MECHANISMS OF PRIMARY RESISTANCE TO TYROSINE KINASE INHIBITOR IN RENAL CELL CARCINOMA

Primary resistance is characterized as a lack of response to therapy, which may be caused by the absence of a particular target's expression or by the existence of inherently resistant clones that do not respond to target therapy. Furthermore, primary resistance may be influenced by spatial and temporal heterogeneity^[30,31].

Primary resistance to VEGF-TKIs

Hypoxia and von hippel lindau pathway

The tumor suppressor protein von Hippel Lindau (VHL) is frequently mutated in hereditary RCC. VHL is a target of hypoxia-inducible factors (HIFs), dimeric proteins composed of O₂-sensitive subunits (HIF-1, -2 or 3) and a subunit (HIF-2). In the presence of oxygen, these factors facilitated its degradation. VHL inactivation creates a pseudo-hypoxic state and HIF dimers can bind to hypoxia response elements (HREs) to induce angiogenesis and cancer cell proliferation. VHL disease is characterized by a decreased expression of HIF-1 and an increased expression of HIF-2, the latter connected with c-Myc activity^[32].

Gordan *et al.* analyzed 160 tumor samples and found that VHL-deficient ccRCCs can be distinguished based on HIF- expression. Three different subgroups have been defined: (1) Wild-type VHL tumors with no HIF- expression; (2) VHL deficient tumors with HIF-1 and-2 expression; and (3) VHL deficient tumors with only HIF-2. The third subgroup (HIF-2 expression) displayed enhanced c-Myc activity and higher rates of proliferation. The authors also demonstrated an interplay between HIF-2, c-Myc and genome instability. Indeed, the VHL-deficient subgroup expressing HIF-2 was even characterized by an upregulation of the homologous recombination (HR) effectors BRCA1 and BARD1, and consequentially, HIF-2 tumors and no HIF-1 ones had a greater ability to repair DNA damage accumulation induced by replication stress^[32,33].

Given that VHL-deficient tumors with only HIF-2 expression experienced primary resistance to angiogenesis inhibition, thus HIF-2a alone may identify a subset of RCCs in which targeted therapies lack efficacy.

Membrane transporters and lysosomal sequestration

The uptake and efflux of several TKIs (e.g., sunitinib, cabozantinib, pazopanib) could be mediated by multidrug resistance (MDR)-related solute carrier (SLC) and ATB-binding cassette (ABC) transporters, respectively^[34,35]. A number of variables, including pH, drug concentration, and affinity, can affect the interaction between TKIs and transporters. As a result of insufficient intracellular drug concentration, these transporters can be responsible for intrinsic resistance.

The most studied ABC transporters implicated in MDR include P-glycoprotein (Pgp, ABCB1), multidrug resistance protein 1 (MRP1, ABCC1), and breast cancer resistance protein (BCRP, ABCG2). Due to a substrate-like characteristic, TKIs can be pumped outside the cells with an efflux mechanism at lower concentrations. However, at higher concentrations, TKIs can act as inhibitors.

TKIs usually inhibit ABC transporters without altering their expression or localization. As an example, cabozantinib competitively interacts with the drug-substrate binding site to decrease the ATPase activity of the ABCG2 transporter^[36]. Pazopanib has both substrate-like and inhibitory effects. In the canine kidney cell line MDCKII, it was reported as both an ABCB1 and ABCG2 substrate and as an inhibitor of ABCB1 and its efflux characteristics^[37-39].

Lysosomal sequestration is another mechanism of resistance based on drug physicochemical properties. This phenomenon is related to ABC transporters since these pumps are present on the membranes of intracellular compartments and regulate the drug's influx into lysosomes^[37,40,41]. Lysosomal sequestration has been shown to impact the effectiveness of the drugs sunitinib and pazopanib^[42].

Lysosomal intake-induced resistance can be reversed. Indeed, after removing sunitinib from tumor cell culture, cell lysosomal capacity was restored, regaining drug sensitivity. This can give an explanation of the recovered sensibility to sunitinib experienced by patients after treatment interruption and subsequent rechallenge^[37,42,43].

SECONDARY AND ACQUIRED RESISTANCE TO VEGFR-TKIs

Bergers and Hanahan categorize resistance to VEGFR-TKI as intrinsic or primary and adaptive or evasive (secondary)^[44]. Sometimes, it was impossible to clearly and immediately shift the biological basis of these two types of resistance. The majority of the time, primary resistance could be explained by the abundance of angiogenic receptors and downstream pathways. However, the hypoxic state induced by VEGFR-TKI therapy could be responsible for an “angiogenic switch” towards a different molecular pathway, driving a different pattern of response [Figure 1].

Acquired resistance develops throughout treatment, usually following an initial response to therapy, and could be induced by the pressure of a specific therapy. The selection of particular clones that are resistant to therapy results in the progression of cancer. Additionally, cancers might develop resistance to a particular treatment through other pathways that are not affected by targeted therapy.

Tumor plasticity

A loss of cell polarity and contact promotes epithelial-mesenchymal transition (EMT). E-cadherin and other epithelial cell markers are downregulated during this transition, while mesenchymal markers including N-cadherin, vimentin, fibronectin, different matrix metalloproteases (MMPs), and 1 and 3 integrins are upregulated^[45,46]. It has been shown that HIF-1 activation caused by hypoxia can induce EMT, a process that is associated with drug resistance^[47-51]. EMT-associated transcription factors (EMT-TFs), such as TWIST1, ZEB1, or SNAI1, can be stimulated to express themselves directly or indirectly by the stabilization of HIFs under hypoxia. TGF/TGFR, NF-B, and NOTCH signaling are the three regulatory mechanisms most extensively studied for their potential role in triggering EMT^[52-55].

Insulin-growth factor (IGF) signaling, which interacts with the NOTCH and Wnt/-catenin pathways, has been shown to be a modulator of EMT^[56].

Sharma *et al.* provided evidence that sunitinib-treated RCC tumors underwent a mesenchymal transformation as seen by higher expression of N cadherin and decreased expression of E cadherin, which were both connected with an elevation of TGF and IGF1R. Patients with mRCC who expressed IGF1R and TGF and subsequently had EMT had worse outcomes, as shown by data from the Cancer Genome Atlas (TCGA) database^[57].

Hwang *et al.* analyzed gene expression profiles and copy number variations of 10 metastatic ccRCC tumor samples before treatment and immediately after disease progression to a TKI. Microarray analysis of pre- and post-treatment ccRCC tumors demonstrated an increased expression of EMT-related genes including CD44, SNAI2, TWIST, and CLDN1 in TKI-resistant cells, acquiring migration and invasion capacity. In this study, the authors demonstrated that CD44 depletion significantly decreased cell invasiveness.

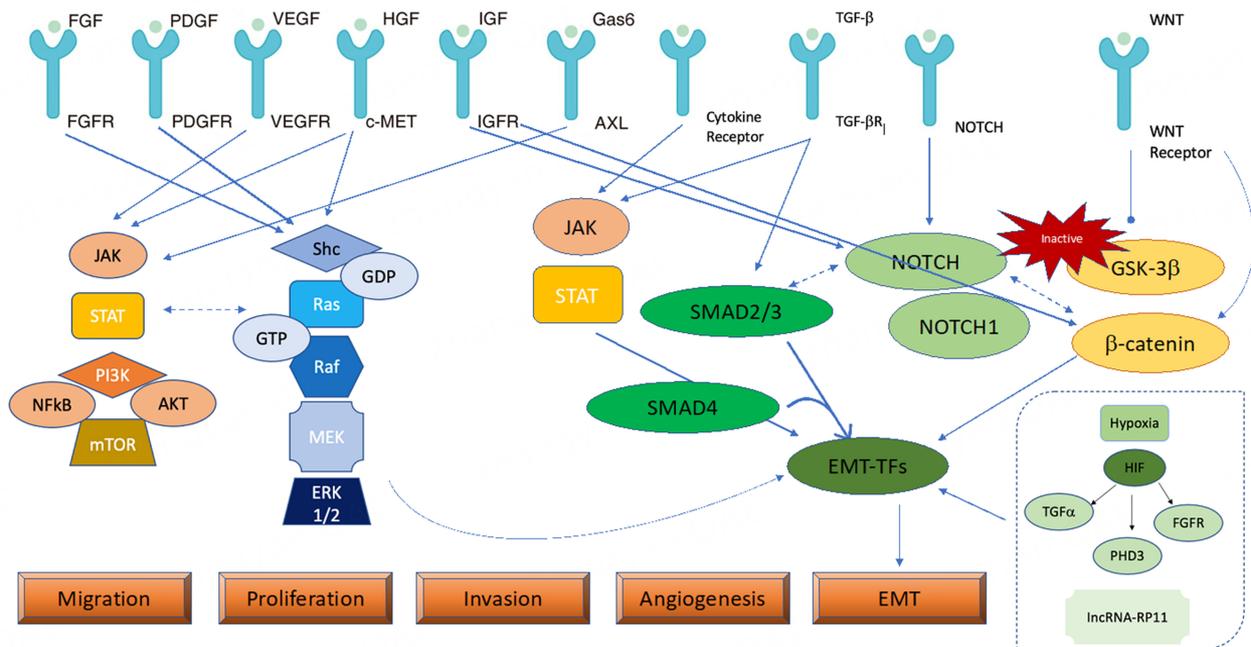

Figure 1. Cross-talking between TKI receptors, hypoxia and growth factor receptors and relationship with tumor growth and resistance to TKIs. Several trans-membrane TKI receptors interact with each other and mediate the activation of shared pathways, most implicated in tumor growth and angiogenesis. TGF β /Smad pathway and the interaction of some cytokines, such as IL-6 with their receptors, together with the Notch signaling pathway and wnt/ β -catenin pathway induce EMT transcription factors and EMT as a mechanism of resistance to the inhibition of angiogenesis. Finally, hypoxia promotes both angiogenesis and EMT. AKT: Protein kinase B; AXL: AXL Receptor; EMT: epithelial mesenchymal transition. EMT-TFs: epithelial mesenchymal transition transcription factors; Erk1/2: elk-related tyrosine kinase; FGF: fibroblast growth factor; FGFR: fibroblast growth factor receptor; Gas6: growth arrest specific protein-6; GSK-3: glycogen synthase kinase 3 beta; HGF: hepatocyte growth factor; HIF: hypoxia-inducible factor; IGF: insulin growth factor; TGF-: tumor growth factor; IGFR: insulin growth factor receptor; JAK: janus kinase; Mek1/2: MAP kinase-ERK kinase; MET: hepatocyte growth factor receptor; mTOR: mammalian target of rapamycin; NF κ B: nuclear factor kappa B; PDGFR: platelet derived growth factor receptor; PDGF- β : platelet derived growth factor- β ; PI3K: phosphatidylinositol 3-kinase; Raf: RAF proto-oncogene serine/threonine-protein kinase; Ras: rat sarcoma protein; STAT3: signal transducer and activator of transcription 3; VEGF: vascular endothelial growth factor; VEGFR: vascular endothelial growth factor receptor; VHL: von hippel-lindau protein.

Claudin-1 is a component of tight junctions, and it has been suggested that it could be implicated in EMT induction. In this study, claudin-1 expression seems to be a mediator of TKI resistance in both clinical and experimental models. Furthermore, compared to pre-treatment ccRCC, TKI-resistant tumors had an increased proportion of sarcomatoid features^[58].

It may be crucial to understand the various pathways that underlie EMT and the indicators of this process in order to design strategies that combine therapies addressing both hypoxia and EMT.

Non-angiogenic pathway and by-pass pathways

Vascular co-option is a way to use pre-existing vessels. Using 164 lung metastasis specimens, Bridgeman *et al.* identified four different histopathological growth patterns (HGPs), each with a different vascularization (alveolar, interstitial, perivascular cuffing, and pushing). The tumors vascularize through angiogenesis exclusively in the pushing HGP pattern; a co-option vascular mechanism was employed in the other patterns. The authors showed that vascular co-option might act as a mediator of sunitinib resistance. In mice models, sunitinib induced a switch from the most frequent angiogenic pushing HGP to an alveolar/interstitial HGP that vascularizes through vessel co-option, thus inducing resistance^[59].

Furthermore, cancer resistance can arise when tumor cells employ other signaling pathways that are unaffected by VEGF/VEGFR suppression.

Fibroblast growth factor/fibroblast growth factor receptor pathway

Fibroblast growth factors (FGFs) are proteins that are involved in proliferation, differentiation, migration, and apoptosis of tumor cells^[60].

FGF2, also known as basic FGF, has been recognized as a potential mediator of TKI resistance. Cell cultures were treated with VEGF and 100 nM sunitinib by Welti *et al.* Endothelial cell proliferation was restored by FGF1 and FGF2 to levels that were comparable to (FGF1) or greater than (FGF2) those seen in the absence of sunitinib^[61]. Indeed, FGF2 induces angiogenesis through the activation of signaling pathways such as Ras-Raf-MEK-ERK 1/2 and PLC-PKC, bypassing the VEGF/VEGFR signal. It has been reported that FGF2 upregulates the expression of both fibroblast growth factor receptor (FGFR) and VEGFR in endothelial cells and systemic administration of VEGFR-2 antagonists inhibits both VEGF and FGF2-induced angiogenesis *in vitro* and *in vivo*^[62-64]. In contrast to what was expected by previous studies, Welti *et al.* showed that while sunitinib inhibits VEGFR2-mediated activation of ERK 1/2 and PLC, it is not able to prevent the FGF2-mediated activation of these pathways, raising the possibility that cancer cells may use this way to bypass VEGF-mediated angiogenesis inhibition^[61].

MET/HGF signaling

When the hepatocyte growth factor/scatter factor (HGF/SF) binds to its receptor tyrosine kinase MET, the activation of the RAS-MAPK and PI3K-AKT pathways results in the development and angiogenesis of endothelial cells. HGF/SF-MET interaction is a potent regulator of the angiogenic switch. Common signaling intermediaries such as ERK-MAPK, protein kinase B (AKT), and focal adhesion kinase (FAK) are activated by both MET and VEGFR^[65-68].

A remarkable new finding is that the MET/HGF pathway may be activated by hypoxia caused by blocking angiogenesis with VEGFR-TKIs in a HIF-mediated manner, hence increasing the MET-dependent spread of cancer cells^[69-72].

Additionally, it is hypothesized a relationship between the MET axis and the immune system. Several immune cells, including mast cells, neutrophils, and dendritic cells (DCs), may have increased MET expression. MET/HGF-SF signaling could impact the ability of T cells to respond competently to cancer cells, by reducing the DCs' capacity to present antigens and recruiting immunosuppressive cells. Therefore, MET inhibition may be a way to restore neutrophils and DCs' capacity^[73,74].

Cabozantinib is an oral multiple tyrosine kinase receptor inhibitor: VEGFR2, c-MET, and RET. Inhibition of VEGFR and c-MET decreases resistance to VEGFR inhibitors via the c-MET axis. However, resistance to MET inhibition can occur. Huang *et al.* reported some of the most common mechanisms inducing acquired resistance to HGF/MET-target therapy: hypoxia-induced MET phosphorylation reduction, with no effect on downstream signaling pathway, mutations in the MET kinase domain, bypass signaling, copy number changes and constitutive activation of AKT and ERK-MAPK pathway^[75-77].

GAS6/Axl signaling

AXL is a receptor tyrosine kinase (RTK) that is a member of the TAM RTK. AXL signaling is implicated in tumor growth, EMT, angiogenesis, metastasis spread, and the development of resistance to targeted therapy. The AXL-ligand Gas6 is a vitamin K-dependent protein and the GAS6/AXL signaling can be constitutively

activated in ccRCC cells^[78-82].

Gustafsson *et al.* found that sunitinib enhanced Gas6-induced AXL phosphorylation in ccRCC, and consequentially activated the AKT pathway. Indeed, in the absence of sunitinib, the activation of the main MAPK pathways (ERK1-2, P38MAPK, and SAPK-JNK) by Gas6 alone was insufficient to activate AXL. Furthermore, it was shown that Gas6 activated the EGFR pathway when sunitinib was present. This pathway, along with AXL, is thought to be implicated in cancer's resistance mechanism^[83].

Cytokines

Treatment with sunitinib has been shown to increase the expression of IL-6 and IL-8. These cytokines have been linked to TKI resistance, suggesting that they could play an important role in inducing angiogenesis in a HIF-independent way. IL-6 activates the AKT/mTOR and transcription factor STAT3 cascade, resulting in increased expression of VEGFA and VEGFR2. In endothelial cells, IL-8 promotes the accumulation of VEGFA mRNA in normoxic conditions as well as the endothelial cells are exposed to hypoxia. Even when HIF-1 is blocked, CXCL8/IL-8 can still induce VEGFA promoter-driven transcription^[84,85].

Pilskog *et al.* evaluated the expression of IL6R in RCC tumor cells and discovered that the expression of IL6Ra may predict responsiveness to TKI treatment. In fact, a significant correlation between IL6R expression and the objective response rate was identified but not with PFS or OS, indicating that IL6R expression may have predictive significance. IL-6 ligand expression may also play a prognostic role, as demonstrated by the association between its lack of expression or low expression with PFS^[86,87].

Huang *et al.* developed sunitinib-resistant xenograft models and discovered that sunitinib-treated ccRCC cell lines developed resistance and displayed an elevated IL-8 expression. They observed that only when sunitinib treatment was sustained over a longer period did the reduction of IL-8 function decrease tumor growth. Only after the emergence of resistance to tyrosine kinase inhibition could IL-8 function inhibition affect tumor growth^[88,89].

Tumor microenvironment and immune cells as mediators of TKI-resistance

There is growing interest in the connection between TIME, immune cells, and angiogenesis, and there is evidence that the tumor microenvironment has a direct role in the emergence of resistance to targeted therapies. The recently approved combination of ICIs and VEGFR-TKIs is also supported by this association. Therefore, it is critical to understand how TIME affects the mechanisms of resistance to target therapy in order to better understand resistance to combination therapy [Figure 2].

MDSCs

MDSCs are the major component of TIME. Growing evidence indicates that tumors release pro-angiogenic signals that recruit MDSCs, which may act as mediators in the development of resistance to TKIs^[91-94].

Ko *et al.* had demonstrated that sunitinib therapy significantly reduced MDSC accumulation in tumor-bearing mice models, leading to improved peripheral T-cell function. It appears that even when sunitinib diminishes peripheral MDSC accumulation, intra-tumoral MDSCs can be much less impacted. Intra-tumoral MDSCs from sunitinib-treated mice retained T-cell suppressive capacities comparable to those from untreated mice. The authors quantified MDSC subsets in tumor specimens of untreated and sunitinib-treated RCC. In contrast to the substantial reduction in peripheral blood MDSCs seen in RCC patients treated with sunitinib, the proportion of MDSCs in tumor samples nevertheless remained greater and these cells maintained their suppressive capabilities, as assessed by IFN production.

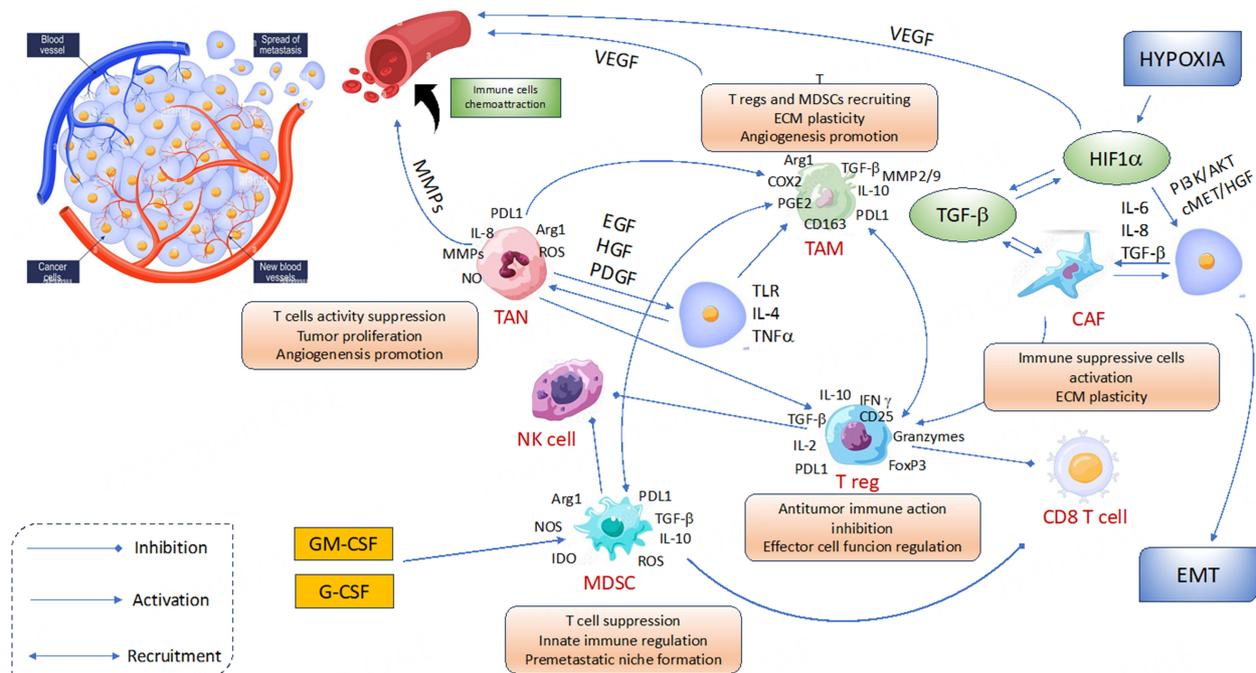

Figure 2. Interaction between angiogenesis and tumor microenvironment. Immune cells are recruited by chemokines and angiogenic factors and the tumor infiltration by immune cells is, in turn, implicated in promoting angiogenesis. The balance between immune response and immunosuppression is crucial to induce tumor killing from one side or tumor escape to the other. CAF: Cancer-associated fibroblasts; EGF: epidermal growth factor; EMT: epithelial-mesenchymal transition; G-CSF: granulocyte colony-stimulating factor; GM-CSF: granulocyte-macrophage colony-stimulating factor; HGF: hepatocyte growth factor; HIF-1 α : hypoxia-inducible factor 1 α ; IFN γ : interferon- γ ; IL-2/4/6/10/8: interleukin; MDSC: myeloid-derived suppressor cell; MMP: matrix metalloproteinases; NK: natural killer; PDGF: platelet-derived growth factor; PDL1: programmed death-ligand 1; TAM: tumor-associated macrophages; TAN: tumor-associated neutrophils; TGF- β : tumor growth factor beta; TLR: toll-like receptor; TNF α : tumor necrosis factor α ; Treg: regulatory T cells; VEGF: vascular endothelial growth factor^[90].

Additionally, sunitinib did not significantly affect the amount of GM-CSF produced by RCC tumors in vitro. Due to the stimulation of the STAT5 pathway, the pro-proliferative cytokine GM-CSF confers peripheral MDSCs sunitinib resistance. Sunitinib decreased pSTAT3 in the absence of GM-CSF, which made MDSCs more susceptible to the drug. In contrast, STAT5-mediated pathways are prominent in the presence of GM-CSF, resulting in a phenotype of MDSCs that is resistant to sunitinib^[95].

These findings have been confirmed by Finke *et al.*, who examined MDSCs both in peripheral blood and in tumors of RCC patients. They discovered that the sunitinib-induced maximum drop in MDSC numbers occurred after the second cycle and continued until later than the fourth cycle, although there is some recovery in MDSC levels at this point. In this study, the impact of pro-angiogenic factors on sunitinib resistance was also evaluated. Pro-angiogenic variables' effects on sunitinib resistance were also assessed in this study. The analysis of tumor tissue lysates from patients who had neoadjuvant therapy revealed that there was an increase in the expression of pro-angiogenic proteins [Matrix metalloproteinase (MMP9), MMP8, and IL-8] in tumors with a greater level of MDSCs. Additionally, sunitinib causes an increase in plasma IL-8 levels, and larger levels are associated with a worse PFS. The presence of MDSCs in tumors might promote the production of IL-8, which could activate alternative pro-angiogenic pathways (MMP9/MMP8/IL8) to prevent cell death^[96].

C Marcela Diaz-Montero *et al.* used a patient-derived xenograft (PDX) model of RCC and performed a microarray analysis of sunitinib-responsive and -resistant tumors. Resistance to sunitinib was associated

with the upregulation of genes involved in cell movement and immune cell trafficking in both human and murine expression analyses. Furthermore, tumors resistant to sunitinib had higher levels of G-CSF and, consequently, higher levels of G-MDSCs. G-MDSCs are MDSCs that resemble granulocytes both phenotypically and functionally. G-MDSCs have the ability to inhibit the immune response, and they can additionally promote angiogenesis and the spread of tumors^[97].

Cancer-associated fibroblasts

Tumor-growth factor (TGF) and platelet-derived growth factor (PDGF) induce the transformation of tumor fibroblasts (FHNR) in cancer-associated fibroblasts (CAFs), which play a key role in tumor progression, producing pro-tumoral cytokines (e.g., IL-6, IL-8, TNF, IL-10). Fibroblast-associated protein (FAP) is a marker of CAFs. Ambrosetti *et al.* demonstrated that high levels of FAP mRNA were correlated with shorter PFS and OS in metastatic ccRCC (PFS, $P = 0.054$ and OS, $P = 0.022$). Sunitinib stimulated FHNR to differentiate towards CAFs. Mice with induced mRCC were treated with sunitinib or with placebo. Compared to the placebo group, the sunitinib-treated mice's tumors had higher FAP mRNA levels ($P = 0.049$). Sunitinib primary resistance has also been linked to CAFs, which create a barrier to the drug's ability to reach tumor cells. Finally, CAFs appear to be a mediator of tumor cell EMT^[98].

TAMs

Some of the most numerous immune cells identified within tumors are TAMs. Two subsets of TAMs are typically recognized: M1 and M2. M1-like TAMs have a pro-inflammatory phenotype and inhibit tumor growth, whereas M2-like TAMs have tumor-promoting capabilities involving immuno-suppression, angiogenesis, and neovascularization, as well as stromal activation and remodeling^[99]. The functional phenotype M2-like is induced by hypoxia of the TIME, resulting in tumor escape^[100].

In the genomic and transcriptomic analysis of ccRCC patients treated with TKIs in the COMPARZ phase III trial, Hakimi *et al.* observed significantly worse OS (HR 1.54; 95%CI: 1.17-2.03; $P = 1.98$) among subjects with high macrophage infiltration and higher macrophage infiltration (Kruskal-Wallis test, $P = 0.02$) in patients who experienced progressive disease. Furthermore, they found that a high M2-macrophage infiltration ($M2^{\text{high}}$) was associated with poor OS (HR 1.38; 95%CI: 1.06-1.81; $P = 0.019$) and PFS (HR 1.40; 95%CI 1.09-1.78; $P = 7.90$) compared to the $M2^{\text{low}}$ group. Depending on the TKI used, macrophage infiltration and its impact on the outcomes differed. TAMs infiltration was a prognostic factor in patients receiving pazopanib but not sunitinib. This supports the notion that sunitinib primarily affects MDSCs^[101].

TIL and TKIs interaction with immune-cell infiltration

TIL correlated with poorer prognosis and shorter survival in RCC^[102]. Liu *et al.* compared the percentage of immune cells in TKI-exposed RCC tissue with control samples and they found an increased CD3+ T-lymphocyte infiltration, CD45RO+ T-lymphocyte infiltration, CD4+ T-lymphocyte infiltration and CD8+ T-lymphocyte infiltration both after sunitinib and bevacizumab treatment. The infiltration of CD68+ macrophages was higher in sunitinib-treated versus control RCC specimens (25.2% vs. 20.3%, $P < 0.05$) but not in bevacizumab-treated samples (21.3% vs. 20.3%, $P > 0.05$). In sunitinib-treated patients, a higher percentage of tumor-infiltrating CD4+ T lymphocytes was associated with shorter OS and PFS. TIL composition might be modulated by VEGF target treatment. Indeed, although not changing either the ratio of CD4+FOXP3+ Tregs to total CD4+ T lymphocytes or the ratio of Treg to CD8+ T lymphocytes, CD4+FOXP3+ Tregs were greater in cases treated with bevacizumab or sunitinib.

Tregs infiltration was higher in sunitinib-treated patients with shorter OS and PFS. Finally, sunitinib directly enhanced PD-L1 expression, and those patients who had higher PD-L1 expression had shorter OS and PFS ($P < 0.05$) after receiving sunitinib treatment^[103].

The analysis of T cell subsets and MDSCs in peripheral blood mononuclear cells (PBMCs) from ccRCC patients receiving cabozantinib and other therapies (nivolumab and pazopanib) revealed that T cell subsets composition changed after treatment. Indeed, cabozantinib treatment increased the proportion of Th9, Th22, and Th17 cells while having no effect on the number of Th2 cells, Th1, Treg, and CD8+ T cell populations. Among these T cells, the proportion of Th22, but not Th9, was associated with better outcomes^[104].

Epigenetic modification

Non-coding and micro RNA

Non-coding RNAs, known as microRNAs (miRNAs), have significant functions in modulating the expression of genes. The role of miRNAs in resistance to TKIs is still being investigated^[105].

Yamaguchi *et al.* conducted one of the first attempts to profile miRNAs in resistant RCC cell lines as they developed two sunitinib-resistant cell lines and performed microarray and RT-qPCR analysis on them. They identified seven miRNAs (miR-575, miR-642b-3p, miR-4430, miR-18a-5p, miR-29b-1-5p, miR-431-3p, miR-4521) whose expression was linked to sunitinib resistance.

It was reported that miR-4430 had a role in modulating expression genes implicated in the inhibition of PTEN/mammalian target of rapamycin (mTOR) signaling pathway. miR-18a-5p is associated with hypoxia-inducible factor 1 alpha (HIF1A)^[106]. Sunitinib-resistant cell lines had higher miR-4430 levels and lower miR-18a-5p ones, suggesting that the acquisition of sunitinib resistance was associated with PTEN downregulation, and FGF1 and HIF1A upregulation^[107] [Table 3].

PRIMARY RESISTANCE TO ICIs

Availability of antigens and dendritic cells' (DCs') presentation of them, T-cell trafficking and tumor infiltration, T-cell effectiveness, and equilibrium between regulatory and cytotoxic cells in the TIME composition are all requirements for an immune response against tumor cells to be successful. Immune escape may occur in any of these phases, resulting in either primary or acquired resistance to immune checkpoint inhibitors^[108].

Antigen availability and DCs presentation capacity

The recognition of a specific antigen by antigen-presentation cells (APCs) is the first step in a successful immune response. Major Histocompatibility Complex (MHC) proteins, which are classed as class I on all nucleated cells or class II on specific immune system cells such as macrophages, dendritic cells, and B cells, are also expressed on the surfaces of APCs. These proteins are necessary for the process of antigen presentation, which activates T cells in response to the antigen and results in a successful immune response^[109].

Antigen availability may be influenced by the tumor mutational burden, and the absence of neoantigens may be caused by epigenetic alterations^[110]. RCC has a relatively low mutational load. De Velasco *et al.* reported a low mutational load in their full exome transcriptome analysis of metastatic RCC patients included in TCGA, with a median of 1.42 mutations/Mb (range: 0.035-2.77). Classifying the 54 patients according to the IMDC risk criteria, no differences were seen in mutational load ($P = 0.39$), as well as in the

expression of cytolytic genes - granzyme A (GZMA) and perforin (PRF1) - or in selected immune checkpoint molecules (PD-1, PD-L1, PD-L2, CTLA-4) ($P > 0.05$ for all)^[111].

Lack of antigen presentation could be affected by MHC mutations or defects in DCs' functions and maturation.

Beta-2-microglobulin (B2M), an important subunit of MHC class I, has essential biological functions and roles in tumor immunity. *B2M* gene deficiency and loss of Beta-2-microglobulin, induced by mutations and epigenetic regulation, can lead to complete loss of MHC class I antigen expression. B2M mutations frequently result in MHC defects that cannot be repaired, and immunotherapy is ineffective at restoring MHC expression^[112].

The maturation of DCs can be influenced by numerous factors. Hypoxia, which creates an acidic environment with a higher amount of lactates, is one of these. Recent data suggests the existence of DCs with immune-suppressive characteristics. These cells may overexpress pathways involved in immune tolerance: e.g., STAT3 which induces S100A9, a gene that prevents DCs from maturing and recognizing antigens, or FOXO3, a transcription factor that induces the expression of indolamine 2,3-dioxygenase (IDO), arginase, and TGF- β and inhibits co-stimulatory molecules^[113].

In the TIME, dendritic cells must already be present. A study conducted by Spranger *et al.* in melanoma murine models revealed that tumor-intrinsic active -catenin signaling results in T-cell exclusion and

resistance to ICIs. Tumors with active β -catenin exhibited a nearly complete absence of activated T cells, according to an analysis of immunological infiltrates. This absence was attributed to the loss of dendritic cells, particularly CD103⁺ dendritic cells with diminished IFN- β expression. The number of CD103⁺ dendritic cells was similarly decreased in the tumor-draining lymph nodes, but not in the spleen, thus reflecting the fact that these DCs were not recruited due to a defect in chemotactic signals, such as CCL4. Furthermore, when treated with dual checkpoint inhibition, no therapeutic effect in reducing tumor growth was detected in active β -catenin mice. Re-introduction of dendritic cells restored tumor response to ICI^[114].

Human endogenous retroviruses

Human endogenous retroviruses (hERVs) are components of about 8% of our genome that possibly originated by incorporating ancestral exogenous viruses. There are only a limited number of tools available for quantifying and identifying hERVs. They could be a source of neoantigen and mediate immune response in TIME. Smith *et al.* identified more than 3,000 transcriptionally active hERVs within the TCGA pan-cancer RNA-Seq database. They explored two mechanisms by which hERV expression could affect the tumor immune microenvironment in ccRCC. The first mechanism involved innate immune response and activation of the RIG-I-like pathway signaling by double-stranded RNAs (dsRNA). The second was related to the adaptive immune response, as documented by the hHERV epitope-triggered activation of the B cells. Patients with both RIG-I-like downregulation and BCR-associated signatures upregulation had significantly shorter overall survival, while those with higher expression of the RIG-I-like signature had longer overall survival. Two significant tumor-specific hERVs were lastly found in ccRCC (CT-RCC hERV-E and hHERV 4700). The CT-RCC hERV-E displayed a Treg signature and was the second most differentially expressed hERV. In an aPD1-treated ccRCC dataset, hERV 4700 (HERVERI/gammaretro-virus-like) expression was higher in tumor samples compared to normal tissue, and it was associated with response to immunotherapy. This could occur because hERV 4700-derived epitopes may be the target of an antitumor response mediated by aPD1 mAb^[115,116].

Immune cell trafficking and recruitment

As discussed above, activation of the WNT/ β -catenin pathway reduces the recruitment of dendritic cells in TIME, affecting T-cell activation^[114].

Given that pre-existing T-cells in the tumor are essential for response to ICIs, various mechanisms that may cause initial resistance to immunotherapy with the end result of the absence of immunologically competent cells in TIME have been investigated so far.

PTEN is a lipid phosphatase that inhibits the activity of PI3K/AKT signaling. PTEN loss has been associated with altered TIME T-cell composition. Peng *et al.* found that a lower CD8⁺ T cell tumor infiltration was present in melanomas with PTEN loss compared to tumors with PTEN expression ($P < 0.001$). Furthermore, PTEN loss resulted in both an up-regulation of inhibitory cytokines including CCL2 and VEGF and a down-regulation of the T cell effector molecules IFN- and granzyme B. Since PTEN loss and PI3K/AKT pathway signaling both contribute to immunotherapy resistance, it is possible to reverse this effect by targeting the PI3K-AKT pathway^[117].

T-cell activity in TIME and microenvironment composition

T cells get activated when they come into contact with APCs and the MHC complex through the TCR. Following this, T cells mostly develop into cytotoxic T cells (CD8⁺ cells) or T-helper (Th) cells (CD4⁺ cells), and they release cytokines that further regulate the immune response^[108]. Cytotoxic CD8⁺ T lymphocytes are mainly responsible for killing tumor cells. MHC class II proteins trigger the activation of CD4⁺ Th cells, which lack the ability to cause cytotoxicity. In fact, they are implicated in the recruitment of additional

immune cells, producing cytokines. IFN- γ is a mediator of the Th1 cell response^[109].

As tumors grow, persistent exposure to IFN- γ may be responsible for a down-regulation of IFN signaling downstream, resulting in primary immunotherapy resistance. Mutations in IFN receptors, Janus kinases JAK 1/JAK2, are studied mechanisms by which cancer cells could have an advantage in developing resistance to IFN-mediated anti-proliferative effects. Shing *et al.* discovered that loss of function mutations in JAK1/2 in melanoma cells could inhibit T cells killing capacity and IFN's ability to induce PD-L1 expression, making pharmacological suppression of the PD-L1/PD-1 interaction ineffective. Reduced T-cell trafficking, along with decreased production of chemokines such as CXCL9, CXCL10, and CXCL11, could potentially account for the lack of response^[118].

For a competent immune response to be effective, there must be a balance between cells that inhibit immunity and cells that promote response inside the tumor microenvironment. TME is dynamic and constantly changes. The TIME of ccRCC is unusual, and it is distinguished by a strong inflammatory profile and T-cell infiltration. The primary immunosuppressive cells in TIME are TAMs, MDSCs, and regulatory T cells (Treg)^[119].

TAMs

In ccRCC, cancer-cell-derived factors such as IL-1 β , IL-6, IL-10, tumor necrosis factor- α , epidermal growth factor, and TGF- β induce macrophage polarization towards a M2 phenotype by cell-cell interactions. CD163+ M2 TAMs contributed to poor clinical prognosis in patients with ccRCC by activating STAT3 pathway. PI(3)Kinase γ (PI3K γ) is found to be implicated in the macrophage switch from a M1-phenotype to a M2-phenotype, inhibiting Akt and mTOR together with the NF κ B and C/EBP β activation. As a result, the immune suppressive phenotype promotes tumor growth and inflammation^[120,121].

Tregs

Through the production of IL-10 and TGF- β , Tregs can mediate immunosuppression by inhibiting T cells and APCs functions. These cells can be recruited in TIME by chemokines and cytokine produced by exhausted T-cells. Furthermore, cancer cells can play out escape mechanisms upregulating Tregs in TIME^[109]. Hyperactivation of focal adhesion kinase (FAK) (also known as FADK) in tumor cells induces overexpression of various chemokines (including CCL5), thus recruiting Treg cells and inducing CD8+ T cell exclusion or exhaustion. Self-antigen-specific CD8+ T cells express restricted co-stimulatory signals, which impair APC activity and enhance suppression by Tregs, whereas Tregs have a stronger affinity for TCRs of non-self-antigen specific CD8+ T cells, which are resistant to suppression^[121,122].

Immune checkpoints like CTLA-4 and PD-1 are expressed by Tregs as well. In human glioblastoma tissue, Tregs with high PD-1 exhibit an exhausted phenotype lacking immunosuppressive activity. Anti-PD-1 mAbs may cause hyper-progression, decreasing the number of Tregs that express PD-1 and restore their ability to inhibit immunological response^[121,123-125].

The contribution of the B7x immunological checkpoint to the growth of the Treg population within the tumor was discussed by John *et al.* In accordance with their suppressive function, B7x+ Tregs exhibited a higher level of TGF-LAP (a surface marker of TGF production) and a lower percentage of ki67 marker, indicating that they originated from peripherally converted CD4+ T cells. B7x increased Foxp3 expression through increasing STAT5 phosphorylation, whereas it inhibited STAT3 phosphorylation, which affected CD4+ T cells' ability to differentiate into the Th17 subtype. What is more intriguing is that the anti-CTLA-4 therapy was not successful in reducing Tregs exclusively in mice that expressed B7x+. In addition, B7x+

mice showed a substantial reduction in the IFN production generally caused by anti-CTLA-4. Tregs play a crucial part in the immune response, as shown by the fact that Treg depletion restored anti-CTLA-4 capabilities in tumor reduction even in B7x+ mice^[126].

MDSCs

MDSCs may differentiate into M2-polarized macrophages with immunosuppressive properties and can decrease T-cell activation by metabolic processes (e.g., iNOS, IDO). Additionally, they are able to express CD40 and to produce TGF- and IL-1, leading to Tregs expansion and decreasing the capacity of effector T cells^[93]. In both melanoma patients and prostate cancer patients treated with ipilimumab, a lower baseline amount of circulating MDSCs was associated with a higher overall survival rate. Furthermore, high myeloid inflammation gene signature expression was associated with reduced PFS in the atezolizumab monotherapy arm and in the atezolizumab + bevacizumab arm, but not in the sunitinib arm in the molecular analysis of the IMmotion 150^[127,22].

DCs

According to their presence in Tertiary lymphoid structures (TLS), DCs in ccRCC can be divided into two subtypes: TLS-DCs (CD83+ DC- LAMP+), which are very uncommon in ccRCC and associated with good outcomes, and non-TLS-DCs (CD209+ CD83), which are dominant in ccRCC TIME and associated with the worst prognosis. In addition to promoting tumor growth by secreting MMP-9 and TNF, NTLs-DCs further inhibit CD8+ T-cell activity by the L-arginine pathway and trigger Treg responses by secreting TGF-^[109,119,128,129].

Genomic and single-gene mutation and TIME

The biomarker analyses conducted among patients treated in the IMmotion 150, the Javelin Renal 101 and the Checkmate 214 had developed the idea that gene expression profile (GEP) in RCC could predict response to ICIs^[22-24].

Based on mRNA expression data, Beuselinck *et al.* performed a clustering analysis and identified four molecular subgroups of ccRCC, even if done in a cohort of patients receiving sunitinib: ccrcc1 (“c-myc-up”), ccrcc2 tumors (“classical”), ccrcc3 (“normal-like”) and ccrcc4 tumors (“c-myc-up and immune-up”). The ccRCC4 subtype displayed a strong inflammatory, Th1-oriented but suppressive immune microenvironment, with a strong expression of myeloid and T-cell homing factors. Furthermore, this subtype had a higher proportion of IL10 as well as inhibitory receptors LAG3 and PD-1 and PD-1 ligands PD-L1 and PD-L2. In the validation analysis of single-gene mutations conducted on TGCA samples, SETD2 mutations were related to a lower T-cell infiltration and immunosuppressive markers (ccrcc1), while BAP1 mutations were expressed in the subtype with the highest inflammatory infiltration but on the other hand, having the strongest expression of immunosuppressive cells (ccrcc4)^[130].

In the BIONIKK trial, the authors used Beuselinck’s clustering classification to undertake a biomarker-driven analysis. Patients with the ccrcc 1 and 4 subtypes were randomized to receive nivolumab either alone or in combination with ipilimumab, whereas those with ccrcc 2 and 3 could receive either nivolumab plus ipilimumab or a VEGF-TKI. In the ccrcc1 (immune desert subtype), ORR and PFS were improved by the dual checkpoint inhibition (HR of PFS for nivolumab *vs.* nivolumab + ipilimumab 1.27; 95%CI 0.77-2.11). In the ccrcc4 (immune infiltrated and inflammatory subtype), both nivolumab alone and in combination with ipilimumab obtained higher ORR and longer PFS compared to the ccrcc 1 group. Thus, ccrcc4 seemed the best candidate for dual checkpoint inhibition. Furthermore, about 30% of patients in the ccrcc4 group who early progressed on nivolumab–ipilimumab did not start a second-line therapy, thus reflecting that

progression at first evaluation, does not always indicate resistance^[131].

PBRM1 and BAP1

PBRM1 encodes for BAF180, a component of the SWI/SNF chromatin remodeling complex and could be inactivated in about 36% of clear cell renal cell carcinoma. Its relationship with prognosis in RCC has been evaluated in several studies, resulting in conflicting findings. PBRM1 mutations have also been documented in VHL-disease-associated RCC. PBRM1 and VHL mutations were most frequently expressed in ccRCC1 subtypes (immune desert one)^[131-134]. In the phase I CA209-009, 35 samples of RCC treated with Nivolumab were whole-exome sequenced and were consequently divided into three categories according to responses. Clinical response to Nivolumab was characterized by a higher percentage of PBRM1 loss-of-function. The same results were seen in a subgroup treated with nivolumab plus ipilimumab^[135].

As reported above, in the molecular subsets analysis of the IMmotion 151, PBRM1 mutations conferred better outcomes to patients, regardless of the treatment arm. However, in patients with PBRM1-non-mutant tumors, the addition of immunotherapy to a VEGFR-TKI confers better outcomes compared to target therapy alone^[31].

SETD2

SETD2 mutations, a histone methyltransferase gene, occur in 10% of ccRCC. Wang *et al.* clustered TCGA RCC samples based on TME expression profiles and observed two different clusters: the first cluster, inflamed subtype (IS), was enriched for Treg cells, NK cells, Th cells, neutrophils, macrophages, eosinophils, B cells and CD8+ T cells, whereas the second cluster, not inflamed subtype (NIS), was enriched for angiogenesis, plasmacytoid DCs, and mast cells. Mutations in BAP1 were most frequently seen in the IS ($P = 7.7 \times 10^{-5}$), whereas the NIS was enriched for PBRM1 mutations. Furthermore, the authors observed that Bap1-mutated mice were more infiltrated by CD4 and CD8 T cells, than Pbrm1-mutated mice, suggesting a causal relationship between BAP1 mutations and the TME-IS phenotype. It is interesting to note that individuals with tumors of the TME-IS subtype had higher rates of thrombocytosis and anemia, which are systemic symptoms of inflammation caused in TME^[136].

GUT MICROBIOME INFLUENCES PRIMARY RESISTANCE TO IMMUNOTHERAPY

The complex system of the gut microbiota interacts with the host. By producing neoantigens and modifying the tumor immunological microenvironment, microorganisms have an impact on immune responses. Furthermore, studies have revealed that antibiotics can affect the metabolic balance of the intestinal microbiome by increasing some species while decreasing others, leading to dysbiosis^[137-140].

Routy *et al.* demonstrated that the use of antibiotics (ATB) influenced response to ICIs in non-small cell lung cancer (NSCLC), RCC and urothelial cancers. As evidenced by poorer outcomes for individuals receiving antibiotic treatment, ATB usage did, in fact, cause resistance to PD-1 blockade in all tumor types. Analyzing the microbiome composition, *Akkermansia muciniphila* conferred better PFS to patients treated with immunotherapy. Th1 and Tc1 cell reactivity against *A. muciniphila* was the only immune response to ICIs that was associated with clinical outcomes^[138].

De rosa *et al.* confirmed that ATB impaired patients' responses to immunotherapy by altering the diversity and composition of gut microbiota in a metagenomic and network analysis of patients treated with nivolumab in the NIVOREN GETUG-AFU 26 phase 2 trial. Responders had an over-representation of distinct species including *A. muciniphila*, *Bacteroides salyersiae*, and *Eubacterium siraeum*, and a trend towards *Clostridium ramosum* and *Alistipes senegalensis*, whereas *E. bacterium_2_2_44A*, *Clostridium*

hathewayi, and *Clostridium clostridioforme* were more represented in non-responders, as observed for those patients using ATB. Due to the fact that the majority of patients had already received a VEGF-TKI, the authors examined the effects of TKI use in combination with ATB on microbiome composition and discovered that axitinib + ATB was the most effective treatment to induce a shift in fecal microbiota. Additionally, most notably with cabozantinib, TKIs promoted a transition to a preponderance of immunostimulatory commensals, such as *A. senegalensis* and *A. muciniphila*. This property could be one of the rational bases for combining VEGFR-TKI with ICIs^[141].

ACQUIRED RESISTANCE TO IMMUNE CHECKPOINT INHIBITORS

Secondary resistance develops throughout therapy and may be driven by the stress that a particular therapy might have on TIME, as well as by temporal variability and plasticity. The same mechanisms that lead to initial resistance also cause secondary resistance to immune-checkpoint inhibitors. Some investigators observed that TILs (the immune response's effectors) are present during relapse but remain restricted to the tumor margin, raising the possibility that these cells have lost the ability to identify antigens or to activate themselves. Utilizing ICIs, the IFN-induced expression of PD-L1 and its negative effects on CD8+ T cells are prevented. To reduce antigen presentation or enable escape from interferon-induced growth inhibition, cancer cells may, however, become insensitive to IFN signaling. JAK mutations have been investigated as a strategy by which cancers develop IFN unresponsiveness^[142].

Numerous investigations conducted on humans have shown that tumor cells can develop resistance to T-cell recognition by having defective HLA class I expression^[142-145]. Loss-of-function in chromosome region 15q21-(where $\beta 2m$ gene maps) induces a $\beta 2m$ gene mutation, leading to the absence of the MHC class I. These alterations can be reversible and the HLA expression can be recovered by using immunotherapy, as a result of transcriptional silencing of genes or irreversible. It has been suggested that resistance to immunotherapy may be caused by the preexistence of metastatic lesions with a $\beta 2m$ gene mutation and that selective pressure during T-cell-based immunotherapy could induce the growth of HLA class-I deficient clones in melanoma patients who have irreversible HLA alterations^[146].

Chronically activated Treg cells showed strong suppressive potential. Tregs increase CD103 expression when activated, and CD103+ Treg exhibited greater levels of inhibitory receptors such as PD-1, TIM-3, and CTLA-4. Additionally, they upregulate functional molecules, granzyme B and IL-10, which are essential to their suppressive actions, such as the decrease in CD8+ T cells^[147].

ALTERNATIVE INHIBITORY RECEPTORS UPREGULATION AS A MECHANISM OF ACQUIRED RESISTANCE

Exhausted CD8+ T cells lose their cytotoxic efficacy against presented antigens. PD-1 is only one of the inhibitory receptors highly expressed on exhausted CD8 T cells and its blockade may have a therapeutical effect. However, blocking this pathway does not completely restore T cell function. Numerous alternative inhibitory receptors, primarily identified in chronic infections, such as LAG-3, TIM-3, 2B4, CD160, or BTLA, are overexpressed in exhausted T cells and may be targeted to enhance immune response or reverse resistance^[147,148].

PD-1

PD-1 is an inhibitor of both adaptive and innate immune responses, and it is expressed on activated T, natural killer (NK) and B lymphocytes, dendritic cells (DCs), macrophages, and monocytes^[149]. In a cohort of patients with NSCLC, gastric cancer (GC) and melanoma treated with Nivolumab, CD8+ T cells of the TIMEs from responders expressed higher levels of PD-1 than those from non-responders. Furthermore,

PD-1 was highly expressed in eTreg (CD45RA⁻CD25^{hi}Foxp3^{hi}CD4⁺) of the TIME of patients with NSCLC and GC which not responded to nivolumab. In this context, the use of aPD-1 mAb could have immunosuppressive effects, enhancing the expression of PD-1 among eTreg, and thus stimulating Treg functions^[150].

PD-1 expression balance between CD8⁺ T cells and Treg cells is crucial for the efficacy of monoclonal antibodies to PD-1.

The prognostic value of PD-L1 expression in RCC is controversial. A meta-analysis of four trials assessed the predictive value of PD-L1 among patients treated with nivolumab + ipilimumab, atezolizumab + bevacizumab, pembrolizumab + axitinib or avelumab + axitinib vs. sunitinib. Patients with PD-L1-positive tumors showed significantly improved ORRs, complete response rates (CRRs) and PFS, and lower progression disease responses (PDRs) compared with those with PD-L1-negative tumors when treated with ICIs vs. sunitinib. Nivolumab plus ipilimumab had the highest likelihood of providing the maximal PFS (p score: 0.90) and the highest ORR (p score: 0.95)^[151].

Overall, even though the findings of this study show that PD-L1 has a predictive value, there are several limitations, such as the fact that PD-L1 is expressed differently in primary tumors compared to metastatic sites, as well as the lack of a standard detection method and the different types of anti-PD-L1 antibody used. Examining the variable pattern of PD-L1 expression on different immune cells in TIME might be more fascinating than examining its expression just on tumor cells. As reported, it appears that the effectiveness of ICIs depends on the balance between PD-1 expression on CD8⁺ T-cells and Treg.

LAG3

Lymphocyte Activation Gene-3 (LAG3; CD223) is expressed on activated human NK and T cell lines and is able to bind MHC class II. A soluble monomeric form of LAG3 (sLAG3) can be released by IFN-producing CD4⁺ T cells. The major ligand of LAG3 is MHC class II. Melanoma cells that express MHC class II attract tumor-specific CD4⁺ T cells through their interaction with LAG3, resulting in impairing CD8⁺ T cell responses. Other putative ligands are Galectin-3, which mediates suppression of CD8⁺ T-cell-secreted IFN in vitro and LSECTin (liver sinusoidal endothelial cell lectin). It was found that the association between LAG3 and the LSECTin ligand inhibits the generation of IFN by effector T cells that are antigen-specific in melanoma cells. Dendritic cell inhibition is one of the ways whereby LAG3-expressing Tregs interact with MHC class II to cause immunological suppression. In fact, when exposed to LAG-3, MHC class II-expressing melanoma cells, but not MHC class II-negative ones, were resistant to Fas-mediated apoptosis^[152-155].

In a study examining the key inhibitory receptors (iR) expression on TILs and PBMCs of 35 patients with RCC, CD8⁺ T cells and non-Treg CD4⁺ cells highly expressed the inhibitory receptors PD-1, followed by LAG-3 and BTLA, whereas Tim-3 and CTLA-4 were less highly expressed. However, the expression profile of the five iR on tumor-infiltrating Tregs was different. Indeed, Tregs upregulated PD-1, LAG-3, Tim-3, and CTLA-4, but not BTLA. Interestingly, as previously reported, the most frequent iR combination was PD-1 and LAG-3, whereas about 10% of CD8⁺ T cells expressed PD-1, LAG-3 and Tim-3 simultaneously. Experimental in vitro demonstrated that blockade of PD-1 plus LAG-3 resulted in a statistically significant higher percentage of CD8⁺ IFN⁺ T cells, than blockade of PD-1 alone.

Additionally, when CD4⁺ and CD8⁺ T cells were co-cultured with anti-PD-1, LAG3 upregulated but not PD-1. These findings suggested that blocking LAG-3 in combination with PD-1 might be an effective

treatment for advanced RCC^[156].

TIM-3

T cell immunoglobulin and mucin-domain containing-3 (Tim-3) is a type I trans membrane protein expressed in IFN- γ -producing Th1 and Tc1 cells. The expression of cytokines such as TNF and INF- γ and Th1 responses are significantly suppressed by Tim-3. Tim-3 is linked to T cell exhaustion and its expression on CD8+ T cells is directly related to PD-1. Indeed, CD8+ T cells co-expressing Tim-3 and PD-1 are “deeply” exhausted T cells. Tim-3 could be expressed on tumor-infiltrating DCs, playing a role as a mediator of the innate immune response. The Tim-3 ligand with the highest affinity is galectin-9, and its interaction with Tim-3 causes the death of effector Th1 cells and CD8+ T cells. Furthermore, galectin-9 increases Tim-3-mediated IFN production in NK cells, activates PI3K-mTOR signaling in myeloid cells, and alters cytokine production by monocytes/macrophages, affecting Th1 and Th17 responses.

Other theorized ligands are being researched. Galectin-9 and Ceacam1 collaborate, both having a comparable effect. Activated DCs release the damage-associated molecular pattern known as HMGB1 (high-mobility group box 1), which stimulates T and B cell responses while inhibiting innate immune responses to tumor-derived nucleic acids. Tim-3 signaling's impact is influenced by the ligands involved, the cellular environment, and the biological state, particularly whether the stimulation is acute or persistent. Tim-3 can have adjuvant effects inducing the expression of co-stimulatory receptors. In contrast, chronic stimulation could enhance the inhibitory functions of Tim-3 signaling, especially as concerns HLA-B associated transcript 3 (Bat3) deficient Th1 and CD8+ T cells, driving these cells to an exhaustion stage^[157-164].

Expression of Tim-3 on T cells also plays a critical role in the generation of MDSCs and is even present in FoxP3+ T regs, contributing to promoting T cell dysfunction and immune suppression^[165,166].

In isolated CD8+ T cells, Tim-3+PD-1+ TILs were identified as an exhausted phenotype of T cells, having a reduced production of IL-2, TNF, and IFN- γ . Combining anti-Tim-3 and anti-PD-L1 therapy reduced the tumor growth in mouse models, and those who underwent a complete regression continued to be tumor-free even after rechallenging^[167].

Tim-3 expression in RCC has been associated with outcomes resulting in contradictory results. Patients receiving nivolumab were assessed in the CheckMate-010 research study conducted by Pignon *et al.* in an attempt to identify the mechanisms causing different responses. Longer median immune-related response progression-free survival (irPFS) and higher ORR were associated with the presence of CD8+ tumor-infiltrating cells that express PD-1 but lack LAG3 and TIM3 and are more likely to be T cell activated. This is in contrast to Zelba *et al.*'s findings, which showed that blocking both PD-1 and Tim-3 simultaneously had no effect on the average cytokine production by TILs, resulting in a lack of the immune response's restoration. Therefore, additional research is required to confirm the usefulness of Tim-3 as a possible target to enhance immune responses driven by the inhibition of checkpoint inhibitors^[168,156] [Table 4].

CONCLUSIONS

Metastatic renal cell carcinoma management has undergone a paradigm shift as a result of the development of combination therapy using ICIs. The choice of first-line treatment and its correct application continues to be crucial factors in tumor evolution and have the potential to cause initial resistance, which may have an impact on overall survival. Because of this, it is now crucial to understand how the combination of ICIs or the addition of a VEGF-TKI to immunotherapy may alter the tumor microenvironment and affect the

Table 4. Major determinants of primary and acquired resistance to ICIs

Primary resistance to ICIs	
Antigen availability	mRCC has a low mutation load
Antigen presentation defects	Beta-2 microglobulin loss might result in a deficiency of MHC class I expression.
Absence of dendritic cells (DCs)	Due to defects in chemotactic signals, active β -catenin signaling causes the depletion of DCs.
Antigen epigenetic modification	hHERVs may influence both innate and adaptive immune responses.
Cells trafficking and recruitment alterations	·WNT/ β -catenin pathway activation reduces DCs recruitment. ·PTEN loss reduces CD8 ⁺ T cell infiltration.
T-cell activity inhibition	JAK1/2 loss of function mutations inhibit T cell killing efficacy and IFN-mediated PD-L1 expression.
Tumor microenvironment composition	TAMs ·M2-like TAMs correlate with worse prognosis in mRCC Tregs ·Anti-CTLA-4 mAbs are not effective in depleting Tregs expressing B7x immune checkpoint. MDSCs ·Low MDSCs infiltration correlates with better outcomes with ICIs DCs ·A specific subtype of DCs (NTLS-DCs) with immunosuppressive functions is dominant in ccRCC.
Genomic and single-gene mutations	PBRM1 ·Regardless of the type of treatment utilized, PBRM1 mutations are correlated with better results. ·Combining VEGFR-TKI with ICI is more effective in PBRM1 non-mutant tumors. ·PBRM1 mutations are more frequent in non-inflamed, angiogenic subtypes. SETD2 ·SETD2 mutations are enriched in inflamed immune infiltrated subtypes.
Gut microbiome composition	Antibiotic use induces resistance to aPD-L1 mAb Different bacterial species are represented in responders vs. non-responders
Secondary resistance to ICIs	
Same mechanisms involved in primary resistance	·IFN unresponsiveness via JAK mutations ·HLA I defects. ·Loss-of-function of Beta-2 microglobulin mutations.
Alternative inhibitory receptors	·LAG3 ·TIM-3

DCs: Dendritic cells; hHERVs: human endogenous retroviruses; HLA: human leukocyte antigen; IFN, interferon; JAK: janus kinases; LAG3: lymphocyte activation gene-3; MDSCs: myeloid-derived suppressor cells; mRCC: metastatic renal cell carcinoma; PD-L1: programmed death-ligand 1; TAMs: tumor-associated macrophages; TIM-3: T-cell immunoglobulin and mucin-domain containing-3; Tregs: T regulator.

tumor's response to treatment. Targeting hypoxia with specific drugs may be a possibility to enhance outcomes in RCC since hypoxia is a defining feature of RCC pathogenesis and is associated with both angiogenesis and the alteration of the tumor microenvironment. HIF-2 inhibitor belzutifan is being tested in patients with previously treated mRCC as a single treatment versus everolimus (NCT04195750) or in combination with lenvatinib versus cabozantinib (NCT04586231). Different inhibitory receptors or metabolic pathways may be the focus of alternative approaches. The phase II trial FRACTION-RCC is studying an anti-LAG3 mAb (relatlimab), in combination with nivolumab (NCT02996110). XmAb[®]22,841, a bispecific antibody targeting CTLA-4 and LAG-3, is under study in the phase I trial DUET-4 (NCT03849469). A randomized phase II trial is investigating the efficacy of axitinib combined with an antibody against OX40, a receptor expressed on memory T cells (NCT03092856). In a phase 1b/2 trial, patients with previously treated mRCC are being treated with cabozantinib in conjunction with the anti-AXL fusion protein AVB-S6-500, which controls the GAS6/AXL signaling pathway (NCT04300140).

