RAB4A*, *CRIP1*, *ZNF552*, *CARHSP1*, *POFUT1*, *EMC10*, *BAX*, *HOXC4*, *DDR1*, *CTSD*, *FEN1*, *SULT1A1*, *DUSP14*, *IRF9*, *TMC4*, *MUC1*, *LMAN2*, *LASP1*, *SHROOM1*^[50,52], *NSL1*, *ENAH*, *UBE2Q2*, *GNPAT*, *THBS2*, *TBCEL*, *FAM46A*, *ZNF678*, *TSEN15*, *ZNF674*, *CNIH4*, *ASAH1*, *SELT*, *ARFGAP3*, *TATDN3*, *FBLN1*, *MOSPD1*, *PPCS*, *NUCKS1*, *PGBD2*, *ACBD3*, *ORMDL2*, *AMMECR1*, *TNFRSF19*, *FOSL2*, *PYCR2*, *WSB1*, *TROVE2*, *RWDD3*^[47,50], *LYSMD3*^[47,50], *APOB*, *SLC3A2*, *CST3*^[52,57], *BOC*^[45,52], *DDX27*, *IL17RC*, *PKP3*, *WNK2*^[52,53], *AGRN*,

ATRN, *NACC1*, *PCSK6*, *PIR*, *PLAUR*, *QSOX1*, *RHBDL2*, *SEC22B*, *SERPINH1*, *TCEAL1*^[50,53], *CSDE1*, *SCUBE3*, *TMEM167A*^[47,53]. Lower expression of the following genes was consistently reported in two different studies: *ORMDL3*^[49,50], *NME1*^[46,50], *SLC35B1*^[46,50], *UTP18*^[46,50], *PHB*^[46,50], *S100B*, *TOM1L1*^[50,52], *HIST1H2BG*, *PRR13*^[47,50], *NXP1*, *CKS2*, *NETO2*, *SLC12A2*^[46,52], *ACSL5*, *CD3E*, *GIMAP7*, *GZMK*, *PPARG*, *SELL*, *VCAM1*^[50,53], *CLEC10A*, *CTLA4*, *FGL2*, *TSPAN7*^[52,53], *DENND3*, *TIAM1*^[47,53]. The following genes were reported to be higher expressed in breast cancer samples of cases compared to controls in two different studies but were reported to be lower expressed in another study: *SFRP1*^[45,46,50], *ACTR1B*, *FASTK*, *TMEM219*, *NDUFA3*^[47,50,52], *ATP5I*^[47,50,52]. The following genes were reported to be lower expressed in breast cancer samples of cases compared to controls in two different studies but were reported to be higher expressed in another study: *PABPC1*^[47,50,52], *ARPC1A*, *TXN*^[47,50,52], *TOB1*^[46,50,52]. Higher expression of the *GOLGA2*^[47,50,52] and *PHF21A*^[47,50,52] genes was consistently observed in three different studies.

Gómez-Pozo *et al.* and Sorokin *et al.* identified several pathways associated with response to trastuzumab, including those involved in EGF receptor signaling, PI3K, apoptosis signaling, and p53^[47,52]. Gómez-Pozo *et al.* observed that the PI3K pathway was the most strongly associated with treatment response^[47] [Supplementary Table 12]. Sorokin *et al.* identified several pathways associated with response to trastuzumab. The most statistically and significantly upregulated ones in the trastuzumab-sensitive group were PPAR Pathway and cAMP Protein Retention Pathway^[52]. Triulzi *et al.* and Sorokin *et al.* reported that breast cancer samples of patients with a lower risk of early relapse showed higher expression of genes enriched in immune system-related pathways and proliferation-associated pathways^[49,52]. For two^[46,48] out of the four included studies that did not report pathway analysis^[45,46,48,50], we performed gene ontology analysis using the list of genes reported as being differentially expressed by the authors using PANTHER. We observed that the Notch signaling pathway was overrepresented in both studies^[46,48], an observation also reported by Sorokin *et al.*^[52]. We observed that Wnt signaling was overexpressed in Khoury *et al.*^[46], as reported by Sorokin *et al.*^[52]. We did not perform pathway analysis for the two remaining studies^[45,53], as the number of differentially expressed genes ($n = 11$) was too small to perform the analysis^[45] or not reported^[53].

In our study, we observed overlap between the identified differentially expressed genes and the strongly differentially methylated (i.e., $|\log_2FC| > 2.0$) genes. *PRKACA* was hypermethylated in our study (within the TSS region as well as the gene body), upregulated in one study^[50], and downregulated in another study^[47].

Genome-wide miRNA expression profile in breast cancer tissues and response to trastuzumab in HER2-positive breast cancer patients treated with trastuzumab

Du *et al.* identified seven upregulated and two downregulated miRNAs in breast cancer tissues of cases compared to controls^[54]. Ohzawa *et al.* identified four upregulated and ten downregulated miRNAs in breast cancer tissues of cases compared to controls^[55] [Supplementary Table 13]. Regarding the miRNAs identified by Du *et al.*, 902 genes were predicted to be targeted by miR-150-5p, 47 genes by miR-4734, 570 genes by miR-361-5p, 1,134 genes by miR-26a-5p, 416 genes by miR-365a-3p, 701 genes by miR-155-5p, 737 genes by miR-205-5p, 1,384 genes by miR-106b-5p, and 187 genes by miR-424-3p (as illustrated in a database for miRNA target prediction and functional annotations available online at www.mirdb.org)^[54]. For the miRNAs reported by Ohzawa *et al.*, 484 genes were predicted to be targeted by miR-210, 242 genes by miR-31-3p, 891 genes by miR-449a, 801 genes by miR-449b-5p, 21 genes by miR-106b-3p, 263 genes by miR-1180, 242 genes by miR-1238-5p, 1,133 genes by miR-142-5p, 902 genes by miR-150-5p, 1,409 genes by miR-181c-5p, 1,266 genes by miR-182-5p, 438 genes by miR-20a-5p, 1,084 genes by miR-218-5p, 1,249 genes by miR-3609, 270 genes by miR-362-5p, 420 genes by miR-3620-3p, 676 genes by miR-4418, 272 genes by miR-4506, 410 genes by miR-4657, 406 genes by miR-505-3p, and 392 genes by miR-505-5p^[55].