Despite the previously mentioned advancements, there is still a significant research gap in the individual biology of tumors. Furthermore, there is no trustworthy biomarker to direct patient selection. The dynamic genomic and immunomodulatory alterations that systemic treatment causes in the TIME in advanced ccRCC may help to partially explain this paucity of biomarkers.

It may be possible to predict therapy response by combining tumor genomic and immune signatures, but much more accurate research is needed to link biological understanding with clinical findings in RCC.

We must change how we approach treating ccRCC due to the advent of clinical resistance to the currently available systemic treatments. Cancer cells are constantly changing as a result of therapy pressure, plasticity, and heterogeneity. We may be able to comprehend, avoid, and overcome resistance mechanisms by estimating the trajectory of ccRCC evolution. In the prospective cohort study TRACERx, the authors conducted a whole genome sequencing of RCC tumor samples to generate information on the timing of driver mutations, level of intratumoral heterogeneity, and presence of parallel evolution in each patient. They found that the loss of heterozygosity of chromosome 3p was the first critical driving event. The most frequent alteration was rearrangement between 3p and 5q (one copy of 3p lost and one copy of 5q earned), defined t (3:5) chromothripsis. Using t (3:5) as the cut-off, they calculated the chronological age at which each mutation occurred. They found that the duplication that caused t (3:5) chromothripsis was an early event (35-50 years before tumor diagnosis), causing a modest initial clonal expansion, and that the mutation rate throughout life remained constant. Due to the latency between the triggering mutational event and subsequent progression, there may be a window for early intervention to prevent RCC. Indeed, the incidence of sporadic RCC could be decreased by reducing the 3p-LOH clone size by 50%. This is reasonable given that this chromosome contains four tumor-suppressor genes (VHL, PBRM1, BAP1, and SETD2) that are crucial for cellular survival^[169].

Based on seven evolutionary subgroups that coincide with clinical characteristics, ccRCCs have been divided into four groups^[169,170]. These groups are distinguished by four features-variations in chromosomal complexity, intra-tumor heterogeneity (ITH), model of tumor evolution, and metastatic potential.

In a review by Kowalewski *et al.*, the authors investigate single group characteristics and describe possible evolution-target strategies according to the evolutionary trajectories. Group 1 tumors are those that have a single VHL mutation and a low genome instability index (wGII), as well as low ITH. Given the positive predictive significance of a low wGII as a measure of response to ICIs, this group may benefit from immunotherapy. Furthermore, a stable tumor burden could be reinforced by adaptive therapy, upfront cytoreductive nephrectomy (CN), and treatment targeting trunk group before the loss of 9p or 14q, which marks the acquisition of metastatic competence. Group 2 tumors are those with an early PBRM1 mutation and a subsequent SETD2 mutation, PI3K pathway mutation, or high wGII, and were distinguished by a “branched” evolutionary pattern. In this group, modulating genomic instability could be useless, whereas targeting immune evasion could be an option. In contrast, Group 3 and 4 tumors are those with multiple driver mutations (VHL plus ≥ 2 BAP1, PBRM1, SETD2, or PTEN) resulting in “punctuated” evolution and characterized by high wGII. ITH is low in group 3 tumors but higher in group 4 tumors, giving that group a rapid dissemination pattern. Due to high wGII and a punctuated evolution pattern in Groups 3 and 4, it may be effective to address genomic instability by enhancing it. The goal of evolutionary herding is to reduce ITH and manage any potential distinct clones that may result from a prior treatment by utilizing a combination of drugs in a specific order. Hence, it should be considered in Groups 1 and 3^[171].

We might be able to transpose this perspective into the real world with the aid of new technologies. For instance, the repeated evolution in cancer (REVOLVER) machine-learning algorithm was created to achieve repeatable disease prognosis based on next-generation sequencing (NGS) count data, thereby classifying patients based on the evolution of their tumors over time^[172]. Trials including biomarkers and evolutionary paths as drivers of chosen treatment will be the new challenge in the future, in order to predict earlier the correct strategy and to prevent a manipulation that could be harmful when applied in the incorrect evolutionary trajectory.

Authors' contributions

Conceptualization, formal analysis, resources, data curation, writing - original draft: Astore S
Data curation, resources, software, writing - review and editing: Baciarello G, Cerbone L
Validation, supervision, project administration, writing - review, project administration: Calabrò F

Availability of data and materials

Not applicable.

Financial support and sponsorship

None.

Conflicts of interest

SA declares no conflicts of interest. FA is a consultant/member of the external advisory board for Pfizer, BMS, Ipsen, MSD, AstraZeneca, Merck and Accord.

Ethical approval and consent to participate

Not applicable.

Consent for publication

Not applicable.

Abstract

Cancer cells adapt to environmental changes and alter their metabolic pathways to promote survival and proliferation. Metabolic reprogramming not only allows tumor cells to maintain a reduction-oxidation balance by rewiring resources for survival, but also causes nutrient addiction or metabolic vulnerability. Ferroptosis is a form of regulated cell death characterized by the iron-dependent accumulation of lipid peroxides. Excess iron in ovarian cancer amplifies free oxidative radicals and drives the Fenton reaction, thereby inducing ferroptosis. However, ovarian cancer is characterized by ferroptosis resistance. Therefore, the induction of ferroptosis is an exciting new targeted therapy for ovarian cancer. In this review, potential metabolic pathways targeting ferroptosis were summarized to promote anticancer effects, and current knowledge and future perspectives on ferroptosis for ovarian cancer therapy were discussed. Two therapeutic strategies were highlighted in this review: directly inducing the ferroptosis pathway and targeting metabolic vulnerabilities that affect ferroptosis. The overexpression of SLC7A11, a cystine/glutamate antiporter SLC7A11 (also known as xCT), is involved in the suppression of ferroptosis. xCT inhibition by ferroptosis inducers (e.g., erastin) can promote cell death when carbon as an energy

source of glucose, glutamine, or fatty acids is abundant. On the contrary, xCT regulation has been reported to be highly dependent on the metabolic vulnerability. Drugs that target intrinsic metabolic vulnerabilities (e.g., GLUT1 inhibitors, PDK4 inhibitors, or glutaminase inhibitors) predispose cancer cells to death, which is triggered by decreased nicotinamide adenine dinucleotide phosphate generation or increased reactive oxygen species accumulation. Therefore, therapeutic approaches that either directly inhibit the xCT pathway or target metabolic vulnerabilities may be effective in overcoming ferroptosis resistance. Real-time monitoring of changes in metabolic pathways may aid in selecting personalized treatment modalities. Despite the rapid development of ferroptosis-inducing agents, therapeutic strategies targeting metabolic vulnerability remain in their infancy. Thus, further studies must be conducted to comprehensively understand the precise mechanism linking metabolic rewiring with ferroptosis.

Keywords: Ferroptosis, glutaminolysis, glycolysis, metabolic vulnerability, ovarian cancer, pentose phosphate pathway

INTRODUCTION

Epithelial ovarian cancer has a poor prognosis because of limited early screening methods and high recurrence rates^[1]. Modern approaches include debulking surgery, platinum/taxane chemotherapy, angiogenesis inhibitors (e.g., bevacizumab), drugs targeting poly(ADP-ribose) polymerase (i.e., PARP inhibitors), and drugs targeting the dysfunctional immune system (i.e., immune checkpoint inhibitors) depending on the histological type and tumor stage^[2]. Thus, establishing more effective treatment options is necessary as ovarian cancer often recurs and becomes resistant to chemotherapy.

High-grade serous ovarian cancer (HGSC) is a common and aggressive subtype of epithelial ovarian cancer^[3]. Clear cell carcinoma (CCC) of the ovary, the second most common histological type in Japan, has distinctive clinical behavior, biological function, and molecular characteristics^[3]. HGSC arises from the implantation of fallopian tube epithelial cells, and it is characterized by TP53 (p53) mutations associated with enhanced genomic instability^[3]. p53 mutation may promote hypoxia-induced genomic instability, leading to the activation of pro-oncogenic signaling such as hypoxia-inducible factor (HIF) 1^[4]. Furthermore, fallopian tube epithelial cells are constantly exposed to potentially toxic constituents [e.g., labile iron and reactive oxygen species (ROS)] derived from retrograde menstrual reflux even before the accumulation of somatic or oncogenic mutations^[5]. The iron content determined in HGSC was almost five times higher than that for normal ovarian cells^[6]. HGSC exhibits an increased expression level of the iron import transferrin receptor 1 and a decreased expression level of the cellular iron exporter ferroportin, thereby enhancing the intracellular iron pool^[7]. In addition, based on previous reports, CCC derived from endometriosis could increase CCC cell proliferation via iron supplied by the surrounding endometriosis^[8]. Rapidly proliferating cancer cells have a unique phenotype of iron metabolism, which increases iron supply and decreases iron loss^[9]. Apart from iron, such cancer cells also require a continuous supply of adequate nutrients and oxygen available within the tumor microenvironment to generate their own bioenergetics (e.g., glucose, glutamine, cysteine, ATP, and fatty acid) and macromolecules (e.g., proteins, lipids, and nucleic acids)^[10]. Glycolysis, mitochondrial oxidative phosphorylation (OXPHOS), glutaminolysis, and fatty acid synthesis are the major pathways of energy metabolism. Ovarian cancer cells switch from OXPHOS to aerobic glycolysis to adapt to environmental changes^[11] through HIF-mediated metabolic reprogramming^[12].

Cancer cells acquire a diverse range of metabolic flexibility and plasticity as an adaptation to ever-changing nutritional microenvironments during tumor evolution^[13]. However, accelerated energy metabolism that supports the enhanced proliferation rate further increases iron demand, oxidative stress, and susceptibility to tumor cell death^[14]. Ferroptosis is a recognized form of regulated cell death associated with iron and ROS

accumulation, which serves as a vital component of various processes in ovarian cancer^[7,15]. Under nutrient-deprived conditions, cancer cells depend on optimal metabolic pathways for survival. This metabolic reprogramming creates an addiction to intracellular and extracellular nutrients (i.e., strong dependencies on nutrients), which may result in acquired resistance to cell death^[13]. Metabolic flexibility and nutrient addiction are critical for cell fate determination. Therefore, forced alterations in metabolic pathways may have great application potential in tumor-targeted therapy. Thus, this review aims to summarize the regulation of ferroptosis evasion and its crosstalk with multiple cellular metabolic pathways in a variety of cancers and to discuss research perspectives, particularly therapeutic strategies targeting ovarian cancer.

METABOLIC FLEXIBILITY, PLASTICITY, AND VULNERABILITY IN CANCER CELLS

Cells have evolved elaborate metabolic flexibility to control cell survival, growth, and defense against oxidative stress for adaptation to ever-changing aerobic or anaerobic environments^[16]. Glucose is the major energy source for eukaryotic cells, and it plays a critical role in redox (reduction/oxidation) homeostasis^[10]. Glucose is transported into cells via transmembrane proteins [e.g., glucose transporter (GLUT)] and metabolized through glycolysis and the pentose phosphate pathway (PPP), an early diverging branch of glycolysis^[17]. The internalized glucose molecule is initially converted to glucose 6-phosphate (G6P) by hexokinase, and then it produces pyruvate through glycolysis as well as abundant reduced nicotinamide adenine dinucleotide phosphate (NADPH) and ribose 5-phosphate through the PPP^[17]. NADPH serves as a cofactor for glutathione reductase and maintains the active state of antioxidants by converting oxidized glutathione [i.e., glutathione disulfide (GSSG)] to glutathione (GSH)^[14]. Ribose-5-phosphate is necessary for nucleic acid synthesis^[14]. Pyruvate is metabolized to lactate in the cytosol or converted to acetyl coenzyme A (acetyl-CoA) in the mitochondria to fuel the tricarboxylic acid (TCA) cycle, enhance OXPHOS, and generate ATP^[18,19]. Under hypoxic conditions, pyruvate is converted into lactate during glycolysis^[20].

Cancer cells adapt to the tumor environment by reprogramming various metabolic pathways to meet their high-energy demands. The upregulation of specific nutrient transporters increases cellular entry of glucose and amino acids^[21]. However, the generation of ATP as an energy source in the mitochondria induces oxidative stress caused by increased ROS production, resulting in cell death^[11,22,23]. In mitigating oxidative stress, glucose metabolism is rewired to the PPP that operates parallel to glycolysis to maintain redox homeostasis by generating ribose-5-phosphate and NADPH^[11]. Cancer cells prefer aerobic glycolysis over OXPHOS to support their proliferation, which is known as the Warburg effect^[22,23]. Pyruvate is irreversibly converted to acetyl-CoA by pyruvate dehydrogenase (PDH) in the mitochondria. Pyruvate dehydrogenase kinase (PDK) inhibits PDH activity^[24]. Thus, PDK suppresses the metabolic shift from glycolysis to the TCA cycle by downregulating PDH, thereby reducing mitochondrial ROS production and suppressing cell death^[24,25]. Furthermore, cancer cells upregulate the PPP, an early diverging branch of glycolysis, thereby promoting NADPH production and exerting antioxidant defenses^[26]. Cancer cells not only switch from OXPHOS to lactate-dependent energy-generating pathways, but also upregulate antioxidant-related genes [e.g., NF-E2-related factor 2 (Nrf2)] to overcome a wide range of oxidative stress^[27]. Furthermore, NRF2 accelerates cellular redox homeostasis by upregulating the transcriptional regulation of multiple NADPH-generating enzyme genes (e.g., G6PD)^[26]. Cancer cells rely not only on glucose, but also on glutamine for their energy demands^[25]. Glutaminase is a critical enzyme that converts glutamine to glutamate in the mitochondria^[28]. Glutamate contributes to GSH synthesis and maintains redox homeostasis through reduced ROS generation^[29]. Apart from glycolysis in cancer cells, glutaminolysis (i.e., a series of biochemical reactions by which glutamine is lysed to glutamate) is another main pillar for energy production, including the conversion of glutamine to α -ketoglutarate (α KG), reaction steps of the citric acid cycle and malate aspartate shuttle, and the conversion of malate to pyruvate and lactate. Glutaminolysis increases OXPHOS and compensates for the energy deficiency in glycolytic cancer cells^[25].

In addition, altered metabolism or metabolic rewiring facilitates the adaptation of cancer cells to changing external environments, and this adaptation may render certain nutrients indispensable, a process known as nutrient addiction^[15]. Glutamine^[30] and cystine addiction have been found in renal cell carcinoma^[31], breast cancer^[32], and non-small cell lung cancer^[15,33]. HGSC and CCC are highly sensitive to cystine-deprived death, exhibiting a cystine addiction phenotype^[15,34,35]. In addition, heterogenous tumors are composed of multiple subpopulations associated with different proliferative and malignant potentials^[36]. For example, specific tumor types have different metabolic features; primary tumors build biomass such as glucose to sustain their high proliferative demands; metastatic tumors rely on pyruvate, glutamine, and lipid metabolism, and cancer stem cells depend on mitochondrial metabolisms such as OXPHOS and aerobic glycolysis^[12,37]. Such a nutrient addiction can be targeted for therapy because many cancer cells have limited energy and nutrient flexibility^[25,26,38].

THE ROLE OF FERROPTOSIS IN CANCER

Eukaryotic cells produce energy in the form of ATP and generate ROS as a byproduct. Such cells have evolved an array of antioxidant mechanisms, such as the thiol system, to combat oxidative stress, including nitric oxide, carbon monoxide, and hydrogen (per)sulfide^[27]. Cancer cells have also evolved the antioxidant defense system to protect themselves from excess ROS, but oxidative stress exceeding the antioxidant defense mechanism leads to cell death. Cell death is divided into two forms, namely, accidental cell death and regulated cell death^[39]. The latter is subdivided into apoptotic and non-apoptotic cell death. The non-apoptotic cell death includes autophagy, ferroptosis, pyroptosis, and necroptosis^[40]. Ferroptosis is characterized by the iron-dependent accumulation of excessive ROS and lipid peroxides, leading to cell death^[15,35,41-44]. Excess iron in ovarian cancer amplifies free oxidative radicals and drives the Fenton reaction, thereby inducing ferroptosis^[7,15]. However, HGSC is characterized by ferroptosis resistance because it can acquire sufficient antioxidant capacity. For example, Nrf2, a representative antioxidant gene, activates the transcription of ferritin heavy chain 1 (a protein involved in iron storage) and heme oxygenase-1 (a protein involved in heme breakdown) to reduce labile iron and regulate iron metabolism and oxidative stress^[15,45]. These antioxidants block ferroptosis by limiting cellular oxidative stress and lipid peroxidation.

In general, ferroptosis is regulated by membrane transporter expression, metabolic flexibility, and nutrient dependency. First, solute carrier family 7 member 11 (SLC7A11), commonly known as xCT, is a cystine/glutamate antiporter^[19]. The xCT pathway plays an important role in antioxidant defense by transporting extracellular cystine into cells and converting cystine to cysteine for GSH biosynthesis and ROS detoxification^[16,46-48]. GSH is synthesized from three constituent amino acids, namely, cysteine, glycine, and glutamic acid, with cysteine being a rate-limiting precursor. Glutathione peroxidase 4 (GPX4) utilizes GSH to convert lipid hydroperoxides into nontoxic lipid alcohols, thereby preventing ferroptosis^[19]. HGSCs are characterized by xCT overexpression along with the activation of GSH biosynthesis^[48]. Such a metabolic landscape suggests that HGSC depends on cystine uptake to counteract high levels of iron-dependent oxidative stress and maintain redox homeostasis, thereby preventing ferroptosis-induced cell death^[16]. Therefore, the inhibition of xCT-mediated cystine transport, cystine depletion, limited cysteine biosynthesis, impaired GSH synthesis, or inactivation of GPX4 can induce ferroptosis^[49]. During ferroptosis, the following breakdown products of lipid peroxides are formed, for example, malondialdehyde (MDA), 4-hydroxynonenal, 4-hydroxyhexenal, and 4-oxo-nonenal, and oxidized and modified proteins^[50]. High serum levels of MDA have been reported in patients with ovarian cancer compared with healthy women^[51], indicating the occurrence of ferroptosis. Such breakdown products may be evaluated as potential surrogate biomarkers for ferroptosis.

Second, ferroptosis is significantly influenced by metabolic flexibility and nutrient dependency. A large amount of NADPH generated via the PPP is consumed to synthesize cysteine and GSH^[26]. Thus, cancer cells must evolve mechanisms to cope with NADPH depletion. For example, cancer cells upregulate the expression level of the PPP^[26], NRF2^[52], and isocitrate dehydrogenase 1 (IDH1)^[48] as backup mechanisms for NADPH production. Nrf2 enhances the cellular antioxidant defense through NADPH regeneration^[53]. NADPH is also produced during the NADP⁺-dependent conversion of isocitrate to alpha-ketoglutarate (α KG) by IDH1^[48]. These backup mechanisms facilitate the survival and proliferation of cancer cells^[26,48,52]. Therefore, drugs that block the uptake of specific nutrients may provide potential therapeutic opportunities to kill cancer cells that rely on the same metabolic pathway^[54]. Therapeutic strategies targeting nutrient addiction or metabolic vulnerabilities may induce ferroptosis and inhibit tumor growth. Strategies targeting metabolic vulnerabilities will not only eliminate backup systems to prevent ferroptosis^[49], but also receive considerable attention in cancer therapeutics^[54].

CURRENT UNDERSTANDING OF METABOLIC PATHWAYS INVOLVED IN FERROPTOSIS

Glucose, glutamine, and fatty acids are major metabolic fuels to meet nutritional demands^[16]. Tumor cells receive energy supplies from unique metabolic pathways such as glycolysis, PPP, glutaminolysis, and OXPHOS; upregulate NADPH and GSH production; and downregulate ROS production to control ferroptosis^[14]. First, we summarized the mechanism by which glucose regulates ferroptosis in the context of energy stress^[18]. Under intact PPP and glycolysis with ample glucose and amino acid supply, NADPH can support the xCT-mediated cystine uptake^[14,48]. Free cystine accumulated in cancer cells forms a water-insoluble toxic crystal, often leading to cell damage (i.e., disulfide stress)^[48]. Cystine crystals induce ROS production through increased disulfide stress and promote oxidative stress reactions within cancer cells^[48]. NADPH can suppress intracellular cystine-dependent disulfide stress by converting cystine into cysteine for GSH synthesis^[14,48]. Thus, the PPP-generated NADPH rescues xCT-overexpressing cancer cells (xCT^{high} cancer cells) from ferroptosis, demonstrating that xCT^{high} cancer cells become highly dependent on the glucose-PPP pathway (i.e., NADPH addiction) to inhibit ferroptosis [Figure 1A].

On the contrary, peritumoral angiogenesis cannot keep up with rapidly proliferating lesions, resulting in regions of low blood supply. Such tumor cells must survive under glucose deprivation-induced metabolic stress conditions^[14,55]. Glucose starvation decreases carbon flux, which leads to the depletion of PPP and NADPH, inhibition of the conversion of cystine to cysteine, and marked accumulation of cystine, a disulfide molecule^[46,56]. xCT-mediated cystine uptake suppresses ferroptosis under conditions with sufficient glucose supply; however, its effect might be limited under glucose starvation, suggesting that glucose starvation may be associated with increased disulfide stress and ferroptosis^[48,56] [Figure 1B]. Sufficient glucose supply prevents ferroptosis in cancer cells, whereas glucose deprivation promotes cell death, indicating that cystine addiction determines the survival or death of cancer cells^[48]. In addition, limited glucose supply results in cell death in xCT^{high} cancer cell lines, including breast, cervical, kidney, and glioblastoma^[48,57]. Further experiments validated that the downregulation of xCT expression suppresses the promoting effect of cancer cell death under nutritional deficiency^[58]. However, persistent chronic glucose starvation in surviving ovarian cancer cells results in phenotypic changes through metabolic plasticity, leading to the acquisition of drug resistance and cancer relapse^[59].

Second, we summarized the mechanism by which energy stress positively and negatively regulates ferroptosis. Recent research has focused on a potential link between AMP-activated protein kinase (AMPK), a critical sensor of cellular energy status, and ferroptosis^[55]. Energy stress caused by glucose starvation activates AMPK^[55], and the activated AMPK circumvents metabolic stress by restoring energy balance^[60]. AMPK inactivates lipogenic genes, such as acetyl-CoA carboxylase (ACC), and it could inhibit ferroptosis^[55]

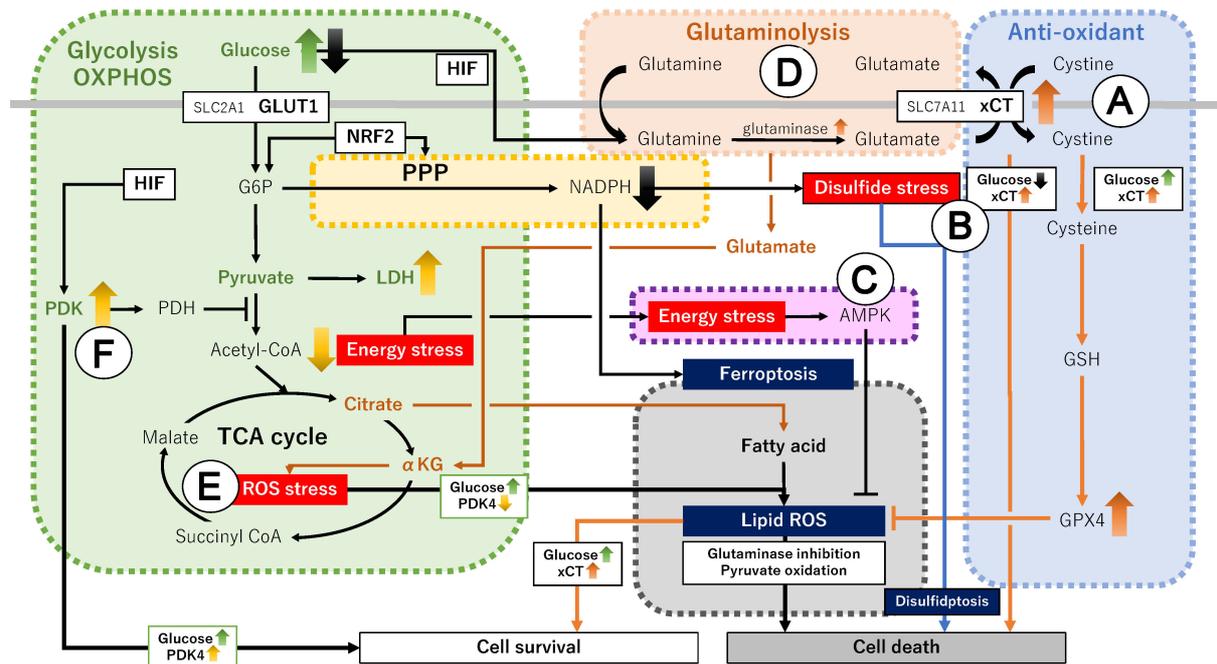

Figure 1. Metabolic pathways involved in ferroptotic cell death. Green, yellow, brown, purple, blue and gray boxes indicate glycolysis and OXPHOS, PPP, glutaminolysis, energy stress, antioxidant, and ferroptosis pathways, respectively. α KG: α -ketoglutarate; AMPK: AMP-activated protein kinase; G6P: glucose 6-phosphate; GLUT1/SLC2A1: glucose transporter 1; GPX4: glutathione peroxidase 4; GSH: glutathione; HIF: hypoxia-inducible factor; LDH: lactate dehydrogenase; NADPH: nicotinamide adenine dinucleotide phosphate; NRF2: NF-E2-related factor 2; OXPHOS: oxidative phosphorylation; PDH: pyruvate dehydrogenase; PDK: pyruvate dehydrogenase kinase; PPP: pentose phosphate pathway; ROS: reactive oxygen species; SLC7A11: solute carrier family 7 member 11; TCA: tricarboxylic acid; xCT: cystine/glutamate antiporter SLC7A11.

[Figure 1C]. However, conflicting data have also been reported, that is, AMPK promotes ferroptosis^[61]. AMPK triggers the formation of a beclin 1 (BECN1)-SLC7A11 complex via BECN1 phosphorylation^[61]. The binding of BECN1 to SLC7A11, a core component of xCT, inhibits the xCT function and promotes ferroptosis^[62], indicating that BECN1 is a key ferroptosis inducer^[63]. In xCT- and BECN1-overexpressing cancer cells, AMPK phosphorylates BECN1, induces binding to SLC7A11, and promotes ferroptosis by directly blocking xCT activity^[64]. Therefore, AMPK either inhibits ferroptosis in response to glucose starvation or promotes ferroptosis by blocking xCT activity. The expression level of ACC or BECN1 in AMPK-activated cancer cells may be critical in determining cell fate. AMPK has also been reported to promote tumor growth by alleviating energy stress or to suppress tumor growth by inhibiting key metabolic pathways such as glucose, glutamine, and fatty acid biosynthesis^[65]. These findings suggest that energy stress exerts inhibitory and promoting effects during ferroptosis, but the detailed mechanism remains unclear. Recent studies have reported that AMPK-activating drugs may affect metabolic plasticity^[66].

Third, we summarized the mechanism by which glutamine metabolism is involved in ferroptosis, particularly on xCT. Under glucose deprivation, tumor cells rely on an alternative energy-generating pathway such as glutaminolysis^[25,67] [Figure 1D]. In meeting the high-energy demand, tumor cells express high levels of glutamine transporters and glutamine synthase, often resulting in glutamine addiction^[13,25,29]. Glutamate is converted to α KG, an intermediate in the TCA cycle in glutaminolysis, which activates the TCA cycle, although much remains exported by xCT in exchange for extracellular cystine^[16]. Therefore, the loss of cellular glutamate could reduce α KG production and suppress TCA cycle activities, thereby leading to reduced lipid ROS levels and decreased ferroptosis sensitivity^[16]. This process may be a characteristic of

xCT^{high} cancer cells. Over time, xCT imports extracellular cystine in exchange for intracellular glutamate release. Glutaminolysis supplies cancer cells with adequate glutamate to maintain extracellular cystine uptake^[16,26,46]; however, the accumulated excess intracellular cystine induces disulfide stress, leading to the overproduction of ROS and gradually promoting ferroptosis^[16]. Furthermore, sustained cystine uptake leads to extracellular cystine depletion, suppressing glutamate export and promoting intracellular glutamate accumulation. Glutamate may be converted to α KG to maintain TCA cycle function and subsequently enhance the production of lipid ROS to induce ferroptosis^[16,68]. In particular, high-OXPHOS ovarian cancer cells were demonstrated to utilize glutamine, reconfirming the importance of glutamine^[69]. Therefore, ferroptosis sensitivity may depend on the glucose starvation status, the level of intracellular NADPH, α KG, or glutamine and extracellular cystine, and the expression level of xCT in each cancer cell^[16,26,46,58].

In addition, energy stress such as the depletion and overproduction of ATP in cancer cells determines cell fate. The mitochondria are the main sites for ATP generation through OXPHOS, producing ROS as a byproduct of cellular metabolism^[13,70]. In cysteine-depleted cancer cells, the TCA cycle activated by α KG induces cellular lipid ROS levels, thereby promoting cell death^[71] [Figure 1E]. The moderate suppression of the TCA cycle and OXPHOS reduces mitochondrial ROS production and inhibits cell death^[71]. However, extreme ATP depletion (i.e., energy deprivation) induces cell death. That is, energy stress can induce cell death by ATP depletion (i.e., energy deprivation) and ATP overproduction (e.g., excess ROS generation caused by increased α KG). In addition, homologous recombination-deficient cancer cells require ATP for poly(ADP-ribose) polymerase (PARP)-dependent DNA repair mechanisms used in ovarian cancer treatment, demonstrating that ATP causes sensitivity to PARP inhibitors^[72].

Fourth, we summarized the mechanism by which metabolic reprogramming of glycolysis and OXPHOS regulates ferroptosis. Hypoxia is the major cause of the rapid growth of cancer cells. Metabolic reprogramming is essential for the adaptation of cancer cells to a hypoxic microenvironment^[73]. HIF-1 α overexpressed under hypoxic conditions contributes to aggressive phenotypes in tumor cells^[13]. There are two types of energy production from glucose: glycolysis and mitochondrial OXPHOS^[74]. HIF-1 activates glycolysis-related genes, including pyruvate dehydrogenase kinase 1 (PDK1), increasing the conversion of glucose to pyruvate and subsequently to lactate by inactivating PDH, which is considered critical for metabolic adaptation to hypoxia^[74] [Figure 1F]. PDK4 has been reported to block a metabolic switch from glycolysis to predominantly fatty acid synthesis and contribute to ferroptosis resistance in certain cancer cells, such as pancreatic ductal adenocarcinoma (PDAC) cells^[18,19]. PDK1 can also mediate a metabolic shift from mitochondrial OXPHOS to glycolysis and increase the proliferation and angiogenesis in ovarian cancer xenografts^[75]. Therefore, the Warburg effect has a profound impact on ferroptosis pathways through PDK-dependent metabolic switches or metabolic adaptations in cancer.

Fifth, we focused on the role of the tumor suppressor p53 in the pathophysiological process of ferroptosis in ovarian cancer. p53 induces essential biological processes such as cell cycle arrest, senescence, DNA repair, apoptosis, autophagy, and the reprogramming of cellular metabolism^[38]. p53 has been reported to regulate various metabolic pathways and promote metabolic reprogramming to induce drug resistance and metastasis^[38]. In particular, p53 inhibits SLC7A11 expression and reduces glutathione synthesis, making cancer cells susceptible to oxidative damage and sensitive to iron by increasing lipid peroxide levels^[32,76,77]. In a previous study, Zhang *et al.* reported that p53 facilitates ferroptosis in ovarian cancer cells treated with iron oxides^[76].

Sixth, a tight interplay between ferroptosis and translation has attracted increasing attention in the field of cancer research. Translation initiation machinery, such as initiation factors and ribosomal proteins,

modulates gene regulation during nutrient deprivation and metabolic stress^[78]. The upregulation of mammalian target of rapamycin (mTOR), a master regulator of translation initiation, results in the increased expression of cancer-promoting genes such as eIF4E, a limiting factor for translation initiation in most cancers, including ovarian cancer^[79,80]. The activation of mTOR leads to the phosphorylation of eukaryotic translation initiation factor 4E-binding protein (4E-BP), increased recruitment of eukaryotic translation initiation factor 4E (eIF4E), and initiation of protein translation^[81]. eIF4E plays a key role in many physiological processes such as protein synthesis, cell growth, proliferation, angiogenesis, and carcinogenesis. eIF4E was found to inhibit aldehyde dehydrogenase (ALDH) activity and increase the ferroptosis sensitivity of ovarian cancer cells by accumulating lethal lipid peroxidation^[82,83]. The ALDH enzyme family detoxifies ROS-mediated lipid peroxidation-generated aldehydes such as MDA. In addition, the stimulation of GPX4 protein synthesis was enhanced through the mTOR/eIF4E axis^[84,85]. Therefore, the dysregulation of translational machinery alters susceptibility to ferroptosis in ovarian cancer cells. Collectively, the mTOR signaling pathway is involved in many crucial biological processes, including ferroptosis, as it is frequently activated in a wide range of tumors, including ovarian cancer.

Finally, cancer cells require not only glucose and glutamine metabolism in the tumor microenvironment, but also iron metabolism to maintain cell survival^[9]. Iron plays an important role in ferroptosis, and ovarian cancer is characterized by high intracellular iron content^[6]. Ovarian cancer cells upregulate transferrin receptor (the iron importer) and downregulate ferroportin (the iron efflux pump), indicating increased iron uptake^[7]. That is, cancer cells increase iron supply and decrease iron loss based on a unique phenotype of iron metabolism^[9]. Therefore, a literature search was performed to determine whether the metabolic pathway characteristic of cancer cells affects iron transport and iron metabolism associated with ferroptosis. Only one paper showed that glyceraldehyde-3-phosphate dehydrogenase, a key enzyme in glycolysis, is involved in iron metabolism as a transferrin-binding protein, independent of its canonical role in glycolysis^[86]. Iron plays an important physiological role, including oxygen transport and energy metabolism, but little is known about whether energy metabolism affects iron homeostasis in ovarian cancer.

THERAPEUTIC STRATEGY BASED ON FERROPTOSIS

Despite the advances in the treatment of ovarian cancer, many patients experience intrinsic and acquired resistance to anticancer drugs, which have poor outcomes. Several recent *in vitro* and animal studies have shown that ferroptosis inducers, chemotherapy, and immunotherapy can synergistically affect ovarian cancer^[35,41]. In this study, two potential treatment options targeting ferroptosis were investigated: The first treatment option directly induces ferroptosis and its downstream pathways, and the other targets metabolic vulnerabilities associated with ferroptosis, such as glycolysis, glutaminolysis, and energy stress dependence. The key molecules associated with the former include xCT, GSH, GPX4, intracellular labile iron, and ferroptosis-inhibitory pathways. Cancer has evolved several regulatory mechanisms of ferroptosis, which neutralize ROS and prevent lipid peroxidation, including the xCT-GSH-GPX4 axis^[15,42,44], ferroptosis-suppressor-protein 1 (FSP1)-coenzyme Q10 (CoQ10)-NADPH axis^[87], and Hippo pathway^[88]. Several studies have also reported on xCT molecular-targeted therapy for *in vivo* application. Considering that highly sensitive xCT inhibitors and cystine deprivation can induce ferroptosis, several ferroptosis-inducing agents have been developed^[15,35,42]. Some recent reviews have provided evidence for the association between ferroptosis inhibition and ovarian cancer progression, discussing the potential therapeutic application of ferroptosis-inducing agents^[15,35,42-44]. On the contrary, the latter is a therapeutic strategy that induces ferroptosis by targeting rewired energy metabolism and its potential metabolic compensation^[31,41]. The suppression of specific metabolism may represent an attractive therapeutic strategy for the treatment of ovarian cancer^[41]. Therapeutic strategies targeting the ferroptosis pathway and metabolic vulnerabilities associated with ferroptosis have been reported in breast cancer and other types of cancer^[13,25]. In this review,

therapeutic strategies were divided into “a therapeutic strategy focusing on the ferroptosis pathway” and “a therapeutic strategy focusing on metabolic vulnerability and nutrient addiction.” However, mechanisms such as “disulfide stress” do not apply to either strategy.

Therapeutic strategy focusing on the ferroptosis pathway

SLC7A11, a molecule that protects cancer cells from ferroptosis-induced cell death, is overexpressed in different types of cancers, including ovarian cancer, lung cancer, triple-negative breast cancer, PDAC, renal cell carcinoma, liver cancer, and glioma, and it is associated with aggressive phenotypes and poor prognosis^[16,46,89]. Ferroptosis resistance involves the sustained overexpression of xCT and activation of its downstream signaling. The upregulation of xCT induces oxidative stress resistance and protects against lipid peroxidation^[90]. xCT inhibitors have drawn increasing attention because of their antitumor effect on ovarian cancer using preclinical animal models^[91]. Class 1 ferroptosis inducers, including erastin, imidazole ketone erastin, sulfasalazine, sorafenib, and HG106, directly inhibit xCT activity^[92,93] and induce ferroptosis by preventing cystine uptake and depleting cysteine or GSH, thereby inducing lipid peroxidation and cell death^[15,49]. Several studies have highlighted the importance of elastin in single or combination therapeutic strategies for ovarian cancer. For example, C-Myc amplified in ovarian cancer cells inhibits ferroptosis by inducing NCOA4-mediated ferritinophagy^[94], but erastin selectively kills iron-addicted ovarian cancer cells by inducing ferroptosis and promoting NCOA4-mediated ferritinophagy and mitochondrial dysfunction^[95]. However, ovarian cancer cells with low intracellular iron pools are resistant to erastin treatment^[95], indicating that iron levels can determine cell sensitivity to ferroptosis. Ovarian cancer cells that are less susceptible to ferroptosis may be platinum-resistant^[96] and may be clinically recommended for co-treatment with ferroptosis-inducing agents. Erastin synergizes with cisplatin to inhibit ovarian cancer growth through ferroptosis^[97]. Erastin sensitizes ovarian cancer cells to wee1 inhibitor AZD1775 and synergistically inhibits their growth^[98]. Wee1 is a G2 checkpoint kinase. PARP inhibitors were reported to promote SLC7A11-mediated ferroptosis^[99]. However, erastin can facilitate ovarian cancer cell invasion in vivo by inducing IL-8 production and then M2 macrophage polarization^[100]. Despite the antitumor effect of erastin, evidence has also shown that iron concentration and macrophage polarization in the tumor microenvironment promote the resistance of ovarian cancer cells to erastin-induced ferroptosis. Although xCT inhibition as a regulator of ferroptosis is a potential strategy for cancer therapy, the potential targets of ferroptosis in the treatment of ovarian cancer in vivo and their mechanisms remain poorly understood. Furthermore, Ras-selective lethal 3 (RSL3) and the 5,6-dihydro-2H-pyrano[3,2-g]indolizine (DPI) class of luminogen (DPI, also known as ML162) are known as class 2 ferroptosis inducers that directly inhibit GPX4 enzymatic activity^[91,93]. RSL3 induces ferroptosis by inhibiting the GPX4 activity in drug-resistant ovarian cancer cells^[101]. Apart from class 1 and class 2 ferroptosis inducers, targeting molecules associated with ferroptosis in ovarian cancer is an emerging field of therapeutics.

In addition, ferroptosis is characterized not only by the loss of GPX4 activity and subsequent accumulation of labile iron and excessive ROS production, but also by the peroxidation of polyunsaturated fatty acids (PUFAs)^[102,103]. The inhibition of GPX4 causes the aberrant accumulation of PUFA hydroperoxides. In general, acyl-CoA synthetase long-chain family member 4 (ACSL4), lysophosphatidylcholine acyltransferase 3 (LPCAT3), and lipoxygenases (e.g., 15-LO) promote the peroxidation of phospholipids containing PUFA during ferroptosis^[104]. Zhao *et al.* summarized several inhibitors targeting different enzymes in the lipid metabolism network (e.g., ACC, fatty acid synthase, sterol regulatory element-binding protein 1, and stearoyl-CoA desaturase) and discussed targeting lipid metabolism in ovarian cancer^[104]. Therefore, the role of lipid peroxidation in ferroptosis in several human cancers, including ovarian cancer, has been emphasized^[44,104]. Targeting lipid metabolism may be an important and potential strategy in cancer therapy; thus, combining drugs that modulate ferroptosis with conventional cancer therapies has received significant interest^[104]. Table 1 shows the agents that affect the ferroptosis pathway by modulating the accumulation of iron, ROS, and lipid peroxides.

Table 1. Agents that affect the ferroptosis pathway by modulating the accumulation of iron, ROS, and lipid peroxides

Agents			
The biological function or action of the agents	Official symbol/Official full name	Function	Ref.
The accumulation of iron			
NRF2 inhibition	NRF2/Nuclear factor erythroid 2-related factor 2	NRF2 decreases the labile iron pool and increases ferroptosis resistance through controlling HERC2 [HECT and RLD domain containing E3 ubiquitin protein ligase 2; E3 ubiquitin ligase for NCOA4 and FBXL5 (F-box and leucine-rich repeat protein 5)] and VAMP8 (vesicle-associated membrane protein 8; mediating autophagosome-lysosome fusion).	[105]
HMOX1 inhibition	HMOX1/Heme oxygenase 1	HMOX1 is the enzyme responsible for degradation of heme and generates antioxidant and anti-inflammatory byproducts. Upregulation of HMOX1 inhibits ferroptosis and promotes ovarian cancer cell growth.	[106]
Ferritinophagy/Autophagic degradation of ferritin		Ferroptosis vulnerability is induced through autophagic degradation of ferritin (i.e., ferritinophagy) of ferritin heavy chain 1 (FTH1) in cisplatin-resistant ovarian cancer.	[107]
Iron nitroprusside		Iron nitroprusside is thought to be an effective treatment for ovarian cancer because it induces lipid peroxidation via the Fenton reaction and subsequently promotes ferroptosis.	[45]
The accumulation of ROS			
SLC7A11 degradation	HRD1/E3 ubiquitin ligase 3-hydroxy-3-methylglutaryl reductase degradation	Promoting ubiquitination-dependent SLC7A11 degradation	[108]
FZD7 inhibition	FZD7/Wnt receptor Frizzled 7	FZD7 reduces ferroptosis sensitivity through the β -catenin-Tp63-GPX4 pathway in platinum-resistant ovarian cancer cells.	[109]
FSP1 inhibition	FSP1/Ferroptosis suppressor 1	FSP1 is a GSH-independent suppressor of ferroptosis that acts as an NADH-dependent CoQ10 oxidoreductase, contributing to ferroptosis resistance via reducing CoQ10.	[15]
The Hippo effectors	YAP/Yes-associated protein 1; TAZ/Transcriptional coactivator with PDZ-binding motif	The Hippo effectors YAP and TAZ induce ferroptosis in ovarian cancer cells through overexpressing Angiopoietin-Like 4 (ANGPTL4) and NADPH Oxidase 2 (NOX2). The Hippo proteins control cell fate.	[110]
NRF2 modulator	NCTD/Norcantharidin	NCTD, a normethyl compound of cantharidin, facilitates ferroptosis by inhibiting the NRF2/HO-1/GPX4/xCT axis.	[111]
The accumulation of lipid peroxides			
SCD1 inhibition	SCD1/Stearyl-CoA desaturase 1	SCD1 catalyzes the formation of monounsaturated fatty acids (MUFAs), specifically oleate and palmitoleate. Inhibition of SCD1 causes iron-mediated lipid peroxidation and mitochondrial dysfunction by downregulating GPX4 and then induces ovarian cancer cell death. SCD1 inhibitor co-treatment may enhance the antitumor efficacy of ferroptosis inducers in ovarian cancer.	[112-114]
ACSL1 inhibition	ACSL1/Acyl-CoA synthetase long-chain family member 1	ACSL1 reduces the level of lipid peroxidation and enhances ferroptosis resistance in ovarian cancer through increasing the stability of FSP1.	[115]
Others			
Ferroptosis-related gene	PRNP/Prion protein	Overexpression of ferroptosis-related gene prion protein (PRNP) inhibits ovarian cancer proliferation and invasion.	[116]
Ropivacaine		A local anesthetic ropivacaine induces ferroptosis in ovarian cancer cells by inactivating the PI3K/Akt pathway.	[117]

GPX4: Glutathione peroxidase 4; SLC7A11: solute carrier family 7 member 11.

Therapeutic strategy focusing on metabolic vulnerabilities and nutrient addiction

In response to dynamically changing nutrient availability in the tumor microenvironment, cancer cells facilitate cellular adaptations to reprogram metabolic pathways. Therefore, metabolic vulnerabilities are attacked using the synthetic lethality approach in ovarian cancer cells overexpressing xCT, rather than directly inhibiting xCT or GPX4. Cancer cell-specific metabolic pathways or nutrient addiction, such as

glycolysis, glutaminolysis, or other energy stress dependence, can also be utilized as therapeutic targets. However, it is difficult to assess in real time which metabolic pathways cancer cells are currently most dependent on. Despite recent progress in the development of xCT inhibitors, effective treatment interventions focusing on metabolic vulnerabilities remain unmet.

First, xCT inhibitors such as erastin have emerged as an effective treatment option to facilitate ferroptosis in a high-glucose tumor environment^[19]. Ferroptosis has been reported to be dependent on glucose uptake by GLUT 1 (also known as SLC2A1)^[18]. The maintenance of glycolysis in xCT^{high} cancer cells is essential for constituting a potential treatment strategy to induce ferroptosis [Figure 2A]. By contrast, glucose deprivation induced by GLUT inhibitors selectively blocks xCT inhibitor-induced ferroptosis, thereby suppressing cancer cell death^[18]. That is, xCT inhibitors may exhibit anticancer properties against cancer cells with elevated GLUT1 expression in a high-glucose tumor environment, whereas glucose deprivation blocks ferroptosis-induced cell death^[18,19] [Figure 2B]. xCT inhibitors show contrasting effects in the presence or absence of glucose in the tumor microenvironment.

Second, the PPP-generated NADPH plays a central role in the cellular metabolic network and redox homeostasis^[14]. NADPH can support the biosynthesis of GSH, thioredoxin, and CoQ10 to boost the antioxidant defense in cancer cells and protect cancer cells from ferroptosis and cell death^[14] [Figure 3A]. Therefore, targeting the PPP in tumor cells may provide a therapeutic strategy based on ferroptosis. Glucose deprivation reduces the PPP-mediated NADPH generation, making it impossible to reduce insoluble cystine imported via xCT to a more soluble cysteine, thereby inducing disulfide stress (i.e., cystine-dependent toxicity) and leading to rapid cell death^[48] [Figure 3B]. This finding suggests that xCT-overexpressing cancer cells are sensitive to glucose starvation-induced cell death. Furthermore, cysteine depletion in CCC abolishes glycolysis and OXPHOS and inhibits cancer cell proliferation^[118], indicating that cysteine depletion caused by the decreased conversion of cystine to cysteine plays a critical role in cancer therapy. Therefore, not only the GLUT inhibitor but also the glucose-6-phosphate dehydrogenase inhibitor or 6-amino-nicotinamide, a nicotinamide analog, may be used as an inhibitor of the PPP. Collectively, these studies suggest that xCT is beneficial for cancer cells by suppressing ferroptosis, while glucose deprivation and NADPH depletion caused by a reduction in carbon from glucose entering the PPP can promote cancer cell death^[26,48].

Third, PDK4 inhibits the TCA cycle and reduces the production of PUFAs to enhance ferroptosis resistance^[18] [Figure 4A]. Dichloroacetate, a PDK inhibitor, induces the metabolic switch from glycolysis to OXPHOS to generate ROS accumulation, thereby facilitating ferroptosis^[119] [Figure 4B]. Erastin can mediate ferroptosis through mitochondrial voltage-gated anion channels (VDAC) and xCT, which impairs VDAC function, thereby resulting in mitochondrial dysfunction, ROS production, and cell death^[120]. Thus, xCT inhibitors enhance mitochondrial respiration and increase ROS production to promote ferroptosis, which may be a potential therapeutic strategy in cancer cells exhibiting metabolic reprogramming from glycolysis to OXPHOS. Furthermore, co-treatment with PDK inhibitors and erastin may synergistically enhance ferroptosis in cancer cells overexpressing GLUTs and xCT^[18].

Fourth, glutaminase mediates the conversion of glutamine to glutamate, leading to the entry of glutamine into the TCA cycle. Cancer cells upregulate and consume glutamine to produce metabolic fuel for cancer cell proliferation and redox status regulation [Figure 5A]. Cancer cells may be more sensitive to glutaminase inhibition under high glutamine import compared with that under low glutamine import^[25]. xCT-overexpressing cancer cells are sensitive to glutaminase inhibition because the inhibition of glutamine metabolism decreases GSH production and increases ROS production^[13,121] [Figure 5B]. xCT not only

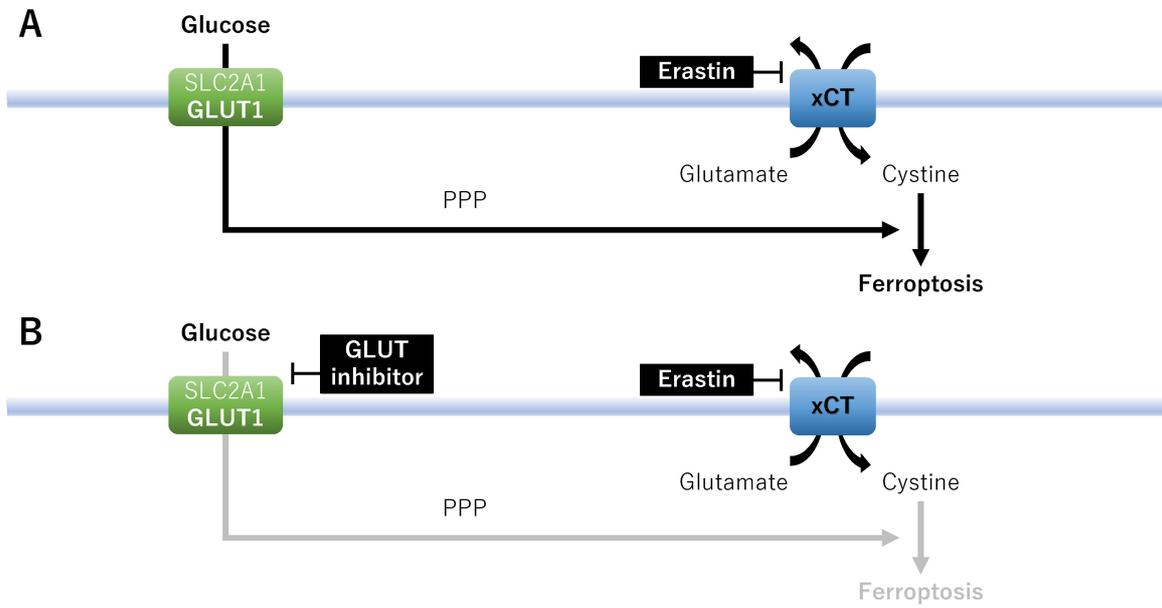

Figure 2. A therapeutic strategy focused on metabolic vulnerabilities and nutrient addiction: glucose metabolism. Effects of erastin on ferroptosis in the absence (A) or presence (B) of GLUT inhibitors. GLUT1/SLC2A1: Glucose transporter 1; PPP: pentose phosphate pathway; xCT: cystine/glutamate antiporter SLC7A11.

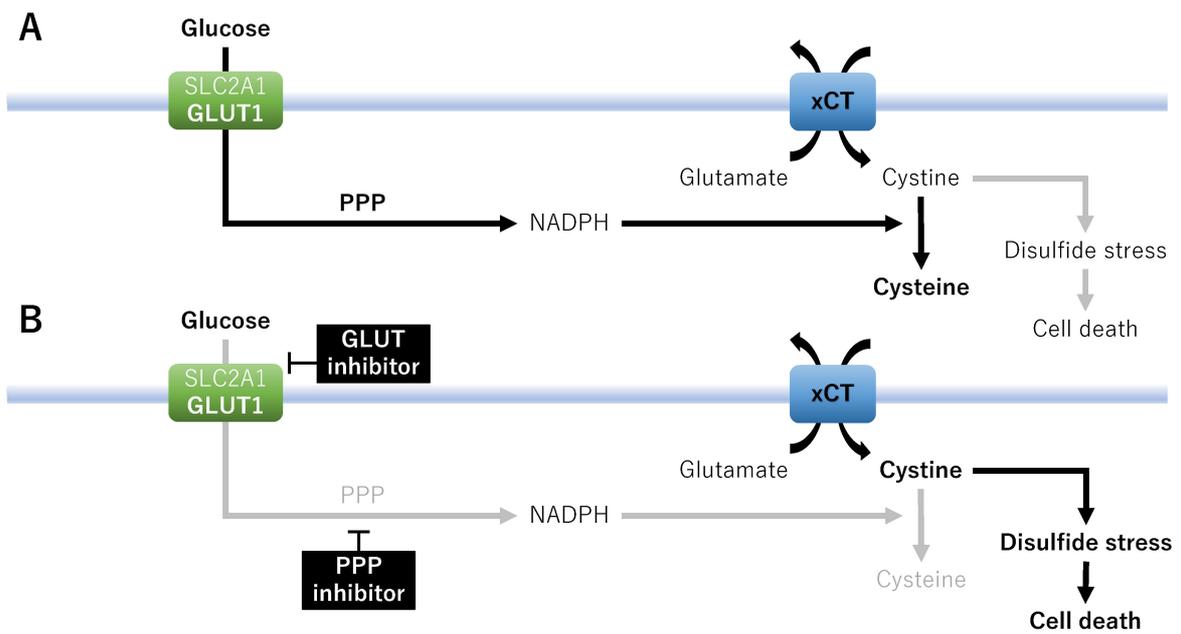

Figure 3. A therapeutic strategy focused on metabolic vulnerabilities and nutrient addiction: the PPP metabolism. Figure 4. A therapeutic strategy focused on metabolic vulnerabilities and nutrient addiction: PDK-dependent metabolism. Effects of xCT on ferroptosis in the absence (A) or presence (B) of erastin or PDK inhibitor. DCA: Dichloroacetate; GLUT1/SLC2A1: glucose transporter 1; PDK: pyruvate dehydrogenase kinase; PDH: pyruvate dehydrogenase; ROS: reactive oxygen species; TCA: tricarboxylic acid; VDAC: voltage-gated anion channels; xCT: cystine/glutamate antiporter SLC7A11.

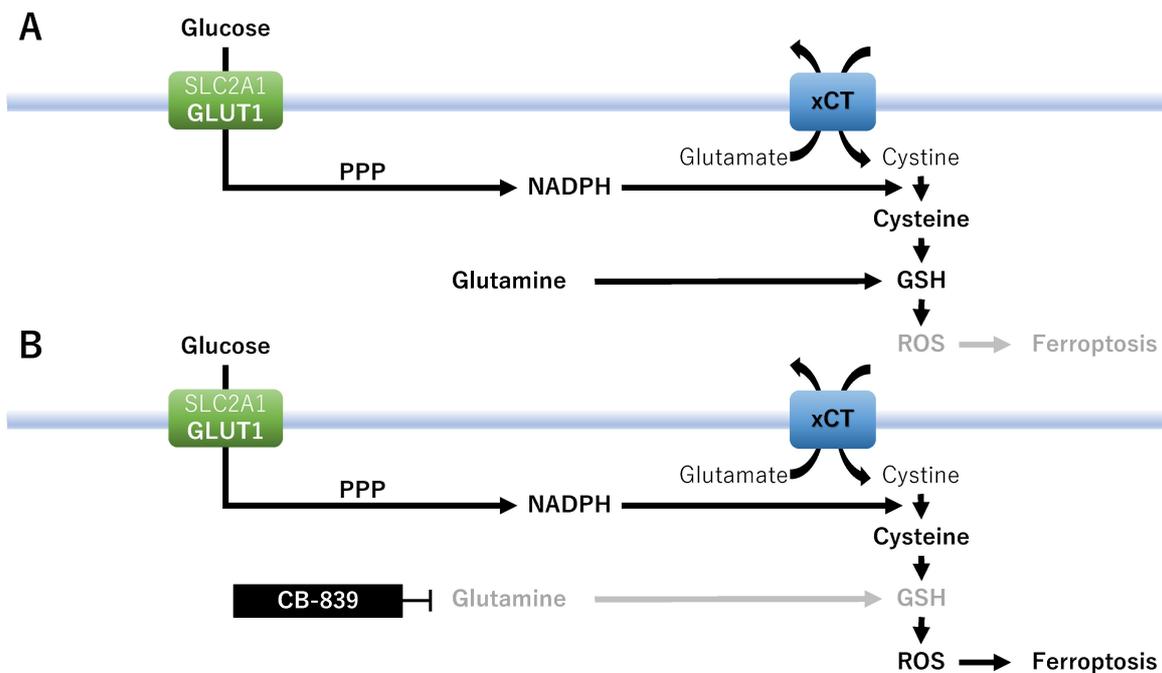

Figure 5. A therapeutic strategy focused on metabolic vulnerabilities and nutrient addiction: glutamine metabolism. Effects of xCT on ferroptosis in the absence (A) or presence (B) of glutaminase inhibitor. GLUT1/SLC2A1: Glucose transporter 1; GSH: glutathione; NADPH: nicotinamide adenine dinucleotide phosphate; PPP: pentose phosphate pathway; ROS: reactive oxygen species; xCT: cystine/glutamate antiporter SLC7A11.

catalyzes glutamate release, but also regulates glutamine uptake^[16]. xCT-overexpressing cancer cells lead to glutamine dependency, which presents potential metabolic vulnerabilities as therapeutic targets. A recent review has discussed new breast cancer treatment strategies based on glutaminase modification, leading to cellular ferroptosis^[25]. CB-839 (telaglenastat), a glutaminase inhibitor, blocks tumor glutamine consumption^[122]. A phase 1 clinical study will assess the safety, tolerability, and preliminary evidence of the antitumor activity of CB-839 in combination with the mTOR inhibitor sapanisertib (MLN0128)^[122].

Finally, some drugs or natural compounds have been reported to have antitumor properties by targeting metabolic vulnerabilities such as alterations in glycolysis, OXPHOS, and glutamine metabolism^[13]. For example, Yung *et al.* reported that dual-targeted therapy utilizing AMPK-activating drugs and vascular endothelial growth factor/programmed cell death 1 blockade may be a new treatment option for ovarian cancer focusing on metabolic vulnerability^[66]. A natural-occurring enzyme, glucose oxidase, converts glucose into non-metabolizable gluconic acid and H₂O₂, amplifying the ferroptotic damage. A bioactive protein, MAP30, isolated from bitter melon seeds, triggered apoptosis and ferroptosis in various ovarian cancer cells^[123]. Furthermore, research on compounds derived from natural products may lead to the development of new treatment options that promote ferroptosis.

DISCUSSION

In this review, the regulatory mechanism of ferroptosis through multiple metabolic pathways was summarized, and therapeutic strategies targeting ferroptosis in ovarian cancer were discussed. In particular, ovarian cancer is strongly influenced by an iron- and ROS-dependent mode of cell death, namely, ferroptosis, from the early stages of carcinogenesis. Changes in iron metabolism, lipid peroxidation responses, and a wide range of energy metabolism play important roles in regulating ferroptosis sensitivity of ovarian cancer cells^[124]. Two therapeutic strategies targeting xCT were highlighted in this review, that is, directly inhibiting xCT activity and targeting glucose/glutamine dependency as a therapeutic vulnerability in xCT-overexpressing cancer cells. New perspectives for improving cancer therapy based on ferroptosis were also discussed. xCT inhibitors (e.g., erastin) can induce cell death when carbon from glucose, glutamine, or fatty acids is abundant^[16]. Conversely, nutrient starvation, such as glucose and glutamine, causes cancer cell death because of dysfunction of the xCT-associated antioxidant system. For example, glucose deprivation induces rapid NADPH depletion, promoting ferroptosis-mediated oxidative stress and cell death^[16]. Glucose-depleted cancer cells may display glutamine addiction, resulting in the survival of such cells. Elevated glutamine metabolism makes cancer cells more susceptible to glutamine deficiency caused by glutaminase inhibitors, which rapidly induces cell death^[122]. Drugs that block intrinsic and acquired nutrient addiction may promote the susceptibility of cancer cells to ferroptosis^[16,57]. Therefore, therapeutic approaches that use nutrient addiction to target metabolic vulnerabilities may be effective in overcoming ferroptosis resistance.