We observed that among the 344 genes that were reported to be differentially expressed (at the mRNA level) between breast cancer tissues of cases and controls in at least two studies, 170 were predicted to be targeted by miRNA identified as differentially expressed between breast cancer tissues of cases and controls in Ohzawa *et al.*^[55] or Du *et al.*^[54] [Supplementary Table 14]. We observed that among the 15 genes identified as differentially methylated in our study, five (*KCNH7*, *ADAMTS2*, *SIX2*, *DOCK1* and *ZNF598*) were predicted to be targeted by miRNA identified as differentially expressed in breast cancer tissues of cases compared to controls in the study of Ohzawa *et al.*^[55] or Du *et al.*^[54] [Supplementary Table 14].

Genome-wide lincRNA expression profile in breast cancer tissues and response to targeted treatment in HER2-positive breast cancer patients treated with trastuzumab

Merry and collaborators observed that 371 lincRNAs were differentially expressed in non-pCR samples compared to pCR samples, where 33 lincRNAs showed decreased expression and 338 increased expression^[50] [Supplementary Table 15]. Among these 371 genes, 97 were reported to be differentially expressed at the mRNA level in breast cancer tissues of cases compared to controls in at least two studies: *FAM84B*, *PHF21A*, *NDUFV3*, *COMMD6*, *SRP9*, *S100B*, *WDR26*, *LYSMD3*, *CSTB*, *C5orf39*, *FOXA1*, *GALM*, *ITGB2*, *SP140*, *UTRN*, *SAA2*, *SHB*, *ZFP64*, *ZC3H12B*, *NADSYN1*, *B4GALNT4*, *AP2B1*, *USP16*, *ARL4D*, *SYNPO2*, *FAIM3*, *CBR1*, *EFR3B*, *IL18*, *LOC389493*, *FBXO16*, *FAM114A1*, *MAP3K9*, *TOX3*, *ZNF681*, *IDH3B*, *TPBG*, *PRKACB*, *UBE2A*, *ID2*, *IRX3*, *CILP*, *COL5A2*, *WRB*, *MBOAT1*, *GCA*, *SATB2*, *HERC6*, *RALGPS2*, *NUF2*, *MIA3*, *FAM91A1*, *FAM5C*, *C1orf227*, *RPP4*, *MYOT*, *PRKAA2*, *MAP1LC3B*, *PEX3*, *MEST*, *F13A1*, *CREB1*, *LRCH2*, *PCF11*, *POLR3G*, *RORA*, *USP3*, *TSHZ3*, *CXCR4*, *CCNH*, *CCM2*, *ZNF814*, *RAPH1*, *ZBP2*, *FBXW4*, *ODF3B*, *CROCC*, *SH3RF2*, *HEATR6*, *CDK13*, *ATF3-1*, *ATF3*, *DTL*, *IARS2*, *RC3H1*, *RC3H1*, *URB2*, *RHOA*, *RC3H1*, *RC3H1*, *SUPT3H*, *ABI1*, *OTUD7B*, *GPATCH2*, *RNF2*, *IRF2BP2*.

Among the differentially expressed lincRNAs reported by Merry *et al.*^[50], we observed 44 genes that were predicted to be target genes of miRNA identified as differentially expressed in the study of Ohzawa *et al.*^[55] or Du *et al.*^[54] [Supplementary Table 14].

None of the genes whose lincRNAs were reported to be differentially expressed between patients showing pCR and those showing non-pCR in Merry *et al.* was reported as differentially methylated with a $|\log_2FC| > 2.0$ between cases and controls in our study^[50]. However, when we consider the entire list of differentially methylated genes in our study, regardless of \log_2 -fold change, we identified six overlapping genes. Among these six genes, five were hypermethylated (*GABRA5*, *ZIC5*, *GRAMD4*, *RSPH3*, and *VCAN*), and one was hypomethylated (*CSMD1*) in breast cancer samples of cases compared to controls.

Genome-wide copy number alterations in breast cancer tissue and response to targeted treatment in HER2-positive breast cancer patients treated with anti-HER2 agents

In their analysis of the association of genome-wide CNA in breast cancer tissues of HER2-positive breast cancer patients who received trastuzumab, lapatinib, or both, with response to anti-HER2 treatment, Guarneri *et al.* reported that, unlike pCR patients, non-pCR patients showed a CNA signature^[48]. Overall, the authors observed CN alterations, mainly CN gains, in 557 genes located on chromosomes 1, 8, 17, 20 [Supplementary Table 16]. We observed that among the 344 genes that were reported to be differentially expressed in breast cancer tissues of cases compared to controls in at least two studies, 23 genes showed CN alterations in non-pCR samples compared to pCR-samples in Guarneri *et al.*^[48]: *FAM84B*^[46,48], *SRP9*^[50,52], *WDR26*^[47,50], *BATF3*^[47,50], *EDARADD*, *ENPP2*, *LAX1*, *NUAK2*, *PTPRC*^[53], *KIF21B*, *RNF19A*, *ZNF831*, *NR5A2*^[52,53], *KIF26B*, *LAMB3*, *C1orf133*^[50,53], *LAMC2*^[52,53], *FAIM3*^[50], *MIA3*^[47], *OTUD7B*, *GPATCH2*, *RNF2*, *IRF2BP2*^[50].

We observed that among the 557 genes that were reported to show CN alteration in non-pCR samples compared to pCR-samples in the study of Guarneri *et al.*^[48], 279 were predicted to be targeted by miRNA identified as differentially expressed in breast cancer tissues of cases compared to controls in the study of Du *et al.*^[54] or Ohzawa *et al.*^[55] [Supplementary Table 14].

Among the genes showing CN alterations in non-pCR samples compared to pCR-samples in the study of Guarneri *et al.*^[48], 18 genes (*FAM84B*, *SRP9*, *WDR26*, *MIA3*, *FAM91A1*, *FAM5C*, *C1orf227*, *ATF3*, *DTL*, *IARS2*, *RC3H1*, *URB2*, *RHOA*, *RC3H1*, *OTUD7B*, *GPATCH2*, *RNF2*, *IRF2BP2*) showed higher lincRNA expression and one (*FAIM3*) showed lower lincRNA expression in Merry *et al.*^[50].

No overlap was observed between genes showing CN alterations in non-pCR samples compared to pCR-samples in Guarneri *et al.* and genes identified as differentially methylated with a $|\log_2FC| > 2.0$ in our study^[48]. However, when we consider the whole list of differentially methylated genes, we identified 27 genes that were differentially methylated in breast cancer tissues of cases compared to controls in our study among the 557 genes showing CNV variations in the study of Guarneri *et al.*^[48]. Of these 27 differentially methylated genes, nine were hypomethylated (*PLD5*, *GJD2*, *C20orf85*, *APCDD1L*, *VASH2*, *PSEN2*, *FMN2*, *EDN3*, *ACTN2*) and 18 were hypermethylated (*TRAF5*, *TSEN15*, *TRIB1*, *TMEM206*, *SNX31*, *SMG7*, *RGS1*, *PRG4*, *PGBD5*, *NID1*, *KCNV1*, *GPATCH2*, *EXT1*, *CDK18*, *CAPN9*, *ADSS*, *ABR*, *C1orf55*).

Genome-wide protein expression profile in blood of breast cancer cases compared to controls

Out of the 18 genes that were reported as differentially expressed (five downregulated and 13 upregulated) in the blood of breast cancer cases compared to controls by Yang *et al.*^[57] [Supplementary Table 17], three (*APOB*, *SLC3A2*, *CST3*) were differentially expressed in breast cancer tissues of cases compared to control in at least two studies. Three (*LDHA*, *DBF4B*, and *MASP1*) were predicted to be targeted by miRNA identified as differentially expressed in breast cancer tissues of cases compared to controls in the study of Du and collaborators^[54] or Ohzawa and collaborators^[55] [Supplementary Table 14].

None of the differentially expressed genes in the study of Yang *et al.* were differentially methylated in our study^[57].

Genome-wide somatic and germline mutations profile in breast cancer tissues of cases compared to controls

Whereas Shi and collaborators observed that higher somatic mutation frequency in the *PIK3CA* gene in the breast tissues of cases was associated with trastuzumab resistance^[59], Lesurf *et al.* reported that no somatic or germline mutations were associated with response to trastuzumab in breast cancer tissues of cases compared to controls^[58] [Supplementary Table 18].

DISCUSSION

In a cohort of 12 HER2-positive breast cancer patients treated with trastuzumab, interrogation of DNA methylation using the Infinium HumanMethylation450 BeadChip allowed identifying genes that were differentially methylated between trastuzumab-resistant and trastuzumab-sensitive HER2-positive breast cancer patients. Interestingly, among the strongly differentially methylated genes, we observed genes associated with human cancer, including *DOCK1*, *ADAMTS2*, *PLEC1*, *USP4*, and *PRKACA*^[60-69].

The guanine nucleotide exchange factor *DOCK1* (Dedicator of cytokinesis protein 1) is involved in cytoskeletal rearrangements required for phagocytosis of apoptotic cells and cell mobility^[70]. A recent study reported that *DOCK1* inhibition leads to suppressed migration of the triple-negative breast cancer cell lines MDA-MB-157 and MDA-MB-231^[68,71]. *ADAMTS2* (ADAM metalloproteinase with thrombospondin type 1

motif 2) belongs to the ADAM metallopeptidase with thrombospondin type 1 motif and processes collagen precursors into mature collagen molecules^[72]. It has been proposed that *ADAMTS2* exerts an anti-tumor effect by inhibiting intratumoral vascularization^[73]. The *PLEC* gene encodes the pectin protein, which plays a role in maintaining tissue integrity^[74]. A recent study suggests that a *PLEC* gene polymorphism (rs138924815) might increase the risk for familial testicular cancer^[75]. *USP4* (Ubiquitin carboxyl-terminal hydrolase 4) is a deubiquitinating enzyme that removes conjugated ubiquitin from target proteins^[76]. It has been reported that *USP4* expression was decreased in breast cancer tissue samples compared to paired normal breast tissues^[63]. Moreover, *USP4* expression was associated with decreased proliferation in two HER2-negative breast cancer cell lines (MCF7 and BT549)^[63]. The *PRKACA* gene encodes for a protein kinase that plays a role in controlling cellular processes such as glucose metabolism and cellular division^[72]. Of note, one recent study suggests that *PRKACA* expression might be associated with the development of trastuzumab resistance in HER2-positive breast cancer patients^[64]. The authors observed that in a subgroup of HER2-positive breast cancer patients who developed trastuzumab resistance (three out of five patients), *PRKACA* expression was highly increased in the breast cancer sample obtained after the onset of trastuzumab resistance compared to the pre-treatment sample. Considering that in our study, the *PRKACA* gene was hypermethylated within the gene body and that hypermethylation within this gene region often promotes gene elongation and, therefore, gene expression, we can postulate that our results might be concordant with those reported by Moody *et al.*^[64]. Although in our study, DNA methylation was exclusively measured in pre-treatment samples and Moody *et al.* observed increased *PRKACA* expression only in breast cancer samples obtained after the onset of recurrence^[64].

Among all genes that we identified as strongly differentially methylated between trastuzumab-resistant and trastuzumab-sensitive HER2-positive breast cancer patients, one of them, *PRKACA*, was reported as being higher expressed in breast cancer tissues of cases compared to controls in the study conducted by Merry and collaborators^[50] and as being lower expressed in breast cancer tissues of cases compared to controls in the study of Gámez-Pozo *et al.*^[47]. In our study, the *PRKACA* gene was hypermethylated within the TSS region and the gene body. Our observation could be partly concordant with the results reported by Merry *et al.*^[50] (but not with those of Gámez-Pozo *et al.*^[47]), as hypermethylation in the gene body (but not within the TSS region) is usually associated with increased gene expression^[34]. Interestingly, the results of Merry and collaborators^[50] (but not those of Gámez-Pozo *et al.*^[47]) are concordant with the study above^[64], where the authors observed that *PRKACA* expression was increased in breast cancer samples of HER2-positive trastuzumab-resistant breast cancer patients.

In one of the studies retained in our systematic review, the authors created a predictive model to differentiate HER2-positive trastuzumab-treated breast cancer patients with a higher risk of relapse from those with a lower risk in a cohort of 53 patients^[49]. The validity of this predictive model was then confirmed in an independent and bigger data set. The authors observed that differentially expressed genes in the breast cancer tissues of patients identified as at low risk for relapse in the independent data set using this model were associated with the immune system. When we performed gene enrichment analysis of genes showing CN alteration in the study of Guarneri and collaborators, we observed that pathways associated with the immune response (inflammation mediated by chemokine and cytokine signaling pathway) were overrepresented. The immune system's involvement in response to anti-HER2 agents in HER2-positive breast cancer patients has also been reported in other studies^[77-82].