Moreover, preclinical studies revealed that ferroptosis inducers contribute to the enhanced efficacy of immunotherapy^[125] and chemotherapy^[126]. For example, PARP inhibitors sensitize ovarian cancer cells to ferroptosis by synergistically activating ATM/ATR and causing DNA damage^[126]. The enhancement of cancer efficacy by eliminating drug resistance may be achieved through synergistic combinations of ferroptosis and existing therapeutic approaches^[15]. Thus, cancer therapy that induces ferroptosis could be an innovative therapeutic strategy in ovarian cancer^[35,41]. However, xCT has been demonstrated to play contradictory roles in ferroptosis regulation in a tumor-promoting or suppressive manner, depending on changes in energy and nutrient metabolic pathways^[48,57]. xCT functions as a double-edged sword to modulate various types of cancer survival and death by regulating the redox balance, nutrient dependency, energy stress, and ferroptosis process^[16]. Furthermore, the role of metabolic flexibility and vulnerability in

regulating xCT-mediated ferroptosis was summarized, and the current understanding of ferroptosis-induced therapy in ovarian cancer was discussed. Ferroptosis inducers should be used on the basis of the metabolic characteristics of cancer cells.

CONCLUSION AND FUTURE PERSPECTIVES

Cells have evolved mechanisms to maintain redox homeostasis through metabolic reprogramming whenever they encounter a large burden of oxidative stress resulting from changes in the microenvironment^[127]. Cancer cells are forced to alter their energy and nutrient metabolic pathways to adapt to ever-changing environmental changes^[127]. Cancer cells acquire autonomous capabilities for tumor promotion by upregulating xCT activity, inducing antioxidant defenses, and suppressing ferroptosis^[16,46]. The key molecules in signaling pathways associated with glycolysis (e.g., PDK4), OXPHOS (e.g., IDH1 and α KG), glutaminolysis (e.g., glutaminase), PPP (e.g., G6PD and NADPH), and P53 pathway are critically involved in regulating ferroptosis in ovarian cancer^[12]. xCT-overexpressing cancer cells depend on glucose, glutamine, and fatty acids for an energy source to acquire proliferative and survival advantages^[16,17,19,68]. All main metabolic pathways, including glycolysis, TCA cycle, glutaminolysis, OXPHOS, and PPP, are individually altered in ovarian cancer cells^[13].

Several reliable molecular biomarkers can predict cell death associated with ferroptosis. However, the biopsy of tumor tissue has its own limitations. Liquid biopsy provides a minimally invasive diagnostic modality to assess the molecular characterization of the tumor and to allow a personalized approach to patients with effective treatment in real time^[128]. Liquid biopsy of the blood and peritoneal fluid in patients with recurrent ovarian cancer may be used as a drug screening platform to select potential drugs. The gene expression profile can be verified by reverse transcription-polymerase chain reaction assay using customized pre-selected genes. This panel should include candidate genes potentially associated with ferroptosis, for example, SLC7A11, GLUT1, PDK, PDH, glutaminase, GPX, BECN1, ACC, and AMPK. xCT inhibitors can also have therapeutic benefits for ovarian cancer cells growing in a high-glucose tumor environment (e.g., ovarian cancer cells overexpressing SLC7A11, GLUT1, PDK, glutaminase, and GPX). By contrast, drugs that target metabolic pathways (e.g., GLUT1 inhibitors, PPP inhibitors, PDK inhibitors, and glutaminase inhibitors) may provide promising efficacy in ovarian cancer cells harboring nutrient addiction. Therefore, drugs can be selected on the basis of the expression pattern of ferroptosis-inducing genes (e.g., SLC7A11, GSH, and GPX) or genes associated with metabolic pathways that affect ferroptosis (e.g., GLUT, PDK4, glutaminase, VDAC, and G6PD). Such gene expression patterns may serve as biomarkers for selecting patients with cancer for personalized treatment. Further studies based on the regulation of xCT expression, ROS stress and redox homeostasis, and energy stress caused by specific nutrient addiction or deficiency will increase the clinical importance of ferroptosis modulation as an effective therapeutic strategy for ovarian cancer.

DECLARATIONS

Acknowledgments

Figures were created by Toyomi Kobayashi (Ms.Clinic MayOne, Nara, Japan; <https://www.mscl-mayone.com/>).

Authors' contributions

Conceptualization and methodology preparation, project administration, writing original draft: Kobayashi H
Software preparation: Kobayashi H, Matsubara S, Yoshimoto C, Imanaka S

Validation: Yoshimoto C, Shigetomi H, Imanaka S

Formal analysis and investigation: Matsubara S, Yoshimoto C, Shigetomi H, Imanaka S

Resources provided and supervision: Matsubara S

Data curation: Matsubara S, Kobayashi H

Writing, review, editing and visualization: Kobayashi H, Matsubara S, Yoshimoto C, Shigetomi H, Imanaka S

Funding acquisition: Yoshimoto C

Availability of data and materials

Not applicable.

Financial support and sponsorship

This work was supported by Japan Society for the Promotion of Science, Japan (Grant Number: 23K08806).

Conflicts of interest

All authors declared that there are no conflicts of interest.

Ethical approval and consent to participate

Not applicable.

Consent for publication

Not applicable.

Abstract

Malignant hematopoietic cells gain metabolic plasticity, reorganize anabolic mechanisms to improve anabolic output and prevent oxidative damage, and bypass cell cycle checkpoints, eventually outcompeting normal hematopoietic cells. Current therapeutic strategies of acute myeloid leukemia (AML) are based on prognostic stratification that includes mutation profile as the closest surrogate to disease biology. Clinical efficacy of targeted therapies, e.g., agents targeting mutant FMS-like tyrosine kinase 3 (FLT3) and isocitrate dehydrogenase 1 or 2, are mostly limited to the presence of relevant mutations. Recent studies have not only demonstrated that specific mutations in AML create metabolic vulnerabilities but also highlighted the efficacy of targeting metabolic vulnerabilities in combination with inhibitors of these mutations. Therefore, delineating the functional relationships between genetic stratification, metabolic dependencies, and response to specific inhibitors of these vulnerabilities is crucial for identifying more effective therapeutic regimens, understanding resistance mechanisms, and identifying early response markers, ultimately improving the likelihood of cure. In addition, metabolic changes occurring in the tumor microenvironment have also been reported as therapeutic targets. The metabolic profiles of leukemia stem cells (LSCs) differ, and relapsed/refractory LSCs switch to alternative metabolic pathways, fueling oxidative phosphorylation (OXPHOS), rendering them therapeutically resistant. In this review, we discuss the role of cancer metabolic pathways that contribute to the metabolic plasticity of AML and confer resistance to standard therapy; we also highlight the latest promising developments in the field in translating these important findings to the clinic and discuss the tumor microenvironment that supports metabolic plasticity and interplay with AML cells.

INTRODUCTION

Acute myeloid leukemia (AML) is a cancer derived from the myeloid lineage of blood cells. It is characterized by overproduction of leukemic blasts and maturation arrest. With approximately 120,000 cases a year globally, AML is the most common type of acute leukemia in adults^[1]. Although conventional chemotherapy is known to eliminate bulk tumor cells, its utility is limited in AML, as older patients lack tolerance to chemotherapy and the drug may lack efficacy at eliminating leukemia stem cells (LSCs). Residual clones that survive chemotherapy lead to disease relapse^[2]. Moreover, AML exhibits extensive genetic heterogeneity, as it often harbors a complex mixture of heterogeneous subclones that possess genetic aberrations in diverse driver genes, with distinct clonal evolutionary patterns existing in single individuals. Cytogenetic abnormalities and acquired somatic mutations are used as surrogate markers for risk assessment and some mutations can be specifically targeted. However, the utility of therapies that target mutations viz. FMS-like tyrosine kinase 3 (FLT3) and isocitrate dehydrogenase enzyme 2 (IDH2) are limited to the context of the particular mutation.

Cancer cells are known to reprogram their metabolism to support their survival and proliferation; this was recently recognized as a hallmark of cancer^[3]. AML cells exhibit unique metabolic dependencies compared with those of their normal counterparts, the noncancerous blasts. Hematopoietic stem cells (HSCs) use mitochondrial oxidative phosphorylation (OXPHOS) during differentiation to meet their higher energy requirements; however, they use anaerobic glycolysis for their routine energy needs and generally avoid aerobic mitochondrial OXPHOS^[4]. Of note, mitochondrial OXPHOS generates reactive oxygen species (ROS), which are deleterious for HSCs. In fact, ROS functions as a signaling mediator in the crosstalk between metabolism and stem cell fate decisions by inhibiting the repopulating capacity of HSCs^[5]. ROS-high-HSCs are characterized by low self-renewal capacity and high myeloid differentiation capacity compared to ROS-low HSCs.

Upon cell division, HSCs have fate choices when they undergo cell division; they either undergo self-renewal, wherein they produce new HSCs, or differentiate, wherein they produce cells that mature into committed cells. On the basis of the status of the daughter cells, HSC division can occur in one of the following ways: (1) asymmetric division, which maintains the HSC pool, in which one daughter cell remains as stem cell while the other differentiates; (2) symmetric commitment, in which both daughter cells differentiate (stem cell exhaustion); or (3) symmetric division, in which two daughter stem cells are produced, which helps in HSC expansion. Interestingly, mitochondria distribution during stem cell division appears to be crucial to determining the fate of HSCs. Of note, mitochondrial division is asymmetrical during stem cell division and daughter cells that receive fewer old mitochondria maintain stem cell traits^[6]. Notably, through a ROS-mediated physiological process, changes in mitochondrial dynamics regulate stem cell fate decisions, triggering a dual program to suppress self-renewal and promote differentiation^[6,7]. Evasion from mitochondrial OXPHOS and reliance on glycolysis help prevent HSC pool exhaustion. In contrast, LSCs rely on mitochondrial OXPHOS to generate high-energy compounds while maintaining ROS levels at non-toxic levels by employing a wide repertoire mechanism for ROS mitigation^[8]. Therefore, it may be possible to target leukemic cells differently based on their metabolic needs for therapeutic purposes.

In this review, we discuss the role of cancer metabolic pathways in AML development that contribute to the metabolic plasticity of the disease and confer resistance to standard therapy. We also highlight the latest developments in the field including clinical trials for translating metabolic inhibitors to clinic [Figure 1] and discuss the role of tumor microenvironment and extracellular vesicles in supporting metabolic plasticity and their interplay with AML cells.

Drug		Clinical trial			Condition/Disease	Trial status	
Name	Description	Identifier	Phase	Purpose		Recruitment	Results
Targeting oxidative phosphorylation (OXPHOS)							
IACS-010759	ETC complex I inhibitor	NCT02882321	<input type="checkbox"/>	DEE	Recurrent AML	<input checked="" type="checkbox"/>	<input type="checkbox"/>
ONC201	ClpP	NCT02392572	<input type="checkbox"/>	Safety, best dose and efficacy	Relapsed or Refractory Acute Leukemias and MDS	<input type="checkbox"/>	<input type="checkbox"/>
CPI-613	lipote analog taregts TCA	NCT05854966	<input type="checkbox"/>	Response rate of CPI-613 and metformin	Relapsed/Refractory AML	<input type="checkbox"/>	<input type="checkbox"/>
Metformin	biguanide	NCT01849276	<input type="checkbox"/>	MTD for Metformin + Cytarabine	Relapsed/Refractory AML	<input checked="" type="checkbox"/>	<input checked="" type="checkbox"/>
Targeting amino acid metabolism							
CB-839 ^a	Glutaminase Inhibitor	NCT02071927	<input type="checkbox"/>	Safety, PK, PD, biomarkers, and efficacy	Newly diagnosed or relapsed AML	<input checked="" type="checkbox"/>	<input type="checkbox"/>
Erwinase	Asparaginase	NCT02283190	<input type="checkbox"/>	Safety and reduction of serum glutamine	AML	<input checked="" type="checkbox"/>	<input type="checkbox"/>
GRASPA ^b	L-asparaginase	NCT01810705	<input type="checkbox"/>	Efficacy and tolerability	AML unfit for intensive chemotherapy	<input checked="" type="checkbox"/>	<input type="checkbox"/>
PEG-BCT-100 ^c	Arginase (PEGylated)	NCT02899286	<input type="checkbox"/>	Reduction of serum glutamine	Relapsed or refractory AML	<input type="checkbox"/>	<input type="checkbox"/>
ADI-PEG 20	Arginase (PEG based)	NCT01910012	<input type="checkbox"/>	Reduction of serum glutamine	AML	<input type="checkbox"/>	<input type="checkbox"/>
Targeting pyrimidine biosynthesis							
BAY2402234	DHODH inhibitor	NCT03404726	<input type="checkbox"/>	Safety, tolerability, PK, and efficacy	AML, MDS, or CMML	<input type="checkbox"/>	<input type="checkbox"/>
Brequinar	DHODH inhibitor	NCT03760666	<input type="checkbox"/>	Safety, tolerability, and efficacy of brequinar	Relapsed or Refractory AML	<input type="checkbox"/>	<input type="checkbox"/>
ASLAN003	DHODH inhibitor	NCT03451084	<input type="checkbox"/>	Efficacy	Relapsed/refractory AML patients	<input type="checkbox"/>	<input type="checkbox"/>
JNJ-74856665	DHODH inhibitor	NCT04609826	<input type="checkbox"/>	DEE	AML/MDS	<input type="checkbox"/>	<input type="checkbox"/>
PTC299	DHODH inhibitor	NCT03761069	<input type="checkbox"/>	Safety and PK, and efficacy	Relapsed/Refractory Acute Leukemias	<input type="checkbox"/>	<input type="checkbox"/>
Targeting mutant IDH1 and IDH2							
Enasidenib (AG-221)	Inhibitor of IDH2	NCT02577406	<input checked="" type="checkbox"/>	Safety and efficacy	IDH2 mutant refractory or relapsed AML	<input type="checkbox"/>	<input type="checkbox"/>
Ivosidenib (AG-120)	Mutant IDH1 inhibitor	NCT03173248	<input checked="" type="checkbox"/>	Safety and efficacy	Untreated AML with an IDH1 Mutation	<input type="checkbox"/>	<input type="checkbox"/>
IDH305	Mutant IDH1 inhibitor	NCT02381886	<input type="checkbox"/>	Maximum tolerated dose / recommended dose	AML with IDH2 mutation	<input type="checkbox"/>	<input type="checkbox"/>
BAY-1436032	Mutant IDH1 inhibitor	NCT03127735	<input type="checkbox"/>	Maximum tolerated dose / recommended dose	Advanced AML with IDH1-R132X mutation	<input checked="" type="checkbox"/>	<input type="checkbox"/>
AG-881	Mutant IDH1/2 inhibitor	NCT02492737	<input type="checkbox"/>	Safety, PK, PD, and efficacy	Advanced hematologic cancers with mutant IDH1/2	<input checked="" type="checkbox"/>	<input type="checkbox"/>
LY3410738	Oral, covalent IDH inhibitor	NCT04603001	<input type="checkbox"/>	DEE; PD, PK, MTD, safety and efficacy	Advanced hematologic cancers with mutant IDH1/2	<input type="checkbox"/>	<input type="checkbox"/>
FT-2102 ^c	Inhibitor of mutated IDH1	NCT02719574	<input type="checkbox"/>	Safety, efficacy, PK and PD	AML, MDS with mutant IDH1	<input type="checkbox"/>	<input type="checkbox"/>

Figure 1. List of clinical trials for metabolic inhibitors in AML. AML: Acute myeloid leukemia; ClpP: caseinolytic protease proteolytic subunit; CMML: chronic myelomonocytic leukemia; DHODH: dihydroorotate dehydrogenase; ETC: electron transport chain; IDH: isocitrate dehydrogenase enzyme; MDS: myelodysplastic syndromes; OXPHOS: oxidative phosphorylation; TCA: tricarboxylic acid cycle.

TARGETING MITOCHONDRIAL OXPHOS

AML cells are more sensitive to mitochondria-targeted drugs, likely because despite having increased respiratory activity, their mitochondria have lower coupling efficiency and spare reserve capacity due to proton leak^[9]. In different cancers, including AML, depletion of mtDNA results in OXPHOS deficiency. OXPHOS-deficient cancer cells fail to form tumors unless mtDNA is restored from stromal cells via the horizontal transfer of whole mitochondria^[10-13], suggesting that functional OXPHOS is essential for cancer development, although it is not clear which component of OXPHOS contributes the most to tumor formation. For instance, aspartate supplementation enables cells to proliferate under pharmacological inhibition of electron transport chain (ETC), suggesting that although adenosine triphosphate (ATP) production is the primary function of OXPHOS, proliferating cancer cells obtain oxidizing power and aspartate for pyrimidine biosynthesis through aerobic respiration^[14,15], thus, in addition to ATP or ROS levels, there may be other mechanisms underlying the antiproliferative effects of ETC inhibition. Several compounds block complex I (i.e., NADH: ubiquinone oxidoreductase), with high affinity viz. IACS-010759^[16], IM156^[17], BAY87-2243^[18], and ME-344^[19].

The OXPHOS inhibitor IACS-010759 is currently being evaluated in phase 1 clinical trials in relapsed/refractory AML [Figure 1]^[16]. BAY87-2243, an inhibitor of hypoxia-inducible factor-1 (HIF-1) that inhibits mitochondrial complex I activity, causes grade III nausea/vomiting [NCT01297530], while ME-344 showed

no clinical efficacy in patients with solid cancers^[18,20].

Oxidative phosphorylation integrity is maintained by a protease, caseinolytic protease proteolytic subunit (ClpP) in AML cells^[21]. The altered function of this protease contributes to misfolding or degradation of respiratory chain subunits and their accumulation, causing respiratory chain dysfunction. The imipridones ONC201 and ONC212 inhibited the growth and viability of leukemia cells by hyperactivating mitochondrial ClpP and thus selectively proteolyzing certain mitochondrial matrix proteins^[21]. A significant reduction in the leukemic burden and improved survival was observed in mice that were administered ONC201 orally^[21]. In a clinical trial, a single oral dose of ONC201 resulted in a decrease in circulating blasts and a subsequent increase in platelet counts in patients with relapsed/refractory AML^[21].

Mubritinib (TAK-165) is a direct and ubiquinone-dependent ETC complex I inhibitor which induces ROS accumulation. Mubritinib also decreases ATP/ADP and NAD/NADH concentration ratios and inhibits the activities of PDH, tricarboxylic acid cycle (TCA), and OXPHOS, which results in the death of AML cells treated with mubritinib^[22]. In vivo, mubritinib delayed AML development without affecting normal hematopoiesis in mice^[22]. An isoquinoline alkaloid, berberine, targets mitochondrial ETC complex I, leading to reduced mitochondrial activity and enhanced antileukemic effects in vitro and in vivo when combined with IDH1 mutant inhibitor AG-120^[23].

A rationally designed lipoic acid analog, CPI-613, is currently being investigated in clinical trials for patients with pancreatic cancer and acute myeloid leukemia^[24]. Mechanistically, CPI-613 inhibits the TCA cycle by displacing lipoic acid, a cofactor for the TCA cycle enzymes pyruvate dehydrogenase and α -ketoglutarate dehydrogenase. This displacement, in turn, prevents the enzymes' activity and halts the TCA cycle^[25].

Metformin is being evaluated in combination with chemotherapy in different cancers; it sensitizes AML cells to Ara-C by reducing the mitochondrial transfer from bone marrow stromal cells (BMSCs) and OXPHOS in the recipient cells^[26]. Metformin was found to synergistically sensitize AML cells to Ara-C by inhibiting the mammalian target of rapamycin (mTOR)C1/P70S6K pathway^[27]. By promoting autophagy and apoptosis mediated by mTOR, metformin sensitizes FLT3-ITD-positive acute myeloid leukemia to sorafenib^[28]. Additionally, metformin and phenformin are also potentiators of the cytotoxicity of Bcl2 antagonist - ABT-737 against leukemia^[29]. By inhibiting protein production, metformin downregulates antiapoptotic Mcl-1 and Bcl-xl expression, resulting in a synergistic anti-tumor effect with ABT-199 in AML^[30]. It also exhibited anticancer activity with the MCL1 inhibitor S63845 via redox remodeling^[31]. IM156 is another oral biguanide OXPHOS inhibitor of mitochondrial ETC Protein Complex 1, which activates AMPK and is well tolerated at doses active in preclinical models with modest clinical efficacy [NCT03272256] in solid cancer patients^[32]. Though the biguanides showed promising efficacy in preclinical studies, they are still under development and warrant further investigation in clinical trials for AML to establish their clinical utility.

Role of mitochondrial OXPHOS in chemoresistance

Cytarabine remains the backbone of AML chemotherapy. Interestingly, pre-existing and persisting cytarabine-resistant cells do not necessarily reside in a quiescent or LSC compartment but rather have higher OXPHOS levels, with polarized mitochondria and an increased mitochondrial mass^[33]. The ability of cytarabine to induce mitochondrial ROS is a major determinant of cytarabine sensitivity in primary AML cells. Resistance to cytarabine is often mediated by SIRT3, a NAD⁺-dependent protein deacetylase that deacetylates mitochondrial anti-oxidant enzymes, including IDH2 and superoxide dismutase 2 (SOD2)^[34]. SIRT3-mediated deacetylation increases the enzymatic activity of its antioxidant targets, thereby restricting

cytarabine-induced mitochondrial ROS production and resulting in reduced apoptosis and increased chemoresistance^[34]. In addition, SIRT3 drives OXPHOS and increases the levels of both dihydronicotinamide adenine dinucleotide phosphate (NADPH) and reduced glutathione (GSH) while decreasing the concentrations of their respective oxidized forms. SIRT3 activation conferred resistance to chemotherapy *in-vivo* and its inhibition showed a synergistic effect with cytarabine^[34]. SIRT3 SUMOylation was higher in Ara-C sensitive primary cells, but lower in resistant primary cells^[35]. De-SUMOylation of SIRT3 is mediated by SUMO-specific peptidase 1 (SENP1), which enhances its deacetylase activity by inhibiting its protein degradation. When SIRT3 is de-SUMOylated, the expression of HES1, a negative regulator of FAO, is decreased and FAO is upregulated; either FAO inhibitors or overexpression of HES1 can attenuate this effect^[35]. The use of Momordin-Ic a, SENP1 inhibitor or HES1 overexpression *in vitro* and *in vivo* showed synergy with cytarabine to eradicate AML cells^[35]. Although these studies demonstrate a role for SIRT3 in chemoresistance in AML, the number of patients included in these studies is limited, and therefore validation is required in larger cohorts.

Notably, following cytarabine therapy, residual cells showed increased FAO, increased CD36 expression, (a fatty acid translocase) and higher expression of an OXPHOS gene signature that is predictive of clinical response to treatment in PDX models and AML patients^[33]. Inhibition of mitochondrial protein biosynthesis, electron transfer, or FAO resulted in reduced OXPHOS and strikingly increased efficacy of cytarabine in AML^[33]. Another mechanism of cytarabine resistance is mediated by upregulation of CD39, an ectonucleotidase that is localized on the cell surface and hydrolyses extracellular ATP and ADP to produce adenosine. Increased activity of CD39 promotes mitochondrial activity and biogenesis by activating the cAMP-mediated adaptive mitochondrial stress response, which promotes resistance to cytarabine. The activation of cAMP-PKA signaling driven by CD39 through P2RY13 purinergic receptor causes metabolic reprogramming and promotes the survival of chemo-resistant AML cells^[36]. Thus, CD39-P2RY13-cAMP-OxPHOS axis plays a key role in cytarabine resistance; inhibiting CD39 ecto-ATPase activity enhanced cytarabine's cytotoxicity in AML by blocking the mitochondrial reprogramming caused by the drug^[36].

TARGETING IDH1/2M

The isocitrate dehydrogenases enzymes, IDH1 and IDH2, catalyze the oxidative decarboxylation of isocitrate to α -ketoglutarate (α -KG) in the cell cytoplasm and mitochondria, respectively, and reduce NADP⁺; this, in turn, contributes to the generation of NADPH. α -KG is essential for the optimal functioning of multiple metabolic and epigenetic processes, while NADPH functions as a reducing agent and plays a crucial role in maintaining the cellular redox state. IDH1/2 mutations have been found in 1 of every 5 AML patients with a higher preponderance among patients with normal karyotypes^[37,38]. IDH1/2 mutations detected in AML are predominantly heterozygous point mutations that not only render the protein incapable of carrying out decarboxylation of isocitrate, but confer it the ability to produce 2-hydroxyglutarate (2-HG), an oncometabolite, by NADPH-dependent reduction of α -KG^[39]. 2-HG inhibits several α -KG-dependent dioxygenases, such as demethylases and the TET family of 5-methylcytosine hydroxylases^[40]. TET regulates the gene expression of its target genes through DNA demethylation and chromatin modification, such as H2B O-linked N-acetylglucosylation (O-GlcNAcylation) or H3K4 trimethylation^[41]. The loss of α -KG in conjunction with the suppression of α -KG-dependent dioxygenases mediated by 2-HG promotes leukemogenesis^[42,43]. In addition, loss of NADPH due to IDH mutations perturbs the regulation of redox balance in the cell^[44].

In recent years, ivosidenib (AG120), an IDH1 inhibitor, has been used in the treatment of relapsed and refractory AML^[45] while many other inhibitors including Olutasidenib (FT-2102), IDH305, Vorasidenib (AG881), BAY1436032, LY3410738 and DS-1001 are currently being evaluated in Phase I/II clinical trials in

patients with IDH1/2 mutant AML. The IDH2 inhibitor Enasidenib (AG-221) and Ivosidenib are approved for relapsed/refractory AML in the presence of relevant mutations and ivosidenib was recently approved, in combination with hypomethylating agents, as first-line therapy for IDH1 mutant AML [Figure 1]. The IDH1 mutant AML cells carrying IDH1R132H, IDH1R132C, IDH1R132G, IDH1R132L and IDH1R132S mutations undergo myeloid differentiation when treated with BAY1436032, a novel pan mutant IDH1 inhibitor which specifically inhibits R-2HG production and colony growth in these cells. Aside from that, the compound affects DNA methylation and attenuates hypermethylation of histones. In two independent xenograft mouse models derived from AML patients with IDH1 mutation, treatment with BAY1436032 increased leukemic blast clearance, myeloid differentiation, and stem cell depletion while prolonging survival^[46]. Combining azacitidine and BAY1436032 increased survival and depleted LSCs by inhibiting MAPK/ERK and RB/E2F signaling^[47]. In a study conducted by Shih *et al.*, AG-221 treatment reduced aberrant hypermethylation in several genes involved in hematopoietic differentiation, suggesting an epigenetically driven differentiation effect. As a single agent, AG221 or 5-azacitidine in vivo stimulated the production of mature myeloid cells from mutant leukemic progenitor blasts. Importantly, in Idh2^{R140Q}Flt3^{ITD} mutant AML combination therapy with FLT3 inhibitor AC220 (quizartinib), significantly decreased mutant cell burden and led to the recovery of normal hematopoiesis from non-mutant stem/progenitor cells^[48].

The emergence of second-site IDH2 mutations in trans, at glutamine 316 (Q316E) and isoleucine 319 (I319M), which are located at the interface of the enasidenib binding site in the IDH2 dimer, were found to confer therapeutic resistance to enasidenib. Although the expression of these mutant proteins alone is not sufficient for the synthesis of 2HG, the presence of R140Q mutation in trans produces 2HG, which is resistant to inhibition by enasidenib^[49]. Mutations in the IDH dimer-interface in cis were found to confer resistance to ivosidenib in AML^[49]. In a high-content shRNA screen of isogenic leukemia cells expressing wild-type and mutant IDH1, Chan *et al.* (2015) found that survival of IDH1/2 mutant cells was highly dependent upon BCL-2 and BCL-W expression^[50]. Venetoclax-based therapy was effective in 6 out of 7 patients with IDH1 mutations who had previously been treated with ivosidenib; however, a lower response rate was reported for patients with FLT3-ITD mutations, indicating that venetoclax is an effective salvage therapy in patients who previously received IDH1/2 inhibitors^[51]. IDH305 is a selective oral IDH1 inhibitor that specifically targets R132* IDH1 mutation. There is a phase I clinical trial currently being conducted on this drug for the treatment of advanced malignancies, including relapsed/refractory AML and myelodysplastic syndromes (MDS) [NCT02381886]^[52].

Vulnerabilities in IDH mutated AML

Mutations in IDH1/2 have been reported to confer sensitivity to several chemotherapeutic agents in most cancer types, including colorectal cancer^[53], glioma^[54,55], cholangiocarcinoma^[53,56], and AML^[50,57]. Conversely, inhibition of mutant IDH1/2 may counteract the cytotoxic effect of chemotherapeutic drugs^[58]. In IDH1/2 mutants, D2HG mediates the downregulation of ATM, a DNA damage response gene. Therefore, IDH1/2 mutant AML cells are sensitive to DNA damage-causing agents, such as daunorubicin, and the PARP inhibitors olaparib and talazoparib, while IDH1/2 mutant inhibitors had a protective effect against these treatments^[58]. Intriguingly, IDH1/2 mutation sensitized primary AML cells to ABT199 by inhibiting cytochrome c oxidase (i.e., Complex IV of ETC) by 2HG^[50]. The cytochrome c oxidase complex contains two heme moieties (a and a3) and two copper atoms (CuA and CuB)^[59]. A binding of (R)-2-HG at or near the binuclear center of heme a3 and CuB inhibits cytochrome c oxidase activity, thereby blocking oxygen reduction at that site^[50]. Suppression of cytochrome c oxidase activity results in oxygen deprivation, which triggers activation of BAX/BAK and leads to outer membrane permeabilization and apoptosis. When BAX/BAK are bound to BCL-2, permeabilization is prevented, but ABT-199 disrupts this binding so that IDH1/2 mutant cells die, while wild-type IDH1/2 cells are relatively unaffected^[33]. IDH1/2 mutant AML exhibited a

superior response (36%) to BCL-2 inhibition compared to IDH1/2 wildtype (9%)^[60]. Patients with IDH-mutant AML show robust responses to venetoclax + azacytidine^[61]. This is a great example of a driver mutation that creates a unique metabolic vulnerability^[62].

Primary resistance to IDH inhibitors is primarily associated with leukemia stemness, while acquired resistance is often conferred by mutations in the genes belonging to the RUNX1/CEBPA or RAS-receptor tyrosine kinase (TK) pathways or genes such as BCOR, and TET2^[63]. These mutations often affect transcription factors that are involved in hematopoietic and myeloid differentiation, particularly RUNX1 and CEBPA. An association was found between co-mutation(s) of RUNX1 at baseline and a lower CR rate with IDH inhibitor^[63]. RUNX1 mutations were also the most frequently acquired mutations in relapsed disease. In addition, co-occurrence of CEBPA mutation was associated with a lack of response to IDH inhibitor, and the mutation was also reported to be acquired at relapse^[63]. Because of their roles as differentiation factors, RUNX1 and CEBPA mutations may interfere with differentiation signals induced by IDH inhibitors, resulting in clinical resistance^[63]. Almost 30% of relapse cases were found to have acquired mutations in either NRAS or KRAS during relapse^[63]. Interestingly, Tateishi *et al.* found that IDH1 mutation may cause addiction to NAD⁺ in solid cancers^[64]. The mutant form of IDH1 lowered NAD⁺ levels through downregulation of the enzyme nicotinate phosphoribosyltransferase (NAPRT1) of the NAD⁺ salvage pathway and thus sensitized cells to NAD⁺ depletion when combined with inhibition of nicotinamide phosphoribosyltransferase (NAMPT). Depletion of NAD⁺ activated AMPK, triggering pro-cell death autophagy, resulting in cell death^[64].

TARGETING AMINO ACID METABOLISM

Role of glutamine and glutaminolysis: as cellular building blocks and in ROS mitigation homeostasis

Besides serving as substrates for protein biosynthesis, amino acids participate in the biosynthesis of purine and pyrimidine nucleotides and provide precursors for energy generation. For instance, acetyl-CoA can be generated by the ketogenic amino acids leucine and lysine. Similarly, the glycolytic amino acids alanine and glycine generate pyruvate and TCA cycle intermediates. Glutamine addiction has been reported in some primary AML patient samples and cell lines^[65-67], and can drive the TCA cycle by providing glutamate; through glutaminolysis, glutamate is then converted to α -ketoglutarate. In addition, it can serve as a substrate in the synthesis of GSH, a ROS mitigator^[66,68] [Figure 2]. Gregory *et al.* demonstrated that inhibition of glutaminase, an enzyme responsible for converting glutamine to glutamate, could perturb GSH balance and adversely affect the redox state in AML^[69]. AML development in NSG mice was dramatically inhibited by knocking down the glutaminase gene GLS1, leading to the failure of conversion of glutamine to glutamate (glutaminolysis); this, in turn, induced apoptosis, and exhibited a synergistic effect in sensitizing leukemic cells to venetoclax^[66].

Drivers of glutaminolysis

The cellular influx and efflux of glutamine in exchange for leucine influences the intracellular levels of glutamine, which is critical for mTORC1 activity, and translation and control of autophagy to coordinate cell survival and proliferation^[70]. Solute-carrier family 1 member 5 (SLC1A5) is responsible for glutamine transport into the cells. Glutamine transport is essentially linked to leucine uptake. The bidirectional transporter, SLC7A5/3A2 is responsible for the uptake of leucine in exchange of glutamine^[71]. Knockdown of SLC1A5 in a murine model of AML resulted in increased apoptosis and reduced tumor formation^[72].

Translation of cellular mRNAs is tightly regulated by mTOR. The mTOR pathway regulates the phosphorylation of 4E-BP1 (at serine 65), which is required for the initiation of translation^[73]. Asparaginases are routinely used in the treatment of acute lymphoblastic leukemia; they catalyze the conversion of

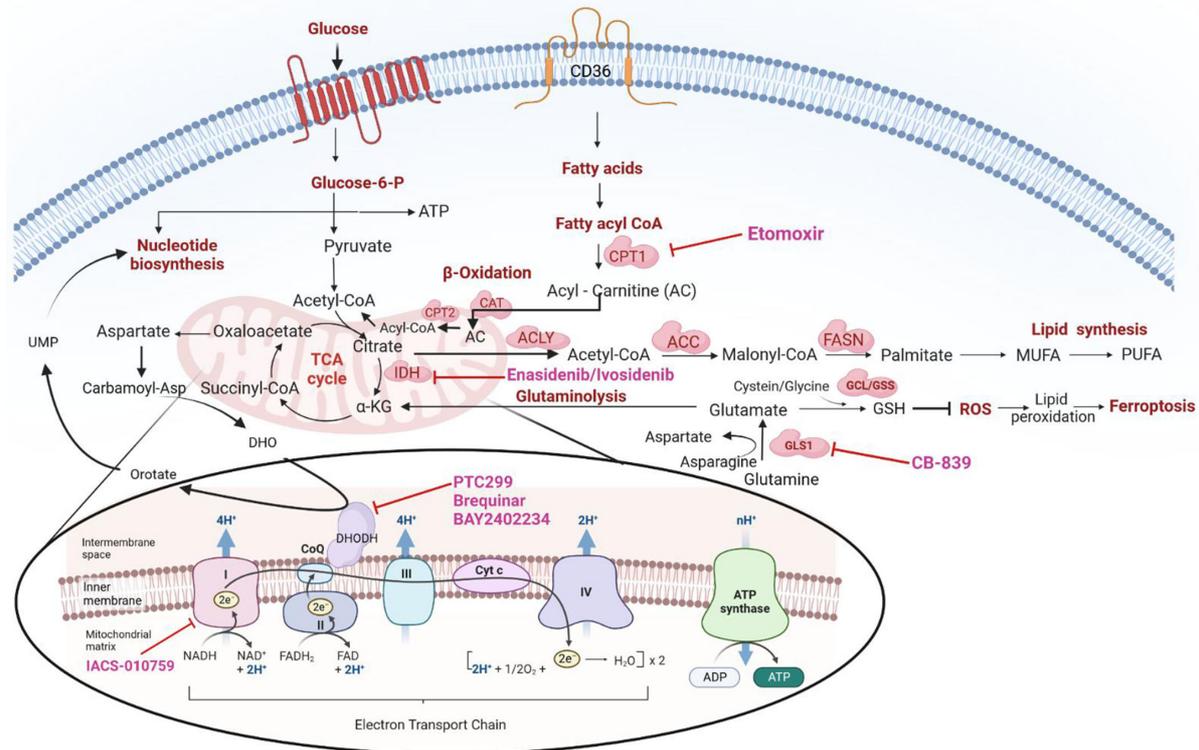

Figure 2. Overview of cellular metabolic pathways and their crosstalk -including: (1) glycolysis; (2) TCA cycle; (3) OXPHOS; (4) glutaminolysis; (5) nucleic acid biosynthesis; (6) lipid synthesis; (7) fatty acid import and oxidation; (8) ROS mitigation by GSH; (9) ferroptosis. ACC: Ac-CoA carboxylase; ACLY: ATP citrate lyase; ADP: adenosine diphosphate; ATP: denosine triphosphate; α -KG: α -ketoglutarate; CAT: carnitine acetyltransferase; CPT1: carnitine palmitoyltransferase 1; CPT2: carnitine palmitoyltransferase 2; DHO: dihydroorotate; DHODH: dihydroorotate dehydrogenase; FAD: flavin adenine dinucleotide; FASN: FA synthase; GSH: glutathione; IDH: isocitrate dehydrogenase enzyme; GCL: glutamate-cysteine ligase; GSS: glutathione synthetase; GLS1: glutaminase 1; NAD: nicotinamide adenine dinucleotide; NADH: nicotinamide adenine dinucleotide (NAD) + hydrogen (H); MUFA: monounsaturated fatty acid; OXPHOS: oxidative phosphorylation; PUFA: polyunsaturated fatty acid; ROS: reactive oxygen species; TCA: tricarboxylic acid cycle; UMP: uridine monophosphate.

asparagine and glutamine to aspartate and glutamate, respectively, and help to reduce the concentrations of asparagine and glutamine in the blood^[74]. Glutamine depletion induced by L-asparaginases inhibits 4EBP1 phosphorylation at residue S65 and decreases protein synthesis in AML cell lines^[72]. When 4EBP1 is dephosphorylated, it binds to eIF4E, resulting in inactivation of translational initiation complexes and a reduction in cap-dependent protein synthesis. In Complex karyotype AML, co-treatment with venetoclax and pegcrisantaspase, an asparaginase, significantly diminished cellular protein synthesis including that of MCL-1, an important antiapoptotic protein in AML, by promoting the interaction between eIF4E and 4EBP1 on the cap-binding complex and interfering with active cap-mRNA translation downstream of mTOR signaling^[75].

Glutaminolysis is a therapeutically targetable vulnerability in FLT3-ITD and other tyrosine kinase (TK) activating leukemias. A synthetic lethality screen using CRISPR/Cas9, metabolomics analyses, and gene expression analysis reveals that FLT3-ITD cells develop glutamine metabolism dependence following FLT3 TK inhibition. FLT3 TK inhibition hinders glucose uptake and use, suppressing the enhanced central carbon metabolism that is found in FLT3-ITD cells and reversing the glycolytic phenotype; as a result, FLT3-ITD cells develop a metabolic dependency on glutamine metabolism. Despite a decrease in glucose uptake, TCA cycle activity and respiratory function are less affected by FLT3 TK inhibition; instead, they are

supported by the continuous uptake of glutamine. FLT3 TK inhibition with concomitant suppression of glutamine metabolism using either GLS chemical inhibition or gene silencing, increased cell death in FLT3-ITD cells^[76]. Glutaminolysis is also upregulated by FLT3-ITD through Foxo3a inhibition. Foxo3a activates the expression of MAX-interacting protein 1 (MXI-1), a protein which can block MAX from binding to Myc. This disruption of the interaction between Myc and MAX reduces the transactivation capacity of Myc^[77]. In AML and other cancer cells, FLT3-ITD inhibits Foxo3a^[77,78], leading to Myc activation and glutaminolysis stimulation, which, in turn, generates anaplerotic substrates that fuel the TCA cycle, increasing citrate synthesis and its transport to cytoplasm. Increased citrate synthesis provides acetyl-CoA, which can feed into the biosynthesis of lipids and participate in the post-translational modification of proteins^[44].

Agents targeting glutaminolysis

Glutaminolysis was recently identified as a therapeutic target for hematological and solid malignancies, and potent inhibitors are now being evaluated in clinical trials [NCT02071862 and NCT02071927]. Inhibition of glutaminolysis with CB-839 blocks glutamine utilization, resulting in decreased levels of glutamate, aspartate and several TCA cycle intermediates. As described in a previous study^[5], inhibition of glutaminolysis with BPTES in mutant IDH1/2 AML may be beneficial, as it arrested cell proliferation, decreased 2-HG levels and enhanced differentiation^[67]. Interestingly, in AML harboring FLT3-ITD mutations, glutaminolysis inhibition alone confers only minor antiproliferative effects. Glutaminolysis inhibition is more effective when combined with FLT3-ITD tyrosine kinase inhibition^[76], which perturbs glycolysis and glucose utilization, with less effect on glutamine metabolism. Therefore, even though glycolysis and glucose utilization are impaired following FLT3 inhibition, glutamine can drive the TCA cycle and participate in GSH synthesis^[76]. Notably, in AML cells treated with quizartinib, glutamine starvation resulted in the depletion of GSH and elevation of intracellular ROS. In addition to glutamine starvation, pharmacological inhibition using CB839 or glutaminolysis gene silencing enhanced the efficacy of FLT3-ITD tyrosine kinase inhibition by reducing the availability of intracellular glutamine (due to TCA cycle inhibition), and GSH generation, thus impacting redox metabolism^[76].

LSCs exhibit increased uptake and catabolism of amino acids. Venetoclax + azacytidine is highly effective in AML patients because of its action at inhibiting amino acid metabolism in LSCs^[79]. Jones *et al.* demonstrated that depletion of amino acids, especially cysteine, was strongly associated with response to venetoclax + azacytidine regimen compared to ROS induction. LSCs in patients with *de novo* AML rely on amino acid metabolism to drive OXPHOS. In LSCs, the depletion of cysteine causes a reduction in GSH levels, which, in turn, leads to decreased glutathionylation of succinate dehydrogenase A (SDHA), a component of ETC complex II. This decreased glutathionylation of SDHA results in OXPHOS inhibition and ATP depletion, ultimately leading to LSC death^[80]. BCL-2 inhibition is believed to promote the generation of mitochondrial permeability transition pores, resulting in leakage of mitochondrial membrane and reduced amino acid metabolism^[81]. The combination of venetoclax and azacytidine has shown good efficacy in older AML patients, who are generally considered unfit for traditional chemotherapy due to high toxicity and poor outcomes with chemotherapeutic agents. In fact, in a Phase III study, this regimen resulted in higher complete remission compared to the placebo control (36.7% *vs.* 17.9%; $P < 0.001$), the composite complete remission was reported in 66.4% AML patients receiving ven + aza *vs.* 28.3% in placebo control; $P < 0.001$ ^[61]. The study reported that almost half of all patients receiving azacitidine plus venetoclax had a first response (complete remission or complete remission with incomplete hematologic recovery) before starting cycle 2, and their remissions lasted an average of 17.5 months. Of note, the remission rate after venetoclax + azacytidine in patients with *de novo* AML is independent of the genetic background, suggesting that venetoclax targets a unique metabolic program of LSCs^[61].

Targeting arginine

Primary AML cells are auxotrophic for glutamine, cysteine, and arginine^[80,82]. As they lack argininosuccinate synthetase-1 (ASS1), a key enzyme required for the generation of arginine, these cells rely on arginine import^[83]. The depletion of extracellular arginine via the use of pegylated arginine deiminase, which converts plasma arginine to citrulline, induced responses in AML through the activation of caspases^[83]. Depleting extracellular arginine shows synergy with cytarabine and enhances its cytotoxicity^[82]. Arginine and cysteine metabolism are also controlled by the stroma in CLL, which may promote the resistance and growth of leukemic cells^[84]; this can be targeted by arginine depletion.

Targeting branched-chain amino acids

The survival of HSCs and LSCs is influenced by branched-chain amino acids (BCAAs), such as leucine, isoleucine, and valine. For instance, valine is essential for survival and maintenance of HSCs^[85,86]. BCAAs promote cancer growth in *de novo* AML^[87]. LSCs exhibit elevated levels of branched-chain amino acid transaminase 1 (BCAT1)^[88], a cytoplasmic aminotransferase that generates glutamate by transferring an amino group from a BCAA to α -KG^[89], which can in turn fuel OXPHOS.

TARGETING PYRIMIDINE BIOSYNTHESIS

Proliferating cells require an abundance of nucleotides. They heavily depend on *de novo* nucleotide biosynthesis to meet their nucleotide requirements. As expected, the expression of enzymes involved in nucleotide biosynthesis is elevated in cancer. Uridine monophosphate (UMP) is generated in *de novo* nucleotide biosynthesis from glutamine. Similarly, dihydroorotate dehydrogenase (DHODH) is a mitochondrial enzyme that converts dihydroorotate (DHO) into orotate through oxidation, in *de novo* pyrimidine biosynthesis and donates the electrons to ubiquinone to generate ubiquinol, which is then re-oxidized by ETC complex III^[90]. In experimental models of AML, inhibition of DHODH enhances myeloid differentiation^[90]. In addition, a decrease in leukemia-initiating cells, as well as increased survival *in vivo*, have also been observed following the inhibition of DHODH^[91]. DHODH inhibition promotes myeloid differentiation by depleting uridine, a precursor of uridine diphosphate-N-acetylglucosamine (UDP-GlcNAc). The depletion of uridine diphosphate-GlcNAc decreases O-linked N-acetylglucosylation (O-GlcNAc) of several proteins including Akt, TET family of proteins and c-Myc^[91]. The loss of O-GlcNAc modification following DHODH inhibition reduced the stability of c-Myc and thereby promoted differentiation in AML^[92]. In addition, DHODH inhibition revealed the dysregulation of several key genes that are involved in a maturation block of AML cells, such as HOXA9, FLT3 and c-Myc^[93]. Of note, DHODH inhibition using BAY 2402234 induced acute downregulation of HMGA1, a chromatin remodeler that is implicated in stemness, and would otherwise negatively regulate differentiation^[93]. In clear cell renal cell carcinoma, the DHODH inhibitor selectively inhibited tumor growth in GPX4-low tumors, while combined treatment with sulfasalazine, which also induces ferroptosis, synergistically inhibited the growth of GPX4-high tumors^[94].

Notably, several clinical trials have reported that brequinar, a DHODH inhibitor, has limited efficacy, likely related to a schedule that did not allow sustained exposure^[91,95]. ETC complex III helps in maintaining the oxidation of ubiquinol, which is essential to supporting DHODH activity^[96]. Interventions targeting respiratory Complex III would increase the generation of ROS and block the activity of DHODH and pyrimidine biosynthesis^[97,98], and could thus be an effective two-pronged strategy involving the exploitation of cell death promoted by ROS^[99] and differentiation induced by DHODH inhibition. Alternative oxidase (AOX) can restore DHODH activity and reactivate CoQ redox-cycling following DHODH inhibition^[100].

Aspartate biosynthesis is a crucial step in pyrimidine biosynthesis, which requires ETC complex I activity^[15]. AML's dependency on ETC complex I has been well-documented. As a result, there has been an increasing interest in targeting ETC complex I and induction chemotherapy together.

TARGETING NICOTINAMIDE METABOLISM

LSCs from relapsed/refractory AML patients are resistant to venetoclax + azacytidine, in contrast to those from *de novo* AML patients, suggesting that they have alternative resistance mechanisms. Jones *et al.* (2020) determined whether LSCs from relapsed/refractory AML patients exhibited altered metabolome profiles compared to those from *de novo* AML; they identified 18 metabolites that were upregulated, including amino acids and nicotinamide^[101]. Interestingly, relapsed LSCs exhibited an enhanced rate of NAD⁺ synthesis driven by the salvage pathway, with no difference in the protein levels of NAMPT, the rate-limiting enzyme responsible for the generation of NAD⁺ from nicotinamide, suggesting an increase in nicotinamide uptake in relapsed/refractory LSCs^[101]. The elevation of nicotinamide metabolism in relapsed LSCs, activates amino acid metabolism and FAO, which in turn drives OXPHOS. An increase in OXPHOS would help LSCs to confer resistance to venetoclax + azacytidine^[101].

Unlike *de novo* LSCs, relapsed/refractory LSCs exhibit extensive metabolic plasticity, which enables them to adapt alternative mechanisms for activating OXPHOS, a key mechanism for developing resistance to chemotherapy^[101]. Given that therapeutic options are limited for relapsed/refractory AML, the inhibition of NAMPT, the rate-limiting enzyme for NAD⁺ synthesis, may be an effective approach^[101]. Notably, relapsed/refractory LSCs were selectively eradicated by the genetic and pharmacological inhibition of NAMPT, while normal hematopoietic stem/progenitor cells were spared. Of note, in secondary transplantation of relapsed/refractory AML LSCs, in-vivo treatment with APO866, a small molecule inhibitor of NAMPT, compromised the engraftment^[101].

TARGETING FATTY ACID METABOLISM

FA catabolism has been implicated in regulating HSC fate (i.e., maintenance *vs.* exhaustion) by providing the required energy to allow the proper execution of asymmetric division, favoring the maintenance and function of the HSC compartment. Loss of the mitochondrial FAO activator peroxisome proliferator-activated receptor δ (PPAR- δ) perturbs HSC maintenance, whereas treatment with PPAR- δ agonists restores HSC maintenance by promoting asymmetric HSC division^[102]. PPAR- δ activates FAO in mitochondria. LSCs from *de novo* AML patients drive OXPHOS exclusively using amino acid metabolism. In contrast, LSCs from relapsed/refractory AML patients tend to compensate significantly through increased FA metabolism^[79]. Despite the importance of FAs for mitochondrial metabolism in LSCs, aberrant lipid metabolism may also promote cancer cell proliferation by increasing its energy availability, structural lipid-based building blocks, and signaling molecules^[103]. Vriens *et al.* demonstrated that cancer cells exhibit extensive plasticity in FA metabolism and can facilitate membrane biosynthesis during proliferation through the FA desaturation pathway^[103]. Further investigation is needed to determine whether such metabolic plasticity exists in leukemic cells and if it could be targeted.

Mcl1 is an antiapoptotic protein that is known to interact with proapoptotic proteins in mitochondria. Mcl1 upregulation is common in venetoclax-resistant AML^[104]. Interestingly, MCL1 in cancer cells regulates lipid metabolism through a functional gain. This is achieved by binding its α -helix of the BH3 domain to very long-chain acyl-CoA dehydrogenase (VLCAD), a key enzyme of the mitochondrial FAO pathway, through its hydrophobic surface^[105]. Thus, MCL1 not only suppresses apoptosis in cancer cells, but also regulates β -oxidation in response to stress. Of note, Mcl-1 is essential for the efficient assembly of F1F0-ATP synthase oligomers and thus is important for maintaining mitochondrial cristae structure and efficient ATP

synthesis^[106]. Another study revealed the bifunctional activities of BAD, demonstrating glucokinase regulation by the proapoptotic BH3 domain of BAD^[107]. The findings of these studies have opened a new paradigm, revealing the role of Bcl2 family proteins in not only regulating mitochondrial apoptosis but also energy metabolism in cancer cells. It would be interesting to further explore whether Bcl2 family protein mediated regulation of metabolism plays a role in resistance to standard chemotherapies in AML and to further identify downstream druggable non-canonical targets.

Fatty acid metabolism and resistance to therapy

Cellular levels of ceramide are key determinants of response to several chemotherapeutic drugs. Modulation of the ceramide pathway has been implicated in apoptosis induced by daunorubicin in AML cells^[108]. Ceramidases convert ceramide to sphingosine. Kao *et al.* found that daunorubicin and cytarabine treatment resulted in the increased expression and activity of enzymes involved in the ceramide pathway, leading to a decrease in ceramide levels and an increase in ceramide 1- and sphingosine 1-phosphate levels. These perturbations induced remodeling of mitochondria in cancer cells and promoted chemoresistance^[109]. For instance, FLT3-ITD signaling activation suppresses pro-cell death lipid ceramide generation in AML cells^[110]. Intriguingly, LCL-461, a mitochondria-targeted ceramide analog, effectively induced lethal mitophagy in human AML blasts and crenolanib (FLT3-ITD inhibitor)-resistant AML xenografts, suggesting that activation of mitochondrial ceramide synthesis overcomes resistance to FLT3 inhibition^[110].

A previous study reported that *de novo* cholesterol synthesis through the mevalonate pathway plays a key role in AML^[111]. Recently, using genome-scale metabolic modeling, Karakitsou *et al.* demonstrated that AraC-resistant cells could be targeted by suppressing cholesterol biosynthesis through the inhibition of squalene synthase^[112].

Acetyl-CoA is converted to malonyl-CoA by Ac-CoA carboxylases (ACCs). FA synthase (FASN) catalyzes the condensation of malonyl-CoA and Ac-CoA to generate palmitate as the first product of FA synthesis^[113]. FASN is significantly elevated in AML blasts compared to healthy granulocytes or CD34+ hematopoietic progenitors at the RNA level. Inhibition of FASN expression on one side accelerated differentiation of APL cells, on the other hand, sensitized ATRA resistant -non-APL AML cells to ATRA, by promoting translocation of transcription factor EB (TFEB) to nucleus and lysosomal biogenesis^[114].

Cellular stress directly regulates FA metabolism by affecting the enzymatic activity of Acetyl-CoA carboxylases (ACC), namely ACC1 and ACC2. AMPK inhibits ACC under energy stress and thus activates fat synthesis and catabolism. Nutrient abundance, on the other hand, downregulates the activity of AMPK, and ACC1 and ACC2 are no longer repressed^[115]. This suggests that ACCs act as a regulatory node in FA metabolism by sensing nutrient availability and balancing the switch between anabolic and catabolic processes. Of note, ACC1 suppressed growth-promoting activity and promoted the generation of ROS in primary BM cultures. In addition, ACC1 has been shown to promote myeloid differentiation and delay the development of AML in mice^[116]. Hydroxylation of ACC2 by prolyl-hydroxylase 3 (PHD3) increases the activity of ACC2, which, in turn, prevents FA utilization^[117,118]. PHD3 levels are decreased in AML^[119], thus generating a vulnerability due to dependence on FAs, which can make FAO inhibition an attractive strategy to control AML.

Venetoclax + azacytidine-resistant LSCs exhibit increased levels of several metabolites that are responsible for the transport of FAs into mitochondria at baseline, including acetyl-carnitine, iso-butylryl carnitine, and hexanoyl-carnitine, compared to sensitive LSCs^[120]. Venetoclax + azacytidine treatment results in a reduction in amino acid uptake by LSCs. Enhanced FA transport facilitates FAO and allows LSCs to compensate for

amino acid uptake loss caused by venetoclax + azacytidine treatment, resulting in resistance. However, this resistance can be overcome by the knockdown of very long-chain acyl-CoA dehydrogenase (ACADVL), an enzyme involved in mitochondrial FA beta-oxidation^[120], suggesting that FA beta-oxidation plays an important role in conferring resistance to venetoclax + azacytidine treatment in LSCs.

FAs are conjugated to carnitine by CPT1 to facilitate mitochondrial translocation, and both the PPARs and the coactivator-1 of PPARs modulate CPT1A expression^[121]. Pharmacological inhibition of CPT1 by etomoxir depleted refractory LSC function^[122], and eliminated venetoclax+ azacytidine-resistant LSCs^[85]. In addition, CPT1A inhibition by etomoxir induced cell death in AML cells and increased cells' sensitivity to cytarabine^[123]. CD36+ LSCs are characterized by an enhanced FAO rate, and disruption of mitochondrial metabolism by targeting CD36-FAO-OXPHOS drives leukemia cells to low OXPHOS and enhances AraC sensitivity^[19]. In addition, topoisomerase inhibitor (mitoxantrone)-resistant AML cells showed activation of lipid metabolic pathways. Inhibition of FAO, using etomoxir in these cells, reduced colony formation ability, suggesting that FA metabolism and dependency on OXPHOS are key vulnerabilities, conferring chemoresistance in AML^[124].

TUMOR MICROENVIRONMENT-MEDIATED METABOLIC PLASTICITY

Tumor microenvironment-mediated OXPHOS regulation

BMSCs, which are composed of endothelial cells, osteoclasts, osteoblasts, adipocytes, and fibroblasts, form the BM microenvironment. BMSCs aid the survival of AML cells and mediate resistance to therapy. Cell-cell communications in the BM microenvironment play a key role in aiding AML cell survival, disease progression, and therapeutic response through the transfer of biomolecules or cellular organelles, such as mitochondria^[125]. Of note, BMSCs supply mitochondria to AML cells in vitro, thus providing them with additional energy^[126]. AML cells were observed to enhance their mitochondrial mass up to 14% by mitochondrial uptake from BMSCs; this transfer increased in response to chemotherapy and contributed to resistance by reducing mitochondrial depolarization^[126]. AML cells exhibited up to a 1.5-fold increase in mitochondrial ATP production following the uptake of mitochondria from BMSCs, were less prone to depolarization of mitochondria following chemotherapy, and showed improved survival^[126]. Of note, transfer of mitochondria to AML cells from BMSCs in the presence of chemotherapeutic agents occurs predominantly through endocytosis and requires cell-cell contacts^[12]. The NADPH oxidase, NOX2 generates superoxide in AML cells, which promotes mitochondrial transfer to AML blasts from BMSCs through AML-derived tunneling nanotubes. Interestingly, suppression of NOX2 reduced the transfer of mitochondria to AML blasts and resulted in enhanced cell death and improved survival of AML-bearing mice^[126]. AML cells show high OXPHOS levels when cocultured with BMSCs. Hou *et al.* showed that the elevation of OXPHOS levels in AML cells in coculture was dependent on the activation of mitochondrial serine-phosphorylated STAT3 (pS-STAT3)^[127]. AML cells in coculture induced the secretion of interleukin-6 from BMSCs, which in turn promoted the activation of total and mitochondrial STAT3 in AML cells, resulting in increased proliferation and chemoresistance^[127].

AML cells are known to harbor abnormally high levels of ROS. Mesenchymal stem cells, a component of BMSCs, support the survival of AML cells by influencing several key metabolic pathways and eliminating ROS. BMSCs expressing the intermediate filament protein nestin provide HSC niche function^[128]. Forte *et al.* reported that after AML induction, unlike bulk stroma, the nestin-expressing BMSC cell population remains stable in MLL-AF9-driven AML, with no reduction in their number over time^[129]. However, these cells undergo changes in their functional behavior to enhance the survival of MLL-AF9 AML cells and promote chemoresistance by promoting TCA cycle and OXPHOS. They also provide a GSH-mediated antioxidant defense, which is critical for ROS mitigation during leukemogenesis and chemotherapy^[129].

Forte *et al.* observed a delay in leukemogenesis, following the depletion of Nestin⁺ BMSCs in primary AML mice^[129]. Most importantly, the depletion of Nestin⁺ BMSCs in chimeric mice reduces AML, but not normal cells^[129]. Thus, BMSCs help AML cells switch their energy sources and provide antioxidant defense mechanisms to survive chemotherapy.

Tumor microenvironment mediated regulation of amino acid and pyrimidine metabolism

Induction chemotherapy causes transient stress in BM, which results in the elevation of glutamine, glutamate, and aspartate with a concomitant increase in the expression of several glutamine transporters, such as Slc1a5, Slc38a1, Slc7a5, and Slc7a6, but no change in the enzymes that metabolize glutamine or glutamate, in residual AML cells^[130,131]. This suggests that glutamine metabolism in AML cells could be regulated by the tumor microenvironment^[130,131]. Interestingly, van Gastel *et al.* showed that glutamine metabolism differed between AML and stromal BM cells, especially LepR⁺ mesenchymal stromal cells^[131]. AML cells took up glutamine to maintain GSH but not to promote the TCA cycle. In contrast, in LepR⁺ mesenchymal stromal cells, glutamine entered the TCA cycle to produce aspartate^[131]. Aspartate is transported to and supports pyrimidine biosynthesis in persistent MLL-AF9 AML cells, thus preventing the metabolic collapse triggered by chemotherapy^[130,131]. These findings suggest that the tumor microenvironment plays a major role in chemoresistance, independent of cell-intrinsic signaling/apoptosis alterations. However, it is unclear whether aspartate-rich locations in the BM provide a protective niche, and if specific AML subclones compete for these spots. Further niche-specific studies are warranted to delineate whether mutational subclones compete for specific hotspots.

Tumor microenvironment mediated regulation of fatty acid metabolism

Accumulating evidence supports the existence of metabolic symbiosis and bidirectional dialogues between leukemic cells and the BM adipose tissue niche, which provides diverse sources of lipids, such as FAs, cholesterol, and eicosanoids, to resident leukemic cells. Leukemic cells meet their energy needs by using FAs to fuel β -oxidation, which eventually supports anabolism^[33,132]. When FAO was inhibited pharmacologically with etomoxir or ranolazine, AML cells were sensitized to apoptosis induction by ABT-737, and proliferation was inhibited in the setting of coculture with BMSCs^[123]. Interestingly, a recent report described two forms of LSCs, distinguished by differences in their expression of CD36 and in their metabolism and cell cycle status. LSCs expressing CD36 (CD36⁺ LSCs) are often localized to gonadal adipose tissue (GAT) which is rich in fatty acids, indicating a tropism rich for microenvironments rich in FAs^[132]. Specifically, these GAT-resident LSCs are more resistant to conventional chemotherapy because they exist in a quiescent cell cycle state. In the context of these findings, leukemic cells co-opt adipose tissue to create a microenvironment to support leukemia growth and provide a drug-resistant niche^[132]. Further, leukemic burden in GAT for the MLL-AF9 model was considerably lower than that in BM, indicating that localization to GAT may be dependent on the specific oncogenes that drive the malignant transformation process^[132]. An interesting question for future investigations would be to understand the role of FA metabolism in conferring drug resistance to LSCs in a niche-specific BM microenvironment.

ROLE OF EXTRACELLULAR VESICLES IN CONFERRING RESISTANCE BY MEDIATING COMMUNICATION BETWEEN LEUKEMIC CELLS AND MICROENVIRONMENT TO ALTER METABOLISM

AML cells alter the BM by releasing exosomes, which promote the proliferation and survival of leukemic cells and suppress normal hematopoiesis. In a study by Javidi-Sharifi *et al.*, the expression of FGF2 and its receptor, FGFR1, were both increased in several stromal cell lines and primary AML stroma. This heightened FGF2/FGFR1 signaling augmented greater secretion of exosomes^[133]. Huang *et al.* (2021), studied the impact of inhibition of small extracellular vesicle (SEV) secretion from various sources on the

progression of MLL-AF9 induced AML, as well as normal hematopoiesis^[134]. A significant delay in AML progression occurred when SEV secretion from endothelial cells was inhibited, but not that from perivascular cells, megakaryocytes, or spleen stromal cells^[134]. SEVs derived from endothelial cells contained high levels of Angiopoietin-like protein 2 (ANGPTL2) protein, which binds to the leukocyte immunoglobulin-like receptor B2 (LILRB2 receptor) and accelerates leukemia progression^[134]. Moreover, Vacuolar protein sorting-associated protein 33B (VPS33B) governed the release of ANGPTL2-SEVs from endothelial cells and this release of ANGPTL2-SEVs was required for primary human AML cell maintenance. These findings demonstrate that SEVs have a role in cancer development and suggest that targeting the release of ANGPTL2-SEVs from endothelial cells would be an effective strategy in the treatment of some types of AML^[134]. While IO-108, an antibody targeting LILRB2, is in Phase 1 clinical development for solid tumors^[135]; LILRB4 antibody (IO-202) is in phase 1 cohort expansion clinical trial [NCT0437243] in combination with azacitidine and venetoclax, for the treatment of AML and likely to be effective in monocytic AML^[136,137].

Cytarabine and decitabine treatment resulted in significantly higher intracellular levels of cholesterol and HMGCR (3-hydroxy-3-methyl-glutaryl-coenzyme A reductase), the rate-limiting enzyme in the cholesterol synthesizing mevalonate pathway, in cultured AML and non-malignant cells. Concomitantly, these cells produced higher levels of SEVs^[138]. Interestingly, there was an increase in HMGCR levels in SEVs in response to chemotherapy. These HMGCR+ SEVs promoted the growth of AML cells by upregulating intracellular cholesterol levels. This chemotherapy-induced enhancement of SEV secretion in AML cells was prevented by HMGCR inhibition^[138]. Thus, HMGCR blockade could potentially provide a therapeutic alternative in AML by inhibiting cholesterol-driven chemoresistance caused by SEV signaling^[138]. Another study reported the secretion of exosomes containing vascular endothelial growth factor (VEGF) and VEGF receptor (VEGFR) by AML cells. These exosomes induced glycolysis in human umbilical vein endothelial cells (HUVECs), which resulted in vascular remodeling and chemoresistance^[139].

BM stromal cells exposed to AML-derived exosomes exhibit decreased expression of genes supporting normal hematopoiesis (CXCL12, KITL, IL-7, IGF1) and osteogenesis (OCN, Col1A1, IGF1) and increased expression of genes supporting AML growth (DKK1, IL-6, CCL3)^[140]. When BM is preconditioned with AML-derived exosomes, AML cell engraftment and growth are significantly accelerated, whereas disruption of exosome secretion in AML cells significantly reduced these cells' ability to engraft and grow *in vivo*^[140]. In coculture, serum and leukemic cells from patients with NPM1-mutated AML impair CD8+ T cells' immune function^[141]. Through SEVs, leukemic cells secrete miR-19a-3p into the tumor microenvironment. This process was mediated by the NPM1-mutated protein/CCCTC-binding factor (CTCF)/poly (A)-binding protein cytoplasmic 1 (PABPC1). MiR-19a-3p released from SEV was found to be internalized by CD8+ T cells, where it inhibited creatine import by repressing the expression of a transporter solute-carrier family 6 member 8 (SLC6A8)^[141]. A reduction in creatine levels lowered ATP production and impaired CD8+ T cell immune function, which caused leukemic cells to escape the immune system^[141]. Interestingly, the exosomes generated by fully engrafted AML PDX mice were similar to exosomes isolated from the plasma of the patients who had donated the cells for engraftment. These exosomes carried human proteins and leukemia-associated antigens, confirming their origin from AML patients^[142].

AML utilizes SEV miRNAs to target the mTOR pathway which suppresses protein synthesis in the LT-HSC to elicit their quiescence^[143]. While LT-HSCs are functional after the recovery, their DNA is damaged for a long time. Hematopoietic stem and progenitor cells (HSPCs) are generally susceptible to SEV entry and use the mTOR pathway, but HSCs selectively enter quiescence because of their unique sensitivity to protein synthesis disruption^[143].

TECHNIQUES TO ASSESS MITOCHONDRIAL FUNCTION AND METABOLISM

A tightly coordinated flux of metabolites occurs in mitochondria, integrating bioenergetics, redox homeostasis, and anabolic metabolism. By assessing mitochondrial function, researchers have gained a better understanding of metabolism in cellular physiology, disease pathology, and etiology. The reduction of oxygen into water is essential to oxidative phosphorylation and measuring oxygen consumption is therefore one way to assess mitochondrial function^[144]. The mitostress test using a high-throughput real-time mode approach in Agilent Seahorse XF analyzers is the best assay for measuring basal cell respiratory rate, ATP production, proton leak, maximum respiration, and spare respiratory capacity in an intact cell^[145]. This single assay yields a wide range of parameters, providing insight into mitochondrial dysfunction and reveals the functional differences between cell types, cellular metabolic state (quiescent versus active), effect of drug candidates, impact of genetic modifications, or biochemical interactions^[146].

Mitochondria are known to generate approximately 90% of cellular reactive oxygen species (ROS)^[147]. As a result of excessive production of ROS and/or decreased antioxidant defense activity, mitochondrial reactive oxygen species (mtROS) accumulate, causing oxidative stress (OS). It leads to oxidative damage that affects several cellular components, including lipids, DNA, and proteins^[147]. To detect mitochondrial superoxide selectively, MitoSOX Red and Green are used, which are fluorogenic reagents designed for highly selective detection of superoxide in the mitochondria of viable cells^[148]. A notable feature of these probes is that they are readily and specifically oxidized by superoxide alone and not by other ROS or reactive nitrogen species (RNS) generating systems at optimum concentration. However, the user should be aware of the cytotoxic or mitotoxic effect of these probes and their potential impact on mitochondrial morphology at higher concentrations^[149]. Furthermore, oxidation of these probes is inhibited by superoxide dismutase. Small, cell-permeant dyes such as TMRM (tetramethylrhodamine, methyl ester) and TMRE (tetramethylrhodamine, ethyl ester) accumulate in active mitochondria and may be used to quantify mitochondrial membrane potential^[150]. They appear bright in healthy cells with functioning mitochondria, but are dimmed or undetectable upon loss of mitochondrial membrane potential^[151].

Metabolome consists of all the molecules with low molecular weight (metabolites) within a cell, tissue or organism. Analyzing the metabolites within a cell, tissue or organism following a genetic change or physiological stimulus is known as metabolomics^[152]. The metabolomics approach can be divided into two distinct types: untargeted metabolomics and targeted metabolomics. Targeted approaches focus on identifying and quantifying a small number of known metabolites, such as those found in clinical analyses. In untargeted approaches or hypothesis-generating approaches, data are obtained for as many species as possible, metabolites are annotated, and metabolic changes are reviewed regardless of whether they are known or unknown^[153]. However, measuring metabolite concentrations by metabolomics only tells half the story. The accumulation of metabolites can be caused not only by increased production, but also by decreased consumption. The metabolic flux, which can be quantified as material flow per unit time, is equally important for understanding pathway activity^[153].

Unlike metabolites, fluxes are not physical entities that can be detected by mass spectrometry. But they can be inferred by using isotope tracers. Radioactive tracer studies laid the groundwork for modern metabolism research^[154]. Today, similar studies can be performed using stable non-radioactive isotope tracers, which can be tracked quantitatively and broadly using MS or NMR^[155]. Furthermore, an approach called metabolic activity screening integrates the metabolomics data with metabolic pathways and systems biology data, including proteomics and transcriptomics, in order to identify endogenous metabolites that may alter phenotypic characteristics and functionality^[156].

CONCLUDING REMARKS

Nine therapeutic agents for AML have been developed and approved since 2017. Treatment improvements have increased the overall survival rate of AML patients, from 13% to 55% in those aged younger than 60 years and 8% to 17% in patients older than 60 years^[157]. Further improvements in our understanding of the disease would further improve outcomes. The genetic makeup of AML, as well as its metabolic requirements for survival and proliferation, are heterogeneous. Diverse types of metabolic vulnerabilities, including dependence on OXPHOS, amino acid metabolism, nucleotide metabolism, and fatty acid metabolism, were reported. In addition, metabolic changes occurring in the tumor microenvironment have also been used as therapeutic targets. However, a thorough understanding of biomarkers of response to these therapies and mechanisms of resistance and combinatorial therapies would pave the way for better clinical management of AML. Understanding how the genetic architecture works with the tumor microenvironment is critical to uncovering new vulnerabilities. In addition, a thorough understanding of the interactions between different cell populations within the BM microenvironment in response to transient stress due to therapy which leads to changes in nutrient availability and metabolic adaptations, will increase the chances of a true cure.

LSCs have metabolically distinct subpopulations and relapsed/refractory LSCs switch to alternative metabolic pathways to fuel OXPHOS, rendering them therapeutically resistant to conventional treatments. Developing treatment strategies that target these metabolic pathways is key to eliminating relapsed/refractory LSC populations and improving treatment outcomes.

DECLARATIONS

Acknowledgments

We thank Ann Sutton, scientific editor at Research Medical Library, The University of Texas MD Anderson Cancer Center, for editing this article.

Authors' contributions

Drafted the article: Sharma P

Revised the article critically for important intellectual content: Sharma P, Borthakur G

Abstract

Cancer Drug Resistance publishes contributions to understanding the biology and consequences of mechanisms that interfere with successful treatment of cancer. Since virtually all patients who die of metastatic cancer have multidrug-resistant tumors, improved treatment will require an understanding of the mechanisms of resistance to design therapies that circumvent these mechanisms, exploit these mechanisms, or inactivate these multidrug resistance mechanisms. One example of a resistance mechanism is the expression of ATP-binding cassette efflux pumps, but unfortunately, inhibition of these transporters has not proved to be the solution to overcome multidrug resistance in cancer. Other mechanisms that confer multidrug resistance, and the confluence of multiple different mechanisms (multifactorial multidrug resistance) have been identified, and it is the goal of this Special Collection to expand this catalog of potential multidrug resistance mechanisms, to explore novel ways to overcome resistance, and to present thoughtful reviews on the problem of multidrug resistance in cancer.

Keywords: Cancer drug resistance, multidrug resistance, ABC transporters, novel mechanisms of drug resistance

WHY MULTIDRUG RESISTANCE IN CANCER REMAINS AN UNSOLVED PROBLEM

The molecular understanding of the factors that contribute to the growth, invasiveness, and metastasis of cancer has led to an explosion of new treatments for cancer, including the development of targeted

chemotherapeutics. Unfortunately, although there have been clear improvements in early diagnosis and treatment of cancer, leading to improved prognosis and duration of survival, the patient with a metastatic solid tumor or many kinds of hematologic cancer will not be cured and will eventually succumb to their disease. This leads inevitably to the conclusion that curative treatments for cancer will require a much better understanding of the many mechanisms that result in resistance to treatment, especially multidrug resistance to chemotherapy.

A summary of the various means by which cancer cells might resist chemotherapy was published in 2016^[1]. These categories are still relevant today and include: (1) For targeted drugs, alterations by mutation in the targets or activation of alternative growth promoting pathways; (2) Changes in cell-based pharmacology, including drug efflux pumps, altered uptake systems, altered metabolism, sequestration and altered trafficking of drugs, *etc.*; (3) Epigenetic alterations in differentiation pathways, such as Epithelial to Mesenchymal Transition (EMT), altered transcription patterns, cell survival adaptations, loss of cell death pathways and stem cell-like states; and (4) Alterations in local tumor physiology and substratum, including other tumor-associated cells, changes in physical properties of the substratum, and altered blood supply. All of these potential resistance mechanisms can be facilitated by many of the known hallmarks of cancer, such as heterogeneity and genetic and epigenetic plasticity, which now include several characteristics such as resistance to apoptosis and avoidance of immune destruction, which help confer resistance to anti-cancer drugs^[2].

Recent reviews and original research articles have identified some novel mechanisms of resistance that fall into these categories but were unexplored until recently. These include the concepts of dormancy^[3], persistence^[4], metabolic plasticity^[5], the role of tumor-associated fibroblasts^[6], the integrated stress response^[7], the role of long noncoding RNAs (lncRNAs)^[8], microvesicles^[9], and transcriptional variability^[10]. To no one's surprise, the microbiome has turned out to affect response to chemotherapy^[11] and the constituents and physical properties of the extracellular matrix are also determinative^[12]. In addition, the use of machine deep learning to analyze the response of human cancer cells to therapy has been proposed as a new way to predict the success of chemotherapy^[13]. Ultimately, it might turn out that as cancers evolve and become more drug-resistant, they begin to morph into cells that are more like non-cancer cells in their metabolic pathways and physiology (and hence relatively resistant to chemotherapy) while still maintaining their growth, invasiveness, and metastatic phenotypes.

There are approximately 10,000 articles listed in PubMed that relate to mechanisms of drug resistance in cancer, yet we are still unable to identify the key features that result in the terminal multidrug resistance of many cancers. This conundrum was pointed out over a decade ago by Piet Borst in a prescient commentary in which he coined the term "pan-resistance" to describe this terminal resistance state^[14]. In this article, he explores a variety of explanations for this phenomenon and concludes that much more work is needed, particularly in the design of relevant animal models to study this phenomenon. We agree that much more information is needed and encourage the submission of articles that explore in more detail the basis of known molecular mechanisms of resistance, identify novel mechanisms of resistance, novel model systems, novel methods of analysis, and novel testable hypotheses.

It is worth considering the ATP-binding cassette (ABC) efflux transporters as a case in point. A substantial part of the existing literature on multidrug resistance is devoted to papers describing new inhibitors of P-glycoprotein (ABCB1) and the ABC transporters ABCG2 (BCRP) and the ABCC family, especially ABCC1 (MRP1). Although these transporters do frequently appear as the cause of multidrug resistance in

tissue culture models, and even animal models of multidrug resistance^[15,16], their major contribution to drug resistance appears to be related to their contributions to ADMET (absorption, distribution, metabolism, excretion, and toxicity) for anti-cancer drugs and many other drugs, and to their barrier functions, particularly the blood-brain barrier where their expression in capillary endothelial cells in the brain prevents brain accumulation of a high percentage of drugs in common use, including many chemotherapeutics^[17]. There is a clear role for ABC transporters in some cases of drug resistance in the clinic (Robey *et al.*^[18]), and new drugs targeted to kill cancer cells frequently turn out to be substrates for ABC transporters^[19]. However, more often than not, even for drugs known to be substrates for P-glycoprotein or ABCG2 efflux pumps, other mechanisms of resistance supervene. The consideration here for the cancer cell is what is the most efficient way to survive killing by anti-cancer drugs, and the use of ABC transporters is quite energy dependent.

In another very thoughtful commentary, Borst warns against expansive and inaccurate claims made about the clinical significance of expression of the ABC transporters in tumor cells^[20]. There is ample reason to study the complex mechanism of action, substrate and inhibitor specificity, physiological function, and pharmacologic impact of the ABC transporters, but claiming that P-glycoprotein (and even ABCG2 and ABCC1) is “responsible for multidrug resistance in cancer” and that there are no adequate inhibitors can be misleading without additional data implicating these transporters in specific cancers treated with specific drugs. It is our hope that articles submitted to the Special Collection of *Cancer Drug Resistance* will shed new light on the role of the ABC transporters in multidrug resistance, but not focus on another new inhibitor unless it is truly miraculous!

SOME QUESTIONS THAT STILL NEED TO BE ANSWERED ABOUT CANCER MULTIDRUG RESISTANCE

Although not intended to be a complete list of challenges remaining in the field of multidrug resistance, there are still quite a few basic questions that need to be more clearly formulated and answered in the literature and would be excellent subjects for papers submitted to this *Cancer Drug Resistance* Special Collection:

(1) Does resistance to a specific chemotherapy protocol reside among the pre-treatment population of cells, and is selected by the therapy, or does it arise through genetic or epigenetic changes in cancer during the course of therapy? This question harkens back to the 1969 Nobel Prize winning work of Luria and Delbruck^[21] that demonstrated using a fluctuation analysis that mutations to resistance pre-existed in the pre-treatment population of bacteria. Similar studies in cultured mammalian cells have confirmed these conclusions, and more recent studies on drug resistance in acute myeloid leukemia (AML), a disease where refractory cells often express ABC transporters^[22,23] suggest that most resistant subclones that arise were present prior to therapy^[24]. Similar conclusions were reached using melanoma cells and a lineage mapping approach known as FateMap^[25]. However, given that most chemotherapy is mutagenic, and that there are quite a few robust transcriptional and epigenetic responses to toxic therapy, it seems unlikely that all cancers will become resistant based on the intrinsic resistance of pre-treatment subclones. This is not an entirely academic question, since if pre-existing mechanisms of resistance can be detected, this would help guide chemotherapy. If resistance occurs post-treatment, then careful monitoring of the tumor population, as by circulating cancer cells or DNA, becomes essential unless these mechanisms turn out to be universal.

(2) Much of the progress in understanding multidrug resistance to date has been based on the application of new technologies. What new technologies should be used to catalog and determine the clinical significance of potential mechanisms of drug resistance? One obvious example is the use of CRISPR-based selections to

determine whether increased or decreased expression of specific genes enhances cell survival or leads to drug resistance^[26]. The downside of this approach is that it is limited to testing one gene at a time, but the advantage is that there is an immediate read-out of individual genes contributing to resistance without the need to identify a gene or genes whose expression or function is altered in tissue culture cells selected for resistance to a specific drug. Another technology that should reveal important information about pre-existing *vs.* induced resistance is lineage tracing, which allows the tracking of individual cells during the drug-selection process^[27]. The application of both of these approaches to model systems that more closely mimic the growth of human cancers will be an important advance.

(3) Can we develop more tractable model systems to study drug resistance? It is well-established that cultured cancer cells may bear little or no resemblance phenotypically and in terms of gene expression patterns to cells derived directly from cancers^[28]. Although some characteristics of the tumor of origin may be obtained, the complex networks that confer a selective advantage under adverse conditions are likely altered in cultured cells. So, a variety of different approaches have been taken to study cancer in the laboratory, including genetically engineered mouse models, primary tumor xenografts, usually in mice but more recently in other easier-to-study models such as zebrafish^[29], and cancer cell organoids^[30]. Very few of these models have been employed to study drug resistance, and more detailed studies of the evolution of drug resistance resulting in terminal pan-drug resistance, utilizing new, more informative technologies, would be welcome.

(4) Why do many cancers, after months or years of therapy and periods of dormancy, emerge, grow, and metastasize in a state that is entirely resistant to therapy? This is a problem in clinical research, requiring detailed timelines of cancer evolution enabled by improved molecular imaging, study of circulating cancer cells and DNA, and either repeat biopsies or rapid autopsies to allow transcriptional profiling of terminal cancers. Very few of these studies have been undertaken, but investment of the time and resources needed to do these studies would yield huge returns in knowledge and improved treatment.

CONCLUSIONS

Cancer is a difficult adversary. The investment in new, more targeted therapeutics has resulted in improved response, but multidrug resistance remains the major barrier to curative treatment of cancer with chemotherapeutics. New advances in technologies to detect drug resistance genes and model systems in which to study the evolution of cancer drug resistance should accelerate discovery in this area. *Cancer Drug Resistance* welcomes manuscripts that address the questions outlined in this Editorial as well as many others that are relevant and give new insights into the problem of multidrug resistance in cancer.

DECLARATIONS

Authors' contributions

Drafted the manuscript: Gottesman MM

Abstract

Aim: Neo-adjuvant chemotherapy is a common approach for the complex treatment of breast cancer (BC) and paclitaxel (PTX) is frequently included in the therapeutic regimen. However, the effect of PTX-based treatment is hard to predict precisely based on routinely used markers. As microRNAs are considered a new promising class of biomarkers, the link between miRNA expression and PTX resistance of BC cells needs to be well investigated. This study aimed at the identification of miRNAs associated with responses of BC cells to PTX.

Methods: Intrinsic PTX sensitivity and miRNA profiling were assayed in five BC cell lines to identify candidate miRNAs. Selected miRNA (*n*. 15) expressions were analyzed by real-time-quantitative polymerase chain reaction (RT-qPCR) in BC tissue samples (*n*. 31) obtained from a diagnostic biopsy. Results were analyzed in the context of the effect of two cycles of PTX and the effect of the completed scheme of neoadjuvant therapy. The study's design facilitated the evaluation of the effect of PTX on cells and the identification of features of the microRNA expression profiles associated exclusively with sensitivity to this drug.

Results: miR-186 and miR-7 expression in BC tissues was higher in patients with better outcomes of PTX-based neoadjuvant therapy.

Conclusion: High expressions of miR-186 and miR-7 are associated with good response to PTX, whereas their low expressions may be associated with resistance to PTX in BC, indicating the possibility of developing innovative test systems for the prediction of the PTX response, which can be used before the start of neo-adjuvant chemotherapy for BC.

Keywords: Breast cancer, paclitaxel, resistance, neoadjuvant therapy, miRNA, miR-186, miR-7

INTRODUCTION

Breast cancer (BC) is a common oncological disease. According to the International Agency for Research on Cancer, more than 2.2 million women were diagnosed with BC in 2020^[1]. Despite the constant progress in the development of new diagnostic and therapeutic approaches, BC poses a significant social burden across countries with different economies and healthcare systems. One of the most intriguing problems encountered in the treatment of BC is the disease's extreme heterogeneity^[2], which makes it difficult to choose the optimal approach for systemic therapy. Different molecular markers including sex hormone receptors (ER, PR), receptor of epidermal growth factors (HER2), markers of active proliferation (Ki-67, survivin, NGAL), and metastatic potency (MMP9, SK1, DcR3, CIX2, EZH2) are used currently in clinical practice to evaluate tumor properties and define the optimal therapeutic approaches. Several new tests and classifiers have been developed recently, although not approved so far, including PAM50^[3], EndoPredict^[4], Oncotype DX, Breast Recurrence Score, EndoPredict, Prosigna^[5], and others. However, the selection of BC chemotherapy regimen in clinical practice is still based on the short list of tumor characteristics such as histology, grade, stage, and IHC status of hormone receptors (HR), HER2, and Ki-67^[6]. These characteristics are far from exhaustive and their complex evaluation does not allow prediction of the inherent sensitivity of BC cells to specific cytostatic agents.

Neoadjuvant therapy (NAT) is integral to the treatment of patients with high-risk breast tumors, large breast tumors, and locally advanced tumors, including those who are initially ineligible for surgery. Several schemes of NAT are approved for early-stage BC of various biological types^[7]. For instance, neoadjuvant chemotherapy of HER2-negative BC may include different combinations of cytostatic agents such as anthracyclines, cyclophosphamide, and taxanes^[7] that can be administered in different sequential orders^[8]. These drugs have varied mechanisms of action-anthracyclines intercalate between DNA base pairs and block essential processes of DNA transcription and replication^[9]; cyclophosphamide is an alkylating agent forming intrastrand and interstrand DNA cross-links, thereby affecting DNA function^[10], whereas taxanes stabilize microtubules and affect the dynamic of the mitotic spindle^[11]. In the background of different mechanisms of action of these drugs, differential intrinsic sensitivity of an individual tumor to each of these is expected. Initiating NAT with presumably the most effective drug or their combination would provide the best response; however, new molecular markers are required to personalize the selection of optimal therapeutic scheme from a list of validated agents.

Paclitaxel (PTX) suppresses the polymerization dynamic of microtubules, resulting in mitotic arrests. Resistance to PTX can be mediated by general mechanisms (such as overexpression of the efflux drug proteins) or is associated with molecular mechanisms of the mitotic process, including tubulin isoforms ratio (TUBB3 overexpression), microtubule-associated proteins (Tau, MAP4) or spindle assembly checkpoint protein (Mad2, BubR1, Aurora A) functionality^[12,13]. Complex analysis of these molecules may be helpful to predict the effect of PTX. Among the various molecular markers of multidrug resistance or PTX resistance, small regulatory RNAs (microRNAs) appear to be a promising class^[14]. MicroRNAs or

miRNAs are involved in the control of all cellular functions, and some of them directly regulate the expression of proteins mediating the response of BC cells to PTX. For instance, miR-125b confers PTX resistance to BC cells through suppression of pro-apoptotic Bcl-2 antagonist Killer 1 (Bak1) expression^[15]. miR-451 is involved in the resistance of BC cells to PTX by targeting key regulators of cell survival and apoptotic machine 14-3-3 ζ proteins (YWHAZ)^[16]. miR-152 suppresses endothelial PAS domain-containing protein 1 (EPAS1), thereby enhancing the apoptosis rate and susceptibility of BC cells to PTX^[17]. miR-155 contributes to PTX resistance of BC cells through tumor protein p53 inducible nuclear protein 1 (TP53INP1)^[18]. miR-16 sensitizes BC cells to PTX through the suppression of IKBKB expression^[19]. miR-520h stimulates PTX resistance by targeting the OTUD3-PTEN axis in BC cells^[20]. Scientific data indicate the involvement of specific miRNA molecules in controlling PTX resistance. However, only a limited number of systemic investigations of the miRNA-mediated response of BC to PTX have been performed so far and the results of these studies are hardly comparable. Uhr *et al.* investigated the expression of 411 miRNAs in the context of sensitivity to 34 drugs (including PTX) in 36 BC cell^[21]. This large-scale experimental study showed an association between PTX sensitivity and miR-187, miR-106a, and miR-556 expression; however, these results were relevant to *in vitro* cultured cells only and were not evaluated in BC tissues. In contrast, Wu *et al.* investigated the network of transcription factor-miRNA-mRNA in samples of BC tissues (*n.* 50) before and after treatment with PTX^[22]. They observed an association between the effect of PTX and the expressional profile shift of several miRNAs (miR-508, miR-4445, miR-3545, miR-1911, miR-584, miR-4782, and miR-219). These exciting computational data require experimental validation.

In our study, we attempted to combine and take advantage of both experimental and observational approaches. First, potential markers of BC cell resistance to PTX were identified by combined analysis of miRNA expression profiles and intrinsic PTX sensitivity of five BC cell lines. Second, the expressions of selected miRNAs were analyzed in tumor tissues of patients with BC and their association with the effect of PTX-based NAT was verified. As the mechanism of PTX action is not related to the HR/HER2 status, patients with different BC subtypes were included in the study. The NAT of all patients was started with PTX, which allowed us to attribute the effect of the first two cycles to PTX sensitivity only. With this approach, we could identify miRNAs that are most likely associated with the phenomenon of inherent resistance of BC cells to PTX.

METHODS

BC cell lines

Cell lines were obtained from the Institute of Cytology (Russian Academy of Sciences). MCF7, BT20, MDAMB231, and MDAMB453 are widely used BC tissue-derived cell lines. The HBL-100 line was obtained from primary cultures of cells derived from an early lactation sample of human milk^[23]; however, following studies revealed the presence of Y chromosome and malignant characteristics of these cells^[24,25]. Small tandem repeat (STR) profiling was performed as a commercial service (InLab-genetics.ru) to confirm the identity of all used cell cultures [Supplementary Appendix 1-5]. All cell lines were cultured in RPMI 1,640 medium (PanEco, Moscow, RF) supplemented with 10% heat-inactivated fetal bovine serum (Biosera, Nuaille, France) and 1% penicillin-streptomycin (PanEco, Moscow, RF) at standard conditions.

Immunohistochemistry

Cells were cultivated on 4-chamber slides till they reached sufficient confluence. They were washed with PBS, fixed with 4% paraformaldehyde, permeabilized (for nuclear receptors assay) with 0.1% Triton X-100, blocked with 2% BSA, incubated with rabbit antibodies against ER, PR, or HER2 (Ventana Medical System Inc., Tucson, USA, cat. No. 790-4,325, 790-429, 6,790-4,493) and stained following the protocol specified in the detection kits (Ventana Medical System Inc., Tucson, USA).

Flow cytometry

Cells in suspension (1 million cells/250 μ L) were treated with BD Cytotfix/Cytoperm Kit (BD Bioscience, Heidelberg, Germany), washed with PBS, incubated with antibodies against ER, PR, or HER2 (Ventana Medical System Inc., Tucson, USA, cat. No. 790-4,325, 790-429, 6,790-4,493), washed again and stained with secondary anti-rabbit FITC-labeled antibodies (Abcam, Cambridge, UK, cat. No. AB6717). Analysis was performed using a CytoFLEX cytometer (Beckman Coulter, Brea, USA).

PTX toxicity and cell viability assays

Cells were seeded into 96-well plates and incubated till they reached 50% confluence. PTX (Sigma-Aldrich, St Louis, USA) was dissolved in DMSO to make the stock concentration of 2 mM, and working concentrations (200-1 nM) of the drug in a complete medium were prepared by serial dilution. PTX was applied to the cells at different concentrations by medium replacement. Control cells were treated with 0.01% DMSO in a complete medium, which corresponded to the amount of DMSO in PTX-treated cells at a maximum concentration (200 nM). Cells were incubated for 72 h and cell viability was assayed with the WST kit (Abcam, Cambridge, UK) following the manufacturer's protocol. The absorbance was measured at 450 nm using a multi-plate reader, Varioscan LUX (Thermo Fisher Scientific, Wolfteam, USA). Each measurement was done in triplicate and the results reflected the average value. The cell viability was expressed as a percentage of viable untreated cells ($\text{Mean OD}_{\text{sample}}/\text{Mean OD}_{\text{control}} \times 100$).

Patients

The study design was approved by the Ethics Committee of Petrov's NMRC of oncology 04.02.2021. All patients involved in the study signed the informed consent form. The diagnostic evaluation included whole breast ultrasound (US) investigation of the tumor and core biopsy; the NAT was started with PTX. The effect of therapy was evaluated after the first two cycles. The majority of patients ($n = 18$) included in the study received PTX monotherapy. In these cases, the expected effect was achieved, which allowed the operation to be performed. In some patients, the clinical effect of PTX was worse and after 6 ($n = 4$) or 12 ($n = 9$) cycles, PTX was replaced by a combination of doxorubicin and cyclophosphamide (AC). Radiation therapy before surgery was not applied in any of the patients. All clinical data obtained were depersonalized before analysis.

RNA isolation

Total RNA was extracted from the cell pellets containing one million cells with miRNeasy Mini kit (Qiagen, Hilden, Germany) following the manufacturer's protocol to analyze miRNA from BC cells. To analyze miRNA from BC tissues, material obtained from diagnostic biopsy was used. After morphological and IHC confirmation of the diagnosis, formalin-fixed, paraffin-embedded (FFPE) tissue samples were sectioned, deparaffinized by incubation with mineral oil and ethanol, and treated with proteinase K (Sileks Ltd., Moscow, RF). The digested samples were centrifuged at 10,000 g for 10 min and the supernatant was mixed with lysis buffer (guanidine thiocyanate, 2 M; sodium acetate pH 4 and 0.6 M; octanic acid, 0.5%, and 2% 2-mercaptoethanol), incubated for 3 min and centrifuged at 10,000 g for 3 min. The supernatant was mixed with 400 μ L of 95% ethanol and transferred into a silica spin column (BioSilica Ltd., Moscow, RF). The columns were washed twice with washing buffer and centrifuged to remove excess liquid. RNA was eluted with 120 μ L RNA elution solution (EDTA pH 9, 510 mM). The RNA quality and concentration were assayed with a Qubit fluorimeter (Thermo Fisher Scientific, Wolfteam, USA).

miRNA analysis

To profile miRNA in the culture of BC cells, the cDNA library was prepared using the Illumina TruSeq Small RNA library preparation Kit following the manufacturer's instructions. The libraries were sequenced on the Illumina HiSeq 3,000 platform, and sequencing reads were aligned with the STAR^[26] and normalized

using DESeq2^[27]. To assay the expression of selected miRNAs in BC tissue samples, reverse transcription was performed with two-tailed primer^[28] followed by PCR using ALMIR-miRNA Assay Kits and protocols (Algimed Techno, Minsk, Belarus) and Real-Time CFX96 Touch instrument (Bio-Rad, Hercules, USA).

Statistical treatment and software

Statistical analyses were performed and images were drawn using Microsoft Excel 2016 (Microsoft Corporation, USA), CytExpert Software 3 (Beckman Coulter, Inc., USA), Quest Graph™ IC50 Calculator (AAT Bioquest, Inc., USA), OriginPro 9.1 software (OriginLab Corporation, USA), GraphPad Prism software (GraphPad Software Inc., USA). To evaluate the statistical significance of the correlation between two parameters, the Pearson correlation coefficient (Pearson's *r*) was estimated. To evaluate the statistical significance of the difference between the two groups, the non-parametric Mann-Whitney test was applied.

RESULTS

Study design

To select miRNAs potentially associated with the response of BC cells to PTX, five cell lines were explicitly characterized for morphology, HR/HER2 status, PTX sensitivity, and miRNA profiling. This step allowed us to select 15 candidate molecules whose expression level was correlated with PTX sensitivity. The expression of these miRNAs was then assayed by RT-PCR in BC tissues from patients (*n*. 31) with different effects of PTX-based therapy [Figure 1].

BC cell line characteristics

To model the diversity of BC, we used five different BC cell cultures (MCF7, BT20, MDAMB231, MDAMB453, and HBL100). All cell cultures included in the study were established and characterized explicitly^[29-33]. Given that many passages can alter the characteristics of the cells, we evaluated their STR profiles and confirmed their identity [Supplementary Appendix 1-5]. The cells exhibited different morphologies [Supplementary Figure 1], thus reflecting the natural diversity of BC. Next, we analyzed the expression of steroid hormone receptors (estrogen receptor, ER α ; progesterone receptor, PR) and receptor of epidermal growth factor (HER2). Expression of ER and PR evaluated by IHC using antibodies routinely used for BC tissue staining was almost non-detectable in all cell lines (not shown). Flow cytometry is an additional approach to validate ER, PR and HER2 marker expression^[34]. Herein, flow cytometry was found to be more sensitive than IHC. Results are presented in Table 1.

Results are presented as a percentage of positive cells estimated as (positive cells · 100)/all assayed cells using CytEXPERT software. The difference in the expression of each marker within the five cell cultures is additionally demonstrated by color, while the maximum expression level is indicated by a completely shaded area, and the lower expression level is indicated by a proportionally smaller colored area.

We confirmed the ER- and PR-positive status of MCF7 cell line using flow cytometry. Moreover, other cell lines also showed ER and PR staining, but the signals were weaker than that of MCF7. This unexpected result was obtained with MDAMB453 cells, which were ER- and PR-positive as shown in Figure 2A (color legend are the same as in Figure 2) and confirmed by IHC [Figure 2B].

These observations contradict previously published data^[32,33] and may reflect the modification of cell phenotype or show the high sensitivity of flow cytometry.

PTX sensitivity of BC cells *in vitro*

All five cell lines were treated with PTX with different concentrations for 72 h and WST test was used to evaluate cell viability. IC50 values were calculated using the Quest Graph™ IC50 Calculator [Figure 3].

Table 1. Expression of ER, PR and HER2 in BC cell lines assayed by flow cytometry

REC\CELLS	MD A321	B T 20	MC F7	MD A435	H B L100
ER	1.78%	1.25%	4.64%	2.14%	1.39%
PR	1.60%	1.37%	3.52%	6.98%	1.71%
HER2	0.55%	2.41%	1.81%	76.25%	1.33%

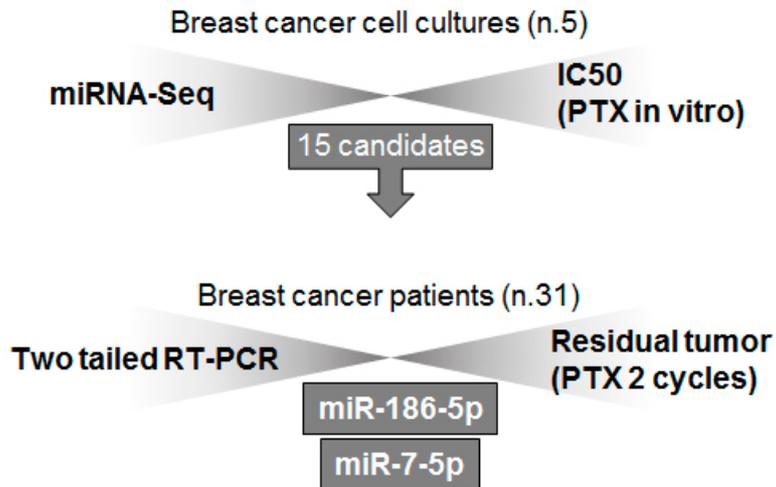

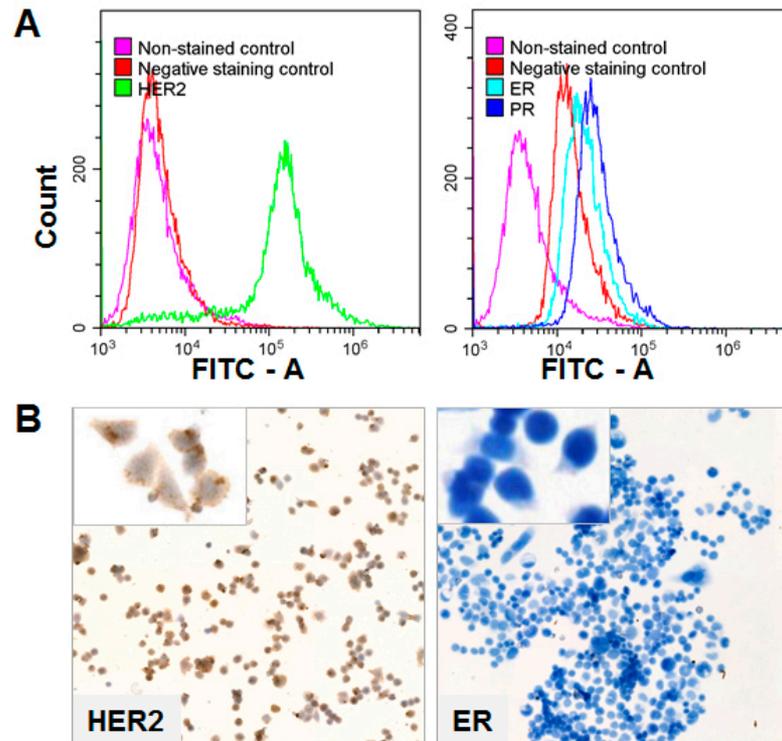

Figure 1. Study design.

**Figure 2.** Expression of HER2, ER, and PR in MDAMB453 cell culture evaluated by (A) Flow cytometry; and (B) immunohistochemistry. Images are shown at 10x and 40x magnification.

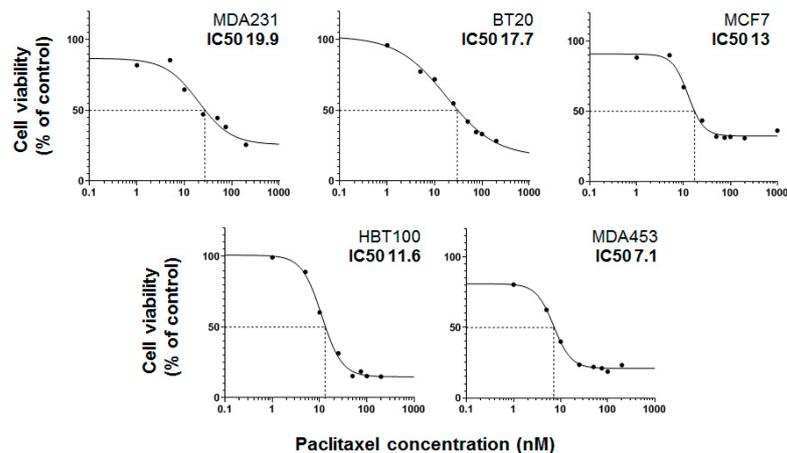

Figure 3. Sensitivity of different BC cell cultures to PTX *in vitro* evaluated by dose-dependent cell viability assay. PTX: Paclitaxel.

The PTX IC₅₀ (IC₅₀-PTX) values in tested cell lines varied considerably, ranging from 7.1 nM to 19.9 nM. MDAMB231 cells (derived from basal-like BC) with specific stellate morphology and low expression levels of ER, PR, and HER2 were relatively resistant to PTX. The BT20 cell line also established from basal-like tumors with similar morphological properties and receptor status was resistant, but slightly lesser (IC₅₀-PTX: 17.7 nM). Maximal sensitivity to PTX was observed in MDAMB453 cells derived from luminal BC with detectable levels of nuclear sex hormones receptors and high expression of the surface receptor, HER2. Both the MCF7 [ER (+)/PR (+)] derived from luminal BC and normal mammary epithelium cell line HBL-100 showed intermediate PTX sensitivity. Thus, cell lines derived from basal-like tumors with low levels of growth factor receptors were relatively resistant to PTX, whereas cell cultures derived from luminal BC or normal mammary epithelium with higher levels of growth factor receptors were more sensitive to PTX.

miRNA expression profiling in BC cell lines

The main goal of our *in vitro* experiments was to evaluate the possible link between miRNA expression patterns and inherent sensitivity to PTX. To assay a broad profile of cellular miRNAs, we performed sequencing. After bioinformatics analysis of miRNA sequencing data, 844 miRNAs were identified at least in one of five cell lines [Supplementary Table 1], with 705 to 750 different miRNAs obtained in each cell line. The total number of reads for each miRNA in each cell type varied from zero to 900,000, indicating a broad range of miRNA expression. Comparative representation of different miRNAs in analyzed samples is graphically shown in Figure 4A using the log scale on X-axis.

Thus, only 250 miRNAs in BT20 cells were quantified by more than 100 reads-292 miRNAs-in HBL100 cell culture, 265 miRNAs in MCF7, 247 miRNAs in MDAMB231, and 245 miRNAs in MBAMD453. Only 145 miRNA molecules reached 100 reads in all five cell lines tested, suggesting that relatively small numbers of miRNAs are represented typically and abundantly in studied cells. These miRNAs play a role in controlling basal cellular functions. Other molecules are less abundant and more variable across cell lines; these miRNAs can mediate temporal expressional alterations and control specific functions.

Next, we estimated the linear correlation between two sets of data (IC₅₀-PTX vs. normalized read count for each miRNA) in five cell lines using the Pearson correlation coefficient (Pearson's r). This coefficient exceeded the value of 0.8 for 48 miRNAs and exceeded 0.9 for 18 miRNAs including cases in both direct and inverse relationships [Supplementary Table 1]. An example of such correlation for miR-27a is

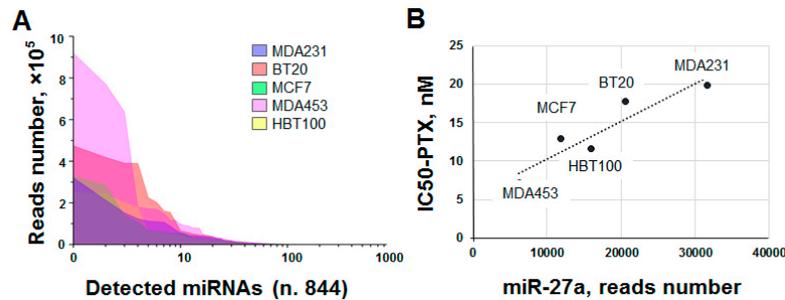

Figure 4. Sequencing of miRNAs in BC cell lines. (A) Overall frequency distribution of detected miRNAs schematically presented using OriginPro 9.1 software; and (B) representative example of the correlation between miRNA-27a expression level and IC50-PTX presented graphically using Microsoft Excel 2016. BC: Breast cancer; PTX: paclitaxel.

illustrated in [Figure 4B](#). We concluded that these molecules might be involved in the response of cells to PTX. In this case, their expression level and functionality might predict the cytostatic effect of the drug. To narrow the list and minimize the number of random matches, relevant scientific data analysis was performed using the PubMed library with the keyword combination of “breast cancer AND paclitaxel AND miR-XXX.” Fifteen miRNAs, listed in [Table 2](#), along with the value of Pearson’s *r* and relevant references, were selected for expressional analysis in BC tissue samples.

Expressional analysis of candidate miRNAs in BC tissue samples

BC tissue samples were obtained through diagnostic core biopsy and used for routine histological and IHC evaluation. The patients assigned to the PTX-based NAT group were included in the study and samples of their BC tissue were used for expressional assessment of the selected miRNAs. Characteristics of patients and tumors are presented in [Table 3](#).

Tumor size (before and after two cycles of PTX) was measured by whole breast ultrasound (US) in three dimensions (width, *W*; length, *L*, and height, *H*) and tumor volume was approximated assuming a rounded shape using the following equation: $V = 4/3 \cdot \pi \cdot 1/2W \cdot 1/2L \cdot 1/2H$. Neoadjuvant chemotherapy was started with an intravenous infusion of PTX at a dose of 80 mg/m² weekly as recommended by the national standard^[48]. The primary effect of therapy was evaluated after two cycles of PTX. Residual tumor volume after two cycles of PTX-based therapy (residual tumor size, RTS) was expressed as a percentage of its initial volume using the following equation: $RTS = (100 \times V_2)/V_1$. All patients underwent dynamic observation and received optimal therapeutic regimens based on their complex parameters [[Table 3](#)]. After NAT was completed, all patients underwent surgery (mastectomy) and the ultimate result of therapy was evaluated histologically [[Table 3](#)].

RTS after two cycles of PTX was a parameter reflecting the effect of a single drug. Interestingly, this parameter had an almost normal (Gaussian) distribution among the analyzed group of patients, reflecting the variability of intrinsic sensitivity of BC to PTX [[Figure 5A](#)].

Moreover, residual tumor size expressed as a percentage of initial tumor size directly correlated with Ki67 expression [[Figure 5B](#)]. Interestingly, we did not find any correlation between the results of histological evaluation of the completed scheme of NAT and Ki67 expression. This observation may indicate the cumulative nature of the action of PTX when an actively proliferating tumor requires long-term exposure to the drug, while a slowly proliferating tumor is suppressed faster. If this explanation is reasonable, it may take more than two weeks for PTX to exhibit a clinical effect.

Table 2. List of miRNAs selected for expressional analysis in BC tissue samples

miRNA	miRNA expression (reads number) in specific cell lines					Pearson's r*	Ref.

*Pearson coefficient for linear correlation between two sets of data (IC50-PTX vs. normalized read count for each miRNA) in five cell lines. PTX: Paclitaxel.

Expressions of 15 selected microRNA were assayed in all 31 samples of BC tissues obtained by core biopsy before the start of NAT. Results were normalized to average Ct (average of 465 individual values, 31 × 15). Subsequently, we attempted to identify the correlation between the expression of each selected miRNA and the known characteristics of the tumor. Patients were distributed into two groups based on tumor residual value after two cycles of PTX, i.e., more (*n*. 15) and less than 50% (*n*. 16). Expressions of miR-185 and miR-7 were higher in the tumor group more sensitive to PTX [Figure 6].

We did not find any correlation between the expression of other miRNAs tested and the effect of PTX. Finally, we did not find any correlation between candidate miRNA expression and results of post-surgery histological evaluation of NAT's effect using either the Miller&Payn system or Residual Cancer Border classification. When the analysis was applied to 18 patients treated only with PTX in the monotherapy regime, a statistically significant difference in miR-186-5p expression level was observed between groups of patients with different Residual Cancer Border statuses [Figure 7].

DISCUSSION

Several comprehensive genome-wide studies revealed alterations of miRNA profile in BC due to PTX treatment. The list of miRNAs affected by taxane includes molecules implicated in intrinsic resistance^[21,22]. MiRNAs apparently involved in acquired taxane resistance were identified by comparative analysis of miRNA profiles of docetaxel-resistant BC cell lines and docetaxel-sensitive parental cells^[49]. However, the results of different genome-wide investigations show negligible overlaps, highlighting the necessity of their confirmation by combining *in vivo* and *in vitro* approaches. Other studies combine BC tissue assessment and *in vitro* experiments, which usually focus on the molecular function of certain miRNAs only (12-17) and aim to identify new approaches to overcome taxane resistance.

This study aimed to identify the most reliable prognostic miRNA markers. As an example of a similar approach, the assay of global miRNA expression in BC tissue of patients with and without recurrence after

endocrine therapy followed by validation of selected miRNAs identified miR-30s, -30b, -182, and -200c as independent predictors of clinical benefit from endocrine therapy^[50]. We attempted to identify miRNA predictors of BC cell sensitivity to PTX, and an advantage of our study was a combination of experimental and observational approaches. First, we selected miRNAs whose expression levels were correlated with PTX sensitivity of BC cells *in vitro*. Second, we explored the correlation between the expression of these miRNAs in BC tissues and PTX-based NAT effect. We believe that this strategy helped us to increase confidence in the obtained results and identify miRNAs truly involved in the response of BC cells to PTX. As the mechanism of action of PTX is not associated directly with HR and/or HER2 status^[51,52], in our study, we analyzed BC tissue specimens from patients with different subtypes of BC, mostly HR+ /HER2-, and we did not attempt to evaluate any correlation between PTX effect and BC subtypes. The design of our study allowed the evaluation of the link between high levels of miR-186-5p and miR-7-5p expression and the effect of two weekly cycles of PTX. The effect of the complete scheme of NAT was associated with high expression of miR-186-5p in a group of patients treated with PTX only. In patients assigned to the neoadjuvant polychemotherapy (PTX-AC) group, no correlation between tested miRNA expression and

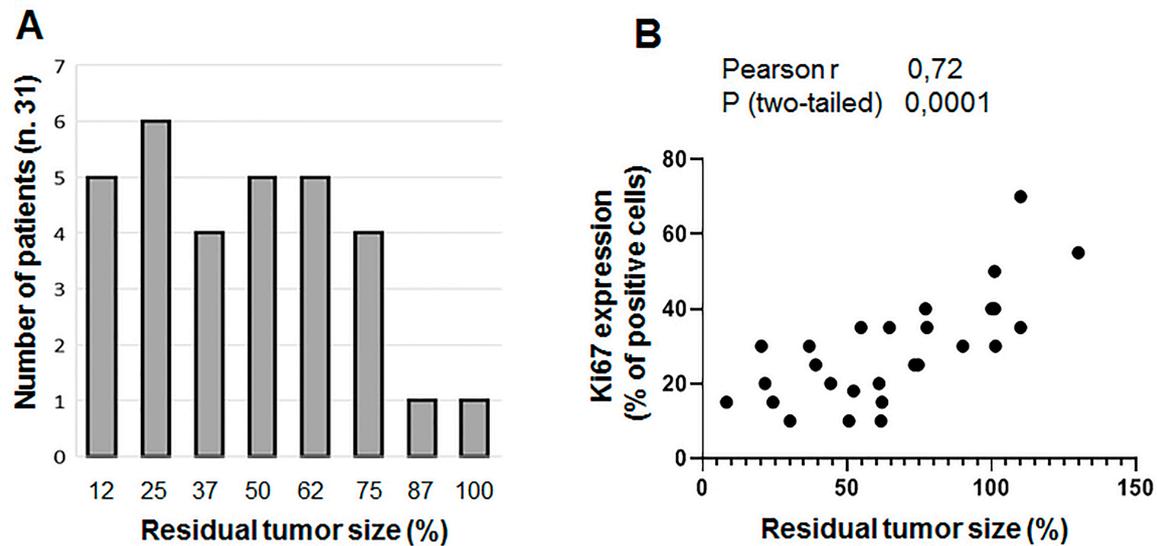

Figure 5. US-based evaluation of PTX-based therapeutic effect. (A) Distribution of patients according to size of residual tumor after two cycles of PTX; and (B) correlation between residual tumor size and Ki-67 expression in specimens from diagnostic biopsy. Both graphs were plotted using GraphPad Prism software. PTX: Paclitaxel.

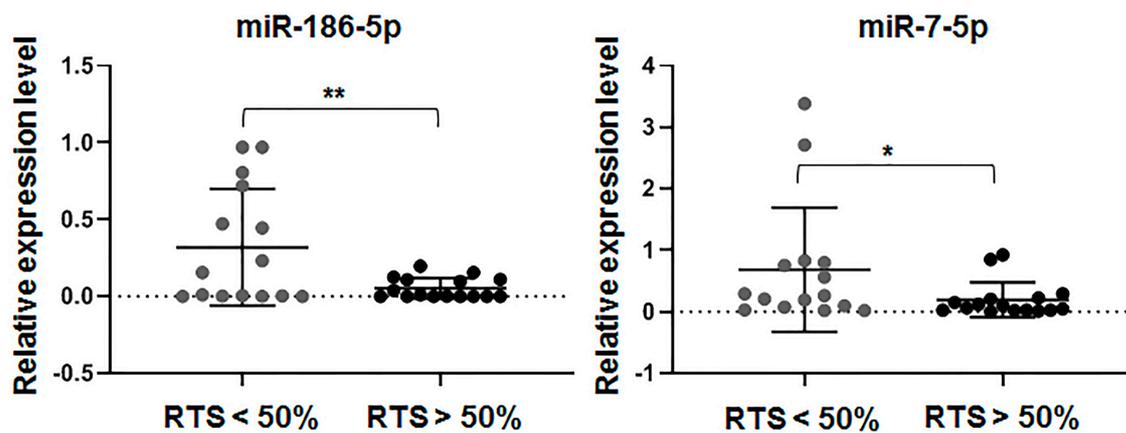

Figure 6. Expression of miRNA (miR-186-5p and miR-7-5p) in BC tissues of patients (*n.* 31) distributed into two groups with the differential effect of PTX-based therapy evaluated as the relative RTS. Statistical significance was estimated by the Mann-Whitney test ($^*P < 0.05$; $^{**}P < 0.005$). Graphs were plotted and statistical analysis was performed using GraphPad Prism software. BC: Breast cancer; PTX: paclitaxel; RTS: size of tumor residual.

residual cancer border classes was found. This might highlight the specific association between miR-186-5p expression and PTX sensitivity.

The role of miRNA-186 in cancer is well-studied. Recent reviews have described the dual properties implicated in carcinogenesis and the involvement in various cellular processes^[53,54]. In the context of BC, miR-186 was reported as an onco-miR that mediates highly aggressive and metastatic phenotype of tumor^[55]. However, miR-186 sensitized non-small lung cancer (*in vitro* and *in vivo*) to PTX by modulating MAPK activity^[56]. After computational prediction of the miR-186 binding site in 3'UTR of ABCB1, the

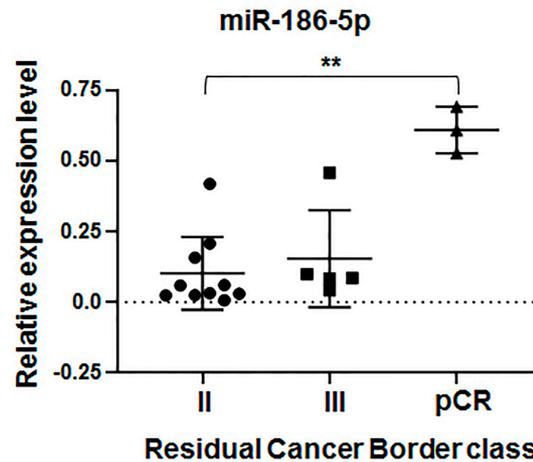

Figure 7. Expression of miR-186-5p in BC tissues of patients ($n = 18$) distributed into three groups with differential effect of complete scheme of PTX-based therapy evaluated after surgery using Residual Cancer Border Classification. Statistical significance was estimated by the Kruskal-Wallis test ($P < 0,005$). Graphs were plotted and statistical analysis was performed using GraphPad Prism software. PTX: Paclitaxel.

mechanism of miR-186-mediated sensitivity to PTX was evaluated in *in vitro* models of ovarian cancer^[57]. As demonstrated here, the expression of miR-186 was higher in BC cell lines sensitive to PTX and in samples of BC effectively treated by PTX. Therefore, miR-186 may sensitize BC cells to PTX through mechanisms described previously for other cancers.

The link between miR-7 expression and PTX sensitivity observed in our study is consistent with results published by other groups. Interestingly, the sensitization to PTX by miR-7 was reported in the same cancer types as miR-186, including non-small cell lung and ovarian cancer^[58,59]. The mechanisms of miR-7 action were non-related to microtubular apparatus and had universal character (regulation of EGFR/ERK signaling). miR-7 was significantly overexpressed (fold change > 3) in response to PTX treatment in a cell line (FaDu) derived from hypopharyngeal tumor^[60], reflecting the implication of this molecule in the adaptive reaction of cells to the drug. As reported recently^[45], in BC cells, miR-7 reversed resistance to PTX by targeting both the multidrug resistance-associated protein 1 (MRP1) and anti-apoptotic B cell lymphoma 2 (BCL2).

In conclusion, presented results showed that miR-185 and miR-7 expressions are higher in PTX-sensitive BC cells than in resistant cells. It was demonstrated for the first time that the overexpression of these molecules in BC tissues is associated with sensitivity to PTX, whereas their downregulation may reflect resistance to PTX applied as monotherapy. The innovative potential of the presented results lies in the possibility of developing new approaches for predicting the effect of PTX therapy based on the analysis of miRNAs in biopsy material. Since different miRNAs reflect the intrinsic resistance of BC to different drugs, a miRNA prediction panel can be developed and proposed as an additive approach for the personalized choice of NAT regimen.

DECLARATIONS

Authors' contributions

Patients evaluation and selection, collection and analysis of clinical data: Apollonova V

Cell culture experiments including WST test and flow cytometry: Plevako D

RNA sequencing including RNA isolation, small RNA library preparation, sequencing and data analysis: Garanin A

Cell culture experiments including WST test, immunocytochemistry, RNA isolation and RT-PCR: Sidina E

Sequencing data analysis and visualization: Zabegina L

Curation of all RT-PCR experiments including evaluation of specific miRNA Assay Kits, adaptation of protocols and data analysis: Knyazeva M

Histological evaluation of core biopsy material, preparation of slides from paraffin blocks: Smirnova V

Histological evaluation of core biopsy material: Artemyeva A

Study design, clinical evaluation of patients: Krivorotko P

Study design, project administration and manuscript writing: Malek A

Availability of data and materials

Not applicable.