To our knowledge, we conducted the first systematic review on the association of epigenetic and genetic alterations in breast cancer tissues or blood with the response to anti-HER2 agents in HER2-positive breast cancer patients. Sixteen studies were included in this review, and very few overlaps between studies were

found. The most consistent results were the higher expression of *GOLGA2* and *PHF21A* genes and the higher expression and CN gain of *MIA3*, *WDR26* and *C1orf133* genes observed in three different studies. Among these five genes, *WDR26* has been shown to promote breast cancer growth and metastasis via the PI3K/AKT signaling pathway^[83]. Gámez-Pozo and collaborators also observed that genes identified as differentially expressed in breast tumor tissues of cases compared to controls were overrepresented in the PI3K pathway^[47]. Interestingly, the study by Shi and collaborators^[59] also reported that PI3K mutations were associated with response to anti-HER2 agents in HER2-positive breast cancer patients and other previously published studies^[84-86]. Taken together, these results suggest that genes of the PI3K pathway might play a relevant role in the development of resistance to anti-HER2 agents in breast cancer patients. Exploring the ramifications of these and other findings in larger cohorts or datasets like TCGA should be considered in future studies.

Several factors might explain why we only observed a few overlaps in our systematic review. Tumor cell content varied from > 40% to > 80% between studies, and in several publications ($n = 4$), this information was not provided. Contamination with cell types other than breast cancer cells can modify the observed pattern of genetic and epigenetic markers, as DNA methylation and other epigenetic or genetic markers widely vary across tissues and cellular types^[87]. Moreover, the type of outcome evaluated in the study might also play a role, as the assessment of pCR in the neoadjuvant setting might mainly identify patients who did not primarily respond to targeted treatment (primary resistance), whereas the evaluation of DFS in the adjuvant setting might allow identifying patients who initially respond to targeted treatment but who develop resistance over time (acquired resistance). Moreover, epigenetic and genetic markers can be influenced by clinicopathological data, including age, stage, ER status, menopausal status, and ethnicity^[88-96]. Unfortunately, it was difficult to evaluate this aspect, as patients' clinicopathological data were not extensively reported in the majority of the included studies. The risk of bias in most studies was due to confounding.

CONCLUSION

In conclusion, although the sample size of the present pilot study was small and despite the lack of validation cohort, using a high-throughput analysis, we identified genes that were differentially methylated in breast cancer tissues of HER2-positive trastuzumab-treated breast cancer patients who developed resistance toward this drug compared to those who responded to targeted therapy. One of the most differentially methylated genes, *PRKACA*, has been reported to be differentially expressed in breast cancer tissues of trastuzumab-resistant compared to trastuzumab-sensitive HER2-positive breast cancer patients in two studies included in our systematic review. Although we identified very few genes that overlap between studies, our review suggests that some of the genes acting in the PI3K pathway, such as *PRKACA*^[97], might play an important role in developing resistance to anti-HER2 agents in breast cancer patients. Although the associations between *PI3KCA* mutations and *PI3K* dysfunctions and anti-HER2 treatment resistance are well documented in the literature^[86,98-100], further studies on this topic are needed, which may help to unveil carcinogenic mechanisms involved in this pathway.

Although the observations reported in the retained studies were only marginally concordant, our work and the studies presented in this article suggest that knowledge gathered from these high-throughput studies could be useful for the identification of novel biomarkers of trastuzumab resistance. This might promote the development of new targeted drugs that could be administered to trastuzumab-resistant HER2-positive breast cancer patients.

DECLARATIONS

Authors' contributions

Conceived, acquired, analyzed and interpreted the data, wrote the original draft: Furrer D, Dragic D

Analyzed the data, edited the manuscript: Fournier F, Droit A, Jacob S

Reviewed and edited the manuscript: Chang SL

Conceived and designed the study, acquired, analyzed and interpreted the data, wrote and edited the manuscript, supervised and acquired funding for the study: Diorio C

All authors read and approved the final manuscript.

Availability of data and materials

All data generated or analysed during this study are included in this published article [and its supplementary information files].

Financial support and sponsorship

This work was supported by the Canadian Breast Cancer Foundation-Canadian Cancer Society Development award (No.703003) and the Fondation du cancer du sein du Québec and the Banque de tissus et de données of the Réseau de recherche sur le cancer of the Fonds de recherche du Québec - Santé (FRQS), which is affiliated with the Canadian Tumour Repository Network and a FRQS Senior Investigator Award to Diorio C. Furrer D was supported by doctoral fellowships from FRQS and the Laval University Cancer Research Center. Dragic D is supported by doctoral fellowships from the University Laval Cancer Research Center and the University Paris-Saclay Doctoral School of Public Health EDSP.

Conflicts of interest

All authors declared that there are no conflicts of interest.

Ethical approval and consent to participate

Ethical approval of the study was obtained from the Research Ethics Committee of the Centre de Recherche du CHU de Québec (# 2016-2802).

Consent for publication

Not applicable.

Abstract

As of today, only two antiangiogenic monoclonal antibodies plus epidermal growth factor receptor-tyrosine kinase inhibitor (EGFR-TKI) combinations are FDA and EMA-approved and are recommended by American Society of Clinical Oncology, European Society for Medical Oncology, and National Comprehensive Cancer Network for the first-line treatment of EGFR+ advanced non-small cell lung cancer patients: erlotinib plus bevacizumab and erlotinib plus ramucirumab. However, all treated patients eventually become unresponsive to such drugs, due to several different acquired resistance mechanisms, mainly represented by T790M substitutions and MET amplifications. While osimertinib treatment in T790M+ patients still represents the only approved treatment, MET-TKIs will likely change this status quo in the near future. In fact, existing clinical data strongly support a role for MET-TKI-based combinations in EGFR+ MET-amplified patients, possibly revolutionizing our current treatment algorithm. Chemotherapy plus immunotherapy plus antiangiogenic therapy combinations could also represent another useful addition.

INTRODUCTION

Epidemiology of EGFR+ NSCLC and preclinical background for antiangiogenic monoclonal antibody plus EGFR-TKI combinations

According to the most recent GLOBOCAN data, in 2020, lung cancer accounted for approximately 2,200,000 new cases and 1,800,000 deaths^[1]. Overall, 85% of these cases are represented by non-small cell lung cancer (NSCLC), and the majority of NSCLC are histologically represented by adenocarcinomas (55%)^[2]. With respect to genetic alterations, the vast majority of currently druggable mutations are diagnosed in adenocarcinomas, and specifically EGFR (epidermal growth factor receptor)-activating mutations (exon 19 deletion and exon 21 L858R substitution) are among the most common ones, accounting for approximately 15% of non-squamous NSCLC cases in North American and European patients and 40%-50% of non-squamous NSCLC in Asian patients^[3].

With reference to EGFR mutations, vast literature data emphasize the link between EGFR axis hyperactivity and VEGF (vascular endothelial growth factor) induction and upregulation, as well as VEGFR (vascular endothelial growth factor receptor)-EGFR synergy, in promoting tumor growth, thus providing a strong preclinical background for the potential benefits of antiangiogenic monoclonal antibody plus EGFR-tyrosine kinase inhibitor combinations in this subset of patients^[4-6].

CURRENT AND FUTURE CLINICAL PERSPECTIVES

Regulatory approvals and current guidelines involving antiangiogenic monoclonal antibody plus EGFR-TKI combinations

As of today, only two antiangiogenic monoclonal antibodies plus EGFR-TKI (tyrosine kinase inhibitor) combinations are FDA (US Food and Drug Administration) and EMA (European Medicines Agency) approved and ASCO (American Society of Clinical Oncology), ESMO (European Society for Medical Oncology), and NCCN (National Comprehensive Cancer Network) recommended for the first-line treatment of EGFR+ advanced NSCLC patients: erlotinib (EGFR TKI) plus bevacizumab (anti-VEGF-A mAb) and erlotinib plus ramucirumab (anti-VEGFR2 mAb)^[7-10].

Pivotal trials involving antiangiogenic monoclonal antibody plus EGFR-TKI combinations

The erlotinib plus bevacizumab combination received regulatory approval and clinical recommendation thanks to the results coming from several different phase II and III trials. In the single-arm phase II BELIEF trial, 109 European naïve non-squamous advanced NSCLC patients with EGFR activating mutations were administered an erlotinib plus bevacizumab combination, achieving an overall PFS (progression-free survival) of 13.2 months and a manageable safety and tolerability profile with grade 4 TRAEs (treatment-related adverse events) in 4% of treated patients^[11].

In the randomized controlled phase II JO25567 study, 154 Japanese naïve non-squamous advanced NSCLC patients with EGFR activating mutations were randomized 1:1 to receive erlotinib plus bevacizumab or erlotinib as monotherapy. The combination arm showed superior results with mPFS of 16.0 months vs. 9.7 months and HR (hazard ratio) for progression or death of 0.54 and comparable safety and tolerability profile with serious TRAEs in 24% of treated patients vs. 25% of treated patients^[12]. However, after an extended follow-up of 34.7 months, while the combination arm continued to show superior results in terms of PFS at 16.4 months vs. 9.8 months (HR for progression or death, 0.52), no significant benefit in terms of OS (overall survival) was observed at 47.0 months vs. 47.4 months (HR for death, 0.81; $P = 0.3267$), and no new safety issues were reported^[13].

Similarly, in the randomized controlled phase III NEJ026 trial, 228 Japanese naïve non-squamous advanced NSCLC patients with EGFR activating mutations were randomized 1:1 to be given erlotinib plus bevacizumab or erlotinib alone. At a first analysis, after a median follow-up of 12.4 months, the PFS results favored the combination arm at 16.9 months vs. 13.3 months (HR for progression or death, 0.60), and a manageable safety profile was observed with serious TRAEs in 8% of treated patients vs. 4% of treated patients^[14]. However, once again, at a longer follow-up of 39.2 months, no significant benefit in terms of OS was reported between the combination and monotherapy arms at 50.7 months vs. 46.2 months (HR for death, 1.007; $P = 0.97$)^[15].

More recently, these conclusions have also been supported by the BEVERLY study. In the phase III randomized controlled BEVERLY trial, 160 Italian naïve advanced NSCLC patients with EGFR activating mutations were randomized 1:1 to receive erlotinib plus bevacizumab or erlotinib as monotherapy. After 31 months of median follow-up, a clear advantage was reported with respect to PFS at 15.4 months vs. 9.7 months (HR for death or progression, 0.60) but not with respect to OS at 28.4 months vs. 23.0 months (HR for death, 0.70; $P = 0.12$)^[16,17].

Even more recently, the results from the randomized controlled phase III ARTEMIS-CTONG1509 trial also seem to be in line with the above-mentioned data. In this trial, 311 Chinese naïve advanced NSCLC patients with EGFR activating mutations were randomized 1:1 to be administered erlotinib plus bevacizumab or erlotinib alone. Once more, favorable PFS data were reported for the experimental arm at 17.9 months vs. 11.2 months (HR for death or progression, 0.55), but OS did not manage to reach significant superiority at 36.2 months vs. 31.6 months (HR for death, 0.92; $P = 0.581$)^[18].

Ramucirumab received regulatory approval and clinical recommendation thanks to the data from the RELAY study. In this randomized controlled phase III trial, 449 European and Asian naïve advanced NSCLC patients with EGFR activating mutations were randomized 1:1 to receive erlotinib plus ramucirumab or erlotinib as monotherapy. At the pre-specified data cut-off after a median follow-up of 20.7 months, the combination arm performed better than the control one in terms of PFS at 19.4 months vs. 12.4 months (HR for death or progression, 0.59), albeit with some safety concerns with grade 3-4 TRAEs in 72% of treated patients vs. 54% of treated patients. OS data are still awaited^[19-21]. In addition, following subgroup analysis, extremely interesting results were reported about TP53- and L858R-mutated patients. While EGFR+ TP53+ patients are classically associated with a worse outcome^[22], they benefited from the experimental combination in terms of mPFS at 15.2 months vs. 10.6 months (HR for death or progression, 0.54); in particular, the HR data prove to be superior to those of ITT (0.59)^[23]. Similarly, the L858R patients presented particularly favorable mPFS results at 19.4 months vs. 11.2 months (HR for death or progression, 0.618)^[24]. It is worth mentioning that this result is superior to the one reported in the FLAURA trial (osimertinib vs. gefitinib or erlotinib in naïve EGFR+ advanced NSCLC patients) at 18.9 months vs. 10.2 months^[25]. These results are particularly relevant because, while osimertinib (a third-generation EGFR-TKI) represents the most used and effective treatment in naïve EGFR+ advanced NSCLC patients, erlotinib plus ramucirumab combination could represent a more useful and attractive choice in these two selected subsets of patients. To further investigate this matter, a phase III trial comparing erlotinib plus ramucirumab to osimertinib monotherapy in naïve EGFR+ L858R advanced NSCLC patients is currently ongoing^[26].