Financial support and sponsorship

The study was funded within the framework of a state assignment (121032300206-4) by the Ministry of Health of the Russian Federation.

Conflicts of interest

All authors declared that there are no conflicts of interest.

Ethical approval and consent to participate

The study was conducted in accordance with the Declaration of Helsinki and approved by the Ethics Committee of N.N. Petrov National Medical Research Center of Oncology (protocol No.1 from 2021.01.28). Informed consent was obtained from all subjects involved in the study.

Consent for publication

Abstract

The development of immune checkpoint blockade (ICB) therapies has been instrumental in advancing the field of immunotherapy. Despite the prominence of these treatments, many patients exhibit primary or acquired resistance, rendering them ineffective. For example, anti-programmed cell death protein 1 (anti-PD-1)/anti-programmed cell death ligand 1 (anti-PD-L1) treatments are widely utilized across a range of cancer indications, but the response rate is only 10%-30%. As such, it is necessary for researchers to identify targets and develop drugs that can be used in combination with existing ICB therapies to overcome resistance. The intersection of cancer, metabolism, and the immune system has gained considerable traction in recent years as a way to comprehensively study the mechanisms that drive oncogenesis, immune evasion, and immunotherapy resistance. As a result, new research is continuously emerging in support of targeting metabolic pathways as an adjuvant to ICB to boost patient response and overcome resistance. Due to the plethora of studies in recent years highlighting this notion, this review will integrate the relevant articles that demonstrate how tumor-derived alterations in energy, amino acid, and lipid metabolism dysregulate anti-tumor immune responses and drive resistance to anti-PD-1/PD-L1 therapy.

Keywords: Immunotherapy resistance, tumor-immune microenvironment, immune checkpoint blockade, energy metabolism, amino acid metabolism, lipid metabolism

INTRODUCTION

The development of immune checkpoint blockade (ICB) therapies revolutionized cancer treatment across a variety of indications. Immune checkpoints are necessary for the controlled initiation and termination of immune responses as well as for the maintenance of self-tolerance, which are critical in preventing autoimmunity^[1]. However, tumors leverage this checkpoint system to inappropriately dampen the immune response and facilitate immune escape^[1]. Continuous antigen stimulation drives the upregulation of checkpoint receptors on CD8⁺ T cells^[2], while tumor cells exploit a variety of mechanisms to upregulate checkpoint ligands. Therefore, blocking the interaction between immune checkpoint receptors and ligands reinvigorates CD8⁺ T cell function to elicit tumor cell killing. There are several ICB therapies that are currently utilized in the clinic, but the most well-studied are anti-programmed cell death protein 1 (anti-PD-1), which is predominantly found on T cells, and anti-programmed cell death ligand 1 (anti-PD-L1), which is expressed on tumor and myeloid cells^[3]. While anti-PD-1/PD-L1 treatments are widely used, a substantial number of patients are resistant to this type of therapy^[4], prompting researchers to identify resistance mechanisms that drive inadequate outcomes. Response to ICB is largely dependent on the existing profile and infiltration of immune cells within the tumor, specifically CD8⁺ T cells, because they are the main contributors to anti-tumor effects^[4]. Therefore, modulating the tumor-immune microenvironment (TIME) to enhance CD8⁺ T cell infiltration and function, in combination with current ICB therapies, serves as an attractive approach to increase efficacy and overcome resistance.

The intersection of cancer and metabolism has been at the forefront of oncology research for several decades. Otto Warburg and his identification of the Warburg effect, wherein malignant cells exhibit a metabolic shift from oxidative phosphorylation to glycolysis^[5], ignited massive research efforts towards uncovering the metabolic reprogramming that occurs in tumors. These efforts led to the classification of dysregulated tumor cell metabolism as one of the hallmarks of cancer in 2022^[6]. Therefore, altered metabolism of lipids, amino acids, carbon, and nucleotides, to name a few, are highly implicated in the development and progression of cancer^[7]. More recently, this field of onco-metabolism has expanded to include the immune system, given its role in regulating tumorigenesis. Immune cells and their subtypes have different metabolic requirements during activation, differentiation, and expansion^[8], wherein alterations in the extrinsic metabolome at any of these stages can lead to immune cell dysfunction. The TIME is an objectively harsh environment for many cell types due to its acidity, hypoxia, nutrient deprivation, and accumulation of inhibitory metabolites^[9]. To the advantage of the tumor, malignant and immunosuppressive cells, such as T regulatory cells (Tregs), myeloid-derived suppressor cells (MDSCs), and macrophages, are better adapted to this oppressive environment compared to anti-tumor CD8⁺ T cells^[10]. These conditions, which are largely facilitated by cancer cells, heavily contribute to decreased CD8⁺ T cell infiltration and function.

There is mounting evidence that tumor-intrinsic metabolic reprogramming has a profound effect on the recruitment and function of various immune cell types within the TIME. As such, it is necessary to identify ways to specifically target malignant cell metabolism to enhance the efficacy of ICB. The scope of this review article will aim to cover the current literature that demonstrates how tumor-derived alterations in energy, amino acid, and lipid metabolism within the TIME mediate CD8⁺ T cell dysfunction and how targeting these pathways combats resistance to anti-PD-L1/PD-1 treatment.

ENERGY METABOLISM

Energy metabolism includes a complex network of biochemical pathways that contribute to sustained cellular function through the production of adenosine triphosphate (ATP). Some of these processes include glycolysis, the tricarboxylic acid (TCA) cycle, and fatty acid β -oxidation. A shift in energy metabolism

towards the Warburg effect in malignant cells generates high levels of lactic acid, while consuming and producing ATP/adenosine diphosphate (ADP) and oxidizing and reducing nicotinamide adenine dinucleotide (NAD). While concurrently studying lactate, adenosine, and NAD⁺ in the context of energy metabolism is important, each individual metabolite uniquely influences the function of malignant and immune cells within the TIME. Therefore, this section will focus on how the altered metabolism of lactate, adenosine, and NAD⁺ by tumor cells impacts the anti-tumor immune response by CD8⁺ T cells and contributes to anti-PD-1/PD-L1 resistance.

Lactate

Lactate is predominantly formed through glycolysis, wherein lactate dehydrogenase (LDH) reduces pyruvate to lactic acid, which then dissociates into hydrogen (H⁺) and lactate ions [Figure 1]. To a lesser extent, glutaminolysis also drives pyruvate formation, resulting in lactic acid production^[11]. Lactate and H⁺ are exported through proton-linked monocarboxylate transporters 1-4 (MCT1-4)^[12], wherein export is highly dependent on the existing concentration of extracellular lactate^[13]. Intracellular lactate levels are also modulated by import through MCT1^[14]. Extracellular lactate facilitates intracellular signaling by binding to hydroxycarboxylic acid receptor 1 (HCAR1), which regulates a variety of downstream oncogenic pathways, such as cell proliferation, migration, and invasion^[15]. Accumulation of H⁺ via lactic acid production contributes to the acidity of the TIME, which promotes an immunosuppressive milieu^[16]. Conversely, lactate ions have both tumor-promoting and -inhibiting effects in CD8⁺ T cells.

T cells require adequate levels of lactic acid for proper development and function^[17,18], but excess amounts in the TIME and intracellularly promote dysfunction. Tumor-derived lactic acid accumulation within the TIME inhibits T cell proliferation and cytokine production by altering redox homeostasis^[19]. Specifically, lactic acid downregulates T cell production of both reactive oxygen species (ROS) and the antioxidant glutathione^[19]. While excess amounts of ROS promote oxidative stress, low levels are important for T cell activation and signaling^[20], suggesting that tumor-derived lactic acid inhibits T cell functions by ablating ROS formation. Additionally, overabundance of lactic acid in the TIME prevents T cell export of lactate and H⁺ ions because of the unfavorable concentration gradient, and subsequent accumulation promotes intracellular acidification and decreases effector function^[21]. In particular, intracellular acidification in T cells due to tumor-derived lactic acid production prevents the expression of nuclear factor of activated T cells (NFAT)^[22], a family of transcription factors that mediate T cell development^[23]. In CD8⁺ T cells, decreased NFATC1 expression reduces IFN γ production, whereas inhibiting lactate dehydrogenase A (LDHA) reduces intracellular acidification and restores CD8⁺ T cell function and tumor infiltration^[22]. Similarly, the hypoxic nature of the TIME drives upregulation of LDHA in CD8⁺ tumor-infiltrating lymphocytes (TILs), leading to excess intracellular lactic acid, which then inhibits IFN γ and granzyme B production^[24] and T cell expansion^[18]. Upon chronic antigen stimulation, CD8⁺ T cells will progress through progenitor exhausted and terminally exhausted states, with the latter resulting in dysfunction and the inability to elicit anti-tumor effects^[25]. Therefore, there has been a significant focus on promoting the expansion of non-exhausted states and inhibiting the progression into terminal exhaustion to reinvigorate the anti-tumor response. Researchers found that treatment of CD8⁺ T cells with IL-21 promotes expansion but does not drive T cells towards an exhausted state, like IL-2^[18]. Moreover, IL-2, but not IL-21, induced metabolic reprogramming in T cells to favor glycolysis and shunt pyruvate towards lactic acid formation^[18]. Treatment with IL-2 and LDH inhibitor invoked a shift from glycolysis towards oxidative phosphorylation, and IL-2 or IL-21 treatment in combination with LDH inhibitor increased stem cell memory T cell formation and reduced tumor growth^[18]. These data demonstrate that tumor-derived lactic acid can directly or indirectly inhibit T cell function and anti-tumor immune response.

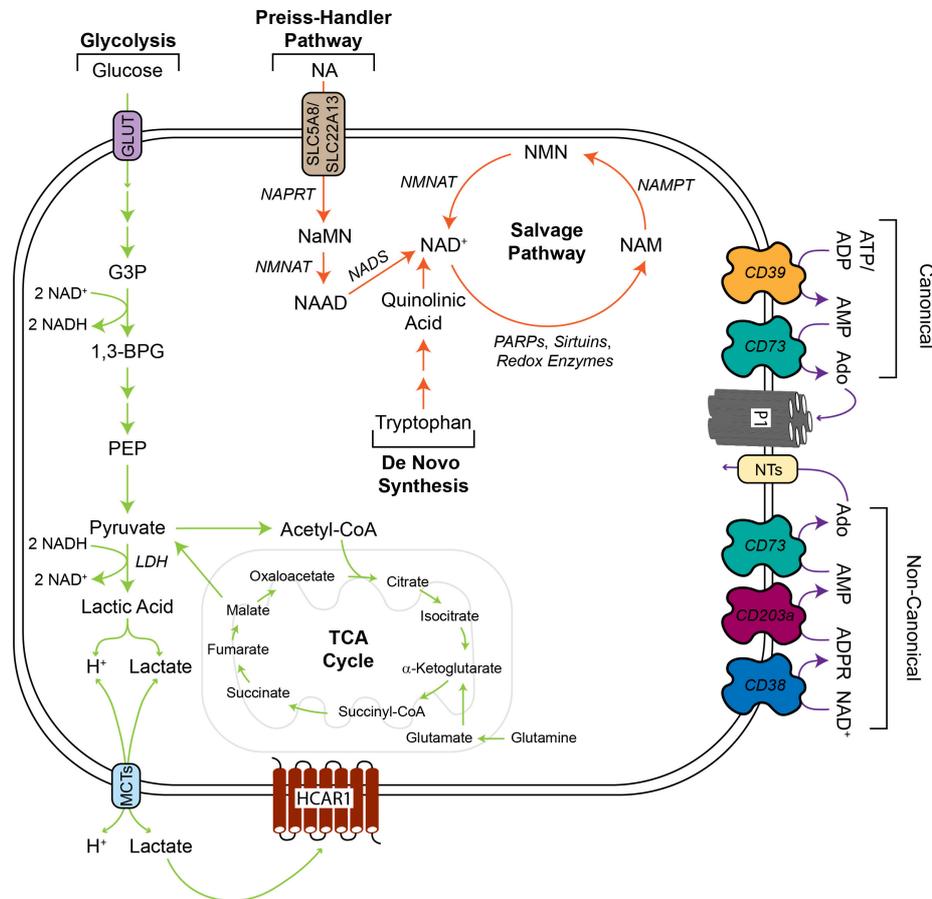

Figure 1. Energy metabolism pathways for lactate, adenosine, and NAD^+ . Pyruvate is generated predominantly through glycolysis, but the TCA cycle also contributes to pyruvate production via conversion from malate. LDH catalyzes the reaction to convert pyruvate to lactic acid, which dissociates into H^+ and lactate ions that are exported and imported through MCTs. Alternatively, pyruvate can be converted to acetyl-CoA to participate in the TCA cycle to drive energy metabolism. In the TIME, H^+ contributes to the low pH and lactate facilitates a variety of intracellular signaling pathways by binding to HCAR1. Extracellular adenosine is formed through both the canonical and non-canonical pathways. The canonical pathway utilizes CD39 to convert ATP or ADP to AMP and CD73 to convert AMP to adenosine. The non-canonical pathway metabolizes NAD^+ to ADPR through CD38, ADPR to AMP through CD203a, and finally, AMP to adenosine via CD73. Extracellular adenosine binds to P1 to initiate intracellular signaling pathways or is imported through NTs. Note: adenosine generated by the canonical and non-canonical pathways participates in both P1 signaling and NT import. NAD^+ is formed through the Preiss-Handler pathway, de novo synthesis, salvage pathway, and various enzymatic reactions in energy metabolism, such as PEP to pyruvate. The Preiss-Handler pathway imports NA and forms NAD^+ through a series of enzymatic reactions. De novo synthesis of NAD^+ results from the metabolism of tryptophan and the salvage pathway recycles NAM to regenerate intracellular NAD^+ levels. NAD^+ serves as a co-factor for many enzymes and participates in redox reactions, such as pyruvate to lactic acid. Ado: Adenosine; ADP: adenosine diphosphate; ADPR: adenosine diphosphate ribose; AMP: adenosine monophosphate; ATP: adenosine triphosphate; GLUT: glucose transporter; G3P: glycerol-3-phosphate; H^+ : hydrogen; HCAR1: hydroxycarboxylic acid receptor 1; LDH: lactate dehydrogenase; MCTs: monocarboxylate transporters; NA: nicotinic acid; NAAD: nicotinic acid adenine dinucleotide; NAD^+ : nicotinamide adenine dinucleotide; NADS: NAD^+ synthetase; NAM: nicotinamide; NaMN: nicotinic acid mononucleotide; NAMPT: nicotinamide phosphoribosyltransferase; NAPRT: nicotinic acid phosphoribosyltransferase; NMNAT: nicotinamide mononucleotide adenylyltransferase; NMN: nicotinamide mononucleotide; NTs: nucleoside transporters; PARP: poly (ADP-ribose) polymerase; PEP: phosphoenolpyruvate; P1: type 1 purinergic receptors; TCA: tricarboxylic acid; 1,3-BPG: 1,3-Bisphosphoglycerate.

Lactate serves as a carbon source in both tumor and T cells^[26-28], but like with any metabolite, overabundance dampens cellular functions. In T cells, increased lactate metabolism depletes NAD^+ levels by reducing it to NADH, preventing the downstream glycolytic processes that rely on NAD^+ ^[29]. Similarly, reduced glycolytic flux in T cells diminishes serine production, which is critical for T cell proliferation^[29]. Moreover, tumor-derived lactate promotes depletion of NAD^+ in naïve T cells, resulting in translation inhibition of FIP200, which forms one subunit of the ULK kinase complex that regulates autophagy^[30]. FIP200 is selectively lost in naïve T cells from ovarian cancer patients, wherein autophagy is suppressed,

leading to mitochondrial dysfunction and, ultimately, apoptosis^[30]. Genetic ablation of FIP200 in naïve T cells reduced CD8⁺ and CD4⁺ T cell infiltration and IFN γ production^[30]. Recently, tumor-derived lactate was also found to diminish TCA-intermediate recycling in CD8⁺ T cells by inhibiting pyruvate carboxylase, which shunts pyruvate to oxaloacetate^[31]. Pyruvate carboxylase is exceedingly important to maintain TCA cycle anaplerosis in CD8⁺ T cells because succinate is diverted from the TCA cycle to participate in autocrine signaling^[31]. In addition to tumor-derived lactate suppressing CD8⁺ T cell function, it also drives the expansion and function of immunosuppressive cells. Tregs inhibit the function of anti-tumor immune cells and require lactate to maintain their suppressor functions in the harsh TIME^[32,33]. Moreover, lactate produced by cervical cancer cells supports immunosuppressive macrophages by regulating anti-inflammatory cytokine production and HIF1 α expression^[34]. Taken together, these data highlight that tumor-derived lactate not only directly inhibits effector T cell functions, but also indirectly through supporting immunosuppressive cell populations. As such, multiple reports have examined the feasibility of inhibiting tumor-intrinsic lactate metabolism in combination with anti-PD-1/PD-L1 therapy.

Several correlative studies through bioinformatic analyses have demonstrated that targeting lactic acid metabolism might overcome ICB resistance and yield better patient outcomes. High LDH expression has been evaluated as a selection criterion for and predicting response to ICB therapy^[35-39]. Similarly, other lactate-related genes have been correlated with the expression of immune checkpoint proteins, CD8⁺ T cell infiltration, and resistance to ICB in breast cancer^[40]. Moreover, decreased glycolytic flux in melanoma patients treated with anti-PD-1 therapy was associated with increased probability of progression-free survival^[41].

In addition to bioinformatics studies, numerous reports indicate that inhibiting tumor-intrinsic lactic acid metabolism in combination with anti-PD-1/PD-L1 therapies combats resistance and increases efficacy. MCT4 is regulated at the mRNA level by the demethylase alkB homolog 5 (ALKBH5)^[42]. Genetic or pharmacologic inhibition of ALKBH5 reduces intratumoral lactate concentration and the number of Tregs and MDSCs, but has no effect on the number of infiltrating cytotoxic T cells^[42]. Furthermore, utilizing a small molecular inhibitor of ALKBH5 significantly improved the efficacy of anti-PD-1 treatment in murine melanoma tumors^[42]. Consistent with the findings that lactic acid benefits immunosuppressive cells, researchers found that lactic acid produced by high-glycolytic tumors drove expression of PD-1 on Tregs, but not CD8⁺ T cells, leading to anti-PD-1 resistance^[43]. However, inhibiting either LDHA in tumors or MCT1 in Tregs combined with anti-PD-1 therapy reversed these effects^[43]. In addition to inhibiting lactic acid production and/or lactate import, antagonizing intracellular lactate signaling in malignant cells through HCAR1 also promotes anti-tumor effects^[44]. Abrogating HCAR1-mediated lactate signaling sensitized tumors to anti-PD-1 and metformin treatment, leading to reduced tumor volume and increased CD8⁺ T cell infiltration and IFN γ production^[44].

While a plethora of evidence supports the notion that lactic acid production by tumors and accumulation in T cells drives oncogenesis, a few reports contradict this idea. In mouse melanoma tumors, blocking the export of lactate and H⁺ ions through MCT1 and MCT4 reduced the acidification of the TIME^[41]. While blocking MCT1 and 4 in T cells decreased lactate secretion and glucose uptake, it surprisingly did not impair IFN γ production^[41], which contrasts with other findings that accumulation of intracellular lactic acid promotes acidification and dampens effector functions^[21,22,24]. The authors found that inhibiting MCT1 and 4 activities in T cells increased glucose flux through the TCA cycle and increased oxygen consumption, thus providing an explanation as to why CD8⁺ T cell effector functions were preserved^[41]. Moreover, pharmacologically inhibiting MCT1 and 4 in combination with anti-PD-1 treatment resulted in increased efficacy and decreased tumor volume^[41]. The results from these findings are indeed surprising given the

mounting evidence that accumulation of lactic acid within T cells dampens their function. Researchers have also found that lactate, when studied separately from H⁺ in the form of sodium lactate, induces stemness and tumor infiltration, and reduces apoptosis in CD8⁺ T cells^[45]. Moreover, sodium lactate supplementation in three mouse tumor models showed synergistic effects with anti-PD-1 treatment^[45]. A plausible explanation for these somewhat contradictory findings is that variations between the TIMEs of different tumor types metabolically reprogram CD8⁺ TILs in distinct ways, wherein some tumors drive increased sensitivity of CD8⁺ TILs to lactic acid. Therefore, it is exceedingly important to delineate the metabolic changes in CD8⁺ TILs from different tumor types to identify the most effective therapy.

Additional research is needed to tease apart the intricate relationship between lactate, lactic acid, tumor cells, CD8⁺ T cells, and immunosuppressive cells. Inhibiting tumor-derived lactic acid production seems to generally have anti-tumor effects, due to the detrimental effects of high acidity on the anti-tumor immune cells within the TIME. While lactate ions serve as a carbon source and promote CD8⁺ T cell stemness, they also benefit immunosuppressive cells and excess amounts can dampen T cell effector functions. Collectively, these data demonstrate that tumor-derived alterations in lactic acid metabolism contribute to ICB resistance and modulating these pathways may augment efficacy, prompting the need for continued research efforts in this field.

Adenosine

Adenosine is formed through two major pathways [Figure 1]. In the canonical pathway, ectonucleoside triphosphate diphosphohydrolase-1 (CD39) hydrolyzes ATP or ADP to adenosine monophosphate (AMP)^[46], which is subsequently converted to adenosine by ecto-5'-nucleotidase (CD73)^[47]. The non-canonical pathway involves the conversion of NAD⁺ to adenosine diphosphate ribose (ADPR) through cyclic ADP ribose hydrolase (CD38); ADPR is then metabolized to AMP via ectonucleotide pyrophosphatase/phosphodiesterase 1 (CD203a), and finally to adenosine through CD73^[48]. Extracellular adenosine has several fates; it is converted to inosine via adenosine deaminase, converted back to AMP through adenosine kinase, or binds to type 1 purinergic receptors, which include A₁, A_{2A}, A_{2B}, and A₃. Both A_{2A} and A_{2B} receptors (A_{2A}R and A_{2B}R) are important for mediating adenosine signaling in immune cells within the TIME^[49]. High affinity A_{2A}R is more broadly expressed on immune cells, while low affinity A_{2B}R facilitates the expansion of MDSC populations^[50].

Within the TIME, adenosine formation is predominantly mediated by malignant and immunosuppressive cells^[51] and the impact of this metabolite on immunosuppression and cancer progression was recently comprehensively reviewed^[52]. Under physiological conditions, extracellular ATP and adenosine levels are low^[53]. However, during cellular stress, such as hypoxia and nutrient deprivation, intracellular ATP is released and serves as a strong pro-inflammatory mediator by recruiting immune cells^[53,54]. On the other hand, adenosine is a potent immunosuppressive metabolite^[50]. As such, it is not surprising that tumor cells highly upregulate CD73 and immunosuppressive cells, such as cancer-associated fibroblasts (CAFs), Tregs, and MDSCs, highly upregulate CD39 to facilitate adenosine accumulation within the TIME^[52,55-59]. Further, terminally exhausted CD8⁺ T cells exhibit increased CD39 expression, therefore contributing to the elevated adenosine levels within the TIME^[60], and adenosine drives the expansion of Treg populations^[61].

Tumor-derived adenosine inhibits CD8⁺ T cell functions in a myriad of ways. Adenosine triggers IL-10 secretion from cervical cancer cells, leading to downregulation of MHC-I expression and subsequent immune evasion from CD8⁺ T cells^[62]. Increased adenosine production also favors tumor growth, as indicated by the negative correlation between CD73 expression and survival in pancreatic adenocarcinoma human cohorts^[63]. Moreover, loss of CD73 in pancreatic ductal adenocarcinoma cell lines leads to increased

activation and IFN γ production in CD8⁺ T cells^[63], highlighting the inverse relationship between adenosine and CD8⁺ T cell function. Adenosine production within the TIME is also regulated by cancer exosomes, which are endosomal-derived extracellular vesicles^[64,65]. Specifically, cancer exosomes were found to express CD39 and CD73, leading to inhibition of T cell activation and proliferation in human neuroblastoma samples^[66] and bladder, colorectal, prostate, and breast cancer cell lines^[67]. Accumulation of adenosine within the TIME also severely hinders tumor infiltration by CD8⁺ T cells due to adenosine-mediated dysfunction of KCa3.1 channels^[68,69]. KCa3.1 is a potassium channel that regulates Ca²⁺ influx, which affects T cell gene expression, activation, and differentiation^[70]. Inhibition of KCa3.1 by adenosine reduced T cell migration and cytokine production^[69], and decreased KCa3.1 channel activity, but not protein expression, resulting in decreased tumor infiltration^[68]. Building on this, the same group later found that anti-PD-1 therapy increased the activity of ion channels KCa3.1 and Kv1.3, leading to enhanced CD8⁺ T cell infiltration in head and neck squamous cell carcinoma (HNSCC) patient samples^[71]. While not the focus of this section, it is important to mention that Treg-derived adenosine also drives CD8⁺ T cell dysfunction^[56,57,72,73]. On the other hand, increased IL-7 signaling in CD8⁺ T cells inhibits FoXO1 activation, which is a transcription factor that controls T cell proliferation, to overcome the suppressive effects of the adenosine-rich TIME and promote tumor infiltration and expansion^[74]. Leveraging these mechanisms might be a viable therapeutic strategy to be used in conjunction with current ICB therapies to overcome resistance.

Adenosine within the TIME engages with the A2A receptor (A2AR) on CD8⁺ T cells to drive adenosinergic signaling that results in impaired anti-tumor effects^[75]. Early studies found that A2AR signaling inhibited T cell activation and proliferation^[76], and in the context of cancer, many studies have shown that A2AR signaling promotes immune evasion and T cell dysfunction. In mouse melanoma and fibrosarcoma models, pharmacological inhibition or genetic deficiency of A2AR increases CD8⁺ T cell tumor infiltration and IFN γ production, and reduces tumor growth^[77,78]. Moreover, targeted knockdown or antagonizing A2AR increases CD8⁺ T cell infiltration^[79] and decreases Treg infiltration and tumor volume in mouse models of HNSCC^[80]. Similarly, administering A2AR agonists during T cell activation impaired cytotoxic function, although proliferative capacity was maintained, and these effects persisted after A2AR agonists were removed^[81]. These data demonstrate that even if CD8⁺ T cells infiltrate the adenosine-rich TIME, adenosinergic signaling reduces their effector functions and renders them incapable of eliminating tumor cells. However, one study showed that complete abrogation of the A2AR gene in CD8⁺ T cells inhibited expansion and effector functions^[75]. In this way, it is important to preserve some degree of A2AR signaling in CD8⁺ T cells to maintain proper cell function, highlighting that complete deletion of immunosuppressive targets might not produce the most efficacious results.

The studies thus far have demonstrated that tumor-intrinsic adenosine metabolism adversely affects CD8⁺ T cell function; therefore, it is not surprising that these metabolic alterations also contribute to anti-PD-1/PD-L1 resistance. To date, there are many drugs in the pre-clinical and clinical stages that target CD39, CD73, and A2AR, either alone or in combination with anti-PD-1/PD-L1 therapies^[82]. Because it is not feasible to cover all these data, we have chosen to focus on the relevant articles from 2020 until now to demonstrate that modulating adenosine metabolism helps overcome resistance to ICB therapies. Using bioinformatics approaches, researchers showed that adenosine signaling gene signatures are inversely correlated with survival and efficacy of anti-PD-1 treatment across multiple cancer indications^[83]. The first-in-human study using an A2AR antagonist with anti-PD-L1 treatment improved the probability of progression-free survival and overall survival, and monotherapy or combination with anti-PD-L1 increased CD8⁺ T cell infiltration^[84]. However, current A2AR antagonists do not perform well in the adenosine-rich TIME, so multiple groups have developed novel A2AR antagonists to increase effectiveness^[85,86]. Both

compounds have shown limited toxicity in Phase I clinical trials^[85,86], with iTeos Therapeutics' compound demonstrating initial signs of clinical benefit^[86]. Dizal Pharmaceuticals' compound was also evaluated in murine models of prostate cancer, where treatment with the novel antagonist and anti-PD-1 significantly reduced tumor volume compared to monotherapy^[85].

There are several pre-clinical and clinical studies that demonstrate promising results for targeting CD39 or CD73 in combination with anti-PD-1 or PD-L1. Cancer exosomes expressing CD39 and CD73 drive adenosine accumulation and were also found to promote CD39 expression on macrophages^[87]. Macrophage-derived CD39 cooperates with tumor-derived CD73 to increase adenosine levels in the TIME, which drives anti-PD-1 resistance^[87]. Targeting CD39 on macrophages in combination with anti-PD-1 therapy abrogated therapeutic resistance and synergistically reduced the volume of murine hepatocellular carcinoma tumors and increased CD8⁺ T cell infiltration and granzyme B production^[87]. Moreover, a first-in-human Phase I clinical trial was conducted in 2020 to assess the efficacy of an anti-CD39 antibody (IPH5201) in combination with anti-PD-L1 treatment^[88], and the first patient for the Phase II study was dosed in June 2023^[89]. A poster presentation at the European Society for Medical Oncology Immunology Summit in 2022 showed pre-clinical data for IPH5201, wherein treatment alone reduced adenosine levels in the TIME of mouse fibrosarcoma tumors^[90]. The data also demonstrated that combining anti-CD39, the chemotherapeutic agent gemcitabine, and anti-PD-L1 controlled tumor growth and increased survival better than monotherapy or anti-PD-L1 with gemcitabine in murine colorectal carcinoma tumors^[90]. In a clinical study of 44 patients, researchers found no major toxicities when combining an anti-CD39 monoclonal antibody with anti-PD-1 and the chemotherapy regimen FOLFOX for the treatment of gastric cancer or gastroesophageal junction adenocarcinoma^[91]. These data are critical first steps in the approval and use of anti-CD39 therapies in combination with anti-PD-1/PD-L1 treatment. The results from a first-in-human Phase I clinical trial with anti-CD73 and anti-PD-L1 recently reported tolerable safety and moderate efficacy^[92]. Further, targeting CD73 has also recently been shown to be a promising therapeutic strategy, wherein Phase II clinical trials combining anti-CD73 with anti-PD-L1 elicit increased response rate and progression-free survival compared to anti-PD-L1 monotherapy in patients with non-small cell lung cancer^[93]. One thing to consider when targeting CD39 or CD73 is that anti-CD39 treatments not only inhibit adenosine production, but also promote accumulation of immunostimulatory ATP.

In addition to more conventional treatment methods, several unique approaches for inhibiting adenosine metabolism and PD-1 have recently been discovered. Because of the ubiquitous expression of A2AR on T cells, localizing inhibition of A2AR signaling to tumor-infiltrating CD8⁺ T cells would likely mitigate off-target effects. In this approach, researchers increased tumor oxygenation to relieve the hypoxic conditions that promote tumor-derived adenosine production^[94]. Using a photo-modulated nanoreactor, hydrogen peroxide is converted to oxygen within the TIME, leading to decreased adenosine production and abrogated A2AR signaling in CD8⁺ T cells^[94]. Moreover, combination with anti-PD-1 therapy synergistically reduced tumor growth and increased CD8⁺ T cell infiltration in triple-negative murine breast cancer tumors^[94]. In another tumor-targeting approach, researchers utilized cancer-derived exosomes packaged with both a CD39 antagonist and AMPK agonist to inhibit adenosine and promote ATP production, respectively^[95]. This method increased CD8⁺ T cell infiltration and production of granzyme B and IFN γ , reduced intratumoral adenosine and Treg populations, and synergized with anti-PD-1 treatment in mouse melanoma models^[95]. The final targeted approach used ROS-producing nanoparticles to deliver a CD39 inhibitor^[96]. Inducing ROS accumulation in the TIME seems counterintuitive, but like hypoxia, ROS trigger the release of ATP. Therefore, ROS would increase ATP concentration and inhibiting CD39 would prevent adenosine formation, thus remodeling the TIME away from an immunosuppressive state^[96]. This method

alone decreased tumor volume and increased CD8⁺ T cell production of IFN γ and, together with anti-PD-1, elicited a more robust anti-tumor effect in murine mammary carcinoma tumors^[96].

Collectively, these data strongly demonstrate that tumor-derived adenosine has detrimental effects on CD8⁺ T cell infiltration and effector functions, thereby contributing to anti-PD-1/PD-L1 resistance mechanisms. As such, there is a compelling need for the continued development of adenosine-targeting drugs that can synergize with current anti-PD-1/PD-L1 therapies to prevent resistance and evoke better patient response.

NAD⁺

NAD⁺ is comprised of adenosine monophosphate linked to nicotinamide mononucleotide. NAD⁺ can be reduced to form NADH or phosphorylated and subsequently reduced to form NADP⁺ or NADPH, respectively. NAD⁺ is synthesized through three pathways: de novo biosynthesis, Preiss-Handler pathway, or the salvage pathway, the latter of which is the predominant way that cells restore NAD⁺ levels^[97] [Figure 1]. NAD⁺ is a co-factor that is involved in a variety of redox and non-redox reactions. In energy metabolism, NAD⁺ and its derivatives are indispensable for cellular function because they accept and donate electrons in a variety of metabolic pathways, such as glycolysis, pentose phosphate pathway, TCA cycle, and fatty acid β -oxidation^[98]. NAD⁺ also acts as a substrate for multiple enzyme families, including sirtuins, PARPs, and ADP-ribosyl cyclases^[97]. Moreover, the metabolic pathways of adenosine and NAD⁺ are tightly linked through CD38, an ectoenzyme present on the surface of tumor and immune cells, which depletes NAD⁺ levels, which ultimately results in adenosine formation^[99].

High NAD⁺ levels are required in malignant cells to meet their increased energetic demands for rapid growth and proliferation. Therefore, malignant cells will upregulate NAD⁺ biosynthesis to replenish intracellular stores, leading to depletion of this metabolite within the TIME. Several enzymes involved in anabolic NAD⁺ pathways, such as nicotinamide phosphoribosyltransferase (NAMPT), have been heavily implicated in cancer progression and severity^[100]. Moreover, drugs targeting these enzymes have shown promising results in pre-clinical and clinical studies^[101]. Targeting tumor-intrinsic NAD⁺ metabolism is a promising therapeutic approach because it would restore NAD⁺ levels in the TIME, thus allowing T cells to utilize this metabolite to maintain proper function.

NAD⁺ is highly important for anti-tumor immune functions and NAMPT is an important regulator of NAD⁺ availability. As previously mentioned, NAD⁺ and adenosine metabolism are highly linked due to the ability of NAD⁺ to be converted to adenosine. Inhibiting NAMPT in tumor cells reduces levels of intracellular NAD⁺ and extracellular adenosine, thereby enhancing CD8⁺ T cell functions^[102]. Further, NAMPT expression in CD8⁺ T cells is necessary to produce NAD⁺ and induce anti-tumor effects^[103]. In tumor-infiltrating lymphocytes (TILs), NAMPT and NAD⁺ levels are lower compared to peripheral T cells^[103], suggesting that the TIME induces NAD⁺ depletion in TILs, leading to impaired function. Mechanistically, NAD⁺ deficiency in TILs drives mitochondrial dysfunction and reduces ATP production, whereas supplementation with nicotinamide (NAM), the substrate of NAMPT, reverses these effects to promote a strong anti-tumor immune response *in vivo*^[103]. Interestingly, TCR stimulation in CD8⁺ T cells leads to a 16-fold upregulation of NAMPT, compared to 1.3-fold upregulation in Tregs^[104]. This suggests that CD8⁺ T cells rely more heavily on NAMPT expression and NAD⁺ levels compared to Tregs, giving these immunosuppressive cells an advantage in the NAD⁺-depleted TIME. Consistently, Tregs are particularly sensitive to NAD⁺-induced cell death^[105], and systemic NAD⁺ treatment preferentially depleted Tregs, leading to decreased tumor volume^[106]. To date, there are several pre-clinical and clinical studies investigating the use of NAMPT inhibitors in both solid and hematologic malignancies^[107]. However, systemic inhibition of NAMPT might have profound adverse effects on CD8⁺ T cell function, decreasing the drugs' efficacy. Perhaps these types of drugs are more effective in cancers that do not have high T cell infiltration but overexpress NAMPT.

In immune cells, CD38 is inversely correlated with NAD⁺ levels because it degrades NAD⁺ to NAM and ADP-ribose^[108,109]. These derivatives of NAD⁺ are important secondary messengers that regulate intracellular calcium levels and storage, which in turn mediates T cell differentiation and activation^[109]. CD38 expression is a marker of T cell exhaustion that contributes to adverse epigenetic modifications in CD8⁺ TILs^[110]. Further, high expression of CD38, PD-1, and CD101 correlates with the inability of CD8⁺ T cells to undergo epigenetic reprogramming to reverse the exhausted state^[110]. Conversely, inhibiting CD38 expression in Tregs and B-regulatory cells induced cell death, but drove proliferation of cytotoxic T cells, likely due to depletion of the immunosuppressive populations^[111]. Consistently, mice deficient in CD38 expression exhibited lower Treg numbers as a result of increased NAD⁺ levels^[106]. CD38 expression on tumor cells has also been implicated in a variety of solid and hematologic malignancies^[112-116]. Increased CD38 expression on malignant cells results in acquired resistance to anti-PD-1/PD-L1 therapy by driving CD8⁺ T cells towards an exhausted state^[114]. Moreover, CD8⁺ T cell function was found to be inhibited by CD38-mediated adenosine production, and anti-PD-L1 and CD38 combination therapy synergistically inhibited the growth of murine lung adenocarcinoma tumors^[114]. Currently, there are two approved anti-CD38 monoclonal antibody treatments (Daratumumab and Isatuximab) and one in clinical trials (MOR202) to treat multiple myeloma; however, these drugs do not inhibit the ectoenzymatic activity of CD38, rather they induce antibody-dependent cell-mediated cytotoxicity^[117-119]. There are several drugs in pre-clinical stages that target the ectoenzymatic activity of CD38 to increase NAD⁺ levels for different diseases^[120-122]. While these drugs are not yet being evaluated in the oncologic space, it would be advantageous because inhibiting CD38 is both beneficial for T cells and detrimental for malignant and immunosuppressive cells, thus eliminating the need for cell-specific drugs.

Taken together, these data demonstrate an important role for lactate, adenosine, and NAD⁺ in regulating immune cell function and ultimately controlling cancer development and progression. Further, pre-clinical studies show promising results that combining these treatments with existing ICB therapies can remodel the TIME to boost the anti-tumor immune response. Thus, continued pre-clinical and clinical efforts are needed to determine whether resistance to anti-PD-1/PD-L1 therapy is ablated when combined with approved anti-CD39/CD73/A2AR/CD38 treatments.

AMINO ACID METABOLISM

Amino acid metabolism is widely implicated in oncogenesis due to the necessity of amino acids in protein synthesis, epigenetic modifications, and fueling energetic processes. Of the 20 amino acids, only a handful are well-studied in the context of immuno-oncology metabolism and resistance to ICB. Because tryptophan is thoroughly researched in this space and was recently comprehensively reviewed^[123], we wanted to focus on amino acids that are sometimes overlooked but still immensely important in regulating cancer development and progression. As such, this section will discuss how tumor-derived alterations in arginine, glutamine, and methionine metabolism contribute to anti-tumor immunity and how modifying the metabolism of these amino acids helps diminish resistance to anti-PD-1/PD-L1 therapy.

Arginine

Arginine is considered a non-essential amino acid in normal cells because it can be imported or synthesized through citrulline metabolism in the urea cycle^[124] [Figure 2]. Conversely, arginine is also catabolized through the urea cycle to form urea and ornithine through arginase (ARG) enzymes^[124]. Extracellular arginine also participates in the activation of intracellular signaling pathways by binding to G protein-coupled receptor family C group 6 member A (GPCR6A)^[125]. While arginine itself is important for many

because they do not express ASS1^[136,137], meaning they must compete with tumor cells and immunosuppressive cells for arginine.

T cell function is highly disrupted by arginine depletion within the TIME, which is mediated by both malignant cells^[138-141] and immunosuppressive cells^[142-147]. In T cells, arginine is important in regulating CD3z expression, which is necessary for proper antigen recognition by the TCR-CD3 complex^[148-151]. For example, ARG2-dependent depletion of arginine by murine renal cell carcinoma cells leads to decreased expression of CD3z in T cells^[139]. Sufficient arginine levels are also necessary during T cell activation because arginine is quickly metabolized to fuel downstream processes^[152]. Moreover, decreased systemic arginine levels in Lewis lung carcinoma^[150] and arginine depletion via ARG1 from cancer-derived exosomes in ovarian carcinoma^[153] inhibit antigen-specific proliferation of CD8⁺ TILs. Arginine depletion also impairs the effector function of CD8⁺ T cells by preventing the secretion of IFN γ and granzyme B^[154,155]. On the other hand, arginine supplementation in CD8⁺ T cells induces metabolic rewiring from glycolysis towards oxidative phosphorylation to promote proliferation, survival, and anti-tumor responses^[152].

Several promising pre-clinical studies have demonstrated that targeting arginine metabolism in combination with anti-PD-1/PD-L1 treatment increases efficacy in overcoming resistance. Employing anti-PD-1 treatment in combination with vaccine inhibition of ARG1 synergistically impaired tumor growth and led to increased CD8⁺ T cell infiltration in mouse models of colorectal carcinoma and fibrosarcoma^[156]. Further, systemic arginine supplementation with anti-PD-1 or PD-L1 treatment increased CD8⁺ T cell infiltration and exhibited more efficacious results than monotherapy in mouse models of colon carcinoma^[157] and osteosarcoma^[158]. Utilizing a unique approach, researchers engineered an *E. coli* strain that localizes to the TIME and converts ammonia to arginine^[159]. This innovative method promoted continuous arginine supplementation in murine colorectal carcinoma tumors, leading to increased CD8⁺ T cell infiltration and synergistic anti-tumor effects when combined with anti-PD-L1 treatment^[159]. Extensive pre-clinical studies for a novel ARG1/2 inhibitor (OATD-02) have shown promising results alone and in combination with both anti-PD-1 and -PD-L1, and researchers are hopeful this drug will enter first-in-human clinical trials soon^[150,160-162]. Moreover, the ARG1 inhibitor CB-1158 entered first-in-human clinical trials in 2017 and was evaluated with anti-PD-1 treatment^[163-165]. The results indicate that CB-1158 monotherapy and combination with anti-PD-1 are well-tolerated and elicit a response in solid tumors^[163-165].

A considerable amount of evidence demonstrates that tumor-mediated depletion of arginine negatively impacts CD8⁺ T cell function and the anti-tumor response. Additionally, the enhanced anti-tumor effects seen by combining anti-PD-1/PD-L1 with ARG inhibitors or arginine supplementation demonstrate that altering tumor metabolism could have profound effects on the efficacy of ICB. However, continued pre-clinical and clinical efforts are necessary to identify additional ways to target tumor-derived arginine metabolism and reinvalidate the anti-tumor immune response to improve ICB.

Glutamine

Glutamine has many essential functions, such as supporting the formation of nucleotides and non-essential amino acids, protein synthesis, energy metabolism, and maintaining intracellular redox states^[166]. Import of glutamine is facilitated by many transporters, predominantly SLC1A5^[136,167] [Figure 2]. Once inside the cell, glutamine is transported to the mitochondria to be converted to glutamate via glutaminase enzymes^[166]. In the cytosol, glutamate serves as a precursor for glutathione synthesis, which is a strong antioxidant^[166]. The metabolism of glutamine also drives the formation of NADPH, which is critical for restoring the intracellular redox balance by reducing oxidized glutathione^[168]. In the mitochondria, glutamate is converted to α -Ketoglutarate to drive the TCA cycle^[166].

Many cancers exhibit a dependence on or addiction to glutamine. As such, increased glutaminolysis is highly important for ATP production, redox homeostasis, and activation of various oncogenic signaling pathways in tumor cells^[168-170]. Glutamine fuels KRAS signaling in pancreatic adenocarcinoma^[168], mTORC1 signaling in osteosarcoma and cervical cancer cells^[170], and promotes lipid biogenesis under hypoxic conditions to provide additional energy sources^[171]. Hypoxia also drives the mitochondrial import of glutamine to support ATP and glutathione production to combat oxidative stress and promote uncontrolled cell growth^[172]. Interestingly, data suggest that some cancers will adapt to the glutamine-deprived TIME and will cease to rely on glutamine. In patient-derived melanoma tumors, for example, excess dietary glutamine inhibits cell growth^[173].

T cells require glutamine for a variety of functions during differentiation and development^[174]; thus, there is stiff competition between tumor cells and T cells for glutamine consumption. Ligation of CD3 and CD28 on T cells induces glutamine uptake via ERK and calcineurin pathways to sustain T cell activation, proliferation, and cytokine production^[175,176]. Interestingly, glutamine is also required for glucose uptake and glycolysis in activated CD8⁺ T cells, and proper effector functions were dependent on both glucose and glutamine^[177]. As such, increasing glutamine availability for T cells, while depriving tumor cells and immunosuppressive cells, has strong anti-tumor effects. For example, selectively inhibiting glutamine uptake in triple-negative breast cancer cells increased CD8⁺ T cell activation and effector function by promoting glutathione production^[178]. On the other hand, non-specific intracellular depletion of glutamine leads to impaired mitochondrial function and CD8⁺ T cell apoptosis^[179], likely due to increased oxidative damage from reduced glutathione production. Data also suggest the temporal importance of glutamine availability in driving T cell function. During TCR stimulation, glutamine deprivation decreases PD-1 and increases Ki67 expression^[180], suggesting that glutamine abundance needs to be tightly regulated at various stages of T cell development to ensure proper functionality. As discussed in previous sections, immunosuppressive cells largely thrive in the nutrient-deprived TIME. Specifically, tumor-associated macrophages respond to low glutamine levels by secreting IL-23 to promote Treg proliferation and activation, resulting in diminished CD8⁺ T cell function^[181].

Several reports have demonstrated that inhibiting tumor-associated glutamine metabolism in combination with anti-PD-1/PD-L1 therapies may be a promising approach to restore CD8⁺ T cell function and overcome resistance. Because glutamine deprivation promotes T cell dysfunction, specifically inhibiting glutamine metabolism in tumor cells would yield the most efficacious results. Two separate groups found that glutamine deprivation in cell lines of human clear cell renal carcinoma^[182], human non-small cell lung carcinoma^[183], and mouse colorectal carcinoma^[183] induced PD-L1 expression, which would theoretically boost anti-PD-L1 response. Byun *et al.* found that anti-PD-L1 monotherapy had almost no effect on tumor volume in murine colorectal carcinoma models^[183]. However, tumor-specific inhibition of glutamine uptake and glutaminase activity in combination with anti-PD-L1 therapy strongly induced CD8⁺ T cell proliferation and granzyme B production, while abating tumor growth^[183]. Similarly, another group targeted tumor-derived glutamine enzymes by creating a prodrug that is only activated by TIME-restricted enzymes to limit the cytotoxic effects of systemic glutamine antagonism^[184]. This treatment method decreased glycolysis in malignant cells, decreased hypoxia, acidosis, and nutrient depletion within the TIME, and increased activation of and oxidative phosphorylation in CD8⁺ T cells^[184]. In combination with anti-PD-1 therapy, tumor-specific glutamine antagonism synergistically reduced tumor growth and increased survival in murine colorectal carcinoma tumors^[184]. Conversely, employing a non-tumor cell specific glutaminase inhibitor does not yield the same efficacious results. Serine/threonine kinase 11 (STK11) phosphorylates AMPK to regulate a variety of downstream pathways, such as cell growth and proliferation, lipid metabolism, and PD-L1 expression^[185]. Several studies have shown that STK11 mutations, resulting in loss

of function, are associated with resistance to anti-PD-1 treatment^[186-188]. Building on this, one group found that STK11-mutated lung adenocarcinomas from both patient samples and cancer cell lines exhibited increased glutamate production, so they hypothesized that targeting glutaminase would be a viable way to overcome resistance to anti-PD-1 treatment^[189]. However, they found that using a non-tumor cell-specific glutaminase inhibitor in combination with anti-PD-1 severely impeded CD8⁺ T cell clonal expansion and anti-tumor functions, and anti-PD-1 efficacy was dependent on intact CD8⁺ T cell glutaminase activity^[189].

These data demonstrate a promising future for targeting glutamine metabolism to bolster CD8⁺ T cell effector function and combat ICB resistance. However, it also highlights the importance of finding ways to specifically target malignant cells due to the highly conserved nature of these metabolic pathways.

Methionine

Methionine is an essential amino acid that is involved in a variety of metabolic pathways, such as methylation reactions, homocysteine synthesis, and the folate pathway [Figure 2]. This metabolite also cooperates with arginine and glutamine to promote polyamine and glutathione synthesis, respectively^[190]. In the methionine pathway, methionine is converted to S-adenosyl methionine (SAM), which is critical for the methylation of histones, DNA, RNA, proteins, and various metabolites^[191]. The loss of a methyl group converts SAM to S-adenosyl homocysteine (SAH), and subsequently homocysteine, which is ultimately metabolized to glutathione^[192]. Methionine regeneration is supported by the metabolism of SAM through the salvage pathway^[192] and through the re-methylation of homocysteine via intermediates in the folate pathway^[193].

The role of methionine in malignant transformation and growth is not as well-studied as other metabolites, but its wide consumption in cancer cells suggests its importance^[194,195]. In tumor-initiating cells, exogenous methionine is consumed at extreme rates, leading to pro-tumorigenic epigenetic modifications through methionine adenosyltransferase 2A (MAT2A), which metabolizes methionine to SAM to promote histone methylation^[196]. In the presence of methionine, malignant cells activate c-MYC, leading to increased MAT2A activity and tumorigenic genome modifications^[197]. On the other hand, tumor overexpression of nicotinamide N-methyltransferase (NNMT), which converts SAM to NAD⁺ and 1-Methylnicotinamide, leads to increased NAD⁺ levels, hypomethylation, and tumor progression^[198], highlighting that altered methionine metabolism can drive oncogenesis in multiple ways.

In T cells, proper metabolic regulation of methionine and its derivatives is necessary for epigenetic reprogramming during activation and differentiation^[199], as evidenced by increased expression of methionine transporters during antigen recognition^[175]. However, dysregulated methionine metabolism by tumor cells alters the abundance of SAM and 5-methylthioadenosine (MTA)^[200], both of which drive the methionine salvage pathway^[201]. Increased abundance of SAM and MTA within the TIME are associated with T cell exhaustion and expression of inhibitory checkpoint markers^[200]. These two metabolites decrease chromatin accessibility in CD8⁺ T cells for genes involved in TCR signaling, lymphocyte proliferation and differentiation, and increase the accessibility of PD-1^[200]. Together, these data indicate that tumor-derived alterations in methionine metabolism have a substantial impact on the anti-tumor immune functions of CD8⁺ T cells, but much remains to be discovered.

Despite the limited studies in this field, two recent reports demonstrate that restricting tumor methionine increases CD8⁺ T cell effector functions and overcomes resistance to anti-PD-1/PD-L1 treatment. The first study shows that dietary restriction of methionine reduces SAM levels in murine colorectal carcinoma tumors^[202]. Mechanistically, SAM controls the expression of immune inhibitory markers PD-L1 and VISTA

through m⁶A methylation, whereby the RNA-binding protein YTHDF1 enhances the translation efficiency of RNA containing m⁶A methylation^[202]. While anti-PD-1 treatment alone in mouse colorectal carcinoma tumors did not significantly alter tumor volume or CD8⁺ T cell infiltration, depletion of YTHDF1 or restricting methionine in the diet synergized with anti-PD-1 treatment to significantly increase survival probability and CD8⁺ T cell infiltration, while decreasing tumor volume^[202]. Similarly, the second study found that methionine-dependent histone methylation regulates CD8⁺ T cell anti-tumor activities. Methionine deprivation in CD8⁺ T cells resulted in reduced H3K79me2 methylation and subsequent STAT5 expression^[203], which is a critical transcription factor that maintains CD8⁺ T cell effector functions^[204]. *In vitro*, methionine supplementation increased CD8⁺ T cell survival and IFN γ and TNF α production, while inhibiting murine melanoma tumor growth^[203]. The authors also found that SLC43A2 and SLC7A5 import methionine in malignant cells, but T cells are predominantly dependent on SLC7A5^[203]. As such, genetic ablation of SLC43A2 in mouse melanoma cells restored CD8⁺ T cell polyfunctionality and survival *in vitro*, and decreased tumor growth *in vivo*^[203]. While anti-PD-1 treatment or pharmacological inhibition of SLC43A2 alone did not elicit significant anti-tumor effects, combination treatment synergistically increased CD8⁺ T cell function and infiltration, and decreased growth of mouse melanoma and ovarian tumors^[203]. These data demonstrate that resistance to anti-PD-1 treatment can be negated by restricting methionine availability and metabolism in tumors.

Taken together, the studies in this section have undoubtedly established that targeting amino acid metabolism is an efficacious way to improve the response to anti-PD-1/PD-L1 treatment. Targeting these metabolic pathways proves to be challenging because, unlike the immunosuppressive metabolites that have been discussed, amino acids are beneficial for both T cells and tumor cells. Therefore, therapeutic strategies have to promote amino acid supplementation in T cells but restriction in tumor cells, which is no easy feat. Despite these challenges, researchers have made great strides in pre-clinical settings towards identifying how to alter amino acid metabolism in a way that impedes ICB resistance.

LIPID METABOLISM

The TIME is enriched with various lipid classes^[205-207], which is in contrast to other metabolites that are predominantly depleted. Lipids are ubiquitously important for structural support, energy supply, and signaling, making them essential for the malignant properties of tumors and for the proper function of anti-tumor immune cells. Specifically, cholesterol is indispensable for cell membrane integrity and facilitating cell-to-cell and intracellular signaling, while fatty acids (FAs) are the most abundant lipid intermediate, so they are more readily detectable and their role in cancer biology is better understood. Therefore, this section will highlight how tumor-mediated cholesterol and FA dysregulation within the TIME affects CD8⁺ T cell function and anti-PD-1/PD-L1 resistance.

Cholesterol

Cholesterol serves as an important component in cellular membranes and regulates membrane fluidity and cell signaling through the formation of lipid rafts^[208] [Figure 3]. Moreover, cholesterol is a precursor for steroid hormones, bile acids, and vitamin D^[208]. Intracellular cholesterol levels are maintained through biosynthesis via the mevalonate pathway, which converts acetyl-CoA to cholesterol through a series of enzymatic reactions. Additionally, cholesterol is imported as low-density lipoproteins, which are small lipid-enclosed particles that facilitate the systemic transport and cellular import of cholesterol^[209]. On the other hand, cholesterol is exported through ATP-binding cassette transporters^[210]. Excess intracellular free cholesterol is converted to cholesteryl esters and stored in lipid droplets, which promote oncogenic signaling and cancer growth^[211].

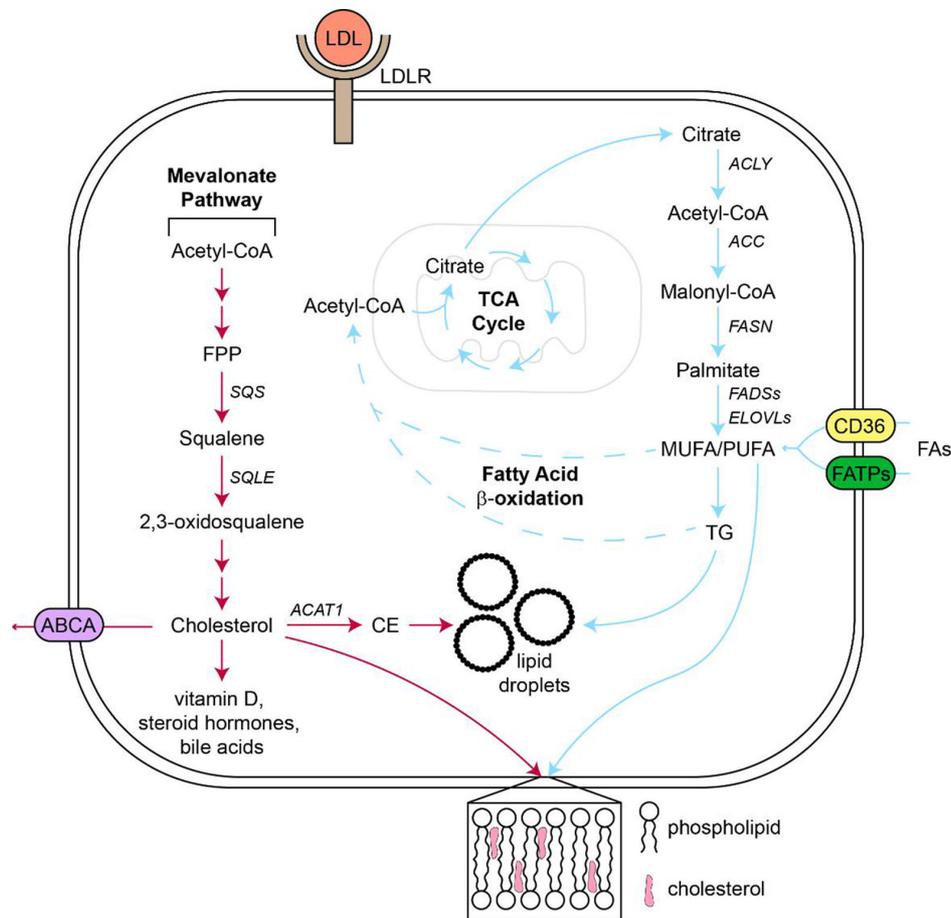

Figure 3. Diagram of cholesterol and FA metabolic pathways. Cholesterol is either imported as LDL through LDLR or it is synthesized through the mevalonate pathway. From there, cholesterol serves as a precursor to vitamin D, steroid hormones, and bile acids or it integrates into the cellular membrane to regulate membrane fluidity and cell signaling. Excess intracellular cholesterol is exported through ABCA or esterified to form CE, which are stored in lipid droplets. FAs are imported via CD36 and fatty acid transport proteins or synthesized through citrate from the TCA cycle. Palmitate, the initial FA that is formed, undergoes elongation and desaturation by ELOVL and FADS enzymes, respectively, to form a variety of FAs with varying chain lengths and degrees of unsaturation. FAs participate in energy metabolism through the FA β -oxidation pathway that generates acetyl-CoA to drive the TCA cycle. Similar to cholesterol, fatty acids are important components of cellular membranes via the formation of phospholipids and excess fatty acids are converted to TG and stored in lipid droplets. ABCA: ATP-binding cassette transporters; ACAT1: Acyl-CoA cholesterol acyl transferase 1; ACC: acetyl-CoA carboxylase; ACLY: ATP citrate lyase; ATP: adenosine triphosphate; CE: cholesteryl esters; ELOVL: elongation of very long chain fatty acids protein; FA: fatty acid; FADS: fatty acid desaturase; FATP: fatty acid transport protein; FASN: fatty acid synthase; FPP: farnesyl diphosphate; LDL: low-density lipoprotein; LDLR: low-density lipoprotein receptor; MUFA: mono-unsaturated fatty acid; PUFA: poly-unsaturated fatty acid; SQS: squalene synthase; SQLE: squalene epoxidase; TCA: tricarboxylic acid; TG: triglyceride.

Malignant cells utilize excess cholesterol to sustain their rapid growth and proliferation^[212-214] and elevated intracellular cholesterol levels are maintained by increasing import and synthesis and decreasing export^[215,216]. Altered cholesterol content in malignant cell membranes regulates apoptosis^[217], proliferation, metastasis^[218], and killing by cytotoxic T cells^[219]. Cholesterol and its derivatives are also involved in various oncogenic signaling pathways and protein modifications^[220]. Unsurprisingly, these metabolites are sequestered by tumor cells to promote malignant growth, and dysregulation of cholesterol in the TIME by tumor cells affects the cytotoxic functions of CD8⁺ T cells.

There are multiple ways in which tumor cells directly alter cholesterol metabolism within the TIME to inhibit CD8⁺ T cell function. Protein convertase subtilisin/kexin type 9 (PCSK9) is a secreted enzyme that

regulates cholesterol levels by facilitating the degradation of low-density lipoprotein receptors (LDLR)^[221-224], which imports low-density lipoprotein cholesterol. Tumor-secreted PCSK9 promotes intratumoral accumulation of cholesterol^[225], prevents LDLR and TCR recycling in CD8⁺ TILs^[226], and inhibits MHC-1 recycling on tumor cells^[227], leading to immune evasion in multiple ways. Further, several reports demonstrate that intratumoral cholesterol accumulation promotes PD-L1 expression^[228-231], thereby contributing to immune evasion. Mechanistically, cholesterol binds to the transmembrane domain of PD-L1 to stabilize cell surface expression^[231]. Cholesterol-derived metabolites produced by malignant cells also dictate anti-tumor response. For example, cholesterol sulfate creates a chemical barrier within the TIME to prevent CD8⁺ T cell infiltration^[232]. Moreover, cholesterol sulfate-producing tumors are more resistant to ICB therapy^[232] than tumors that do not produce this metabolite, demonstrating that targeting tumor-intrinsic cholesterol metabolism could enhance ICB outcomes.

In addition to cholesterol biochemical pathways regulating CD8⁺ T cell function, mechanical forces driven by altered cholesterol levels within tumor cells also influence anti-tumor immune response. Cancer cells accumulate cholesterol within the cell membrane, leading to increased membrane fluidity, or “cell softening”^[219]. This phenomenon is associated with cancer development and progression because cancer cell softening impairs the cytotoxic effects of T cells, leading to immune escape^[219]. By reversing these effects and promoting cancer cell stiffening, increased T cell forces and actin accumulation at the immunological synapse enhance tumor killing^[219]. Notably, cancer cell stiffening did not alter TCR signaling or cytokine production, demonstrating that these effects were purely through mechanical forces^[219].

In T cells, maintaining a proper balance between membrane and intracellular cholesterol levels is important for development, activation, and effector functions. Cholesterol in the cell membrane is essential for the intricate formation of lipid rafts which regulate TCR signaling^[233]. In TILs, several studies report that the allocation of cholesterol towards cell membrane formation instead of storage as cholesterol esters promotes anti-tumor activities. Pharmacologic inhibition in tumor cells and CD8⁺ T cells of acyl-CoA cholesterol acyltransferase 1 (ACAT1), which promotes cholesterol esterification, inhibits cancer cell growth^[234]. Similarly, another group found that RORa, a nuclear hormone receptor, promotes CD8⁺ T cell membrane cholesterol accumulation by inhibiting cholesterol esterification, thus enhancing anti-tumor functions^[235]. On the other hand, intracellular cholesterol accumulation in CD8⁺ T cells due to cholesterol enrichment in the TIME leads to endoplasmic reticulum (ER) stress, which causes T cell exhaustion and increased expression of immune checkpoint markers^[207]. Mechanistically, ER stress promotes upregulation of the ER stress sensing protein XBP1, which drives the expression of immune inhibitory markers, namely PD-1 and 2B4^[207]. As a result, inhibiting XBP1 or reducing cholesterol in CD8⁺ T cells or the TIME boosts the anti-tumor functions of CD8⁺ T cells^[207]. These studies demonstrate that shifting cholesterol away from intracellular stores towards membrane formation in T cells might be an effective therapeutic strategy to diminish resistance to ICB therapy.

Given the profound effect of tumor-derived cholesterol on CD8⁺ T cell function, it is no surprise that targeting this altered metabolic pathway inhibits resistance to anti-PD-1 treatment. Building on the idea that allocating cholesterol towards cellular membranes in CD8⁺ T cells is beneficial for the anti-tumor response, researchers found that pharmacologic inhibition of ACAT1 in combination with anti-PD-1 treatment synergistically reduced the growth of mouse melanoma tumors^[236]. Further, slight anti-tumor effects were observed in four mouse tumor models following genetic ablation of PCSK9, but combination of genetic or pharmacologic inhibition of PCSK9 with anti-PD-1 resulted in robust synergistic effects to increase MHC-I expression and survival and reduce growth of murine melanoma and colorectal carcinoma tumors^[227]. Another emerging target is squalene epoxidase (SQLE), which catalyzes one of the rate-limiting steps in

sterol synthesis [Figure 3]. Bioinformatics approaches have identified a negative correlation between SQLE expression in human pancreatic adenocarcinoma and immune cell infiltration and immunotherapy response^[237], prompting the need for further validation of this potential target. While the intersection of tumor-mediated cholesterol metabolism and ICB response is not as robust as other metabolic programs, these recent studies hint at how this relationship can be exploited to overcome ICB resistance.

Fatty acids

Similar to cholesterol, FAs have a variety of cellular functions, including cell membrane formation through phospholipids, energy metabolism, and precursors for signaling lipids [Figure 3]. Intracellular FA abundance is regulated by import through CD36 or FA transport proteins and synthesis via fatty acid synthase (FASN) from acetyl-CoA or malonyl-CoA^[238]. FAs undergo modifications to chain length to form long-chain FAs (LCFAs) or very long-chain FAs (VLCFAs) and saturation to form mono-, di-, and poly-unsaturated FAs. Saturation and chain length dictate FA function and their role in oncogenesis^[239]. In energy metabolism, FAs are subject to fatty acid β -oxidation (FAO) in the mitochondria to generate FADH, NADH, and acetyl-CoA to fuel a variety of energetic processes^[240].

The increased demand for FAs in malignant cells sustains their rapid proliferation by serving as an energy source via FAO and as an indispensable component for cell membrane formation. Moreover, certain FAs are important precursors for a variety of oncogenic signaling mediators^[241-243]. To meet these metabolic demands, cancer cells will increase the uptake and synthesis of fatty acids, while also inducing lipolysis of neighboring adipocytes^[244-248]. Continuous evidence is emerging that altered FA metabolism by tumor cells alters the lipidome in the TIME, contributing to CD8⁺ T cell dysfunction. However, the effect of tumor-derived FA metabolic alterations on ICB resistance is not well-studied.

Malignant cells exploit the increased lipid availability in patients with obesity and remodel the TIME to inhibit CD8⁺ T cell function and promote cancer growth. High-fat diet-induced obesity in multiple mouse models of cancer alters the metabolic profile of malignant cells to increase FA uptake and utilization and creates an immunosuppressive TIME that inhibits CD8⁺ T cell infiltration and function^[249]. Moreover, inhibiting obesity-induced metabolic rewiring in murine colorectal carcinoma tumors restores CD8⁺ TIL function and increases anti-tumor immune function^[249]. Mechanistically, researchers found that CD8⁺ T cells in obesity-associated breast cancer tumors exhibit ligation of leptin and PD-1 to reduce effector functions through activation of STAT3, which promotes FAO and inhibits glycolysis^[250]. PD-1 ligation also promotes FAO in T cells through upregulation of carnitine palmitoyltransferase 1A (CPT1A), an essential enzyme involved in FAO^[251]. Further, obesity in mice, humans, and non-human primates leads to increased PD-1 expression and CD8⁺ T cell exhaustion^[252]. These data are consistent with the notion that CD8⁺ T cells exhibit a shift from glycolysis to FAO as they become exhausted, highlighting the need to further explore targeting metabolic reprogramming as a way to reinvigorate CD8⁺ T cells and abate ICB resistance.

Similar to obese models of cancer, non-obese models show that CD8⁺ T cell function is inhibited by an overabundance of FAs within the TIME. In response to excess lipid content within the TIME, CD8⁺ TILs exhibit increased intracellular lipid levels compared to peripheral CD8⁺ T cells^[205]. Exhaustion in CD8⁺ TILs is characterized by the expression of CD36, which imports oxidized low-density lipoproteins, oxidized phospholipids, and long-chain fatty acids^[205]. Increased uptake of oxidized low-density lipoproteins promotes lipid peroxidation in CD8⁺ TILs, leading to decreased cytokine production and effector function^[205]. Moreover, the accumulation of VLCFAs within the TIME drives the uptake of LCFAs in CD8⁺ T cells, and instead of serving as an energy source, they promote mitochondrial dysfunction, lipotoxicity, and exhaustion^[253]. Like cancer cells, immunosuppressive cells, such as Tregs, macrophages, and MDSCs,

rely heavily on exogenous FAs to sustain their increased rate of FAO^[254-257]. In this regard, increased FA abundance within the TIME hinders CD8⁺ T cell function, while benefiting malignant and immunosuppressive cells.

FAs are the building blocks for a variety of bioactive lipids, which are involved in signaling pathways. Tumor cells, and to a lesser extent CAFs^[258], secrete the enzyme autotaxin (ATX) that converts ubiquitously available lysophosphatidylcholine (LPC) to the bioactive lipid lysophosphatidic acid (LPA)^[259]. LPA modulates numerous signaling pathways through lysophosphatidic acid receptors 1-6 (LPAR1-6), which are present on a variety of cell types^[259]. In malignant cells, the ATX/LPA axis also functions in an autocrine manner by promoting oncogenic signaling through LPAR1^[260]. On CD8⁺ T cells, tumor-derived LPA binds to LPAR6 and prevents tumor infiltration by inhibiting migration^[260]. LPA also signals through LPAR5 on CD8⁺ T cells to induce cytoskeletal dysfunction, immunological synapse malformation, and impaired cytokine secretion and intracellular calcium release^[261-263]. LPAR5 signaling on CD8⁺ T cells also induces an exhausted-like state by promoting metabolic stress through ROS production and ultimately impairing antigen-specific killing^[264]. The recent development of a first-in-class ATX inhibitor demonstrated tumor growth inhibition in mouse models of breast cancer^[265,266]. The safety of this compound was tested in Phase I clinical trials in 2021, where the drug was well-tolerated with no significant clinically adverse effects^[266]. These promising results demonstrate the previously unexplored capacity to target ATX in solid tumors, with the future potential to combine this treatment with pre-existing ICB therapies.

There is very limited research on targeting FA metabolism in combination with anti-PD-1/PD-L1 therapy, but more evidence is emerging that supports this approach to overcome ICB resistance. Bioinformatics methods have identified that FASN expression in patients with bladder cancer, melanoma, and non-small cell lung carcinoma is linked to immune infiltration and ICB response^[267,268]. Interestingly, ICB is more efficacious in obese patients with melanoma compared to non-obese patients^[252,269-272]. While this may seem contradictory, obesity drives PD-1 expression on CD8⁺ T cells, thus eliciting a more robust response. On the other hand, CD8⁺ TILs in pancreatic adenocarcinoma exhibit increased expression of checkpoint inhibitors, but ICB therapy largely fails^[273-275]. The variability in ICB response between cancer types prompts the need for a deeper understanding of the mechanisms that contribute to resistance. To further complicate things, under hypoxic and hypoglycemic conditions, pharmacologically enhancing FA catabolism in CD8⁺ T cells promotes effector function^[206]. Moreover, anti-PD-1 treatment, in combination with increased FA catabolism, synergistically reduced the volume of murine melanoma tumors and promoted anti-tumorigenic metabolic reprogramming in CD8⁺ T cells^[206]. These data suggest that under stressful conditions, i.e., oxygen and glucose depletion, increased FAO is required for CD8⁺ T cell function, but this contradicts other studies that demonstrate a shift towards FAO promotes exhaustion.

Together, these research efforts have laid the groundwork to further characterize the intricate relationship between tumor-mediated cholesterol and FA metabolism and CD8⁺ T cell function within the TIME. To date, it is not clear whether inhibiting cholesterol or FA metabolism is a viable treatment option to improve response to anti-PD-1/PD-L1 therapies. As new data emerges, researchers will have a better understanding of the tumor-specific cholesterol and FA metabolic programs that are exploited by cancer cells and if these can be targeted to prevent ICB resistance.

CONCLUSION

While ICB therapies have been an imperative advancement in cancer treatment, a majority of patients exhibit resistance, prompting the need for researchers to identify and target these resistance mechanisms. This review has provided a multitude of examples wherein tumor-intrinsic alterations to energy, amino

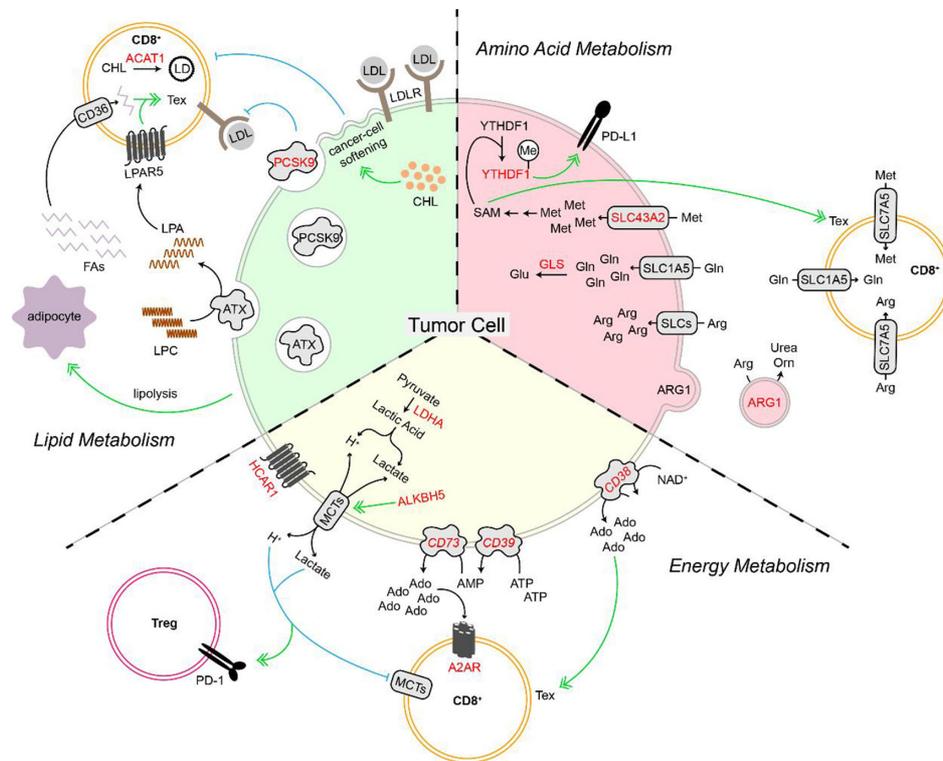

Figure 4. Summary schematic of how altered tumor-intrinsic energy, amino acid, and lipid metabolism drive CD8⁺ T cell dysfunction and resistance to anti-PD-1/PD-L1 treatment. Targets in red are described in the previous sections and modulating these targets overcomes resistance to anti-PD-1/PD-L1 therapy. ACAT1: Acyl-CoA cholesterol acyl transferase 1; Ado: adenosine; ALKBH5: alkB homolog 5, RNA demethylase; Arg: arginine; ARG1: arginase 1; ATX: autotaxin; A2AR: adenosine A2A receptor; CD8⁺: CD⁺ T cell; CHL: cholesterol; FAs: fatty acids; Gln: glutamine; GLS: glutaminase; Glu: glutamate; HCAR1: hydroxycarboxylic acid receptor 1; LD: lipid droplet; LDHA: lactate dehydrogenase A; LDL: low-density lipoprotein; LDLR: low-density lipoprotein receptor; LPA: lysophosphatidic acid; LPAR5: lysophosphatidic acid receptor 5; LPC: lysophosphatidylcholine; MCT: monocarboxylate transporter; Me: methyl; Met: methionine; NAD⁺: nicotinamide adenine dinucleotide; Orn: ornithine; PCSK9: proprotein convertase subtilisin/kexin type 9; PD-L1: programmed cell death ligand 1; PD-1: programmed cell death protein 1; SAM: S-adenosylmethionine; SLC: solute carrier; Tex: CD8⁺ T cell exhaustion; Treg: T regulatory cell; YTHDF1: YTH N6-methyladenosine RNA binding protein F1.

acid, and lipid metabolism have a significant impact on CD8⁺ T cell function and resistance to anti-PD-1/PD-L1 therapies [Table 1 and Figure 4]. In many of the studies presented here, anti-PD-1/PD-L1 therapy alone elicits limited anti-tumor effects but, when combined with targeting metabolic pathways, the response is significantly more robust. Nevertheless, there are a limited number of metabolism-targeting drugs that make it to the clinic because these pathways are highly conserved and not tumor-cell specific. As such, this warrants either unique ways to mitigate systemic effects, some of which have been provided in this review, or continued efforts to identify tumor-specific pathways. However, the extreme heterogeneity of the TIME, metabolome, and lipidome between cancer types necessitates large research efforts to uncover these distinct metabolic programs.

Future directions for the fields of immuno- and onco-metabolism are rooted in the utilization of metabolomic and lipidomic analyses to understand the metabolic landscape of cancer and develop efficacious cancer treatments. Taking a true multi-omics approach by incorporating proteomics, transcriptomics/spatial transcriptomics, and metabolomics/spatial metabolomics will greatly advance our understanding of targetable pathways, both within malignant cells and T cells. These methods are gaining more traction within the oncology research space and hopefully will be more widely utilized in the coming years.

Table 1. Tumor-intrinsic metabolic targets, the resulting metabolites, and the drug or compound used against the target that have been evaluated pre-clinically and/or clinically in combination with anti-PD-1/PD-L1 therapy

Target (metabolite)	Drug/Compound	Pre-clinical or clinical	Combination with anti-PD-1/PD-L1	Ref.
ALKBH5 (lactate)	ALK-04	Pre-clinical	Anti-PD-1	[42]
LDHA (lactate)	GSK2837808A	Pre-clinical	Anti-PD-1	[43]
HCAR1 (lactate)	3-OBA	Pre-clinical	Anti-PD-1	[44]
A2AR (adenosine)	CPI-444	Clinical	Anti-PD-L1	[84]
A2AR (adenosine)	DZD2269	Pre-clinical	Anti-PD-1	[85]
CD39 (adenosine)	IPH5201	Clinical	Anti-PD-L1	[89]
CD39 (adenosine)	IPH5201	Pre-clinical	Anti-PD-L1	[88-90]
CD39 (adenosine)	TTX-030	Clinical	Anti-PD-1	[91]
CD73 (adenosine)	MEDI9447 (oleclumab)	Clinical	Anti-PD-L1	[92,93]
A2AR (adenosine)	Nanoreactor	Pre-clinical	Anti-PD-1	[94]
CD39 (adenosine)	POM-1	Pre-clinical	Anti-PD-1	[95]
CD39 (adenosine)	ARL67156	Pre-clinical	Anti-PD-1	[96]
CD38 (NAD ⁺)	Anti-CD38 and RHein	Pre-clinical	Anti-PD-L1	[114]
ARG1 (arginine)	Vaccine	Pre-clinical	Anti-PD-1	[156]
ARG1/2 (arginine)	OATD-02	Pre-clinical	Anti-PD-1	[150,160-162]
ARG (arginine)	CB-1158	Clinical	Anti-PD-1	[163-165]
SLC1A5 (glutamine)	V-9302	Pre-clinical	Anti-PD-L1	[183]
Glutamine-utilizing enzymes (glutamine)	JHU083	Pre-clinical	Anti-PD-1	[184]
YTHDF1 (methionine)	Short-hairpin knockdown of YTHDF1	Pre-clinical	Anti-PD-L1	[202]
SLC43A2 (methionine)	BCH	Pre-clinical	Anti-PD-L1	[203]
ACAT1 (cholesterol)	CI-1011	Pre-clinical	Anti-PD-1	[236]
PCSK9 (cholesterol)	AMG-145 and D10335	Pre-clinical	Anti-PD-1	[227]

ACAT1: Acyl-CoA cholesterol acyl transferase 1; ALKBH5: alkB homolog 5; ARG1: arginase 1; A2AR: adenosine A2A receptor; HCAR1: hydroxycarboxylic acid receptor 1; LDHA: lactate dehydrogenase A; PCSK9: proprotein convertase subtilisin/kexin type 9; PD-L1: programmed cell death ligand 1; PD-1: programmed cell death protein 1; SLC: solute carrier; YTHDF1: YTH N6-methyladenosine RNA binding protein F1.

PERSPECTIVES

In recent years, immense strides have been made in studying the intersection of metabolism, cancer, and the immune system. In addition to the metabolites and pathways covered in this review, there are a plethora of others waiting to be linked to CD8⁺ T cell dysfunction and ICB resistance. For example, other amino acids and lipid classes, metabolites produced by the gut microbiome, and a closer look at the metabolites associated with oxidative phosphorylation and ATP production. Moreover, there is much to uncover about how tumor-derived metabolic alterations affect other immune and non-immune cell types. Continued research efforts in this field will provide a more comprehensive understanding of tumor-intrinsic metabolic alterations and reveal nuanced ways to target tumor metabolism and overcome resistance to ICB therapies.

DECLARATIONS

Abstract

The introduction of immune checkpoint inhibitor (ICI) has revolutionized the treatment of metastatic renal cell carcinoma (mRCC) and has dramatically improved the outcomes of patients. The use of monotherapy or combinations of ICIs targeting PD-1/PD-L1 and CTLA-4, as well as the addition of ICIs with tyrosine kinase inhibitors, has significantly enhanced the overall survival of mRCC patients. Despite these promising results, there remains a subset of patients who either do not respond to treatment (primary resistance) or develop resistance to therapy over time (acquired resistance). Understanding the mechanisms underlying the development of resistance to ICI treatment is crucial in the management of mRCC, as they can be used to identify new targets for innovative therapeutic strategies. Currently, there is an unmet need to develop new predictive and prognostic biomarkers that can aid in the development of personalized treatment options for mRCC patients. In this review, we summarize several mechanisms of ICI resistance in RCC, including alterations in tumor microenvironment, upregulation of alternative immune checkpoint pathways, and genetic and epigenetic changes. Additionally, we highlight potential strategies that can be used to overcome resistance, such as combination therapy, targeted therapy, and immune modulation.

Keywords: Renal cell carcinoma, immunotherapy, immune checkpoint inhibitors, primary resistance, acquired resistance, immune exhaustion markers, immunosuppressive tumor microenvironment

INTRODUCTION

Renal cell carcinoma (RCC) accounts for approximately 3% of all adult malignancies^[1]. The incidence of RCC has been steadily increasing with 81,800 new cases estimated to be diagnosed in the United States in 2023^[2]. The 5-year relative survival rate has increased over time, with 72% survival for patients with locoregional disease, but the survival for metastatic RCC is still poor: 15%^[2]. There are different types of RCC with diverse clinical and epigenetic characteristics, of which clear cell type is the most common variant (80%), followed by papillary (15%) and chromophobe (3%-5%) histological variants^[3].

The main therapeutic options in metastatic RCC (mRCC) were interferons and interleukins till 2006. Significant advancements have been made in the field of RCC with the development of vascular endothelial growth factor receptors (VEGFR) inhibitors and mammalian target of rapamycin (mTOR) inhibitors^[4-6]. RCC has been recognized as an immunosuppressive disease. With the advent of novel immune checkpoint inhibitor (ICI) targeting programmed death-1 (PD-1), programmed death ligand-1 (PD-L1) and cytotoxic T-lymphocyte associated protein-4 (CTLA-4), the treatment paradigm of RCC has changed tremendously^[4,7,8].

Currently, ICI monotherapy and ICI combination with TKI/ICI are the standard of treatment in advanced RCC, which have significantly improved the survival of treatment-refractory mRCC patients. Nivolumab, an anti-PD-1 antibody, was approved for use in mRCC in 2015 based on the overall survival benefit seen in the CheckMate 025 trial. The objective response rate (ORR) with nivolumab was 25% compared to 5% with everolimus^[9]. Following this, based on the results of the CheckMate 214 trial, the combination of nivolumab and ipilimumab was approved for use in treatment-naïve intermediate and poor-risk mRCC patients [International Metastatic Renal Cell Carcinoma (IMDC) risk stratification criteria]^[10]. The combination has resulted in an improvement in overall survival, with an ORR of 42% and a complete response rate of 11% over a span of 5 years^[11]. Several VEGFR-TKIs have shown survival advantages in mRCC when used in combination with the ICI. The combination of pembrolizumab (PD-1 inhibitor) and axitinib (VEGFR inhibitor) (Keynote-426), nivolumab and cabozantinib (CheckMate 9ER), lenvatinib and pembrolizumab (CLEAR trial), avelumab (PD-L1 inhibitor) and axitinib (JAVELIN Renal 101) are approved as first-line options for patients with mRCC^[12-15]. All these treatments have resulted in a superior response rate and progression-free survival (PFS) compared to comparator, sunitinib.

Although these treatments have shown long-term clinical benefits in a large fraction of patients, some patients have progressive disease as the best response, consistent with primary resistance. Some patients progress after responding for a certain period, reflecting acquired resistance to these systemic treatment options. All these treatments have improved the outcomes in mRCC; however, these are limited by the innate and acquired resistance that emerges. The cancer-immunity cycle, which involves the development of neoantigens, antigen presentation, T-cell responses, and the recognition and destruction of cancer cells, describes the inherent immune biology of cancer and resistance to ICIs^[16]. Understanding the mechanisms behind the resistance is needed to develop therapeutic strategies to overcome it and thus maximize therapeutic efficacy. In this review article, we mention the mechanism of action of ICI, highlight the mechanisms of resistance to ICI, and the potential approaches to overcome resistance to ICI in mRCC.

Mechanism of action of immune checkpoint inhibitors

The mechanism of resistance to ICI is not completely understood. To understand the biology behind the resistance formation, an adequate understanding of the mechanism of action of immunotherapy is necessary. The major histocompatibility complex (MHC)/antigen on the antigen-presenting cells (APCs) interacts with the T cell receptors (TCR) and activates the T cells which lead to a cascade of events involving

stimulatory and inhibitory signals^[17]. Upon activation, the T cells release interferon-gamma (IFN- γ), which promotes cytotoxicity and results in the upregulation of PD-L1 expression in the tumor cells. The PD-1, which is expressed on the activated T cells, interacts with the PD-L1, resulting in the inhibition of the antitumor response by the T cells^[18]. Similarly, the interaction of CTLA-4 expressed on the T cells with its ligands CD80/CD86, B7 on APC prevents the stimulation, proliferation, and activation of T cells, thus diminishing the immune response^[19,20]. The above is responsible for T cells being anergic and relatively inactive against certain cancers like RCC and melanoma. Expression of other coinhibitory receptors, such as TIM-3 and LAG-3, leads to T-cell exhaustion^[21]. ICIs targeting PD-1/PD-L1, and CTLA-4 can facilitate T-cell activation and overcome anergy and thus improve the antitumor immune response^[7] [Figure 1].

Mechanism of resistance to immunotherapy in RCC

The resistance to ICI occurs due to the complex and evolving interactions between the immune system and cancer cells. Several patient factors, tumor microenvironment factors, and oncogenic signaling pathways play an essential role in the development of resistance to systemic therapies. The resistance to immunotherapy can be classified broadly into two categories: (a) primary resistance, in which patients will have progressive disease as best response to immunotherapy; and (b) acquired resistance, in which patients will respond to immunotherapy for some time and eventually have progression of the disease. This could occur in two ways: (a) resistance formation while on the drug (acquired resistance) and (b) progression of disease after a long treatment-free interval, which is uniquely seen after discontinuation of therapy upon the development of immune-related adverse events (IRAE) (we call it “loss of response”) [Figure 2]. There is no specific consensus regarding the timeline of the development of the acquired resistance^[21]. High tumor mutational burden (TMB) and high neoantigen expression have been associated with a more consistent response to ICI^[22]. Resistance to ICI therapy can be due to a defect in any of the steps explained in the mechanism of action of ICI. It could be due to insufficient production or impaired function of antitumor T-cells, or lack of adequate memory T-cell formation. Several patient factors, tumor microenvironment (TME) factors, oncogenic pathways, and immune checkpoints impact the creation and sustainment of an antitumor microenvironment.

Tumor microenvironment

TME in RCC is composed of several factors, such as extracellular matrix, immune cells, stromal cells, aberrant blood vessels, cytokines, and growth factors, which affect the growth, development and progression of the tumor and the treatment response. RCC is one of the tumors which has a high immune microenvironment composed of T cells. Increased proportion of the T regulatory cells (Tregs) in the TME is associated with an immunosuppressive environment in several malignancies^[23]. Tregs suppress the T effector (T-eff) cells through inhibitory cytokines such as transforming growth factor (TGF)- β , interleukin (IL)-10, direct cytotoxicity through perforins/granzyme, promotion of T cell exhaustion and thus prevent the tumor-specific immune response which leads to resistance to ICI^[24-26]. The proportion of Tregs has predictive and prognostic values^[27-29]. In a study by Griffiths *et al.*, a high frequency of Tregs in the peripheral blood of RCC patients was found to be associated with reduced survival^[30].

Myeloid-derived suppressor cells (MDSCs) in the TME are potent suppressors of various T cell functions, which facilitate tumors to evade immune responses. They regulate T cell proliferation, induce T cell apoptosis, and are involved in the inhibition of MHC class II proteins through several mechanisms such as arginase and nitric oxide production^[31]. Tumor-associated factors such as TGF- β , platelet-derived growth factors (PDGFs), and Interleukins (IL-3, IL-6, IL-10) induce the production of reactive oxygen species (ROS) by the MDSCs. ROS has been postulated to be one of the mechanisms through which MDSCs inhibit the cytotoxicity of T cells and create an immunosuppressive environment^[32]. In one of the studies, the depletion of MDSCs reinstated IFN- γ production and T-cell proliferation in RCC^[33]. Thus, MDSCs, along

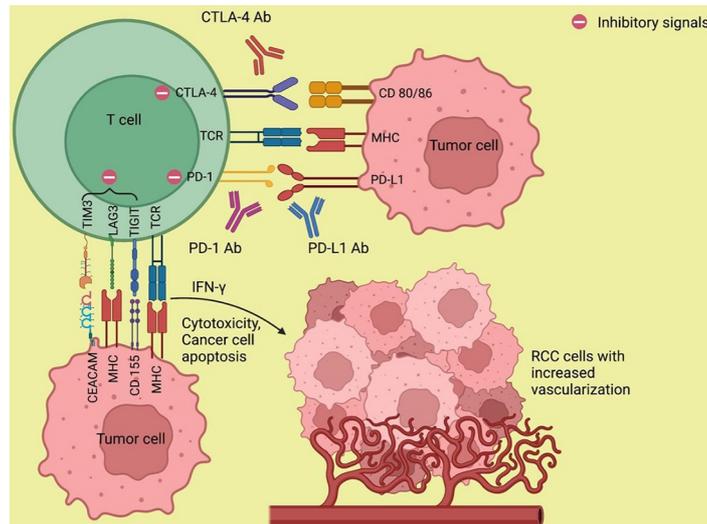

Figure 1. Mechanism of action of immune checkpoint inhibitors. The monoclonal antibodies against PD-1/PD-L1 and CTLA-4 abolish the T-cell inhibitory responses that are stimulated by the interaction of PD-1 with PD-L1 and CTLA-4 with its ligand CD 80/86 and thereby enhance antitumor immunity. Ab: Antibody; CD 80/86: cluster of differentiation 80/86; CEA/CAM: carcinoembryonic antigen-related cell adhesion molecule; CTLA-4: cytotoxic T lymphocyte-associated protein 4; IFN- γ : interferon- γ ; LAG3: lymphocyte-activation gene 3; MHC: major histocompatibility complex; PD-1: programmed death-1; PD-L1: programmed death ligand-1; RCC: renal cell carcinoma; TCR: T cell receptor; TIGIT: T cell immunoglobulin and ITIM domain; TIM3: T cell immunoglobulin and mucin domain 3. Figure 2. Types of resistance. ICI: Immune checkpoint inhibitor; IRAE: immune-related adverse events; RCC: renal cell carcinoma. (Figure credits: Roy AM).

with Tregs, create an immunosuppressive tumor environment that resists the activity of ICI.

Another component of the TME that impacts the response to ICI is tumor-associated macrophages (TAMs). During tumor development and progression, macrophages are recruited into the TME and differentiate into mature forms which aid in tumor progression. Macrophages are classified into M1 and M2 subtypes^[34]. M1 macrophages are associated with inflammatory responses by secreting pro-inflammatory cytokines such as IL-6, IL-12, IL-23, and tumor necrosis factor- α (TNF- α). Nevertheless, the M2 macrophages, especially M2d, employ anti-inflammatory and pro-tumorigenic activities^[35,36]. Studies have shown that TAMs promote tumor growth, invasion, and metastasis by altering the TME, enhancing angiogenesis and resulting in immune evasion and thus therapeutic resistance^[37-39]. TAM also has prognostic

implications; malignancies with high TAM density have been shown to have poor disease-free survival (DFS) and overall survival (OS)^[40,41].

Several cytokines in the TME also play a major role in immunoregulation. The cytokines CCL5, CCL17, CCL22, CXCL8, and CXCL12 promote immunosuppression by recruiting Tregs and MDSCs to the TME^[42]. Similarly, cytokines also promote antitumor effects, as exhibited by the increased recruitment of cytotoxic T cells (CTLs) to the TME by the cytokines CXCL9 and CXCL10^[43]. Several growth factors, such as TGF- β , Vascular endothelial growth factor (VEGF), emulate immunosuppression by upregulating Tregs and inhibiting the CTLs which impacts the response to ICI^[44,45]. By priming the vascular endothelium to allow for the extravasation of Tregs and resistance to the migration of CTLs to the TME, VEGF contributes to immune evasion and promotes rapid tumor growth and progression, while also resulting in resistance to immune checkpoint inhibitors (ICIs).

Single-cell transcriptomic studies and paired single-cell T-cell receptor sequencing have enabled us to comprehend the immune cell composition and the role of T-cell clonotype expansion in response to ICIs^[46,47]. The study by Braun *et al.* shows progressive immune dysfunction in metastatic RCC, as evidenced by a higher proportion of exhausted T-cells and immunosuppressive M2 macrophages. Additionally, it was observed that TAMs exhibit reduced production of inflammatory cytokines in advanced stages. While their study did not find a higher T-cell exhaustion/TAM interaction signature to be predictive of response to ICI, it was associated with poor overall survival^[46]. The role of CD8 T-cells in the clinical outcomes of mRCC patients treated with ICI remains controversial. Several studies have linked the infiltration of CD8 T-cells in the tumor microenvironment of RCC patients to a poorer prognosis^[48,49]. Exploratory data from the JAVELIN RENAL 101 trial revealed an association between high CD8 T cell infiltration and poor PFS in mRCC patients treated with sunitinib^[50]. This trend was not evident among patients treated with the combination of avelumab + axitinib. In another study by Voss *et al.*, no association was found between CD8 T cell density and clinical response to ICI^[51]. Hence, based on the current literature, we are unable to definitively establish a correlation between CD8 T cells and treatment response or resistance to ICI therapy, although such a possibility warrants consideration.

Oncogenic pathways and antigen presentation

Impaired antigen presentation could be associated with ICI resistance. The loss of MHC class molecules results in immune evasion and is known as a mechanism of acquired resistance to ICI. Loss of function of B2-microglobulin results in defective transport of the MHC-1 class molecules and selective downregulation of MHC-1 is associated with resistance to ICI^[52]. This was evident in a study led by Zaretsky *et al.*, which showed that a truncated mutation in the gene encoding the antigen-presenting protein B2-microglobulin led to the loss of surface expression of MHC-1 molecules and resulted in acquired resistance to PD-1 blockade immunotherapy in melanoma^[53].

Several signaling pathways mediate immune responses and contribute to the resistance to immunotherapy. JAK/STAT receptor upregulates MHC-1 expression through IFN- γ signaling which enhances antigen presentation. It also recruits immune cells to the TME and has antiproliferative effects on tumor cells and also enhances apoptosis^[54]. It was noted that the loss of function mutations in the genes encoding JAK1 or JAK2 resulted in a lack of response to IFN- γ , affects the antiproliferative effects on tumor cells, and thereby affects the response to ICI therapy in malignancies^[53]. Simultaneously, JAK/STAT receptors also increase PD-L1 expression on tumor cells through interferon regulatory factor 1 (IRF1) which grants resistance to tumor cells to the innate immune system of the body^[55]. In the setting of ICI targeting PD-1, PD-L1 amplification has shown an improved response to treatment in some malignancies^[56]. Acquired JAK/STAT

mutation results in loss of IFN- γ signaling and leads to resistance to ICI treatments through the inability to upregulate MHC-1 and PD-L1 expression^[53,57].

The mitogen-activated protein kinase (MAPK) pathway has been shown to have a significant role in immune evasion. Increased MAPK signaling impairs the recruitment and function of T cells, resulting in immune evasion. MAPK signaling is also involved in the proliferation, apoptosis, and motility of tumors^[58]. It has been shown that MAPK inhibitors promote cytotoxicity by enhancing IFN- γ signaling, MHC-1 expression, tumor-infiltrating lymphocytes and upregulating PD-L1 expression^[59].

The Wnt/ β -catenin pathway is overexpressed in many cancers. It takes part in tumorigenesis through the maintenance of cancer stem cells and metastasis and also affects cellular immune regulation^[60]. Spranger *et al.* demonstrated that the activation and overexpression of the Wnt/ β -catenin pathway are associated with resistance to anti-PD-L1 and anti-CTLA-4 monoclonal antibody therapies through T cell exclusion from the microenvironment. They also showed that activation of the WNT/ β -catenin signaling pathway results in the absence of a T-cell gene expression signature^[61]. Loss of phosphatase and tensin homolog (PTEN) leads to the expression of VEGF and activation of the phosphatidylinositol 3-kinase (PI3K) pathway, which aids in tumorigenesis. PTEN deletion also leads to the recruitment of immunosuppressive cytokines in the TME, decreased infiltration of CTLs into tumor sites and has shown inferior outcomes with PD-1 therapy^[62].

Immune checkpoints

PD-1 has been well-known as a marker of T-cell exhaustion. The other relevant immune checkpoints include CTLA-4, T-cell immunoglobulin mucin-3 (TIM-3), and lymphocyte-activation gene 3 (LAG-3), B and T lymphocyte attenuator (BTLA), T-cell immunoreceptor with immunoglobulin and ITIM domains (TIGIT). As mentioned earlier, the exhausted T-cells in advanced RCC exhibit several exhaustion markers, such as PD-1, TIM-3, TIGIT, and CTLA-4^[46,47]. Cai *et al.* demonstrated that in RCC, TIM-3 expression was associated with infiltration of dysfunctional CTLs and blockage of TIM-3 pathway in enhanced IFN- γ production and enhanced antitumor immunity^[63]. It has been demonstrated that the co-expression of these inhibitory immune checkpoints such as PD-1, TIM-3, CTLA-4, and LAG-3 is associated with the progression of lung cancer^[64]. Expression and upregulation of multiple immune checkpoints lead to T-cell exhaustion and have been linked with acquired anti-PD-1 and anti-CTLA-4 resistance in mouse models and clinically in several malignancies^[64-66]. Persistence of antigen or chronic exposure to antigen results in over-expression of these inhibitory immune checkpoints and leads to impaired effector T-cell function. Studies have shown that high expression of PD-1 leads to excessive T cell exhaustion and results in poor response to ICI, although tumors with low/intermediate PD-1 expressing CD8 T cells can be stimulated with ICI and lead to therapeutic response. Therefore, a threshold level of PD-1 expression on the intratumor CD8 T-cells can predict treatment response in at least some cancers^[67]. In addition to its role in the T-cell compartment, CTLA-4 is also reported to play a role in T-cell priming, peripheral tolerance, thymic development, and various other immunological functions that hold potential for therapeutic applications^[68].

Impaired T-cell memory

At least ICI-ICI combination has long-term durable responses as evidenced by the extended follow-up of Checkmate -214, where the combination immunotherapy ipilimumab + nivolumab remained efficacious even after 4 years^[11]. The effector CD8 T-cells play a pivotal role in the response to ICI as explained. A minority of the effector T cells transform into memory T cells inducing memory and remain inactive until repeated exposure to the antigens, thought to be the reason behind durable responses to dual CTLA-4/PD-1 blockade. It is evident that if the formation of the memory T cells is impaired, it can lead to the loss of response to ICI and will also lead to the development of acquired resistance^[69,70]. In a study by Ribas *et al.*, it was demonstrated that patients who had poor response to anti-PD-1 therapy had significantly lower tumor-

associated memory T cells compared to those who responded^[69].

Other mechanisms of resistance

Given that RCC is a hypervascular tumor, the excessive demand and inadequate supply of nutrients lead to hypoxia, which plays a role in generating an immunosuppressive microenvironment for the tumor to facilitate its progression. This acts as a vicious cycle as hypoxia upregulates genes involved in angiogenesis, cellular proliferation and it aids in the recruitment of immunosuppressive T-regs, MDSCs and accelerates the polarization of macrophages to TAMs, leading to the inhibition of the production and function of CD8 T-cells^[71]. In addition, the release of hypoxia-induced-factors (HIF) 1 and 2 leads to overexpression of inhibitory checkpoints CTLA4, TIM3, and LAG3 through the generation of VEGF, leading to a more complex tumor microenvironment and thus resistance to ICI^[72].

The association of gut microbiome in the response to ICI has been revealed. Analysis of the fecal microbiota sample showed a significant relative abundance of specific species of microbes (Ruminococcaceae family) in the anti-PD-1 responders in melanoma. Enhanced systemic and antitumor immunity was observed in anti-PD-1 responders with favorable gut microbiota. In addition, this response was observed in germ-free mice with fecal transplants from responders. The tumors of mice that received the fecal microbiota transplant from the anti-PD-1 responders had higher CD8 T-cell density compared to the mice that received the transplant from the non-responders^[73]. The utilization of antibiotics altering the gut microbiota has been shown to have a negative impact on the overall survival of several malignancies including RCC^[74-76]. Lalani *et al.* have demonstrated that the use of antibiotics 8 weeks before to 4 weeks after the initiation of immunotherapy has been associated with lower ORR and poor clinical outcomes with significantly reduced PFS^[74]. Data are lacking regarding the duration and timing of antibiotics that could impact the clinical outcomes of ICI. Increased stress-related β -adrenergic signaling has been shown to create an immunosuppressive TME and promote tumor growth^[77].

The role of cytoreduction nephrectomy in relation to ICI response remains relatively unestablished. Currently, there are no phase III clinical trials that have comprehensively evaluated the impact of cytoreductive nephrectomy on ICI response in RCC. A meta-analysis indicated that cytoreductive nephrectomy did not exhibit a significant association with the response to ICI treatments^[78].

The main mechanisms of resistance to ICIs in RCC are discussed in [Table 1](#). All the above factors contribute to the response of tumors to ICI, and by understanding the molecular mechanisms behind the resistance to ICI, we can identify potential targets for therapeutic interventions to sensitize tumors to ICI in RCC. The main mechanisms of resistance to ICIs and major trials addressing the mechanisms of resistance in RCC are given in [Table 1](#).

Strategies to overcome resistance to immune checkpoint inhibitors

As mentioned above, the mechanisms of resistance to ICI are diverse, including the intra (PD-1 expression, TMB, *etc.*) and extra-tumoral factors (T-cell types and their infiltration, T-cell activation status, TAM, *etc.*). The main strategies that are utilized to overcome the primary resistance and prevent the acquired resistance to ICI are depicted below.

Combination of treatments

One of the main strategies that is used to overcome resistance to ICI is a combinatorial approach. The combination of anti-PD-1 nivolumab and anti-CTLA-4 ipilimumab ICIs has already been approved and used with excellent clinical benefit in mRCC^[10]. The clinical benefit was observed to be higher in the combination of ICIs compared with ICI monotherapy. The ORR with nivolumab monotherapy was 25%

BTLA: B and T lymphocyte attenuator; CTLA-4: cytotoxic T lymphocyte-associated protein 4; ICI: immune checkpoint inhibitor; IFN- γ : interferon- γ ; LAG3: lymphocyte-activation gene 3; MAPK: mitogen-activated protein kinase; PD-1: programmed death-1; PD-L1: programmed death ligand-1; RCC: renal cell carcinoma; TIGIT: T cell immunoglobulin and ITIM domain; TIM3: T cell immunoglobulin and mucin domain 3.

(refractory RCC population) and that of the ipilimumab/nivolumab combination was 42% (treatment naïve RCC population). Similarly, better OS was observed with the combination therapy when used in the first-line setting; OS of ipilimumab/nivolumab therapy in intermediate and poor-risk mRCC patients was 48.1 months (55 months in the ITT) and that of nivolumab monotherapy was 25 months (second line)^[9-11]. CTLA-4 inhibition has been involved in the priming of T cells, depleting the immunosuppressive Tregs in the TME and anti-PD-1 has a role in reversing T cell exhaustion^[80].

Another strategy that is used to tackle acquired resistance to ICI is rechallenging the tumors after losing the response to ICI. One of our mRCC patients had a response for 18 months and single-agent pembrolizumab was discontinued for cutaneous irAE. This response was maintained off therapy for another 18 months and then had progressive disease. We rechallenged the patient with single-agent pembrolizumab and observed a partial response again prior to a treatment holiday. This was consistent with loss of response rather than resistance formation. Although we have observed this in clinical practice, the accurate mechanism behind response on rechallenge is not completely understood. In metastatic melanoma, rechallenging patients with primary and secondary resistance to ICI have shown to have better therapeutic outcomes. In addition, the escalation of treatment (ICI combined with additional agents) has been shown to have higher response rates in melanoma^[81]. A phase II study of salvage ipilimumab/nivolumab by Atkins *et al.* in mRCC has shown only modest benefit and is associated with increased side effects^[82]. The benefit of Salvage ipilimumab and nivolumab in mRCC patients with primary and acquired resistance was analyzed in the TITAN-RCC trial^[83]. They observed that half of the patients who received salvage ipilimumab/nivolumab for progression of the disease had clinical benefits (PR/CR 18% and SD 30%). This was irrespective of the timing of resistance development. In the recently published preliminary results of the phase III CONTACT-03

multicenter trial, patients with locally advanced or mRCC who progressed on prior ICI were randomized to receive atezolizumab and cabozantinib vs. cabozantinib alone. The addition of atezolizumab to cabozantinib did not lead to improved clinical outcomes. The median PFS in the atezolizumab and cabozantinib arm was 10.6 months (95%CI 9.8-12.3) compared to 10.8 months (95%CI 10.0-12.5) in the cabozantinib arm (HR = 1.03, $P = 0.78$). Similarly, the median OS in the combination arm was 25.7 months (95%CI 21.5-not evaluable) and was not evaluable in the cabozantinib arm (HR = 0.94, $P = 0.69$). The toxicities were higher in the combination arm, with 17 deaths compared to 9 deaths in the cabozantinib arm^[84]. Another ongoing randomized phase III trial, TiNivo-2 trial, compares the effect of the combination of nivolumab and tivozanib with tivozanib monotherapy in patients who progressed on at least one line of ICI (NCT04987203)^[85]. More biomarker studies are required to effectively understand the role of rechallenge/escalation strategy in mRCC without increasing the immune-related toxicities^[86]. It would be ideal if such studies incorporated a measure of the immune status, which could ideally include factors of tumor (real-time), T-cell/ TAM, T-cell receptor repertoire, and other relevant host factors.

ICIs are combined with several targeted agents to enhance their efficacy. Several combinations of TKIs are approved in combination with ICIs, as mentioned previously. The addition of cabozantinib to nivolumab in the first-line setting in mRCC, as noted in the Checkmate 9ER, resulted in prolonged overall survival than that was observed with sunitinib alone. The OS with the combination was 49.5 months and that of sunitinib was 35.5 months. The ORR was significantly higher with the combination (55.7% with cabozantinib + nivolumab: 28% with sunitinib), which points to the fact that the combination of TKIs and nivolumab has an additive effect^[9,14,87]. VEGF inhibitors have been studied in combination with ICIs and are shown to reverse resistance to ICI to a certain extent by regulating the immunosuppressive TME^[88]. VEGF induces various changes in the TME, including the upregulation of PD-L1, PD-1, and CTLA-4 expression on dendritic cells and other immune cells, leading to immune exhaustion^[89]. VEGF also elevates the proportion of MDSCs and T-regs in the TME, fostering an immunosuppressive environment^[90,91]. Moreover, it impedes the differentiation of CD8+ T cells and exerts an inhibitory impact on effector T-cells^[92]. When TKIs, which inhibit VEGF, are combined with ICIs, they reverse these immunosuppressive effects of VEGF, thereby enhancing T-cell priming and promoting the cytotoxic activities of immune cells^[93].

The combination of VEGF inhibitor bevacizumab and anti-PD-L1 atezolizumab has been studied in mRCC, and it was found that the combination increases CD8 T-cell density in the tumors and aids in antigen-specific T-cell migration^[94]. Unfortunately, this clinical trial was negative and failed to demonstrate meaningful improvement in survival.

Targeting TME components

As immunosuppressive TME is a major factor causing resistance to ICIs, several components of the TME such as MDSCs, Tregs, and cytokines can be targeted to potentially reverse the resistance. As mentioned above, several cytokines play a role in recruiting immunosuppressive cells and CTLs into the TME. Epigenetic silencing of CXCL9 and CXCL10 expression can lead to resistance to ICI by reduction of the tumor-infiltrating lymphocytes^[43]. In an ovarian cancer model, epigenetic modulator therapy reversed the suppression of these cytokines and improved response to ICIs^[95]. In metastatic urothelial cancer, the inhibition of TGF- β is found to be associated with improved response to ICIs^[96].

Targeting immune exhaustion markers

The overexpression of the immune exhaustion marker such as TIM-3, and LAG-3 leads to resistance to ICI therapy as mentioned above. TIM-3 has been reported as a predictive biomarker of ICI response in RCC. In RCC, co-expression of TIM3 and PD-1 correlated with large tumor size, aggressive phenotype, lower PFS, and OS and showed a higher risk of relapse^[97]. Therefore, targeting these exhaustion markers alone or in

combination with PD-1 can lead to better clinical response. There are several ongoing clinical trials studying the effect of anti-TIM3 antibodies alone and in combination with anti-PD-1/PD-L1 antibodies in advanced solid tumors and hematological malignancies (NCT02817633, NCT03099109). The benefit of anti-LAG3 has been extensively investigated in solid tumors including mRCC. A phase I trial evaluating the utility of a recombinant soluble LAG-3 fusion protein, IMP321, showed an acceptable toxicity profile and better clinical outcomes^[98]. There are several ongoing clinical trials evaluating the efficacy of relatlimab, an anti-LAG3 antibody in combination with ICI in advanced solid tumors, including mRCC (NCT02996110, NCT05328908).

Cancer vaccines incorporating dendritic cells, tumor-specific peptides, and oncolytic virus therapy have been investigated in various tumors. These have been found to induce antigen presentation and T-cell priming^[99]. A clinical trial investigating a multi-peptide vaccine with nivolumab has demonstrated immunologic activity with promising survival in high-risk melanoma^[100]. Clinical trials investigating oncolytic virus therapy in advanced solid tumor malignancies are ongoing (NCT03206073, NCT05346484). A phase II trial investigating pexa-vec, an oncolytic vaccinia virus, has shown a 76% disease control rate including one CR in patients with mRCC^[101]. Given the benefit of fecal microbiota transplant in germ-free mice to overcome resistance to PD-1 blockade, gut microbiota modulation is emerging as a strategy to improve the efficacy of ICI and reverse resistance^[73]. As stress pathways and β -adrenergic signaling play a significant role in the enhancement of an immunosuppressive TME, thereby decreasing the clinical response of ICI, blocking of the adrenergic pathways would enhance the activity of ICI. This was evidenced in a phase I clinical trial in which the addition of propranolol, a β -blocker to pembrolizumab in metastatic melanoma, showed promising clinical activity^[102].

CONCLUSION AND FUTURE DIRECTIONS

With the use of ICI, the survival of patients with mRCC has improved significantly. Although many patients have achieved durable clinical benefits, including CR, primary and acquired resistance to ICI is a significant challenge that remains to be addressed. This resistance may be due to various factors, such as alterations in the tumor microenvironment, activation of alternative signaling pathways, or overexpression of immune exhaustion markers. Thus, there is an unmet need to elucidate the mechanisms underlying immunotherapy resistance in metastatic renal cell carcinoma and to develop strategies to overcome this issue. Addressing this problem is crucial to improve the efficacy of immunotherapy and ultimately improve outcomes for patients with metastatic renal cell carcinoma.

DECLARATIONS

Abstract

Immunotherapy has become integral in cancer therapeutics over the past two decades and is now part of standard-of-care treatment in multiple cancer types. While various biomarkers and pathway alterations such as dMMR, CDK12, and AR-V7 have been identified in advanced prostate cancer to predict immunotherapy responsiveness, the vast majority of prostate cancer remain intrinsically immune-resistant, as evidenced by low response rates to anti-PD(L)1 monotherapy. Since regulatory approval of the vaccine therapy sipuleucel-T in the biomarker-unselected population, there has not been much success with immunotherapy treatment in advanced prostate cancer. Researchers have looked at various strategies to overcome immune resistance, including the identification of more biomarkers and the combination of immunotherapy with existing effective prostate cancer treatments. On the horizon, novel drugs using bispecific T-cell engager (BiTE) and chimeric antigen receptors (CAR) technology are being explored and have shown promising early efficacy in this disease. Here we discuss the features of the tumour microenvironment that predispose to immune resistance and rational strategies to enhance antitumour responsiveness in advanced prostate cancer.

Keywords: Prostate cancer, immunotherapy, immune checkpoint inhibitor, immune resistance, tumour microenvironment

INTRODUCTION

Prostate Cancer has the second highest cancer incidence worldwide and is the 5th leading cause of cancer death in men^[1]. The cornerstone treatment of locally-advanced and metastatic prostate cancer centres upon androgen deprivation therapy. Patients who experience disease progression while having castrate levels of testosterone are considered castration-resistant. In the advanced prostate cancer setting, additional treatment modalities include novel hormonal agents (NHAs), chemotherapy, radioligand therapy, poly(ADP)-ribose polymerase (PARP) inhibitors, and immunotherapy. Successive waves of clinical trials in the past decade have brought these treatment modalities forth from the castration-resistant setting into the hormone-sensitive setting, showing improved survival with early introduction of chemotherapy, NHAs, or combinations of these^[2]. Despite these advances in prostate cancer treatment, the 5-year survival for metastatic prostate cancer patients in 2022 remains low at 32.3%^[3].

Immunotherapy, in the form of sipuleucel-T, received FDA approval in 2010 for the treatment of patients with asymptomatic or minimally symptomatic metastatic castration-resistant prostate cancer (mCRPC). In patients with deficient mismatch repair or microsatellite-high (dMMR/MSI-H) tumours, pembrolizumab and dostarlimab are FDA-approved options^[4,5]. However, the prevalence of dMMR/MSI-H in prostate cancer is dismal at 1%, with *MSH2* being the most frequently implicated (other MMR genes being *MSH6*, *MLH1*, *PMS2*)^[6]. Owing to an immunologically “cold” microenvironment in unselected acinar prostate adenocarcinoma, to date, no other immunotherapeutic agents have shown to be beneficial in the current treatment of advanced prostate cancer. In this review, we look at the current treatment paradigm, the role of immunotherapy, and existing and up-and-coming methods to overcome immune therapy resistance in prostate cancer.

IMMUNE REGULATION IN THE TUMOUR MICROENVIRONMENT (TME) OF PROSTATE CANCER

Immuno-oncology has changed the treatment paradigm of multiple tumour types, including melanoma, renal cell carcinoma, and lung carcinoma. The cancer-immunity cycle is depicted in [Figure 1](#), explaining how the innate immune system fends off cancer cells and the various points at which therapeutic targets act. Despite successes in these typically immunogenic tumours, prostate cancer has traditionally been considered to have an immunologically “cold” tumour microenvironment (TME) characterized by T cell exclusion, low neoantigen load, and a highly immunosuppressive microenvironment comprising a high proportion of myeloid-derived suppressor cells (MDSCs)^[7,8]. Factors that suggest a maladaptive immune response against tumour cells include lack of tumour-infiltrating lymphocytes (TILs), presence of M2-polarized tumour-associated macrophages (TAMs) and MDSCs, with evidence that increment in such cell populations within the TME is correlated with tumour progression^[9]. MDSCs are immune cells that are activated in cancers and display potent immunosuppressive effects leading to prostate cancer resistance to anti-hormonal therapy^[10]. Furthermore, CRPCs frequently exhibit *PTEN* loss, which is associated with increased MDSC infiltration^[11] and may interact with the interferon-1 pathway required for innate immune activation^[12]. Other immune-suppressive factors within the TME, such as soluble tumour necrosis factor (sTNF), interleukin-1 beta (IL-1 β), TGF- β , and IL-10, promote chronic inflammation and increase myeloid cell differentiation into MDSCs^[13,14].

Reduced immune stimulatory factors can also contribute to the immunologically cold TME in prostate cancer. CRPC patients have decreased peripheral natural killer (NK) cell pools, and this may be due to increased NK cell group 2 member D (NKG2D) serum receptor levels from the tumour^[15]. This phenomenon is more pronounced with metastatic disease^[9]. NK cells are lymphocytes that have roles in innate and adaptive immunity, whereas NKG2D is an activating cell surface receptor expressed on NK cells,

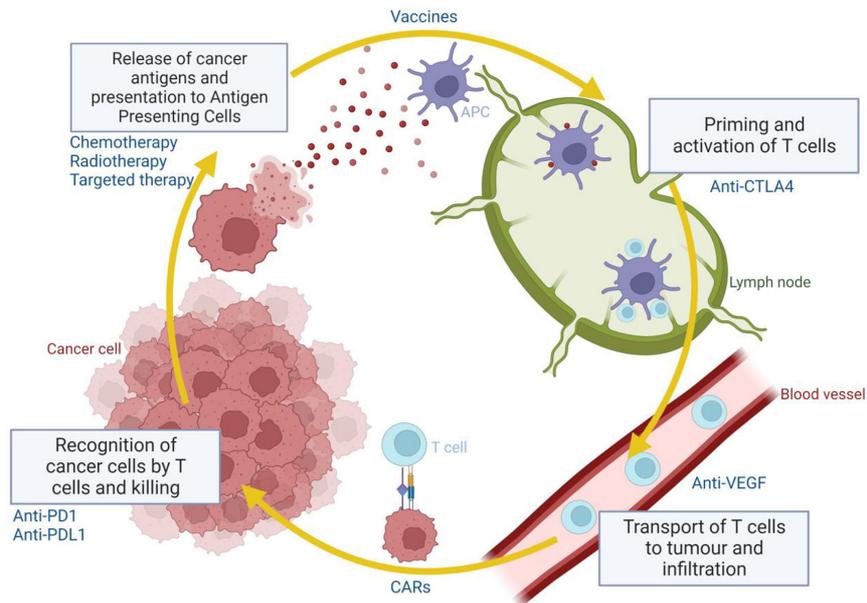

Figure 1. The cancer immunity cycle and where various classes of drugs act on.

NKT cells, and subsets of $\gamma\delta$ T cells. Although initially thought to enhance immune responses against cancer, it appears that when NKG2D ligands are expressed chronically, this can instead lead to inhibition of immune cell function^[16]. Low tumour mutational burden (TMB) in prostate cancer is associated with reduced neoantigen load recognised by the immune system^[17]. These mechanisms enable immune evasion by cancer cells and directly impact the therapeutic response to anti-PD(L)1/anti-CTLA4 immune checkpoint inhibitors (ICIs)^[18]. **Figure 2** illustrates the interplay amongst the immune cells, cancer cells and vascular supply within the TME.

Potential biomarkers for ICI response include dMMR/MSI-H as mentioned above and tumours with DNA damage repair (DDR) pathway deficiencies. Tumours with DDR pathway deficiencies have increased mutational load as a result of decreased DNA repair capacity, leading to genomic instability^[19]. Patients with somatic alterations in genes involved in DNA replication or repair have been shown to express higher neoantigen load, higher mutational burdens, higher levels of CD3+ and CD8+ TILs and higher PD-1/PD-L1 levels, all of which correlate with sustained ICI responses^[20-24]. Despite this, dMMR and *CDK12*-altered prostate cancers have more aggressive biology^[25,26]. A retrospective study of prostate cancer patients from the Royal Marsden Hospital showed that 8.1% of the patients had dMMR, which was correlated with decreased survival (median OS 4.1 years for dMMR vs. 8.5 years for proficient MMR)^[26]. *CDK12* alterations were found in 6% of advanced prostate cancer in one study^[25], and were typically linked to poor prognosis as well as insensitivity to PARP inhibitors^[27]. However, these tumours have increased neoantigen load and tumoural lymphocyte infiltration, which may increase their response to ICIs^[27].