Acquired resistance mechanisms to antiangiogenic monoclonal antibody plus EGFR-TKI combinations

As the above-mentioned data extensively show, antiangiogenic monoclonal antibody plus EGFR-TKI combinations have managed to grant excellent results in terms of survival and safety, comparable with those of EGFR-TKI monotherapy [Table 1]. This is especially true when we compare these results with those

Table 1. Overview of data from trials exploring approved antiangiogenic mAbs plus EGFR-TKI combinations for the treatment of aNSCLC with activating EGFR mutations

Name of the trial (number of patients)	Phase of the trial	Experimental arm	Control arm	Efficacy data in months
BELIEF (n = 109)	II	Erlotinib + bevacizumab	/	mPFS: 13.2
JO25567 (n = 154)	II	Erlotinib + bevacizumab	Erlotinib	mPFS: 16.4 vs. 9.8 (HR: 0.54) mOS: 47.0 vs. 47.4 (HR: 0.81; P = 0.3267)
NEJ026 (n = 228)	III	Erlotinib + bevacizumab	Erlotinib	mPFS: 16.9 vs. 13.3 (HR: 0.60) mOS: 50.7 vs. 46.2 (HR: 1.007; P = 0.97)
BEVERLY (n = 160)	III	Erlotinib + bevacizumab	Erlotinib	mPFS: 15.4 vs. 9.7 (HR: 0.60) mOS: 28.4 vs. 23.0 (HR: 0.70; P = 0.12)
ARTEMIS-CTONG1509 (n = 311)	III	Erlotinib + bevacizumab	Erlotinib	mPFS: 17.9 vs. 11.2 (HR: 0.55) mOS: 36.2 vs. 31.6 (HR: 0.92; P = 0.581)
RELAY (n = 449)	III	Erlotinib + ramucirumab	Erlotinib	mPFS: 19.4 vs. 12.4 (HR: 0.59)

EGFR-TKI: Epidermal growth factor receptor-tyrosine kinase inhibitor; NSCLC: non-small cell lung cancer; HR: hazard ratio.

granted by standard chemotherapy and/or immunotherapy regimens^[27-29]. However, even with these treatments, the progression of disease is inevitable. In fact, all the treated patients eventually become unresponsive to such drugs due to several different acquired resistance mechanisms that have been best investigated in patients treated with erlotinib with or without bevacizumab. Thanks to the vast literature data, it is now well established that the main acquired resistance mechanism in erlotinib-treated patients is represented by exon 20 T790M substitution (55%-60% of cases), followed by MET amplification (5%), HER2 amplification (5%-10%), SCLC (small cell lung cancer) transformation (2%-10%), and epithelial-mesenchymal transition (2%-10%)^[30-33].

The same applies to erlotinib plus bevacizumab-treated patients, albeit with different incidences. In fact, these patients seem to present lower rates of these mutations: T790M substitutions (35%-45% of cases), MET amplifications (3%-6%), HER2 amplification (2%-5%), and SCLC transformation (3%-5%)^[18,34,35].

Current strategies and future perspectives in overcoming acquired resistance mechanisms

As of now, the only FDA- and EMA-approved and ASCO-, ESMO-, and NCCN-recommended treatment for EGFR+ advanced NSCLC patients progressing after EGFR-TKI therapy is osimertinib, the administration of which is limited to T790M+ patients. No approved agents are available for EGFR+ MET-amplified advanced NSCLC patients progressing after EGFR-TKI therapy, and platinum-based chemotherapy still represents the standard of care in this subset of patients^[7-10].

Osimertinib received regulatory approval and clinical recommendation following the results from the AURA 3 trial. In this randomized controlled phase III trial, 419 EGFR+ T790M+ advanced NSCLC patients whose disease had progressed after first-line EGFR-TKI treatment were randomized 2:1 to receive osimertinib or cis/carboplatin plus pemetrexed followed by pemetrexed maintenance. At data cut-off, the osimertinib arm clearly outperformed the control one in terms of both response and survival with ORR (objective response rate) of 71% of treated patients vs. 31% of treated patients, PFS of 10.1 months vs. 4.4

months (HR for death or progression, 0.30) as well as in terms of safety and tolerability with grade ≥ 3 TRAEs in 23% of treated patients vs. 47% of treated patients^[36]. However, in the final analysis, osimertinib did not show a significant benefit in terms of OS at 26.8 months vs. 22.5 months (HR for death, 0.87; $P = 0.277$). However, this result seems to be linked to the very high rate of crossover from platinum plus pemetrexed to osimertinib (73% of platinum-treated patients). In fact, very different results were reported after adjusting OS data for crossover: 26.8 months vs. 15.9 months (HR for death, 0.54)^[37]. On a side note, it is worth mentioning that the main acquired resistance mechanism in patients progressing on second-line osimertinib is represented by MET amplification, accounting for 5%-50% of all cases^[38]. The addition of bevacizumab to osimertinib failed to show meaningful PFS or OS improvement in both T790M+ pre-treated patients and naïve patients^[39,40].

With respect to EGFR+ MET-amplified advanced NSCLC patients progressing after EGFR-TKI therapy, even though no drugs are approved yet, several encouraging trials have already assessed and are currently further investigating the safety and efficacy of different MET-TKIs, savolitinib, tepotinib, and capmatinib being the most promising ones^[41]. In the phase Ib NCT02374645 trial, the savolitinib plus gefitinib (EGFR TKI) combination was administered to 57 Chinese EGFR+ MET-amplified advanced NSCLC patients progressing after EGFR-TKI therapy, reporting a manageable safety profile with grade ≥ 3 TRAEs in 27% of treated patients and reasonable ORR in T790M patients (52% of treated patients) and patients whose T790M state was unknown (40% of treated patients)^[42].

Another savolitinib-based combination (osimertinib plus savolitinib) was investigated in the phase Ib TATTON trial. All 180 included patients were EGFR+ MET-amplified advanced NSCLC patients progressing after EGFR-TKI therapy. Patients in Cohort B1 were pre-treated with osimertinib; patients in Cohort B2 were not pre-treated with osimertinib and were T790M-; patients in Cohort B3 were not pre-treated with osimertinib and were T790M+; and patients in Cohort D were not pre-treated with osimertinib, but T790M-, and received a smaller dose of savolitinib. No dose-limiting toxicities were reported, 57% of patients in Cohort B and 38% of patients in Cohort D experienced grade 3 or worse TRAEs, and partial responses were reported in 48% of patients in Cohort B and 64% of patients in Cohort D^[43].

The randomized controlled phase II NCT04606771 trial is currently recruiting EGFR+ MET-amplified advanced NSCLC patients progressing after osimertinib therapy to be randomized 1:1 to receive savolitinib plus osimertinib or savolitinib plus placebo. ORR is the primary objective, and the study completion date is estimated to be February 29, 2024^[44].

Tepotinib was first investigated in combination with gefitinib in 55 Asian EGFR+ advanced NSCLC patients with acquired resistance to a previous EGFR-TKI (MET-amplification or overexpression) in the randomized phase Ib/II INSIGHT study. Even though this trial failed to show favorable survival results in the intention to treat population and was thus terminated early, extremely promising results were reported for the MET-amplified population: PFS of 16.6 months vs. 4.2 months (HR for death or progression, 0.13) and OS of 37.3 months vs. 13.1 months (HR for death, 0.08)^[45]. These results were further confirmed in the final analysis: PFS of 19.3 months vs. 5.5 months (HR for death or progression, 0.18) and OS of 37.3 months vs. 13.1 months (HR for death, 0.08)^[46]. Tepotinib with or without osimertinib is currently being investigated in the phase II INSIGHT 2 trial in EGFR+ MET-amplified advanced NSCLC patients progressing after osimertinib therapy. Recruitment is currently ongoing, dose-limiting toxicities and ORR are the primary objectives, and the study completion date is estimated to be March 30, 2023^[47].

Table 2. Ongoing trials investigating MET-TKI-based combinations in advanced NSCLC patients

Clinical trial name	Phase	Subset of patients	Experimental arm	Control arm	Primary objective(s)	Study completion date
NCT04606771	II	EGFR+ MET-amplified progressing after osimertinib	Savolitinib + osimertinib	Savolitinib + placebo	ORR	February 29, 2024
INSIGHT 2	II	EGFR+ MET-amplified progressing after osimertinib	Tepotinib ± osimertinib	No control arm	Dose-limiting toxicities and ORR	March 30, 2023
GEOMETRY-E	III	EGFR+ MET-amplified T790M- progressing after EGFR TKI	Capmatinib + osimertinib	Cis/carboplatin + pemetrexed followed by a pemetrexed maintenance	Dose-limiting toxicities and PFS	March 30, 2027

MET-TKI: Mesenchymal epithelial transition-tyrosine kinase inhibitor; EGFR: epidermal growth factor receptor; NSCLC: non-small cell lung cancer; ORR: objective response rate.

Finally, capmatinib was assessed in combination with gefitinib in the phase Ib/II NCT01610336 study, in which 161 EGFR+ advanced NSCLC patients with acquired resistance to a previous EGFR-TKI (MET-amplification or overexpression) received a capmatinib plus gefitinib combination therapy. Modest results were reported for the intention to treat the population with an ORR of 27%; however, remarkable results were reported for MET-amplified patients with an ORR of 47%^[48,49]. The randomized controlled phase III GEOMETRY-E trial is currently recruiting EGFR+ MET-amplified T790M- advanced NSCLC patients progressing after EGFR-TKI treatment to be randomized 1:1 to receive a capmatinib plus osimertinib combination or cis/carboplatin plus pemetrexed followed by pemetrexed maintenance. Dose-limiting toxicities and PFS are the primary objectives and the study completion date is estimated to be March 30, 2027^[50].

On a more general side note, it is worth mentioning that, in the recent IMpower150 trial, building on promising preclinical data^[51], the carboplatin plus paclitaxel plus bevacizumab plus atezolizumab combination managed to be the first and currently only association of chemotherapy plus immunotherapy plus antiangiogenic therapy to show favorable results in EGFR-TKI-pretreated EGFR+ aNSCLC patients. In fact, when compared to the control arm (carboplatin plus paclitaxel plus bevacizumab), the former combination managed to outperform the latter with mOS of 27.8 months vs. 18.1 months (HR for death, 0.74)^[52], thus representing another promising strategy in overcoming resistance mechanisms.

CONCLUSION

With reference to the main known acquired resistance mechanisms to the antiangiogenic monoclonal antibody plus EGFR-TKI combinations in EGFR+ advanced NSCLC patients (T790M substitution and MET amplification), we can report that, while osimertinib treatment in T790M+ patients still represents the only approved treatment, MET-TKIs will likely change this status quo in the near future. In fact, the extensive above-mentioned clinical data strongly support a role for MET-TKI-based combinations in EGFR+ MET-amplified patients, possibly revolutionizing our current treatment algorithm [Table 2]. Chemotherapy plus immunotherapy plus antiangiogenic therapy combinations could also represent another useful addition.

DECLARATIONS

Authors' contributions

All the authors contributed to the concept, design, draft and revision of this manuscript.

Abstract

P-glycoprotein (ABCB1) is the first discovered mammalian member of the large family of ATP binding cassette (ABC) transporters. It facilitates the movement of compounds (called allocrites) across membranes, using the energy of ATP binding and hydrolysis. Here, we review the thermodynamics of allocrite binding and the kinetics of ATP hydrolysis by ABCB1. In combination with our previous molecular dynamics simulations, these data lead to a new model for allocrite transport by ABCB1. In contrast to previous models, we take into account that the transporter was evolutionarily optimized to operate within a membrane, which dictates the nature of interactions. Hydrophobic interactions drive lipid-water partitioning of allocrites, the transport process's first step. Weak dipolar interactions (including hydrogen bonding, π - π stacking, and π -cation interactions) drive allocrite recognition, binding, and transport by ABCB1 within the membrane. Increasing the lateral membrane packing density reduces allocrite partitioning but enhances dipolar interactions between allocrites and ABCB1. Allocrite flopping (or reorientation of the polar part towards the extracellular aqueous phase) occurs after hydrolysis of one ATP molecule and opening of ABCB1 at the extracellular side. Rebinding of ATP re-closes the transporter at the extracellular side and expels the potentially remaining allocrite into the membrane. The high sensitivity of the steady-state ATP hydrolysis rate to the nature and number of dipolar interactions, as well as to the dielectric constant of the membrane, points to a flopping process, which occurs to a large extent at the membrane-transporter interface. The proposed unidirectional ABCB1 transport cycle, driven by weak dipolar interactions, is consistent with membrane biophysics.