ICI MONOTHERAPY IN THE UNSELECTED PROSTATE CANCER PATIENT

Cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) is a receptor found on the surface of T lymphocytes. When APCs activate T cells in response to the presence of foreign antigens, there is involvement of costimulatory molecules such as CD28 and B-7, which enhance the immune response. CTLA-4 acts as an immune checkpoint by binding to B-7, counteracting the costimulatory effect of CD28 and overall cause suppression of the immune response^[28,29]. Cancer cells can downregulate the immune

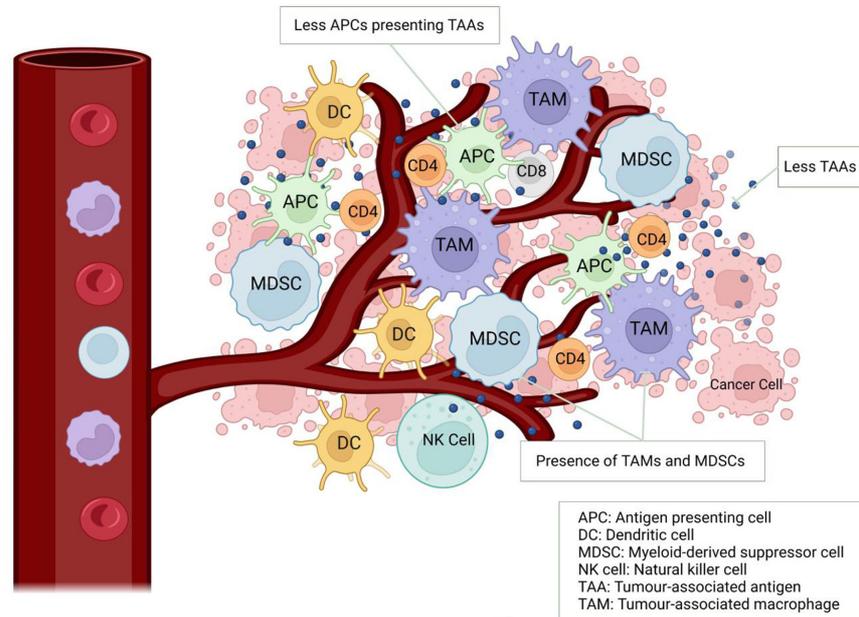

Figure 2. The immunologically "cold" tumour microenvironment in prostate cancer.

response by exploiting CTLA-4, and this forms the basis of targeting CTLA-4 with monoclonal antibodies such as ipilimumab. Inhibition of CTLA-4 activity causes activation and proliferation of cytotoxic T cells against tumour cells^[30,31]. To date, two phase 3 trials have looked at the activity of ipilimumab in mCRPC patients. The first study, CA 184-043, recruited 799 mCRPC patients with at least one bone metastasis and have progressed on docetaxel chemotherapy. Patients were randomised to receive either one fraction of bone-directed radiation therapy followed by ipilimumab at 10 mg/kg or placebo. There was no overall survival benefit seen in this study (median OS 11.2 vs. 10 months, HR 0.85, 95% CI 0.72-1.00), but a progression-free survival (PFS) benefit (4.0 vs. 3.1 months, HR 0.70, 95% CI 0.61-0.82) was seen^[32]. The second study by Beer *et al.* (2017) randomised 602 mCRPC patients who were chemotherapy-naive and had no visceral metastases to ipilimumab at 10 mg/kg vs. placebo. The study showed no overall survival benefit (median OS 28.7 vs. 29.7 months; HR 1.11, 95% CI 0.88-1.39), although a PFS benefit (median PFS 5.6 vs. 3.8 months; HR 0.67; 95% CI 0.55-0.81) was observed. Exploratory analyses further showed a higher prostate-specific antigen (PSA) response rate with ipilimumab (23%) than with placebo (8%)^[33]. Taken together, the PFS and PSA response with ipilimumab suggests antitumour activity despite the lack of survival benefit.

PD-1 is a transmembrane glycoprotein found on the surfaces of activated cytotoxic T cells, B cells, dendritic cells, NK cells, and macrophages^[34]. The binding of PD-1 to its ligands programmed death ligands 1 and 2 (PD-L1 and PD-L2) found on cancer cells delivers inhibitory signals for T-cell activation, suppressing an immune response^[35,36]. Monoclonal antibodies targeting PD-1/PD-L1, such as nivolumab and pembrolizumab, have shown activity in multiple cancer types, leading to regulatory approval for their use^[37,38]. Pembrolizumab was studied in the phase 1b KEYNOTE-028 and phase 2 KEYNOTE-199 trials as monotherapy in mCRPC, showing poor responses^[39,40]. The objective response rate (ORR) was 5% in PD-L1 combined positive score (CPS) ≥ 1 patients in KEYNOTE-199, compared with 3% for patients with a negative PD-L1 expression^[39]. Three phase 1 dose-escalation trials of nivolumab monotherapy in mCRPC patients likewise showed no objective response^[41-43]. As mentioned, the paucity of PD-L1 expression in the TME in prostate cancer patients could account for this. Despite the glaringly low response rates for anti-PD(L)1/anti-CTLA4 monotherapies in unselected prostate cancer, the expression of immune

checkpoints has been reported to be dynamic, and various agents such as ipilimumab, sipuleucel-T and enzalutamide can increase T cell infiltration into the TME and modulate response to anti-PD(L)1 therapy^[44]. This sets the stage for combination of various therapies with ICIs to improve immunotherapeutic response in prostate cancer.

ONGOING STRATEGIES TO OVERCOME IMMUNE RESISTANCE

Several strategies have been examined to modulate antitumour immunity in advanced prostate cancer.

PARP inhibitors and ICIs

PARP inhibitors are small molecules that prevent the repair of single-strand DNA breaks. Pathogenic DDR gene alterations are found in 23% of mCRPCs^[45], with *BRCA2*, *ATM*, *CHEK2*, and *BRCA1* being the most frequently implicated genes^[46]. The resulting homologous recombination deficiency (HRD) leads to sensitivity to PARP inhibition as a result of synthetic lethality^[47]. Presently in mCRPC patients, the FDA has approved rucaparib for use in those with germline/somatic *BRCA* mutation and olaparib for those with germline/somatic homologous recombination repair (HRR) gene mutations. This is based on a high ORR of 50.8% seen with rucaparib use in the phase 2 TRITON2 study and improved radiologic PFS with olaparib use over enzalutamide/abiraterone in the phase 3 PROfound study^[48,49]. The phase 3 TRITON3 study showed similar results^[50]. Furthermore, efforts made in examining PARP inhibition in unselected patients have been successful as well, with the phase 3 PROpel trial showing improvement in radiologic PFS with combination abiraterone plus olaparib over abiraterone plus placebo as first-line treatment of mCRPC patients, overall suggesting an increasing role in PARP inhibition^[51].

Increased micronuclei and cytosolic double-stranded DNA release after PARP inhibitor treatment as a result of PARP-DNA trapping and DNA damage leads to increased neoantigen formation, increased PD-L1 expression, increased intra-tumoural CD8 T cell infiltration and increased interferon production in the TME, forming the basis for ICI-PARP inhibitor combinations, and potentially expanding the benefit of PARP inhibitors beyond tumours harbouring alterations^[52,53]. A phase 2 open-label clinical trial combining durvalumab with olaparib in men with mCRPC showed a response (radiographic or biochemical) in 9 out of 17 patients. Five of the 9 responders were found to have dysfunctional DDR genes based on genomic analysis and the presence of mutated DDR genes was associated with significantly higher 12-month PFS than those without (83.3% vs. 36.4%). Interestingly, patients with fewer peripheral MDSCs were more likely to respond^[54]. This study showed early evidence of combining PARP inhibitors and ICIs, and other ongoing studies looking at similar combinations are listed in [Table 1](#).

As mentioned, *CDK12*-altered prostate cancers typically carry poor prognosis and do not respond well to PARP inhibition, yet they present increased neoantigen load and lymphocytic infiltration, which may increase responsiveness to anti-PD1 therapy^[25,27]. A retrospective study of 60 men with *CDK12*-altered advanced prostate cancer showed that of the 9 men who received PD-1 inhibitor therapy, 33% had a PSA response and the median PFS was 5.4 months^[27,55]. Similarly, the ongoing phase 2 IMPACT trial has shown a 21.4% PSA response with ipilimumab-nivolumab combination in these patients^[55].

Vaccines and ICIs

Anti-cancer vaccines can be classified into four groups: cell-based, viral-based, DNA/RNA-based, and peptide-based vaccines^[56,57]. The goal of vaccine therapy is to stimulate the host's adaptive immune response against tumour-associated antigens (TAA). Prostate cancer is suitable for vaccine therapy because it has many TAAs such as PSA, prostate-specific membrane antigen (PSMA), prostate acid phosphatase (PAP), prostate stem cell antigen (PSCA), prostate cancer antigen 3 (PCA3), mucin-1, and six-transmembrane epithelial antigens of the prostate (STEAP)^[58].

Table 1. Trials looking at ICI combinations in treatment of advanced prostate cancer

Trial number	Phase	Intervention arm(s)	Population	Outcome	Status
ICIs + PARP inhibitors					
NCT02484404	2	Durvalumab + Olaparib	mCRPC after progression with 1 NHA or Docetaxel	ORR, safety, DOR, PSA response	Completed
NCT04336943	2	Durvalumab + Olaparib	Recurrent prostate cancer with immunogenic signature	PSA response	Active, recruiting
NCT03834519	3	Pembrolizumab + Olaparib NHA (Abiraterone or Enzalutamide)	mCRPC after progression with 1 NHA and chemotherapy	OS, rPFS	Active, not recruiting
NCT02861573	1/2	Pembrolizumab + Olaparib Multiple cohorts	mCRPC	ORR, safety, PSA response	Active, recruiting
NCT05568550	2	Pembrolizumab + Olaparib + RT Pembrolizumab + RT	High-risk localised PC	PSA response	Not yet recruiting
NCT03338790	2	Nivolumab + Rucaparib Nivolumab + Docetaxel Nivolumab + Enzalutamide	mCRPC	ORR, PSA response	Active, not recruiting
NCT04592237	2	Maintenance Cetrelimab + Niraparib Maintenance Niraparib	Aggressive variant mPC given induction Cabazitaxel + Carboplatin + Cetrelimab	PFS	Active, recruiting
ICIs + vaccines					
NCT03024216	1	Atezolizumab + Sipuleucel-T	mCRPC	Safety	Completed
NCT01832870	1	Ipilimumab + Sipuleucel-T	CRPC eligible to receive Sipuleucel-T in accordance to FDA-approved labeling	Antigen-specific T cell response, antibody response	Completed
NCT00113984	1	MDX-010 (anti-CTLA-4) + PROSTVAC-V/TRICOM (virus vaccine)	mCRPC after progression with anti-androgens and ≤ 1 chemotherapy	Safety	Completed
NCT02933255	1/2	Nivolumab + PROSTVAC-V/F	mCRPC Neoadjuvant therapy for localised PC planned for surgery	Safety, changes in T-cell infiltration	Active, recruiting
NCT03315871	2	M7824 (anti-PD-L1/TGF β) + PROSTVAC + CV301 (virus vaccine)	CRPC	PSA response	Active, recruiting
NCT03532217	1	Ipilimumab + Nivolumab + PROSTVAC-V/F + Neoantigen DNA vaccine	mHSPC	DLT, safety, immune response	Completed
NCT03493945	1/2	M7824 (anti-PD-L1/TGF β) + BN-Brachyury (virus vaccine) + N-803 (IL-15 superagonist complex) + Epacadostat (IDO1 inhibitor)	CRPC	CBR	Active, recruiting
NCT02325557	1/2	Pembrolizumab + ADXS31-142 (bacteria vaccine)	mCRPC after progression on ≤ 3 systemic therapies	Safety	Unknown
NCT02499835	1/2	pTVG-HP + concurrent Pembrolizumab pTVG-HP + sequential Pembrolizumab	mCRPC	ORR, safety, PSA response, PFS	Active, not recruiting
NCT04090528	2	Pembrolizumab + pTVG-HP (DNA vaccine) + pTVG-AR HP (DNA vaccine) Pembrolizumab + pTVG-HP	mCRPC	PFS	Active, recruiting
NCT04382898	1/2	Cemiplimab + BNT112 BNT112 (RNA vaccine)	mCRPC after progression on 2-3 therapies including NHA and/or chemotherapy	DLT, ORR, Safety	Active, recruiting
ICIs + tyrosine kinase inhibitors					
NCT04446117	3	Atezolizumab + Cabozantinib + NHA (Abiraterone or Enzalutamide)	mCRPC after progression on 1 NHA	PFS, OS	Active, recruiting
NCT03170960	1/2	Atezolizumab + Carbozantinib	mCRPC after progression on ≤ 1 NHA	DLT, ORR	Active, not recruiting
NCT04477512	1	Nivolumab + Cabozantinib + Abiraterone	mHSPC	DLT	Active, recruiting
NCT04159896	2	Nivolumab + ESK981 (Pan-VEGFR/TIE2 TKI)	mCRPC after progression on 1 NHA and 1 chemotherapy	Safety, PSA response	Unknown
Combination ICIs					
NCT04717154	2	Ipilimumab + Nivolumab	mCRPC with immunogenic signature	DCR	Active, recruiting
NCT03570619	2	Ipilimumab + Nivolumab	mCRPC with CDK12 aberration	ORR, PSA response	Active, not recruiting

NCT03061539	2	Ipilimumab + Nivolumab	mCRPC with immunogenic signature after progression on 1 systemic therapy	ORR, PSA response	Active, not recruiting
NCT02985957	2	Ipilimumab + Nivolumab Ipilimumab Cabazitaxel	mCRPC	ORR, rPFS	Active, not recruiting
NCT03333616	2	Ipilimumab + Nivolumab	Non-adenocarcinoma PC	ORR	Active, recruiting
NCT02788773	2	Durvalumab + Tremelimumab	mCRPC with prior exposure to 1 NHA	ORR	Active, not recruiting
ICIs + androgen receptor antagonist					
NCT03016312	3	Atezolizumab + Enzalutamide Enzalutamide	mCRPC with prior exposure to 1 NHA and 1 chemotherapy	OS	Completed
NCT02787005	2	Pembrolizumab + Enzalutamide	mCRPC progressing on Enzalutamide	ORR	Completed
NCT04191096	3	Pembrolizumab + Enzalutamide Enzalutamide	mHSPC	rPFS, OS	Active, not recruiting
NCT03834493	3	Pembrolizumab + Enzalutamide Enzalutamide	mCRPC, allows for prior Abiraterone exposure	rPFS, OS	Active, not recruiting
NCT02312557	2	Pembrolizumab + Enzalutamide	mCRPC after progression on Enzalutamide	PSA response	Active, not recruiting
NCT03338790	2	Nivolumab + Rucaparib Nivolumab + Docetaxel Nivolumab + Enzalutamide	mCRPC	ORR, PSA response	Active, not recruiting
NCT01688492	1/2	Ipilimumab + Abiraterone	mCRPC	Safety, PFS	Active, not recruiting
ICIs + chemotherapy					
NCT03338790	2	Nivolumab + Docetaxel	mCRPC	ORR, PSA response	Active, not recruiting
NCT04100018	3	Nivolumab + Docetaxel Nivolumab	mCRPC after progression on 1-2 NHAs	rPFS, OS	Active, recruiting
NCT03834506	3	Pembrolizumab + Docetaxel Docetaxel	mCRPC with prior exposure to 1 NHA	rPFS, OS	Active, not recruiting
NCT02861573	1/2	Pembrolizumab + Docetaxel Multiple cohorts	mCRPC	ORR, safety, PSA response	Active, recruiting
NCT03409458	1/2	Avelumab + PT-112 (Platinum + Pyrophosphate ligand)	mCRPC	Safety, PSA response	Active, not recruiting
NCT02601014	2	Nivolumab + Ipilimumab	AR-V7-expressing mCRPC	PSA response	Completed
NCT02788773	2	Durvalumab + Tremelimumab Durvalumab	mCRPC with prior exposure to 1 NHA	ORR	Active, not recruiting
ICIs + radiopharmaceuticals					
NCT02814669	1	Atezolizumab + Radium-223	mCRPC after progression on 1 NHA and 1 chemotherapy	ORR, safety	Completed
NCT04109729	1/2	Nivolumab + Radium-223	mCRPC with symptomatic bone metastases	Safety, ctDNA reduction	Active, recruiting
NCT03658447	1/2	Pembrolizumab + 177Lu-PSMA	mCRPC after progression on 1 NHA	Safety, PSA response	Completed

CBR: Clinical benefit rate; CRPC: castration-resistant prostate cancer; DCR: disease control rate; DLT: dose limiting toxicity; DOR: duration of response; ICIs: immune checkpoint inhibitors; mCRPC: metastatic castration-resistant prostate cancer; mPC: metastatic prostate cancer; NHA: novel hormonal agent; ORR: objective response rate; OS: overall survival; PARP: poly(ADP)-ribose polymerase; PC: prostate cancer; PFS: progression-free survival; PSA: prostate-specific antigen; rPFS: radiologic progression-free survival; RT: radionuclide therapy.

Sipuleucel-T is a therapeutic dendritic cell-based vaccine that has received FDA approval for use in the treatment of patients with asymptomatic or minimally symptomatic mCRPC, based on overall survival (OS)

benefit seen from the phase 3 IMPACT trial^[59]. It is prepared from autologous peripheral blood mononuclear cells obtained by leukapheresis, and pulsed *ex vivo* with PAP2024, a unique fusion protein of granulocyte-macrophage colony-stimulating factor (GM-CSF) and prostatic acid phosphatase (PAP). GM-CSF fosters the maturation of dendritic cells and other APCs to present PAP to the patient's T cells, resulting in PAP-specific T-cell proliferation targeting the PAP-expressing prostate cancer cells for killing. Both humoral and cellular responses have been reported, with peripheral immune responses to PAP and measures of APC activation correlating with improvements in OS^[60,61]. Despite success with the use of sipuleucel-T, other vaccines studied have not been as successful. G-VAX is another cell-based GM-CSF-secreting vaccine that utilises irradiated TAAs^[62]. The TAAs are derived from two cell lines: one hormone-sensitive (LNCaP) and one hormone-resistant (PC3)^[63]. Despite initially promising results in asymptomatic mCRPC, the phase 3 VITAL 1 and VITAL 2 trials in asymptomatic mCRPC and symptomatic mCRPC patients, respectively, failed to show the OS benefit of G-VAX plus docetaxel against docetaxel alone. Both studies were terminated early based on futility assessments. A viral-based vaccine, PROSTVAC, utilizes recombinant poxviruses that express PSA with immune-enhancing costimulatory molecules to stimulate immune response^[64,65]. In addition to induced modified human PSA, they contain three costimulatory domains for T cells (B7.1, leukocyte function-associated antigen-3, and intercellular adhesion molecule-1), called TRICOM^[66]. The phase 3 PROSPECT trial was unable to demonstrate the OS benefit of PROSTVAC against placebo control^[67].

Given the increase in T cell infiltration and inflammation within TME with sipuleucel-T^[60,61], it is therefore postulated that synergy might be observed with the combined use of vaccines and ICIs. Ipilimumab and PROSTVAC were combined in a phase 1 dose-escalation trial, showing evidence of improved clinical and immunologic outcomes. The median OS was 34.4 months^[68], which appears to be numerically larger than PROSTVAC alone in its original study^[67]. There was a PSA reduction in 54% of patients and a PSA decline of more than 50% was seen in 25% of patients. ADXS31-142 is a live, attenuated, bioengineered listeria-based vaccine targeting PSA. It is being studied as part of the KEYNOTE-046 trial, with current results showing a median OS of 33.7 months for patients treated with combination vaccine and pembrolizumab^[69]. Other ongoing studies of vaccine therapy with ICIs are listed in [Table 1](#).

Tyrosine kinase inhibitors and ICIs

Prostate cancers have dysregulated vasculature that promotes an immunosuppressive TME^[7,8]. These include promoting a shift in TAMs toward M2-like immunosuppressive phenotype, reduced maturation of dendritic cells which results in reduced antigen presentation, and increased PD-L1 expression^[70]. Vascular endothelial growth factor (VEGF) overexpression has been found to prevent the differentiation of monocytes into dendritic cells^[71]. Meanwhile, an improvement in the regulation of local vascular in preclinical models was associated with the assimilation of TAMs with M1-like immune-stimulatory phenotype, increased CD4+ and CD8+ T-cell infiltration into the TME, and reduction of MDSCs^[72-75]. These suggest that targeting angiogenesis in tumours can inhibit tumour-induced dysregulation of local vasculature and promote immunogenicity in the TME, forming the basis of combining antiangiogenesis agents with ICIs. Indeed, it has been shown in renal cell carcinoma that anti-VEGF therapy leads to a reduction in immune inhibitory stimuli such as regulatory T-cells and MDSCs^[76,77]. Aside from VEGFR targeting, the TAM family of receptor tyrosine kinases comprising TYRO3, AXL and MER has been shown to promote immune suppression as well, making it an attractive target^[78,79].

Cabozantinib is a multi-kinase inhibitor targeting MET, VEGFR-1, -2 and -3, AXL, RET, ROS1, TYRO3, MER, KIT, TRKB, FLT-3, and TIE-2^[80]. Preclinical data suggests that it has an effect on the TME by reprogramming M2 TAMs to "pro-inflammatory" M1 macrophages, in addition to reducing MDSCs and T regulatory cells^[81]. A dose-expansion cohort in the phase 1b COSMIC-021 trial evaluated the combination

of cabozantinib with atezolizumab (anti-PD1) in mCRPC patients who have had disease progression following treatment with novel hormonal agents such as abiraterone or enzalutamide. An ORR of 32% was observed in 132 patients treated with the combination, with a disease control rate (DCR) of more than 80%. This effect was consistent in patients with visceral disease as well^[82]. Due to promising results from this study, this combination is now being evaluated in a phase 3 clinical trial for mCRPC patients. Other ongoing studies looking at combination anti-VEGF therapy with ICIs are listed in [Table 1](#).

Combination ICIs

CheckMate-650 is a phase 2 study looking at various dosing combinations of nivolumab with ipilimumab in asymptomatic or minimally symptomatic mCRPC patients who have progressed on novel hormone therapy in two cohorts (chemotherapy-naive and chemotherapy-exposed). In the chemotherapy-naive cohort, nivolumab/ipilimumab achieved an ORR of 25% with a median radiological PFS of 5.5 months and a median OS of 19.0 months. In the chemotherapy-exposed cohort, the ORR was 10%, with a median radiological PFS of 3.8 months and a median OS of 15.2 months^[83]. Exploratory analyses revealed that PD-L1 $\geq 1\%$, the presence of DDR or homologous recombination deficiency (if at least one gene in the relevant gene panel had a deleterious mutation/homozygous deletion) were associated with higher ORR^[83]. In this study, 44 patients had quality-controlled whole-exome sequencing data, giving rise to a median TMB of 74.5 mutations/patient. Tumours harbouring TMB exceeding this median were associated with higher ORR, PSA response rate, radiologic PFS, and median OS^[83].

Combination nivolumab and ipilimumab has been examined in AR-V7 expressing mCRPC patients as well. Androgen receptor splice variant 7 (AR-V7) expression is found in approximately 20% of mCRPC patients and is associated with alterations in a greater number of DDR genes, which could increase susceptibility to ICIs^[84]. The STARVE-PC trial is a phase 2 non-randomised study that evaluated the activity of nivolumab and ipilimumab in 15 AR-V7 expression mCRPC patients, showing an ORR of 25%, PSA response rate of 13% and OS of 8.2 months^[85]. Responses were more pronounced in six of the patients who were found to have mutations in DDR genes (three in *BRCA2*, two in *ATM*, and one in *ERCC4*)^[86]. Lastly, an ongoing phase 2 randomised study is looking at mCRPC patients following progression on novel hormonal agents, randomising them to receive durvalumab or combination durvalumab plus ipilimumab. The ORR with combination ICI was 16% vs. 0% with durvalumab monotherapy in this study^[87]. Other ongoing trials evaluating the efficacy of combination ICIs are listed in [Table 1](#).

Androgen receptor antagonists and ICIs

How prostate cancer treatment impacts the immune response is variable. ADT enhances lymphopoiesis, which can mitigate immune tolerance to prostate cancer antigens^[88]. On the other hand, androgen receptor antagonists have been shown to inhibit T cell responses^[89].

ADT and anti-androgens can both target the AR signalling pathway and have been shown to result in an increase in the number of TILs, and a decrease in the number of regulatory T cells supporting an antitumour response to ADT^[90,91]. Animal models confirm that while ADT induces pro-inflammatory conditions initially, the subsequent development of castration resistance and immune tolerance to prostate cancer antigens reduces this^[92,93]. Therefore, the combination of AR-signalling blockade with ICIs, especially during its pro-inflammatory state, may be beneficial in the treatment of advanced prostate cancer.

The phase 2 IMbassador250 trial examined 759 advanced CRPC patients who had progressed on abiraterone and docetaxel, randomising them to receive combination enzalutamide and atezolizumab vs. enzalutamide alone. The study was closed prematurely due to futility (combination therapy vs. enzalutamide monotherapy, 15.2 vs. 16.6 months; HR 1.12, 95% CI 0.91-1.37). However, pre-planned

exploratory analyses showed a longer PFS with combination therapy in patients with high PD-L1 IC2/3, CD8 expression^[94]. The study also performed an unbiased RNA sequencing-based analysis of immune-related gene expression that had previously correlated with mCRPC responses to immunotherapy^[95], and found longer PFS with combination therapy in patients harbouring genes related to pre-existing immunity such as TAP-1, CXCL9, interferon signalling^[94]. The multicohort phase 2 KEYNOTE-199 trial examined combination pembrolizumab with enzalutamide in mCRPC patients whose disease were refractory to enzalutamide. In the cohorts with measurable disease and bone-predominant disease (cohorts 4 and 5), the disease control rate was 51% and ORR was 12%. The duration of response was almost 6 months in 60% of responders^[96]. This strategy is being evaluated further in an ongoing phase 3 trial [Table 1].

Systemic chemotherapy and ICIs

Chemotherapy may potentiate antitumour immunity by various mechanisms, including the release of TAAs and enhancing antigen presentation, stimulating the activity of cytotoxic T lymphocytes^[97,98]. Importantly, chemotherapy may reduce immunosuppressive cell populations such as MDSCs and regulatory T cells, known to maintain prostate cancer immune evasion^[99,100]. Preclinical studies have suggested that chemotherapy does improve antitumour immune responses, showing that the addition of taxanes can cause a shift in macrophage populations toward the M1-like (immune-activating) phenotype and reduce regulatory T cell and MDSC populations in mouse models^[101,102]. The multicohort phase 2 trial CheckMate 9KD showed that combination nivolumab and docetaxel in 41 chemotherapy-naive mCRPC patients who have progressed on novel hormonal agents achieved an ORR of 36.8%, radiologic PFS of 8.2 months and PSA response of 46.3%^[103]. KEYNOTE-365 is an ongoing multicohort phase 1b/2 study examining combination pembrolizumab and docetaxel in mCRPC patients, yielding an ORR of 18%, PSA response of 28%, radiologic PFS of 8.3 months, and OS of 20.4 months^[104]. Ongoing phase 3 trials (CheckMate7DX and KEYNOTE-921) evaluating the superiority of combination chemotherapy with immunotherapy over chemotherapy alone will shed light in this area [Table 1].

Radiopharmaceuticals and ICIs

¹⁷⁷Lu-PSMA-617 has gained regulatory approval for the treatment of mCRPC patients who have been treated with androgen receptor (AR) pathway inhibition and taxane chemotherapy, based on positive results on a phase 3 trial^[105]. In murine models, targeted radionuclide therapy (TRT) may increase PD-L1 expression on T cells and the combination of TRT with ICIs leads to increased infiltration of CD8 T cells^[106]. There is, hence, interest in combining radionuclide therapy with ICIs. Despite low clinical response (ORR 6.8%, PSA response 4.5%, radiologic PFS 3 months) seen on a phase 1b trial combining Atezolizumab and Radium-223 in mCRPC^[107], the interim results of another phase 1b/2 PRINCE trial are relatively promising. In this study, 37 mCRPC patients who have progressed on a novel hormonal agent and docetaxel were treated with pembrolizumab and ¹⁷⁷Lu-PSMA-617, yielding an ORR of 78%, PSA response of 73%, and 24-week radiologic PFS of 65%^[108] [Table 1].

FUTURE DIRECTIONS AND CONCLUSIONS

Research is ongoing to identify more immunogenic targets and pair them with the multiple TAAs that prostate cancer expresses. Amongst these, cellular-based therapy is an area that deserves special mention. Adoptive cell therapy involves the engineering of patients' T lymphocytes to target specific viruses or tumours. The use of chimeric antigen receptors (CAR) allows for the creation of artificial T-cell receptors used in adoptive cell therapy^[109]. A first-in-human phase 1 study of 13 CRPC patients tested PSMA-targeting CAR T cells armoured with a dominant-negative TGF- β receptor. TGF- β is an inhibitory factor found at high levels within the prostate TME. In this study, 4 patients had a $\geq 30\%$ reduction in PSA and 1 patient had a $> 98\%$ reduction in PSA. Five patients experienced grade 2 or higher cytokine-release syndrome (CRS)^[110]. Another CAR T therapy using P-PSMA-101, which targets PSMA, was evaluated in 10

heavily-pre-treated CRPC patients, yielding PSA decline in 7 patients, with 4 patients having > 50% reduction in PSA. CRS was seen in 60% of patients^[111]. Other CAR T products targeting Epithelial cell adhesion molecule (EpCAM) and Natural Killer Group 2D (NKG2D) have shown activity in prostate cancer patients as well^[112,113]. Other potential targets of interest with adoptive cell therapy include PSA, PAP, PSCA, and B7-H3^[114], and [Table 2](#) shows a list of ongoing clinical trials.

Bispecific T cell engager (BiTE) antibodies is another technology that has been developed to target TAAs such as PSMA in prostate cancer cells. Structurally, these are bispecific monoclonal antibodies that can crosslink TAAs with the coreceptors on T cells, generating an antitumour immune response. Pasotuxizumab is a bispecific monoclonal antibody that crosslinks CD3 and PSMA, and its efficacy has been studied in 16 mCRPC patients on a phase 1 trial, showing $\geq 50\%$ decline in PSA in 3 patients, of which two were long-term responders treated for 14.0 and 19.4 months, respectively. 81% of the patients had adverse events of grade ≥ 3 ^[115]. The efficacy of AMG 160, a BiTE product that binds CD3 on T cells and PSMA on cancer cells, was evaluated in mCRPC patients on a phase 1 trial. In the preliminary report, 27% of patients had confirmed PSA responses and 84% of patients experienced CRS (10% grade ≥ 3)^[116]. The study also had a subset of patients who received AMG 160 with pembrolizumab, and such a combination will likely be examined in future studies as well. Other potential BITE targets including STEAP, CEACAM5, DLL3, HER2 are being studied^[117,118], and a list of ongoing trials can be seen in [Table 2](#). [Figure 3](#) shows a schematic diagram of BiTE therapy.

On the horizon, relevant and novel targets to modulate antitumour immunity in prostate cancer may include the targeting of relevant immune-metabolic pathways, such as the adenosine receptor^[119-121], or cytokine-directed efforts, such as IL-8 involved in the differentiation of TAM to M2 phenotype (promotes immune resistance and tumour metastasis)^[122,123], IL-23 which is a cytokine secreted by MDSCs^[124] and TGF- β which promotes tumour growth and immunosuppression in the TME^[81]. Targeting cell signalling pathways such as the phosphoinositide 3-kinase/mammalian target of rapamycin (*PI3K/mTOR*) pathway has also been shown to downregulate immunosuppressive cells such as T regulatory cells and may have a role in improving ICI efficacy in prostate cancer^[125,126]. For example, in prostate cancer mouse models, intermittent *PI3K* inhibition was able to alleviate *PTEN*-null cancer cell-intrinsic immunosuppressive activity and turn “cold” tumours into T cell-inflamed ones^[127]. Novel immune checkpoints may be worth exploiting in prostate cancer. Increased expression of V domain Ig suppressor of T Cell activation (VISTA) was found to promote immune resistance following Ipilimumab treatment, which may serve as a new immunotherapeutic target in advanced prostate cancer^[128].

There are presently limited biomarkers that can identify prostate cancer patients who may benefit from ICI therapy. It appears that combination strategies to promote immunogenicity within the “cold” TME of prostate cancer can increase the effect of ICIs. We recognise that the majority of the existing efforts are presently in the preclinical or early phase setting and may not be ready for use in the clinics yet. It would nevertheless be interesting to monitor this space for future developments.

Table 2. Trials looking at novel therapies in advanced prostate cancer

Trial number	Phase	Intervention arm(s)	Population	Outcome	Status
CAR T					
NCT04227275	1	CART-PSMA-TGFβRDN	mCRPC after progression on 2 NHAs	DLT, safety	Active, not recruiting
NCT03089203	1	CART-PSMA-TGFβRDN	mCRPC after progression on ≥ 1 systemic therapy	Safety	Active, recruiting
NCT04053062	1	LIGHT-PSMA-CART	mCRPC after progression on Abiraterone and chemotherapy	Safety	Suspended
NCT04249947	1	P-PSMA-101 CAR-T	mCRPC	ORR, DLT, safety	Active, not recruiting
NCT03873805	1	Anti-PSCA-CAR-4-1BB/TCRzeta-CD19t-expressing T-lymphocytes	PSCA+ mCRPC	DLT, safety	Active, recruiting
NCT02744287	1/2	BPX-601 (PSCA-specific CAR-T cells)	PSCA+ mCRPC	DLT, safety	Active, recruiting
NCT03013712	1/2	EpCAM-specific CAR T Cells	EpCAM+ mCRPC	Safety	Unknown
BiTE					
NCT04104607	1	CC-1 (PSMAxCD3)	mCRPC after progression on ≥ 3 systemic therapies	Safety	Active, recruiting
NCT03792841	1	Acapatamab (PSMAxCD3)	mCRPC after progression on 1 NHA and 1 chemotherapy	DLT, safety	Active, not recruiting
NCT01140373	1/2	HPN424 (PSMAxCD3)	mCRPC after progression on ≥ 2 systemic therapies	ORR, DLT	Active, not recruiting
NCT03972657	1/2	REGN5678 (PSMAxCD28) + Cemiplimab	mCRPC after progression on ≥ 2 systemic therapies	ORR, DLT, safety	Active, recruiting
NCT04221542	1	AMG 509 (STEAP1xCD3)	mCRPC after progression on 1 NHA and 1 chemotherapy	DLT, safety	Active, recruiting
NCT03406858	2	HER2Bi-armed activated T cells (HER2xCD3) + Pembrolizumab	mCRPC	PFS	Active, not recruiting

DLT: dose limiting toxicity; EpCAM: Epithelial cell adhesion molecule; mCRPC: metastatic castration-resistant prostate cancer; NHAs: novel hormonal agents; ORR: objective response rate; PFS: progression-free survival; PSCA: prostate stem cell antigen.

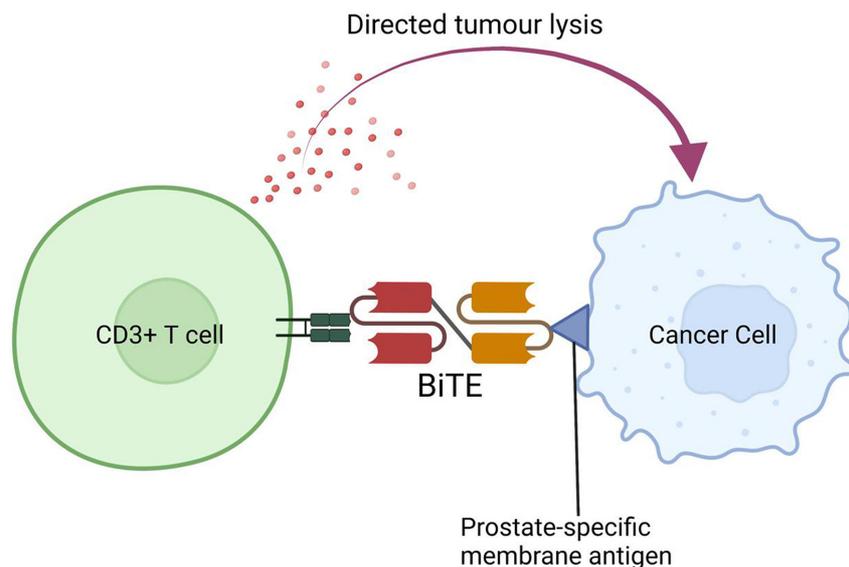

Figure 3. Bispecific T cell engager binding CD3 on T cell with PSMA on prostate cancer cell. BiTE: Bispecific T-cell engager; PSMA: prostate-specific membrane antigen.

Abstract

Acute myeloid leukemia (AML) is a heterogeneous and aggressive hematologic malignancy that is associated with a high relapse rate and poor prognosis. Despite advances in immunotherapies in solid tumors and other hematologic malignancies, AML has been particularly difficult to treat with immunotherapies, as their efficacy is limited by the ability of leukemic cells to evade T cell recognition. In this review, we discuss the common mechanisms of T cell evasion in AML: (1) increased expression of immune checkpoint molecules; (2) downregulation of antigen presentation molecules; (3) induction of T cell exhaustion; and (4) creation of an immunosuppressive environment through the increased frequency of regulatory T cells. We also review the clinical investigation of immune checkpoint inhibitors (ICIs) in AML. We discuss the limitations of ICIs, particularly in the context of T cell evasion mechanisms in AML, and we describe emerging strategies to overcome T cell evasion, including combination therapies. Finally, we provide an outlook on the future directions of immunotherapy research in AML, highlighting the need for a more comprehensive understanding of the complex interplay between AML cells and the immune system.

Keywords: Acute myeloid leukemia, T cells, immune checkpoint, immune evasion

INTRODUCTION

Acute myeloid leukemia (AML) is a devastating blood cancer and is the most common form of acute

leukemia in adults. Long-term outcomes for AML have not significantly improved over the past few decades, with a suboptimal 5-year overall survival rate of 30% for AML patients ages 20 and older and less than 10% for AML patients ages 65 and older^[1]. The current standard of care approaches for AML, including induction chemotherapy, combinations of venetoclax with hypomethylating agents, and stem cell transplantation, still yield high relapse rates with significant toxicities. Therefore, new less toxic therapeutic approaches need to be developed to improve survival and prevent relapse in this disease.

Hematopoiesis is the process through which all mature blood cell lineages are generated from hematopoietic stem cells (HSCs), which have the capacity to both self-renew and differentiate. Without proper regulation of their cell-intrinsic and cell-extrinsic cues (primarily signaling pathways, transcription factors, and epigenetic regulators), HSCs and downstream progenitors can acquire unlimited self-renewal potential at the expense of differentiation, as well as increased proliferation and survival, leading to AML development^[2-5]. AML blasts develop from aberrant HSCs or progenitors - termed the leukemic stem cell (LSC). LSCs are undifferentiated blood cells that have pathologic self-renewal properties and lead to abnormal blood production. Phenotypically, LSCs share some of the same cell surface markers as HSCs, but unique LSC and pre-LSC gene expression signatures have been identified by high throughput sequencing^[6-9]. Like HSCs, LSCs are primarily quiescent and are therefore resistant to chemotherapy and other therapies that target actively cycling cell populations^[3,10]. Yet, the standard induction “7 + 3” chemotherapy regimen remains the preferred up-front treatment strategy for AML patients who are fit enough to tolerate intensive induction therapy, which, in addition to sparing LSCs, results in various toxicities, such as pancytopenia and infection^[11,12]. This has led to enhanced research efforts to identify novel therapies that target the LSC population while sparing healthy HSCs to improve AML patient outcomes.

However, in addition to the cell-autonomous mechanisms AML cells have employed to persist despite the cytotoxic effects of chemotherapy, AML cells have developed additional ways to persist despite treatment, including resistance mechanisms to targeted therapies and immune evasion. Notably, AML cells employ several mechanisms, such as reliance on immune cells, to establish an immunosuppressive environment to ensure their survival. This is accomplished through the reduction of cytotoxic and effector T and NK cells, increased T cell exhaustion, and recruitment of immunosuppressive populations such as regulatory T cells, myeloid-derived suppressor cells (MDSCs), and M2 macrophages^[13]. Importantly, it has been reported that the number of effector and cytotoxic T cells, termed tumor-infiltrating lymphocytes (TILs), present in the bone marrow can be a prognostic marker for overall survival and leukemia-free survival^[14]. In addition, increased numbers and function of regulatory T cells in both the peripheral blood and bone marrow of AML patients have been reported, with bone marrow-resident regulatory T cells exhibiting more immunosuppressive effects on CD4+ effector T cell proliferation^[15]. A lower frequency of regulatory T cells was found to correlate with complete remission rates in AML patients, while a higher frequency was observed in patients who relapsed^[15].

Despite advances in immunotherapies in solid tumors and some lymphoid malignancies, AML has been particularly difficult to treat with immunotherapies, primarily due to poor T cell recruitment to the bone marrow and because LSCs are immune privileged. Because even with the current therapeutic options, AML remains a lethal disease with a suboptimal long-term survival rate, it is imperative to identify and exploit the mechanisms by which AML cells evade immune detection to unleash the potential benefits of immunotherapy in AML treatment. This review summarizes the roles of T cells in the immune response, and highlights the challenges that AML cells pose to the efficacy of ICIs by evading T cell detection.

T CELLS FRONT THE ADAPTIVE IMMUNE RESPONSE

The adaptive immune system plays an essential role in eliminating a variety of threats to our bodies, including cancer and infection. Key players in the adaptive immune response are B lymphocytes (B-cells) and T lymphocytes (T cells). They are distinguishable from cell types that primarily function in the innate immune response because they have antigen-specific receptors - B-cell receptor (BCR) and T cell receptor (TCR), respectively^[16]. T cells can differentiate into three different cell types: effector T cells, cytotoxic T cells, and regulatory T cells. Effector T cells, also known as “helper T cells”, which express the cell-surface protein CD4, function through cytokine signaling, such as interferon gamma (IFN γ) and tumor necrosis factor alpha (TNF α), which stimulate other immune cells^[16]. Cytotoxic T cells, which express the cell-surface protein CD8, program invading cells to undergo apoptosis via the secretion of granzyme B, perforin, and IFN γ ^[16]. Unlike effector and cytotoxic T cells, regulatory T cells function to suppress immune cells to mitigate any possible damage from a prolonged immune response, and to prevent auto-immunity^[16]. They can be identified through flow cytometry by the expression of CD4, CD25, and FoxP3^[16].

In order to activate a T cell-mediated immune response, two different signals are required. The first signal occurs when the disease-causing cell presents an antigen, or host-derived protein molecule, to a T cell [Figure 1]. Specifically, short peptide fragments of an antigen are presented on the surface of host cells, termed antigen-presenting cells (APCs), by major histocompatibility complex (MHC) molecules. There are two classes of MHC molecules, MHC class I and MHC class II. Notably, CD8+ T cells selectively recognize MHC class I molecules, while CD4+ T cells selectively recognize MHC class II molecules. MHC class II molecules are often expressed on dendritic cells and macrophages, which engulf the antigen and process it for presentation. MHC class II molecules can also be present on the surface of foreign APCs. The Class II transactivator (CIITA) is a master regulator of MHC gene expression^[17]. CIITA responds to IFN γ activation, where it then acts as a transcriptional activator to turn on MHC gene expression^[17].

The second signal required for T cell activation is termed the co-stimulatory signal, and co-stimulation is thought to occur through the interaction between the CD28 molecule on T-lymphocytes and either CD80 (B7.1) or CD86 (B7.2) molecules on the APC^[18] [Figure 1]. The discovery of CD28 and its essential role in T cell activation has led to further discovery of other cell-surface molecules that regulate T cell activity. Interestingly, the discovery of cytotoxic T lymphocyte antigen 4 (CTLA4) on T cells identified another binding partner of B7-1. However, CTLA4 expression is induced following T cell activation, where it can out-compete CD28 binding to B7.1 to dampen the T cell response^[18].

This has led to the discovery and categorization of other cell-surface molecules that positively (referred to as co-stimulatory receptors) and negatively (co-inhibitory receptors) modulate T cell activity. Other co-inhibitory receptors on T cells include programmed cell death protein 1 (PD1), which binds to its ligands programmed death-ligand 1 (PD-L1, also known as B7-H1) or programmed death-ligand 2 (PD-L2, also known as B7-H2) on APCs; T cell immunoglobulin and mucin domain-containing protein 3 (TIM3), and lymphocyte activation gene-3 (LAG3)^[19,20]. TIM3 binds to various ligands (including Galectin-9, Ceacam-1, and HMGB-1), while LAG3 binds to MHC class II molecules with higher affinity than the CD4+ TCR^[19,20]. Other co-inhibitory ligands on APCs include B7-H3, B7-H4, and B7-H5^[21].

MECHANISMS OF IMMUNE EVASION IN AML

There are currently several different immunotherapy strategies being investigated in hematologic malignancies, including in AML^[11,21]. Immune checkpoint inhibitors, such as antibodies targeting CTLA4 and PD1, have been approved for the treatment of some types of lymphoma and some solid tumors, including melanoma, lung cancer, kidney cancer, head and neck cancer, bladder cancer, and colorectal

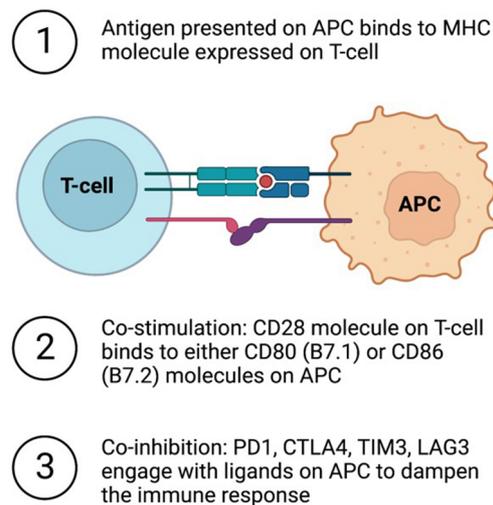

Figure 1. T cell-mediated immune response. Overview of the steps required for full T cell activation. Figure created with [Biorender.com](https://www.biorender.com). APC: Antigen-presenting cell; CTLA4: cytotoxic T lymphocyte antigen 4; LAG3: lymphocyte activation gene-3; MHC: major histocompatibility complex; PD1: programmed cell death protein 1; TIM3: T cell immunoglobulin and mucin domain-containing protein 3.

cancer^[22]. However, in AML, the use of immune checkpoint inhibitors has been more challenging, and there are no FDA approvals of this class of agents in AML to date. This is in part due to the various cell-autonomous and cell non-autonomous mechanisms that leukemic cells employ to reprogram themselves and the bone marrow microenvironment to render them immune privileged [Figure 2]. Additionally, ICIs are often most effective in cancers with a high mutation burden (i.e., melanoma, lung cancer), which is often not as high in AML^[23]. For example, many AML patients have a defined blast population with 1-2 driver mutations and/or cytogenetic alterations, with sub-clones that may not arise until disease progression or relapse^[24].

Increased immune checkpoint expression

Immune checkpoints are known to be a key mechanism that mediates T cell immunosuppression in AML. Interesting work using PD1 knockout mice delineated the importance of this axis in regulatory T cells and CD8+ cytotoxic T cells. Specifically, AML development was impeded when AML cells were injected into PD1 knockout mice^[25]. This was dependent on the ability of regulatory T cells to suppress CD8+ T cells via enhanced PD1 expression on T cells and PD-L1 expression on APCs^[25]. Interestingly, treating mice that developed AML with IL-2 linked to diphtheria toxin (IL-2DT), followed by anti-PDL1 monoclonal antibody treatment, markedly reduced the AML tumor burden^[25]. Therefore, this work suggests that strategies to deplete regulatory T cells and inhibit the PD1/PD-L1 interaction could be effective in overcoming the AML-privileged microenvironment.

T cell exhaustion is also a mechanism for immune evasion and is often phenotypically characterized by the expression of the immune checkpoint TIM3. In one study evaluating the role of exhausted T cells in AML relapse following transplantation, the frequency of PD1-high TIM3-positive T cells was significantly correlated with AML relapse^[26]. These T cells were confirmed to be exhausted, as they exhibited reduced production of IL-2, TNF α , and IFN γ ^[26]. The impact of this study was clinically significant, as the expression of exhaustion markers on T cells could be detected before the diagnosis of relapse^[26]. These results were echoed in a subsequent study that characterized the exhausted T cell population following AML relapse post-transplantation, which, despite displaying specific leukemic blast recognition (determined by CDR3

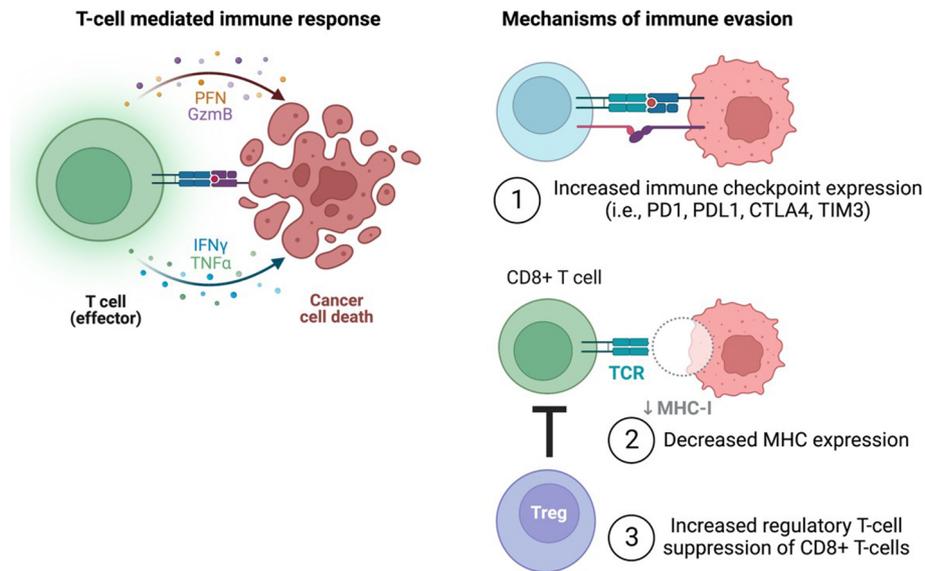

Figure 2. Mechanisms of T cell evasion in AML. T cells engage with and kill cancer cells through the presentation of MHC molecules and subsequent T cell co-stimulation (left). Mechanisms to evade T cell detection employed by AML cells include (1) increased expression of co-inhibitory immune checkpoints; (2) decreased MHC expression; and (3) suppression of cytotoxic CD8+ T cell function through increased regulatory T cells (right). Figure created with [Biorender.com](https://www.biorender.com). AML: Acute myeloid leukemia; CTLA4: cytotoxic T lymphocyte antigen 4; IFN γ : interferon gamma; MHC: major histocompatibility complex; PD1: programmed cell death protein 1; PFN: perforin; TCR: T cell receptor; TIM3: T cell immunoglobulin and mucin domain-containing protein 3; TNF α : tumor necrosis factor alpha.

sequencing of TCR- α and TCR- β chains), had impaired effector T cell function^[27]. As the prognosis for patients who relapse after transplantation is poor, early detection of T cell exhaustion markers could be a useful predictive tool^[26,27].

Modulation of checkpoint expression on AML cells themselves is another key driver of immune evasion. For example, increased PD-L1, PD-L2, and CTLA4 expression on AML cells has been shown to correlate with poor overall survival^[28,29]. PD-L1 expression was found to be elevated in AML patient blasts, both at diagnosis and at relapse^[30]. Furthermore, CTLA4 was previously discovered to not be restricted to the lymphoid lineage, as AML cells from both diagnostic and relapsed patients, but not healthy CD34+ cells, were found to express CTLA4^[31,32]. Therefore, the upregulation of inhibitory immune checkpoints on AML cells is another potential mechanism for immune evasion in AML.

Downregulation of MHC expression

Dampening of MHC expression on AML cells is also an important mechanism of immune evasion. Specifically, RNA sequencing analysis of paired AML samples collected at diagnosis and at relapse post-transplantation identified altered expression of immune-related genes, including decreased expression of CIITA, the master regulator of MHC-II expression, and of MHC-II molecules at relapse^[33]. *Ex vivo* treatment of AML blasts isolated from relapse patients with IFN γ was able to restore MHC-II expression^[33]. The clinical significance of this is revealed by the differences in CD4+ effector T cell activation, as measured by IFN γ production, following co-culture of either diagnostic or post-transplantation relapsed AML samples with CD4+ T cells, as CD4+ T cell activity was diminished in post-transplantation relapse co-culture assays^[33].

Accordingly, in a recent transcriptome analysis of AML cells from patients who relapsed following transplantation, a transcription factor complex consisting of IRF8, MYB, MEF2C, and MEIS1 was found to regulate MHC expression in AML, and combinatorial changes in their expression are essential for reduced MHC expression at relapse^[34]. Interestingly, the authors found a small cell population with silenced MHC expression at leukemia diagnosis, and concluded that, similar to resistant LSC populations, this population may be selected after transplantation and can contribute to relapse^[34]. Overall, these mechanisms are plausible explanations for why the treatment of patients who relapse post-transplantation is particularly challenging. Identifying ways to overcome decreased MHC expression following transplantation is underway. For example, a recent study using AML xenograft mouse models reported that MDM2 inhibition can increase MHC-II production, and CD8+ T cells isolated from MDM2 inhibitor-treated primary AML mice can eradicate disease in secondary recipients^[35].

The role of regulatory T cells in the immunosuppressive microenvironment

The increased number and activity of regulatory T cells (Tregs) in the leukemic bone marrow renders the bone marrow an immunosuppressive microenvironment due to their effects on effector and cytotoxic T cell populations. Recent insights have identified mechanisms for increased Treg function in the AML microenvironment, such as via increased expression and production of IFN γ by AML cells, leading to upregulation of genes that promote differentiation into Tregs^[36]. Recognizing the correlation between increased Treg numbers and poor AML outcomes, one group investigated the effects of Treg ablation on leukemogenesis^[37]. Using Foxp3-DTR to ablate Tregs in mice, they observed prolonged survival in MLL-AF9-induced AML mouse models and increased CD8+ T cell activity^[37]. As Treg ablation is likely not easily transferrable to the clinic, they also identified additional ways to impede Treg accumulation in the leukemic microenvironment in mice, including CCL3-CCR1/CCR5 and CXCL12-CXCR4 blockade^[37]. Importantly, as increased regulatory T cell populations are also a predictor of AML relapse following transplantation^[27], it is critical to exploit mechanisms that decrease Treg numbers and function.

NK cell-mediated immune evasion mechanisms

AML cells can also evade detection by NK cells, which are canonically activated by the recognition of stress-induced ligands on foreign cells^[38]. Similar to their evasion of T cells, AML cells can also evade NK-cell recognition and elimination through multiple mechanisms, including (1) the reduced expression of stress-induced ligands on AML cells; (2) increased expression of inhibitory receptors on NK cells to suppress NK cell function; (3) the induction of the immunosuppressive environment to limit NK cell numbers and function; and (4) activation of anti-apoptotic pathways to resist NK-cell induced cell death^[39,40]. These NK-cell evasion mechanisms, as well as strategies to target them, have been extensively reviewed elsewhere^[39,41-44]. For example, it was shown that epigenetic mechanisms mediate the silencing of NKG2D ligands in AML, and that treatment with hypomethylating agents can increase their expression and subsequent NK-cell recognition^[45]. Furthermore, pivotal work demonstrated that LSCs are immune privileged through their lack of expression of NKG2D ligand, which is essential for NK-cell detection and subsequent clearance^[46]. As NKG2D remains a hot target for immunotherapy in AML^[47-49], it is important to appreciate that other mechanisms may be required to eliminate the LSC population.

Another mechanism that can mediate NK-cell evasion is CD48 silencing^[50-52]. It was demonstrated that high CD48 expression on AML cells is correlated with a favorable prognosis. However, in a subset of AML patients, CD48 expression can be suppressed through enhanced methylation^[52]. Therefore, treatment with hypomethylating agents may be able to increase CD48 expression to increase NK-cell killing^[53]. Overall, understanding NK-cell evasion mechanisms is critical to overcoming immunotherapy resistance and identifying targets for immunotherapy.

CLINICAL INVESTIGATION OF IMMUNE CHECKPOINT INHIBITORS IN AML

Several strategies that incorporate checkpoint inhibitors have been tested in AML in clinical trials, and several more clinical trials are underway [Table 1]. In a phase 1/1b clinical trial of ipilimumab (anti-CTLA4) in patients with hematologic malignancies that relapsed after allogeneic stem cell transplantation, analysis of the AML subset (12/28 patients) showed that 5/12 patients achieved complete remission following treatment, and this was accompanied by a reduction in the frequency of circulating Tregs compared to non-responders^[54].

Furthermore, in a Phase II study investigating the combination of high-dose cytarabine and pembrolizumab (anti-PD1) in relapsed/refractory AML patients, 14 out of 37 patients achieved complete remission (CR). Interestingly, of the patients that achieved a CR, TCR signaling identified a trend towards increased TCR diversity in these patients, as well as decreased regulatory T cell and increased CD8⁺ T cell frequencies^[55]. Of note, RNA-seq analysis of AML blasts from these patients revealed that increased MHC expression was significantly upregulated at baseline in patients who achieved CR compared to non-responders^[55].

Interestingly, recent data suggests that PD1 signaling may be implicated in the poor response to hypomethylating agents (HMAs), including azacitidine and decitabine, as patients who are resistant to HMAs show higher expression of PD-L1, PD-L2, and CTLA4^[56-58]. On the other hand, preclinical findings from single-agent immune checkpoint inhibitor trials in AML have demonstrated limited efficacy. This has prompted the investigation of checkpoint inhibitors in combination with HMAs^[57]. In a phase 1b trial investigating the combination of ipilimumab with decitabine in relapsed/refractory AML, patients who were transplant naïve ($N = 23$) observed a higher response rate than those who relapsed following stem cell transplantation ($N = 20$) (CR + CRi + mCR 52% vs. 20%, $P = 0.034$; median overall survival 16.2 months vs. 8.6 months)^[59]. Not surprisingly, when performing integrative transcriptome-based analysis of bone marrow infiltrating cells from participating patients, a high baseline ratio of T cells to AML cells was associated with higher response rates^[60]. The authors speculated that the inadequate clearance of the immature LSC population triggered relapse in patients following stem cell transplantation, but also noted that ipilimumab exposure resulted in increased memory T cell bone marrow infiltration and high expression of CTLA4 and FOXP3, suggesting that the efficacy of ipilimumab and decitabine may be impacted by these immune evasion mechanisms employed by LSCs^[60]. The results of the ipilimumab and decitabine combination studies also highlight the limitations of ICIs in AML. A comparison of the memory and exhaustion gene scores associated with CD8⁺ T cells from AML bone marrow with those from CD8⁺ TILs isolated from solid tumors, in which ipilimumab demonstrates high clinical activity, revealed higher exhaustion profiles and checkpoint expression in solid tumor-derived T cells^[60].

In two ongoing trials testing the combination of pembrolizumab and decitabine in relapsed/refractory AML, interim results showed a tolerable safety profile with promising efficacy data^[56,61]. Furthermore, through the generation of RNA expression datasets from patients who were treated with conventional cytotoxic chemotherapy or with pembrolizumab and azacitidine in relapsed/refractory AML, Rutella *et al.* revealed a newly defined CD8⁺ T cell senescent gene population with a distinct gene expression signature^[62]. These cells were impaired in their ability to kill AML blasts isolated from the same patient sample, and their frequency negatively correlated with overall survival^[62]. However, there is still promise for the combination of PD1 blockade and HMA, as results from the Phase II trial investigating nivolumab and azacitidine in relapsed/refractory AML yielded a 33% overall response rate, with a higher response rate in HMA naïve vs. HMA pre-treated patients (58% vs. 22%)^[63]. Based on these clinical trials, the possible predictors of response to immune checkpoint inhibitors are summarized in Table 2. Overall, given these data, the field is anxiously awaiting the results of additional clinical trials currently that are investigating

Table 1. Overview of ongoing clinical trials of immune checkpoint inhibitors in AML

Target	Agent	Regimen	Population	Phase	NCT identifier	Primary endpoints
PD-1	Pembrolizumab	IC ± Pembrolizumab	ND AML	2	NCT04214249 (BLAST MRD AML-1)	MRD-CR
		VEN + AZA ± Pembrolizumab	ND AML	2	NCT04284787 (BLAST MRD AML-2)	MRD-CR
		HiDAC followed by Pembrolizumab	R/R AML	2	NCT02768792	CR
		Decitabine + Pembrolizumab ± VEN	ND or R/R AML	1	NCT03969446	Incidence of AE, MTD, CR
	Nivolumab	Nivolumab	AML patients in remission after IC	2	NCT02275533 (REMAIN TRIAL)	PFS
		Nivolumab	AML patients in remission after IC	2	NCT02532231	Recurrence-free survival
		AZA + Nivolumab ± Ipilimumab	ND or R/R AML	2	NCT02397720	MTD, ORR
		Decitabine + VEN + Pembrolizumab	ND TP53-mutant AML	1	NCT04277442	Incidence of AE, CR
CTLA-4	Ipilimumab	Nivolumab ± Ipilimumab	AML patients post-HSCT	1	NCT03600155	Optimal dose
		Decitabine + Ipilimumab	R/R AML	1	NCT02890329	MTD

immune checkpoint inhibitors in AML.