INTRODUCTION

P-glycoprotein (ABCB1) (170 kDa) was discovered in 1976 by Juliano and Ling^[1] in Chinese hamster ovary (CHO) cells, selected for resistance to colchicine. These cells displayed *pleiotropic cross-resistance* to a wide range of *amphiphilic* drugs. Because the glycoprotein altered the *membrane permeability (P)*, it was called P-glycoprotein. This first description comprises the key characteristics of the protein (highlighted in italics), which will play a recurrent role in this review. ABCB1 is the first mammalian member of a large family of ATP binding cassette (ABC) transporters present in prokaryotes^[2] and eukaryotes, from plants^[3] to humans^[4]. Most ABC transporters move compounds (allocrites^[5]) across membranes, using the energy of ATP binding and hydrolysis. The functional unit of ABC transporters consists of two highly conserved nucleotide-binding domains (NBDs) forming together two nucleotide-binding sites (NBSs) for ATP hydrolysis and two more variable transmembrane domains (TMDs), which are assumed to form the translocation pathway for allocrites. In prokaryotes, the functional unit consists of a homodimer formed by two polypeptides with one NBD and one TMD each. In most eukaryotes, these two polypeptides are linked and the transporters function as monomers. In recent years, approximately 250 structures of ABC transporters have been obtained, allowing the establishment of a new classification system based on TMD folds^[6]. Prokaryotic ABC transporters revealed seven types of folds (I-VII), while eukaryotic ABC transporters had only two (IV and V). The seven subfamilies (ABCA-G), defined previously based on phylogenetic analysis^[7], are maintained as subcategories within the type IV fold (subfamilies B-D) and type V fold (subfamilies A and G). Although the large number of structural approaches have provided important information, “the question as to how substrate binding and translocation are coordinated and coupled with ATP binding and hydrolysis, in any ABC transporter, remains elusive”^[8,9].

Several models for ABCB1 function have been suggested. Senior and colleagues^[10] observed that both NBSs of ABCB1 were catalytically active and seemed to alternate in activity, hydrolyzing one ATP per catalytic cycle with a turnover of 1-10 molecules s^{-1} . They suggested a scheme of alternating catalytic sites, in which drug transport is coupled to the relaxation of a high-energy catalytic site conformation, generated by the hydrolysis step^[10]. Experiments by Sharom and colleagues^[11] supported this model (for review, see^[12]). More recently, one study demonstrated that ABCB1 “mutants with one intact catalytic center preserve the ability to hydrolyze ATP and to promote drug transport, suggesting that the two catalytic sites are randomly recruited for ATP hydrolysis”^[13]. An analogous observation was made for ABCC7 (cystic fibrosis transmembrane conductance regulator, CFTR) that lacks the catalytic glutamine in NBD1^[14]. Ambudkar and Sauna suggested that transport is coupled to the hydrolysis of a first ATP and resetting of the transporter to the hydrolysis of a second ATP^[15].

On the basis of the first low-resolution structures of ABCB1 in the absence and presence of nucleotides^[16], Higgins and Linton proposed the currently prevailing “ATP switch model”^[17]. This model assumes that binding of two ATP molecules induces an outward-facing (OF) conformation for drug release, and hydrolysis of two ATP molecules leads to a nucleotide free (apo-form) with an inward-facing (IF) conformation for drug binding. Support for this switch, or alternating access model, was inferred from the OF high-resolution conformation of the homodimeric Sav1866 in the presence of two AMP-PNP molecules^[18], and the IF conformation of apo-ABCB1^[19,20]. An IF conformation of ABCB1 was also observed in permeabilized, ATP-depleted cells, in the presence of the conformation-sensitive antibody UIC2 mAb^[13]. The resemblance of the alternating access model to the early “simple allosteric model for membrane pumps” by Jardetzky^[21] proposed for moving inorganic ions across membranes was taken as further support for this model (for review, see e.g.,^[22,23]).

The currently prevailing “alternating switch model” raises several questions. (i) Is the aqueous cleft of the apo-state, wide open to the cytosol, useful for the transport of amphiphilic compounds that highly accumulate in membranes and access the transporter within the membrane^[24-27]? (ii) Is the assumption of an apo ground state realistic, considering the high intracellular ATP concentration ($c_{\text{ATP}} = 1-10 \text{ mM}$)^[28-30] and the comparatively low K_m values for ATP binding to the transporter ($c_{\text{ATP}} = 0.4-0.8 \text{ mM}$)^[31,32]? Are two ATPs hydrolyzed, or is one ATP hydrolyzed per transport cycle?

To obtain information on the conformation of the NBDs and TMDs under turnover conditions, we analyzed the results of multiple double electron-electron resonance (DEER) spectroscopy experiments performed with spin label pairs introduced at strategic locations in different ABC transporters and compared them with X-ray structures. The DEER experiments revealed a wide range of conformations that were not fully accounted for in the proposed models (see Ref.^[33] and Supplementary Table 1 therein).

For further insight, we performed molecular dynamics (MD) simulations for different nucleotide occupancy states of Sav1866 structure, a prokaryotic ABCB1 homolog^[33]. The two transporters (both with a type IV fold^[6]) show overlapping substrate specificity^[32,34]. Our simulations revealed an outward closed conformation of the transmembrane domain that is stabilized by the binding of two ATP molecules. The hydrolysis of a single ATP leads the X-loop, a key motif of the ATP binding cassette, to interfere with the transmembrane domain and favors its outward open conformation. These findings provided a structural basis for the unidirectionality of transport in ABC exporters and suggested that one ATP is hydrolyzed per transport cycle^[33]. However, the role of the amphiphilic allocrites in the transport process remained unclear.

Here, we demonstrate that a quantitative understanding of the interactions between the amphiphilic allocrites and the transporter is possible if the membrane environment is taken into account. For this purpose, we review the thermodynamics (allocrite binding) and kinetics (ATP hydrolysis and allocrite transport rate) of ABCB1, published over approximately the past 25 years. Altogether, this work provides a compelling quantitative description of the nature of the intermolecular interactions relevant for ABCB1 function: Allocrite binding within the membrane, the rate of ATP hydrolysis, and allocrite transport are driven by weak dipolar forces that depend on the nature of the surrounding membrane. Combining the insights gained with the conclusions from our previous molecular dynamics simulations^[33] generates a unidirectional allocrite transport cycle for ABCB1 that is consistent with the principles of membrane biophysics. Special emphasis is placed on clarifying the mechanism of ABCB1 inhibition, which is of crucial relevance for pharmacotherapy.

THE REACTION PARTNERS AND THEIR ENVIRONMENT

Understanding chemical processes generally starts with structural analysis of the reactants, in the present case, the ABCB1 transporter and its allocrites. Allocrites include substrates, modulators, and inhibitors (for definitions used, see Ref.^[35]). Although less recognized, the environment in which the reaction partners meet determines the nature of interactions. Because ABCB1 and its allocrites meet in the membrane, we first provide a short description of the lipid bilayer and its properties relevant for the subsequent discussion of allocrite-transporter interactions ([Supplementary Equation 1](#), discussed in detail below).

Characteristics of lipid membranes relevant for allocrite-transporter interactions

ABCB1 is abundant in plasma membranes. The plasma membrane shows an asymmetric lipid distribution between the bilayer leaflets. The extracellular leaflet is composed essentially of electrically neutral lipids