Further investigation into the molecular mechanisms that both AML cells and T cells employ to evade immune detection may help to identify novel combination strategies for ICIs in AML. For example, altered signaling and expression of cellular proteins due to genetic alterations are hallmarks of AML cells. With both approved and investigational therapies available to target oncogenes (e.g., FLT3, IDH1/2, NPM1c/Menin inhibitors) responsible for regulating the expression and/or post-translational modifications (e.g., methylation, acetylation, glycosylation, ubiquitination) of proteins in AML cells, it is critical to determine if targetable driver mutations are important for the increased expression of immune checkpoints in AML cells.

Alternatively, further investigation into the mechanisms that T cells employ to increase checkpoint expression or to increase Treg function is warranted to improve ICI outcomes in AML. For example, a recent study analyzing the transcriptome of CD8 T cells from the bone marrow of AML patients demonstrated the downregulation of genes responsible for T cell activation, differentiation, and function (e.g., NF-KB, FOXO, cytokine/chemokine signaling)^[64]. With several of these genes being involved in epigenetic regulation, the authors postulate that epigenetic changes to T cells may impair TCR activation and overall T cell function^[64]. However, additional studies are necessary.

Lastly, additional studies are underway to identify mechanisms that increase the frequency of Tregs, with some insights regarding tumor necrosis factor receptor-2 (TNFR2) and the TNF α pathway playing an important role in increasing the frequency of Tregs in AML patient samples^[65], in addition to increased expression of IFN γ via *IDO1* overexpression in mesenchymal stem cells^[36]. Importantly, the mechanisms

Table 2. Possible predictors of response to immune checkpoint inhibitors in AML or MDS

Immune checkpoint inhibitor	Clinical setting	Possible predictors of response	Response assessment	Ref
Ipilimumab	Post-HSCT	-Baseline donor T cell chimerism of > 99% -Lower frequency of CD4+ Tregs -Increase in plasma CXCL2, CXCL5, CXCL6, IL1R, ANGPT-1 and -2, VEGF	CR or stable disease	[54]
Pembrolizumab	R/R AML, post-HiDAC	-Trend towards higher TCR diversity at baseline -Higher frequency of senescent T cells in BM -Higher frequency of terminally differentiated effector T cells in PB -Increased frequency of CD8+ T cells expressing CD28, PD-1, and TIGIT in BM -Presence of pre-treatment CD8+ T cells co-expressing TCF-1 and PD-1 -Transcriptional upregulation of PI3K/AKT/MTOR signaling pathway in BM blasts	CR	[55]
Ipilimumab	In combination with decitabine in AML or MDS before and after HSCT	-No clear predictors of response	Leukemic cell burden, frequency of infiltrating lymphocytes	[59]
Ipilimumab	In combination with decitabine in AML or MDS before and after HSCT	-Lower VAF of recurrent AML/MDS-associated mutations -Higher T cell to AML ratio -Increased T cell to myeloid ratio -Donor-derived myeloid cells present at higher % in responders -Higher circulating expression of CCL17, CXCL1, CXCL5, EGF, LAMP3, and PDGF subunit B	CR/CRi	[60]
Pembrolizumab	In combination with decitabine in R/R AML	-Trend towards increased CD3+ infiltrates in BM during treatment -No association of TCRb sample clonality with response	CR	[61]
Pembrolizumab	In combination with azacitidine in newly diagnosed AML vs. cytotoxic chemotherapy	-Increased proportion of CD3+CD8+CD57+KLRG1+ senescent T cells in baseline BM associated with worse OS -Increased proportion of senescent T cells in BM post-treatment associated with worse OS -High IED signature score associated with worse OS	OS	[62]
Nivolumab	In combination with azacitidine in R/R AML	-Trend towards association with improved response: no prior HMA, presence of ASXL1 mutation -Higher frequency of pre-treatment BM % CD3+ T cells in responders -Trend towards higher frequency of CD4+ T effector cells and CD8+ T cells in pre-treatment BM in responders	ORR	[63]

AML: Acute myeloid leukemia; BM: bone marrow; CR: complete remission; CRi: incomplete remission; HiDAC: high-dose cytarabine; HMA: hypomethylating agent; HSCT: hematopoietic stem cell transplantation; IED: immune effector dysfunction; MDS: myelodysplastic syndrome; ORR: overall response rate; OS: overall survival; PB: peripheral blood; R/R AML: relapsed or refractory acute myeloid leukemia; TCR: T cell receptor; Tregs: regulatory T cells; VAF: variant allele frequency.

employed by AML cells and T cells may be interrelated, as suggested by recent evidence collected in AML cell lines that induced expression of PD-L1 on AML cells could result in the conversion and subsequent expansion of CD4+CD25+FoxP3+ Tregs from CD4+ T cells^[66].

CONCLUSION

In summary, through antigen recognition and co-stimulation, T cells front the adaptive immune response, causing AML cells to employ both cell-autonomous and cell non-autonomous mechanisms to create an immunosuppressive microenvironment and evade detection and killing by T cells. These mechanisms include (1) reduced expression of antigens and MHC molecules on the cell surface of AML cells; (2)

immune checkpoint activation to suppress T cell responses, both on T cells and on AML cells themselves; (3) induction of T cell exhaustion; and (4) the induction of an immunosuppressive environment by increasing the numbers of regulatory T cells and other immunosuppressive populations in the bone marrow to inhibit effector and cytotoxic T cell activity. All of these mechanisms ultimately promote AML cell survival. This review complements several other recent review articles in this field, which illustrate the importance of understanding the mechanisms of immune evasion in AML to overcome immunotherapy resistance and improve AML outcomes^[13,53,67-69].

In our review of the current ICI landscape for hematologic malignancies, evident frustrations arise when comparing the success of checkpoint inhibitors in solid tumors to the more limited progress made with these agents in AML. The mechanisms highlighted above undoubtedly contribute to the slow adoption of ICIs in AML. With many clinical trials underway in this space, continued research efforts identifying ways to overcome immunotherapy resistance, such as combining ICIs with targeted therapies against components of signaling pathways notoriously activated in AML, as seen in solid tumors^[70], are warranted. Furthermore, while not a major focus of this review, it remains a challenge to identify tumor-specific targets for personalized immunotherapies for AML, such as CAR T cells and bispecific antibodies^[71-73].

While this review provides some insights into the roles of immune evasion mechanisms in relapse following stem cell transplantation, as well as the clinical trials underway utilizing ICIs for this patient population, the poor prognosis rates for AML patients who relapse after transplantation highlight the need for a review focused on this specifically. Some groups have taken this initiative already, including a summary of the current understanding of the downregulation of HLA molecules and inhibitory checkpoints between T cells and AML cells^[74]. Additionally, recent insights into novel mechanisms by which an altered immune landscape following transplantation – characterized by increased expression of TIGIT and CD161 within the CD4+ T cell population post-transplantation – has begun to identify predictors of relapse^[75]. A more recent review focuses on epigenetic mechanisms that underlie T cell evasion in the relapse post-transplant setting, and is also a good source for this topic^[76].

Lastly, this review does not cover the advances and limitations of emerging immunotherapy treatment modalities in AML- notably chimeric antigen receptor (CAR) T- and NK-cell therapies, bispecific antibodies, dual affinity re-targeting (DART) molecules, monoclonal antibodies, and antibody-drug conjugates. While these agents are approved in other cancers [e.g., acute lymphocytic leukemia (ALL), non-Hodgkin lymphoma (NHL) subtypes, and multiple myeloma (MM)], their adoption in AML has been slow, due to the difficulty of finding AML-specific antigens that are not also expressed on HSCs or myeloid progenitors. Furthermore, mechanisms of antigen escape, the AML immunosuppressive environment, and the impaired quality of autologous cells are also potential problems with these approaches, as reviewed elsewhere^[72]. Nonetheless, current clinical trials underway in relapsed/refractory AML include CD33, CD38, CD123, and CD19 CAR-T cell therapies, allogenic CAR NK-cells, and CD33xCD3 and CD123xCD3 bispecific antibodies^[11,41].

Overall, as we continue to uncover the mechanisms underlying immune evasion in AML, exploiting these mechanisms will be of high priority to unleash the potential of immunotherapy in this disease. This is exemplified by the pivotal work done already, identifying a niche for immune checkpoint inhibitors after observing increased checkpoint expression in AML cells following HMA treatment^[58]. Additionally, it will be important to identify strategies to suppress regulatory T cell activity in AML to allow for the unleashing of effector and cytotoxic and T cell activity. Thinking ahead, continued efforts to identify patient populations at higher risk for immune evasion during available treatments or following stem cell

transplantation, such as characterizing TIL populations prior to and during treatment, or examining T cell and NK cell numbers and function in specific molecular or cytogenetic subgroups of AML will pave the way for more personalized AML treatment plans.

DECLARATIONS

Authors' contributions

Wrote, reviewed, and edited the manuscript: Gurska L, Gritsman K.

Abstract

As the most common and aggressive type of primary brain tumor in adults, glioblastoma is estimated to end over 10,000 lives each year in the United States alone. Standard treatment for glioblastoma, including surgery followed by radiotherapy and chemotherapy (i.e., Temozolomide), has been largely unchanged since early 2000. Cancer immunotherapy has significantly shifted the paradigm of cancer management in the past decade with various degrees of success in treating many hematopoietic cancers and some solid tumors, such as melanoma and non-small cell lung cancer (NSCLC). However, little progress has been made in the field of neuro-oncology, especially in the application of immunotherapy to glioblastoma treatment. In this review, we attempted to summarize the common drug resistance mechanisms in glioblastoma from Temozolomide to immunotherapy. Our intent is not to repeat the well-known difficulty in the area of neuro-oncology, such as the blood-brain barrier, but to provide some fresh insights into the molecular mechanisms responsible for resistance by summarizing some of the most recent literature. Through this review, we also hope to share some new ideas for improving the immunotherapy outcome of glioblastoma treatment.

Keywords: Glioblastoma, immunotherapy, drug resistance, tumor microenvironment, immunosuppression

INTRODUCTION

Brain tumors affect more than ~17,000 people in the United States each year, where gliomas are considered

the most common type of primary brain tumor^[1]. Glioblastoma is a grade IV astrocytoma that was initially categorized into four molecular subtypes, termed neural, proneural, classical, and mesenchymal subtype^[2]. Transcriptional profiling and genetic modeling in mice showed that glioblastoma originated from neural stem cells (NSC), NSC-derived astrocytes, and oligodendrocyte precursor cells (OPCs)^[3-5]. Besides the four molecular subtypes based on their transcription profiling, glioblastoma tumors can also be classified by the status of the isocitrate dehydrogenase gene (IDH) as IDH wild-type and IDH-mutant tumors. Similarly, epigenetics factors, such as CpG island methylation phenotype of O6-methylguanine-DNA methyltransferase (MGMT) promoter, are also commonly used for glioblastoma tumor stratification^[6,7].

Since the approval of Temozolomide (TMZ) for newly diagnosed glioblastoma treatment by the FDA in early 2000, surgery followed by radiotherapy and TMZ treatment has remained the first-line glioblastoma treatment^[8]. However, none of these therapies eliminate cancer cells entirely because of challenges marred by high infiltration rate, tumor heterogeneity, blood-brain barrier (BBB), and immunosuppressive environment factors^[9,10]. The highly infiltrative nature of glioblastoma does not allow the removal of cancerous cells using resection; self-renewing cells followed by resection become more prone to radioresistance and chemoresistance. Similarly, cellular heterogeneity and BBB prevent targeted drug delivery in glioblastoma^[11,12].

COMMON DRUG RESISTANCE MECHANISMS IN BRAIN CANCERS

Blood-brain barrier

Although the BBB in glioblastoma is compromised to some extent, tumor BBB still presents a great challenge for therapeutics to reach glioblastoma cells. As the intrinsic barrier for brain cancer, BBB is a microvasculature structure surrounding the central nervous system (CNS), tightly regulating the movement of molecules and cells between the CNS and blood. Normally, BBB maintains the homeostasis of CNS and prevents infiltration of toxins, pathogens, inflammation, and harmful metabolites^[13-15]. Disruption of the neurovascular unit (NVU) is associated with blood-brain dysfunction in neurodegenerative disease and brain tumors^[16]. The NVU consists of vascular cells (endothelial, pericytes, and vascular smooth muscle cells), glia (astrocytes, microglia, and oligodendroglia), and neurons, and it plays an important role in maintaining BBB functional integrity and regulating the volume of cerebral blood flow^[17,18]. The endothelial cells in neurovascular parenchyma form capillary beds connected through tight junctions (TJs), surrounded by a specialized basal lamina shared with pericytes and astrocytic end feet. They are sparsely interconnected by neuronal endings and microglia^[19,20]. Astrocytes and pericytes, an essential constituent of NVU, release Sonic Hedgehog and vitronectin and angiopoietin I, respectively, acting on endothelial cells for their survival and maintaining BBB.

Overexpression of efflux pumps

Efflux transporters on the BBB membrane also contribute to cerebrospinal fluid homeostasis by protecting it from potentially harmful endogenous and exogenous substances^[21,22]. These transporters also pose challenges by blocking therapeutic compounds from entering the brain parenchyma. Efflux transporters on compartments of the BBB belong to either ATP-binding cassette (ABC) or the solute carrier (SLC) superfamilies^[23,24]. Organic anion-transporting polypeptides (OATP) are a superfamily of solute carrier organic anionic (SLCO) transmembrane transporters that are known for cancer drug resistance^[25,26]. These peptide transporters regulate a variety of xenobiotic and endogenous substrates, including endogenous hormones, their conjugates, and anticancer drugs^[27]. OATP1A2 is a sodium-independent uptake transporter family member and is highly expressed on the luminal membrane of BBB in tumors and adjacent healthy tissues^[28]. A study by Cooper *et al.* in glioblastoma patients showed significant over-expression of all the OATP isoforms (OATP1A2, 2B1, 1C1, and 4A1) in tumor tissues compared to non-neoplastic brain^[29].

Enhanced DNA damage repair pathways (MGMT) and abnormal activation of survival signaling pathways

As part of the glioblastoma standard treatment regimen, TMZ is a potent DNA alkylating agent that leads to DNA damage in cancer cells and cell death^[30]. However, TMZ treatment often results in drug resistance in ~50% of glioblastoma patients due to overexpression of MGMT, which reverses the methylation of the O6 position of guanine. In addition to upregulated MGMT expression, glioblastoma often exhibits enhanced DNA damage repair capacity through several related mechanisms. For instance, poly(ADP-ribose) polymerase (PARP) was shown to interact with MGMT and enhance MGMT function in the removal of O6-methylation of DNA^[31]. Interestingly, even in MGMT-deficient glioblastoma, TMZ resistance may still arise due to the loss of mismatch repair (MMR) pathway in tumor cells. Recent work by Lin *et al.* developed a new class of compound (KL-50) to achieve MMR-independent glioblastoma cell killing. It demonstrated a promising strategy to exploit cancer-specific deficiencies in DNA repair pathways^[32]. Glioblastoma tumors also have elevated levels of receptor tyrosine kinases, such as EGFR gene amplification or mutation (EGFRvIII), PDGFR and FGFR, and aberrant activation of PI3K/ATK signaling and other growth factors (e.g., IGF-1, CTGF, and TGFβ)^[33-39], with a potential contribution to the drug resistance phenotype.

Role of glioma stem cells

Glioma stem cells (GSCs) represent a subpopulation of relatively undifferentiated cells capable of self-renewal while also generating clonal populations of differentiated tumor cells in glioblastoma. These cells are increasingly recognized as a driving force supporting glioma genesis, therapy resistance, and recurrence^[40]. GSCs have high regenerative capacity and can differentiate into cells expressing several lineage markers such as CD133, SOX2, CD15, CD44, integrin α6, and CD36^[41]. Along with heterogeneity, various factors contribute to the chemoresistance of GSCs. Intrinsic factors include upregulated MGMT, higher anabolic capacity, and autophagy-mediated clearance of ROS induced by chemotherapy. Extrinsic factor is mainly hypoxic tumor microenvironment (TME). Hypoxia promotes the expression of GSC markers and a cancer stem-like phenotype^[42]. Hypoxia-response genes, such as hypoxia-inducible factor HIF-2α and VEGF, are highly expressed in GSCs. Intriguingly, two reports have demonstrated that hypoxia-associated transcriptional signatures can be used as prognostic markers for glioblastoma patients^[43,44].

Epigenetic modulations

Epigenetic dysregulation has been increasingly recognized as one of the significant drivers of oncogenesis, and several subtypes of glioblastoma are associated with epigenetic alterations^[45,46]. These epigenetic modifications may serve as valuable biomarkers for tumor stratification and prognostic prediction. For instance, the glioblastoma resistance to receptor tyrosine kinase (RTK) inhibitors has been found to involve both genetic and epigenetic mechanisms^[47], resulting in subclones with a gain of copy number in the insulin receptor substrate-1 (IRS1) and substrate-2 (IRS2) loci. Another study identified a long non-coding RNA (LINC00021) that promotes TMZ resistance through Notch signaling and epigenetically silenced p21 expression via recruiting EZH2^[48], one of the methyltransferases responsible for histone methylation. Epigenetic modifications in glioblastoma are also exploited as drug targets. Among the promising epigenetic interventions for glioblastoma are the histone deacetylase (HDAC) inhibitors^[49], which have been extensively tested in various cancers^[50]. HDAC inhibitors can block cancer cell proliferation by inducing cell cycle arrest, cell differentiation, and/or apoptosis^[51]. With a large amount of supportive preclinical data, various HDAC inhibitors in glioblastoma clinical trials are underway.

DRUG RESISTANCE TO IMMUNOTHERAPY IN GLIOBLASTOMA

Current status of immunotherapy trials in glioblastoma

Although immune checkpoint inhibitors have greatly improved cancer treatment today, the clinical trials in glioblastoma treatment have been largely unsuccessful.

We summarized the most common immunotherapies that have been evaluated in glioblastoma in either preclinical or clinical trials [Figure 1]. The most widely tested immunotherapies in glioblastoma (like in all other cancers) are immune checkpoint inhibitors (ICIs). Immune checkpoint molecules are typically expressed on the surface of immune cells, and they play a crucial role in maintaining immune balance, preventing excessive immune activation, and avoiding auto-immune response. This function of immune regulation is achieved through the interaction of immune checkpoints with their corresponding ligands on other cells, and cancer cells often hijack this communication mechanism to suppress the anti-tumor immunity and evade immune surveillance^[53-55]. A common working mechanism of ICIs is to block the inhibitory signal to the immune cells (usually from cancer cells) through an antibody binding to the checkpoint or its ligand to disengage their interaction. Since the discovery of the first immune checkpoint, cytotoxic T-lymphocyte-associated protein 4 (CTLA-4), more than a dozen of these checkpoint molecules have been identified to date, such as PD1 and its ligand PD-L1/L2, TIM3, lymphocyte activation gene-3 (LAG3), and TIGIT^[54]. Among various ICIs, α -PD-1 has been widely studied as a monotherapy^[56] or in a combination of either radiation or radiation plus TMZ in multiple trials (CheckMate 143, 498 and 548)^[57-59]. Overall, the clinical outcome has been rather murky in both primary and recurrent glioblastoma due to multiple resistance mechanisms, including high tumor heterogeneity, low mutational burden, systemic immunosuppression, and local immune dysfunction^[60].

CAR-T therapy has been studied in glioblastoma^[61]. The targets of these CARs in clinical trials span from growth signaling receptors (EGFR/EGFRvIII, Her2), cytokine receptors (IL13R α 2), immune checkpoint (B7-H3) to even matrix metalloproteinase (MMP2), and disialoganglioside (GD2)^[62]. Besides very limited responders, including pediatric patients with diffuse intrinsic pontine glioma (DIPG)^[63,64], most trials failed to demonstrate a sustained clinical benefit, mainly due to CAR-T-associated severe side effects, including cytokine release syndrome and high grade of neurotoxicity^[65,66].

Cancer vaccines have also been explored in glioblastoma trials with minimal success. A peptide vaccine targeting EGFRvIII called rindopepimut has been tested in various trials, with only one trial (phase II) reporting a marginal increase in median overall survival of 12.0 months with rindopepimut plus bevacizumab compared to 8.8 months with bevacizumab plus vaccine placebo^[67]. The main limitation of EGFRvIII vaccine is that the expression of EGFRvIII is only limited in some glioblastoma patients, and there is also an intra-tumoral heterogeneous pattern of EGFRvIII expression, which further hinders the overall immune response to the tumor. Another cancer vaccine strategy is to use patient-derived dendritic cells with ex vivo exposure to glioblastoma neoantigens. For instance, ICT-107 and DCVax-L both used patient autologous dendritic cells with pulse to either peptides designed based on patient tumors (ICT-107) or autologous tumor lysates (DCVax-L). Both trials have reached phase 3 and had an acceptable safety profile, though the efficacy was minimal^[68,69].

Oncolytic virus (OV) can be viewed as a gene & immuno-hybrid therapy. Typically, an OV exerts its anti-tumor function through a dual mode of action - tumor cell killing (lysis) and induction of systemic anti-tumor immunity^[70]. An OV can selectively infect and lyse cancer cells, and various viruses have been employed to develop oncolytic viruses^[71]. Upon lysis of tumor cells due to OV replication, many tumor antigens will be released, leading to a local and systemic anti-tumor reaction^[72]. One of the main issues associated with OV therapy is the host's anti-viral immune response to the OV^[73]. Currently, a modified herpes simplex virus type 1, named tesorparev or G47 Δ , is the only OV that received conditional approval (in Japan) for glioblastoma treatment^[74], and many more oncolytic viruses are currently in clinical trials for glioblastoma treatment (reviewed by Suryawanshi & Schulze^[75]). Among them, a retroviral OV called Toca511 reached phase III clinical trial, but was terminated due to its failure to improve survival and meet

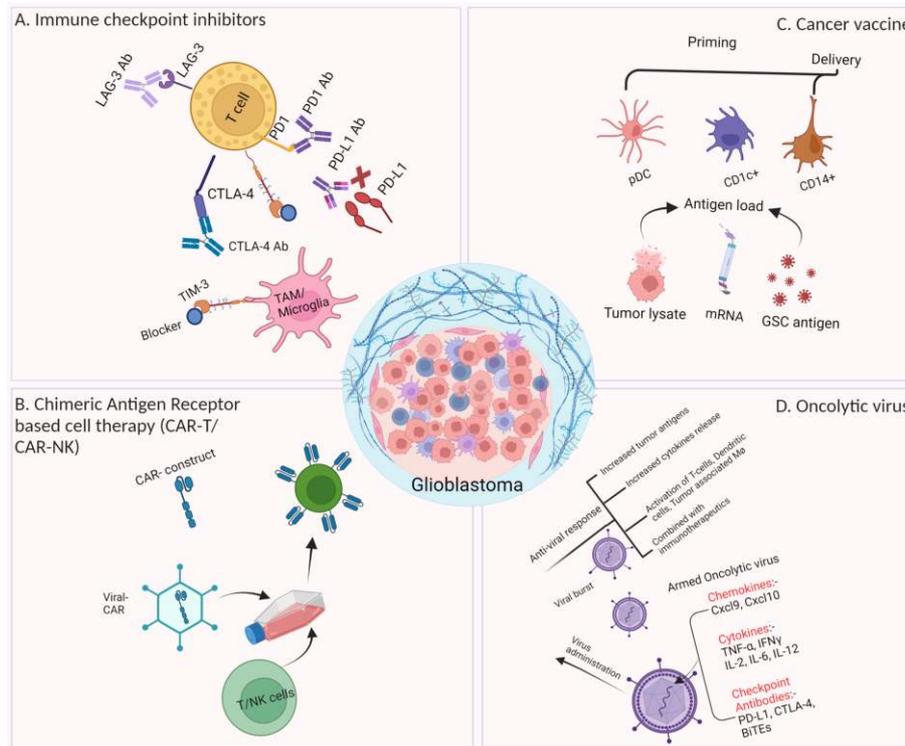

Figure 1. Various forms of immunotherapy in preclinical and clinical trials for glioblastoma treatment. (A) Various checkpoint inhibitors, including α -PD1, α -PD-L1, α -CTLA-4, and α -TIM-3, have been studied in glioblastoma treatment; (B) CAR-based adoptive cell therapies have attained immense success against hematopoietic cancer, but have shown limited effects on glioblastoma; (C) Cancer vaccine has been tested in glioblastoma treatment by priming antigen-presenting cells (e.g., Dendritic Cells) with tumor antigens/lysate or synthetic antigen peptides, followed by infusion back to the patients; (D) An OV can lyse tumor cells through replication. OV can be armed with immunotherapy in which a virus is genetically modified to carry checkpoint inhibitors (e.g., α -PD-L1 and α -CTLA-4), therapeutic proteins, chemokine (Cxcl9, Cxcl10) or cytokines genes (IFN γ , IL-6, IL-12). Those armed OVs are more potent in killing cancer cells^[52]. (Created with BioRender.com). CTLA-4: Cytotoxic T-lymphocyte-associated protein 4; GSC: glioma stem cell; LAG-3: lymphocyte activation gene-3; OV: oncolytic virus; TAM: tumor-associated macrophage.

other endpoints^[75].

Immunosuppressive TME

Glioblastoma tumors generally have a low to moderate mutation rate, especially compared to other solid tumors such as melanoma, non-small cell lung cancer, GI cancer, and head and neck cancer^[76]. The tumor mutation burden was found to be correlated with immunotherapy treatment response^[77]. In addition, glioblastoma also has a highly immune-suppressive microenvironment with a large amount of infiltrating myeloid cells, including bone marrow-derived macrophages (M Φ), myeloid-derived suppressor cells (MDSCs), dendritic cells (DCs), and neutrophils^[78]. T lymphocyte dysfunction in the glioblastoma is very severe and was found to be mediated partially by IL-10 produced by the myeloid cells^[79]. Additionally, within the TME, prolonged antigen exposure to T cells leads to the expression of LAG3, which in turn causes T cell exhaustion^[80]. More strikingly, patients with glioblastoma also have systemic immune suppression. For instance, glioblastoma patients have lower numbers of circulating T cells due to the sequestration of T cells in the bone marrow, possibly due to loss of sphingosine-1-phosphate receptor 1 (S1P1) expression^[81]. S1P1 is a GPCR that binds the lipid second messenger, sphingosine-1-phosphate (S1P), and the S1P-S1P1 axis plays a pivotal role in lymphocyte trafficking^[82]. Typically, surface S1P1 affords T cell egress from the spleen, lymph node, and thymus. In a mouse glioblastoma model, the T cells from tumor-bearing mice were found to have lost surface expression of S1P1, leading to T cells sequestered

mainly in bone marrow^[81]. This may partially explain the T cell lymphopenia in glioblastoma patients. However, treatment (radiation and TMZ) associated T cell lymphopenia was also very common^[83,84].

Glioblastoma tumors can produce IL-6 and drive myeloid immunosuppression by inducing PD-L1 expression on MDSCs^[85]. Glioblastoma can also utilize the natural immune tolerance mechanisms to recruit regulatory T cells (Tregs) through the expression of indoleamine 2,3-dioxygenase (IDO)^[86], as well as the tumor-associated macrophages (TAMs) expression of TIM4^[87]. Besides soluble factors, extracellular vesicles containing various signaling molecules, including growth factors, non-coding RNAs, cytokines, and other functional proteins, have been found to play an important role in the regulation of glioblastoma TME^[88]. Those mechanisms involve an extensive network of DCs, TAMs, MDSCs, and T lymphocytes with complex and dynamic crosstalk [Figure 2].

Heterogeneity in tumor microenvironment

Tumor heterogeneity has been well-known in glioblastoma biology at multiple levels^[89], including genetics/epigenetics (molecular subtypes), molecular signaling (tumor driver mutations), cellular components (clonal and subclonal tumor cells *vs.* tumor microenvironment), and temporal (primary *vs.* secondary). scRNAseq analysis of infiltrating neoplastic cells in human glioblastoma revealed vast genomic and transcriptomic heterogeneity^[90]. Another work in brain endothelial cells derived from human glioblastoma using a similar approach (scRNAseq) showed five distinct endothelial cell phenotypes representing different states of EC activation and BBB impairment and association with different anatomical locations within and around the tumor^[91].

With the advancement of multi-omics platforms, tumor heterogeneity at both inter- and intra-tumoral levels has been much better depicted in glioblastoma^[92-94]. The inter-tumoral heterogeneity can be readily appreciated by the molecular subtyping of human glioblastoma tumors by their transcriptional profile and phenotypical response to therapy^[2,95,96]. Consistent with the four molecular subtypes of glioblastoma, a more recent scRNAseq analysis showed that glioblastoma cells can differentiate into four principal states, including astrocyte-like, oligodendrocyte progenitor-like, neural progenitor cell-like, and mesenchymal-like state^[97]. These four cellular states are influenced by the tumor microenvironment and oncogenic drivers with certain plasticity^[97].

The intra-tumoral heterogeneity in glioblastoma is characterized by the presence of clonal and subclonal differentiated tumor cells, glioma stem cells (GSCs), and various components of the tumor microenvironment (stromal, endothelial, and infiltrating immune cells). A recent study by Schaettler *et al.* using scRNAseq revealed the differences between primary and secondary glioblastoma in their genomic abnormality and neoantigen formation, as well as the spatially differential T cell clones within the glioblastoma^[98]. The authors used TCR β -chain CDR3 sequences as unique barcodes of individual T cell clones, as TCR β -chain CDR3 is highly diverse with a significant role in antigen recognition^[99]. Their results demonstrated a topological clonal diversity of T cells in glioblastoma^[98]. Besides microglia, another representative cell population that further complicates glioblastoma heterogeneity is a large variety of myeloid cells in the TME^[100]. They mainly comprise TAMs, MDSCs, DCs, neutrophils, and undifferentiated monocytes^[78,101]. Another study using scRNAseq and multiplexing tissue-imaging techniques demonstrated a spatially differential tumor microenvironment characterized by inflammatory signaling and hypoxia in glioblastoma^[102]. The authors revealed that CD73, a critical regulator of local purinergic signaling with an essential role in inflammatory response^[103], was mainly expressed in glioblastoma cells with a positive correlation between levels of CD73 and HIF1 α expression in the hypoxic tumor regions, where the CD73+ glioma cells co-localize with CD39+ microglia to form a spatially compartmentalized microenvironment to

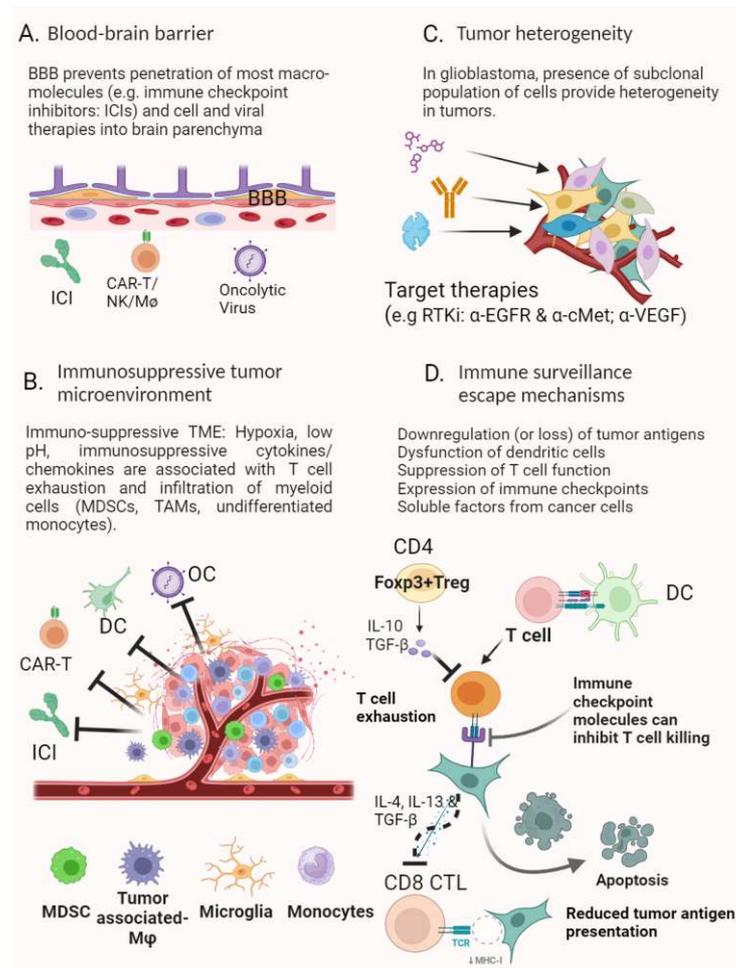

Figure 2. Main determinants of therapeutic failures in glioblastoma. (A) BBB can prevent the transport of most macromolecule therapeutics (e.g., immune checkpoint inhibitors), cell-based therapies, and most oncolytic viruses; (B) Within the glioblastoma, TME is a severely immunosuppressive local environment that can inhibit the function of most immunotherapies; (C) Clonal heterogeneity represents a complex problem for targeted therapeutics (e.g., receptor tyrosine kinase inhibitors and α -VEGF) to attack glioblastoma tumor cells effectively; (D) Various mechanisms for glioblastoma tumor cells to evade immune attack: tumor cells derived soluble factors (e.g., IL-4, IL-13, prostaglandin E2, and TGF- β) can suppress T cell proliferation; T cell exhaustion induced by prolonged antigen exposure can severely diminish CD8 CTL mediated cancer killing; FOXP3+ CD4 Tregs also block T cell activation. (Created with BioRender.com). BBB: Blood-brain barrier; CTL: cytotoxic T cell; DC: dendritic cell; ICIs: immune checkpoint inhibitors; MDSCs: myeloid-derived suppressor cells; TAMs: tumor-associated macrophages; TME: tumor microenvironment.

regulate the production of adenosine, a potent immunosuppressive metabolite^[102].

Immune surveillance escape mechanisms

The crosstalk between glioblastoma and the TME through which glioblastoma tumors escape immune surveillance is very complex and highly dynamic, involving many signaling mechanisms, including both soluble factors and cell-cell interactions. Besides the BBB, which prevents drugs from reaching their target sites, these mechanisms include various immune-suppressive mechanisms, such as secretion of immunosuppressive cytokines (IL-10, TGF- β , and IL-6)^[104,105], expression of immune checkpoints^[106], and recruitment of regulatory T cells (Tregs)^[107], induction of M2-like phenotype of tumor-associated M ϕ and microglia^[106], reduced tumor antigen presentation through downregulation of MHC expression, and the ability to evade immune through soluble ligands^[108,109] [Figure 2].

T cell exhaustion

T cell exhaustion is exceptionally severe in glioblastoma^[110], resulting in poor therapeutic efficacy of immunotherapy. Most immunotherapies focus on eliciting an anti-tumor T cell response that requires a collaboration of at least CD4 T Helper cells and CD8 cytotoxic T cells (CTLs). CD4 T Helpers can modulate antigen-specific immune response through their high plasticity and cytokine production, while CD8 CTLs exert cancer cell killing through direct cell-cell interaction and targeted release of effector molecules (perforin and granzymes)^[111]. T cell exhaustion is mainly induced by persistent antigen exposure, and it is commonly seen in chronic infections and cancers. It is generally characterized by elevated expression of various immune checkpoints (PD-1, CTLA-4, LAG-3, and TIM-3). Remarkably, T cell exhaustion was also found to correlate with hypoxia in glioma, and both the number of exhausted T cells and the associated exhaustion markers (PD-L1, FOXP1, and PRDM1) correlated with HIF1 α levels^[112].

The presence of regulatory T cells (Tregs) is another contributing factor for the dysregulation of T cell function in glioma TME [Figure 2]. Tregs are a subset of CD4 T cells that usually prevent autoimmunity response via suppression of inflammation and maintenance of self-tolerance^[113]. Tregs (CD4+ Foxp3+) naturally arise from thymic differentiation^[114] or are induced in the already differentiated Foxp3- CD4+ T cells in the periphery^[115]. A recent study showed that Tregs promote CD8 T cell exhaustion and restrict clonal diversity of tumor-infiltrating CD8 CTLs^[116]. Therefore, strategies to eliminate Tregs have been developed to restore anti-tumor immunity in glioblastoma, including activation of glucocorticoid-induced tumor necrosis factor-related protein (GITR). GITR is an immune checkpoint constitutively expressed in Tregs, and its activation through ligand binding leads to the depletion of Tregs and reduced immunosuppression. A preclinical study by Amoozgar *et al.* demonstrated that targeting Tregs with anti-GITR antibodies can relieve resistance to immunotherapy (e.g., anti-PD1) in mouse glioblastoma models^[117].

Immunosuppression by myeloid cells

A large number of myeloid cells, such as monocytes, macrophages and MDSCs, in the glioblastoma TME impose another great challenge for immunotherapy to function [Figure 2]. Among the tumor-infiltrating myeloid populations in glioblastoma, TAMs play a pivotal role in tumor progression, immunosuppression, and therapy resistance. TAMs are usually found to exhibit a tumor-promoting phenotype by producing immune suppressive cytokines such as IL-6, IL-10, and TGF- β ^[104,105], and they represent a large population of cells with immunosuppressive function in TME. Various approaches have been proposed to target TAMs for glioblastoma treatment. For instance, by dual targeting IL-6 and CD40, Yang *et al.* showed that they could reverse TAMs-mediated tumor immunosuppression and sensitize the glioblastoma tumor to immune checkpoint inhibitors (anti-PD1 and anti-CTLA-4) in mouse tumor models^[118]. In addition, the relatively undifferentiated monocytic MDSCs have been found to play a significant role in glioblastoma-associated immunosuppression. Domenis *et al.* demonstrate that CD14+ monocytic MDSCs were the primary mediators of the T cell suppression induced by the GSC-derived exosomes containing various immune suppressive cytokines^[119].

Glioblastoma can also evade immune attack by down-regulating tumor antigen expression. Tumor antigen loss during immunotherapy treatment, especially by CAR-T therapy, has been frequently reported^[120]. Migrating or invading glioblastoma cells were found to have reduced expression of major histocompatibility complex (MHC) class I and II genes, resulting in significant down-regulation of tumor antigen presentation^[121]. Additionally, glioblastoma TME is quite a hypoxic and acidic environment. Both hypoxia and acidosis are essential environmental cues for maintaining GSCs, especially in a HIF1 α -dependent manner^[122,123]. GSCs are believed to be primarily responsible for tumor resistance to chemotherapy and radiotherapy^[124,125]. More importantly, GSCs have also been shown to have a significant role in the evasion of

immune function^[126].

Resistance to ICIs

ICIs are currently the most prevalent immunotherapy for cancer treatment. Since the approval of the first ICI (α -CTLA-4) by the FDA in 2011, these antibodies have been studied in an increasingly growing number of clinical trials, including those cancers with low response rates, such as breast cancer, cervical cancer, and brain cancer^[60,127,128]. Despite the success of ICIs in treating hematopoietic cancers, the clinical trials in glioblastoma have been underwhelming. Besides the BBB, several contributing factors that render ICIs ineffective in glioblastoma treatment have been identified.

Low tumor mutational burden in glioblastoma tumor

Glioblastoma is generally considered an immunologically “cold” tumor type with a relatively lower tumor mutational burden (TMB). Thus, the neoantigen levels are also lower^[129,130]. Higher TMB often leads to the formation of a greater number of neoantigens and a greater potential for T-cell repertoire against tumor-specific antigens^[131]. TMB has been found to be correlated with the clinical outcome of cancer immunotherapy^[76]. Compared with the immunologically “hot” tumor types such as melanoma and NSCLC, glioblastoma shows a much lower neoantigen burden^[132].

T cell dysfunction

Glioblastoma patients are often found to have T cell dysfunction in both CNS and peripheral blood, and T cell exhaustion is pervasive and severe in glioblastoma TME. CD8 T cell exhaustion usually starts with the loss of IL-2 production, a cytokine crucial for T cell proliferation, followed by loss or decreased production of TNF- α , IFN- γ , and granzyme B^[133]. Tregs also make a significant contribution to the T cell dysfunction in glioma. Both natural and induced Tregs can suppress the cytotoxicity of CD8 CTLs. Tregs were found to be associated with worse prognosis in glioblastoma patients^[134], and it seems that the natural Tregs are the dominant subpopulation of Tregs in glioblastoma. Besides dysregulated T cell function, surprisingly, neurons have been shown to play a role in the ICI therapy resistance in glioblastoma. A recent study reported neuronal calmodulin-dependent kinase kinase-2 (CaMKK2) as a driver for the resistance to ICIs in glioblastoma^[56], in which CaMKK2 increased CD8 T cell exhaustion, reduced CD4 effector cell expansion, and played a role in the maintenance of immunosuppressive phenotype of tumor-associated microglia^[135].

Deficits in antigen presentation by microglia

In glioblastoma TME, antigen presentation machinery is dysregulated in almost all types of antigen-presenting cells. The immunosuppressive microenvironment in glioblastoma leads to the downregulation of MHC expression in microglia^[136,137]. The decreased MHC expression significantly impairs the ability of microglia to effectively present antigens, limiting the activation of other immune cells and undermining the immune response against the tumor. Similarly, TAMs were found to be deficient in antigen presentation, lacking costimulatory molecules CD86, CD80, and CD40 critical for T-cell activation^[138]. In fact, although glioblastoma tumor-infiltrating dendritic cells seemed more efficient than both M Φ and microglia in priming T-cells with exogenous antigens^[139], data from a preclinical study demonstrated that a better anti-tumor immunity is associated with both tumor-infiltrating dendritic cells and microglia^[140].

TAMs

A new study using patient-derived recurrent glioblastoma tumors with neoadjuvant PD-1 antibody treatment showed that α -PD-1 activated T cells and dendritic cells, but was unable to reverse the immunosuppressive phenotype in TAMs^[141]. Work by Chen *et al.* analyzed scRNAseq data from a combined of >19,000 individual macrophages from 66 human glioma cases (50 glioblastomas and 16 low-

grade gliomas) and discovered a pro-tumor subset of bone marrow-derived macrophages with the expression of a scavenger receptor MARCO^[142]. More interestingly, this subpopulation of MARCO⁺ TAMs was found almost exclusively in the IDH-WT glioblastoma, and they exhibited a completely opposite dynamic in α -PD-1 responders vs. non-responders^[142]. Park *et al.* studied the immune landscape of mouse glioblastoma with α -PD-1 treatment, and found that chemokine CCL5 induced by α -PD-1 treatment seemed to recruit the anti-inflammatory TAMs into the glioblastoma TME^[143]. A CyToF-based high-plexing immune profiling approach revealed that ICI-sensitivity in both human and mouse tumors was associated with a higher number of T cells and dendritic cells (DCs) and a lower number of PD-L1 positive TAMs^[144].

Anti-inflammatory glucocorticoids

Glucocorticoids have been used to control certain adverse effects associated with cancer immunotherapy. Interestingly, concurrent administration of dexamethasone, a potent corticosteroid frequently used in glioblastoma patients to decrease tumor-associated edema, has been shown to be detrimental to immunotherapy for patients with glioblastoma^[145]. Though the clinical data in this study was limited to a subset of patients with wild-type IDH-1 glioblastoma under α -PD-L1 treatment, the concurrent dexamethasone diminished the response to α -PD-1 therapy in two different mouse glioma models^[145]. It is worth mentioning that glioblastoma patients under standard (radiation plus TMZ) treatment who received dexamethasone treatment also showed a worse outcome^[146]. However, this is likely because MGMT promoter contains two nonconsensus glucocorticoid-responsive elements and glucocorticoids can upregulate MGMT expression^[147]. A comprehensive study of MGMT promoter activity in glioblastoma cell lines further clarified that dexamethasone, but not TMZ or irradiation, can induce the upregulation of MGMT expression via a SP-1 dependent fashion^[148], while not through altering the epigenetic status (i.e., methylation) of the MGMT promoter.

Role of non-coding RNAs

Long non-coding RNAs (LncRNAs) have been increasingly recognized for their essential role in cell growth, survival, proliferation, pluripotency, and immune functions correlating to the malignant transformation of normal cells into cancerous cells^[149-151]. MALAT1, NEAT1, and H19 are among the common LncRNAs that influence the response of glioblastoma/glioma to chemotherapeutics^[152]. Another lncRNA, LINC00021, was significantly upregulated in glioblastoma, especially in the TMZ resistance cells or tissues, enhancing resistance to TMZ through Notch pathway and epigenetically silencing p21 expression^[48]. A study also showed that LncRNA SNHG15 promotes pro-glioblastoma cytokines TGF- β and IL-6 in TMZ-resistance cells via M2-polarization of microglial cells^[153].

Micro RNA (miRNA) also plays a role in the regulation of glioblastoma TME. One example is the miR-15/16 cluster, which was found to be differentially expressed in various human cancers such as glioma and prostate cancer^[154,155]. In a mouse glioblastoma model, Yang *et al.* demonstrated that loss of miR-15/16 in mice carrying GL261 tumors resulted in improved survival, enhanced CD8 T cell infiltration, and reduced expression of T cell exhaustion markers (PD1, TIM-3, and LAG-3)^[156]. An *in vitro* study by Hubner *et al.* identified miR-93 as an anti-inflammatory tumor suppressor in glioblastoma^[157]. Their data showed that miR-93 was downregulated in human glioblastoma cell lines, and restoration of miR-93 levels in glioblastoma cells led to a decreased expression of an array of inflammatory genes (HIF-1 α , MAP3K2, IL-6, G-CSF, IL-8, LIF, and IL-1 β)^[157]. More interestingly, TCGA data mining confirmed that high expression of miR-93 was associated with better survival in the MGMT-methylated cohort of glioblastoma patients.

OPPORTUNITIES

Approaches to alter immuno-suppression in glioblastoma TME

Many great efforts have been made to overcome the difficulty of immunotherapy applications in neuro-oncology. For example, a clinical trial found that neoadjuvant PD-1 blockade resulted in significantly improved overall survival and progression-free survival in patients with recurrent glioblastoma^[158]. In this study, patients received anti-PD1 treatment ~2 weeks before surgery, and the PD1 antibody was able to elicit both systemic and local anti-tumor immunity. Other attempts are primarily focused on modulating the immune suppression in the glioblastoma tumor microenvironment by targeting various components of the TME, such as TAMs and MDSCs (summarized in a recent review by Wang *et al.*^[159]). In the meantime, new targets have been identified for future immunotherapy development. For instance, TAMs associated CD73 was found to be a promising target with potentially synergistic effects along with dual inhibition of PD1 and CTLA-4^[160]. CD47/SIRP α axis is another exciting target to consider. SIRP α governs the phagocytosis activity of M Φ . When CD47 on the cancer cell surface engages with SIRP α on M Φ , it sends a “Don’t-eat-me” signal to prevent phagocytosis of cancer cells by M Φ . Treatment with anti-CD47 plus TMZ was shown to activate both innate and adaptive anti-tumor immunity in a preclinical study^[161].

A single-cell RNA-seq study of patient glioma infiltrating T cells revealed CD161 (KLRB1) as a promising immunotherapy target. Depleting CD161 led to T cell activation and anti-tumor immunity both *in vitro* and *in vivo*^[162]. An independent study using data from a large cohort of glioma patients confirmed that CD161 might play an important role in promoting glioma progression via inhibition of T cell function^[163].

Besides checkpoint inhibition, a deeper understanding of the resistance mechanism to CAR-T therapy in solid tumors was achieved through a genome-wide CRISPR knockout screen in glioblastoma^[164]. A recent study using a genome-wide CRISPR knockout screen in glioblastoma revealed a functional requirement of IFN- γ receptor in glioblastoma for sufficient adhesion of CAR-T cells to mediate productive cytotoxicity^[164]. This study suggests that strategies to enhance the binding of CAR-T cells to the solid tumor will likely result in a better treatment response. Another strategy to enhance the infiltration of CAR-T cells into glioblastoma tumors by combining CAR-T with a CXCL11-armed oncolytic virus also demonstrated an improved anti-tumor immunity in a syngeneic mouse glioma model^[165].

Combinatorial approaches and new forms of immunotherapies

Combination therapy has been extensively explored to improve glioblastoma treatment. For instance, resistance to α -VEGF monotherapy was common in glioblastoma. A new study reported that combined blockade of VEGF, Angiopoietin-2, and PD1 could reprogram glioblastoma endothelial cells into quasi-antigen-presenting cells and induced a durable anti-tumor T cell response^[166]. A recent review has nicely summarized the current status of combinatorial approaches, including both chemo- and immunotherapies, for glioblastoma treatment^[167]. Additionally, many new forms of immunotherapy are emerging with great hope to shift the paradigm of glioblastoma treatment. A recent study reported a nanoporter (NP)-hydrogel complex for local induction of CAR-macrophages (CAR-M Φ) targeting CD133+ glioblastoma stem cells in tumor resection cavity with promising results^[168]. This nanomicelle complex consists of a self-assembled peptide-based hydrogel loaded with the CD133-targeting CAR construct and then was coated with a citraconic anhydride-modified dextran with the ability to bind to CD206, a typical surface marker of M2 macrophages. Different from the *ex vivo* engineering of CAR-M Φ developed by Klichinsky *et al.*^[169], the nanoporter-hydrogel-based *in situ* induction of strategy CAR-M Φ largely simplified the process of CAR-M Φ preparation and minimized potential systemic toxicity from CAR-M Φ .

The CAR-NK cells have also been explored to treat glioblastoma either by Her2 targeting monotherapy^[170] or in combination therapy. For instance, the Off-the-Shelf EGFR-targeting CAR-NK cells have been tested in combination with an oncolytic virus expressing the IL15/IL15Ralpha complex and the combinatorial therapy demonstrates a strong anti-tumor immunity^[171]. A significant problem associated with CAR-NK cell therapy is the shedding or down-regulation of the ligands in cancer cells that bind natural killer group 2D (NKG2D) receptors on the natural killer (NK) cells. NKG2D is an activating receptor widely expressed in NK cells as well as in some subsets of T cells^[172]. To overcome the limitation of NKG2DL heterogeneity in the tumor, a recent study using a bispecific antibody with two ScFv fragments (linked with a IgG4-Fc) that target Her2 (tumor) and NKG2D (NK cells), respectively, in combination with human NK-92 cells, showed synergistic tumor cell killing effects in both *in vitro* and *in vivo* conditions^[173]. Although the syngeneic tumor model they used represents a situation of a heterogenous expression of NKG2DLs in tumor cells, the flank tumors they used did not address the difficulty in delivery of the combination therapy across the BBB^[173].

Another interesting phenomenon is the sex difference in response to immunotherapy in glioma. The sex disparity in brain cancer has been reported by several groups^[174-177]. A recent meta-analysis revealed that female patients with glioblastoma treated with immunotherapy had a statistically significant survival advantage in overall survival over their male counterparts^[178]. They also found that female patients exhibited a more robust survival advantage with cancer vaccine treatment. Another study by Bayik *et al.* discovered that two subsets of myeloid-derived suppressor cells (MDSCs) have a sex-specific tumor-promoting phenotype in both mouse and human glioblastoma^[179]. All these data suggest that a more personalized approach, which at least considers sex differences in glioblastoma treatment, will more accurately evaluate the efficacy of immunotherapy.

New drug delivery technologies to overcome BBB limitation and activate glioblastoma TME

Various new technologies have demonstrated promising progress in overcoming BBB, and we summarized a few new approaches with great potential to improve the glioblastoma treatment outcome [Figure 3]. Among those new approaches, the use of ultrasound to open BBB for glioblastoma treatment has been applied in several areas, including immunotherapy delivery. Using low-intensity pulsed ultrasound to temporarily disrupt BBB, Sabbagh *et al.* demonstrated a significantly improved BBB penetration of both anti-PD1 antibody and EGFRvIII targeting CAR-T cells, as well as significantly improved survival in mouse glioblastoma models^[180]. Another study by Sheybani *et al.* applied MRI-guided focused ultrasound with systemic injection of microbubbles and studied the impact of this approach on temporary BBB disruption in a mouse glioma model^[181]. This approach caused a transient local inflammatory phenotype in the mouse glioblastoma, with an increased number of dendritic cells and the upregulated maturation marker. However, they did not see a significant increase in CD8 T cells in the TME^[181].

Another technology to modulate BBB function is photodynamic therapy (PDT). Conventionally, PDT relies on a photosensitizer, such as 5-aminolevulinic acid (5-ALA)^[182], that can accumulate in tumor tissue, plus a laser that can stimulate the photosensitizer, followed by energy transfer to generate reactive oxygen species, leading to damages to the cancer cells^[183]. It is noteworthy that PDT has shown promise in temporary opening of BBB, possibly through modulating certain components of TJs^[184]. Interestingly, PDT can also induce an acute inflammatory response in which both innate and adaptive immune systems are activated^[185]. Recently, BBB opening was shown to affect the meningeal lymphatic system characterized by an anti-tumor effect of talaporfin sodium (TS)-PDT as well as its synergy with the immune checkpoint inhibitor^[186]. *In vitro* studies have demonstrated that targeted TS-PDT triggers various forms of cell death, including apoptosis, necrosis, and autophagy-associated cell death. Furthermore, TS-PDT induces the acute activation of lymphatic drainage in the brain and the clearance of unwanted molecules from the CNS^[187,188].

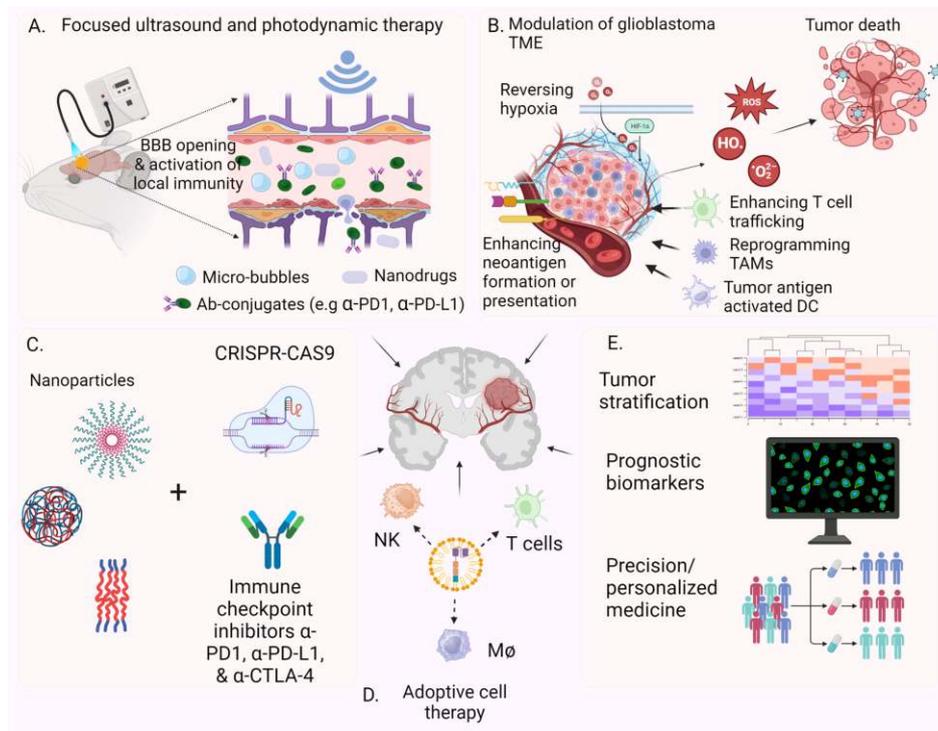

Figure 3. Potential new approaches to improve glioblastoma treatment. (A) The focused ultrasound in combination with micro-bubbles and photodynamic therapy (PDT) can temporarily open BBB to allow therapeutics crossing. PDT can also activate local immunity in TME; (B) New approaches to modulate glioblastoma TME by targeting hypoxia, activating suppressed local immunity, or enhancing cancer neoantigen formation in tumor cells; (C) Novel nanodrug delivery technologies in combination with CRISPR/Cas9-based gene editing and immune checkpoint inhibitors; (D) Various forms of adoptive cell therapies; (E) Better strategies for tumor stratification, prognostic prediction and personalized medicine would enhance the clinical outcome of glioblastoma treatment. (Created with BioRender.com). BBB: Blood-brain barrier; DC: dendritic cell; TAMs: tumor-associated macrophages; TME: tumor microenvironment.

The approval of 5-ALA by the FDA for fluorescence-guided glioblastoma resection has sparked a renewed interest in its potential application for PDT^[182].

Nanotechnology has also made significant advancements in the field of glioblastoma treatment. Various forms of nanomedicines have exploited the features of the glioblastoma tumor microenvironment for efficient BBB crossing and release of payloads^[189-191]. Fan *et al.* engineered an MMP-2-activated nanoparticle to carry anti-CD276 & CD3 bispecific antibodies and demonstrated that this strategy enhanced IFN- γ -induced tumor cell ferroptosis^[192]. A polylactic-co-glycolic acid (PLGA) nanoparticle encapsulated disulfiram was used to block hypoxia-induced NF- κ B signaling and glioma stem cells^[193]. Zou *et al.* devised a polymer-based CRISPR-Cas9 nano-capsule for systemic gene therapy delivery to glioblastoma^[194]. This nano-capsule has both the BBB crossing and tumor targeting functions mediated through an angiopep-2 peptide^[195]. By targeting polo-like kinase (PLK-1) via a sgRNA, the strategy demonstrated a significant survival advantage over the control mice^[194].

CONCLUSION

Despite advances in surgical technologies and therapeutics development, there has been limited improvement in the long-term survival rate of glioblastoma patients, with a 5-year survival still around 5%-10%. Many lessons have been learned in glioblastoma drug resistance mechanisms, especially with cutting-edge scRNAseq, spatial biology, and other-omics platforms. Efforts are needed to overcome BBB and tumor heterogeneity, targeting glioma stem cells and their niches, enhancing T cell trafficking and preventing their

exhaustion, and modulating the immunosuppressive TME in glioblastoma. A complex disease, such as glioblastoma, would require a complex solution. Multidisciplinary approaches involving nanodrug carriers, focused ultrasound, plus temporary BBB permeability enhancement technologies (micro-bubbles, phototherapy) in combination with gene and immuno-therapy will likely lead to an improved outcome [Figure 3]. In addition, a much less traveled path is to enhance glioblastoma neoantigen formation. Glioblastoma tumors have a relatively lower TMB, which was shown to correlate with immunotherapy outcomes in solid tumors^[76,196]. Lower TMB results in lower neoantigen generation, which enables a stealth mode of glioblastoma cells. Therefore, increasing the formation of neoantigens may significantly promote tumor recognition and clearance by the immune system^[197]. Besides T cells, strategies to activate other infiltrating immune cells (TAMs, microglia, and MDSCs) that reside in the glioma TME in large abundance may effectively reverse the local immunosuppression. Finally, a more precise tumor stratification approach and improved prognostic biomarkers will help determine the most effective combinatorial therapies for glioblastoma treatment.

Abstract

Aim: Acquired resistance to the targeted agent cetuximab poses a significant challenge in finding effective anti-cancer treatments for head and neck squamous cell carcinoma (HNSCC). To accurately study novel combination treatments, suitable preclinical mouse models for cetuximab resistance are key yet currently limited. This study aimed to optimize an acquired cetuximab-resistant mouse model, with preservation of the innate immunity, ensuring intact antibody-dependent cellular cytotoxicity (ADCC) functionality.

Methods: Cetuximab-sensitive and acquired-resistant HNSCC cell lines, generated *in vitro*, were subcutaneously engrafted in Rag2 knock-out (KO), BALB/c Nude and CB17 Scid mice with/without Matrigel or Geltrex. Once tumor growth was established, mice were intraperitoneally injected twice a week with cetuximab for a maximum of 3 weeks. In addition, immunohistochemistry was used to evaluate the tumor and its microenvironment.

Results: Despite several adjustments in cell number, cell lines and the addition of Matrigel, Rag2 KO and BALB/C Nude mice proved to be unsuitable for xenografting our HNSCC cell lines. Durable tumor growth of resistant SC263-R cells could be induced in CB17 Scid mice. However, these cells had lost their resistance phenotype *in vivo*. Immunohistochemistry revealed a high infiltration of macrophages in cetuximab-treated SC263-R tumors. FaDu-S and FaDu-R cells successfully engrafted into CB17 Scid mice and maintained their sensitivity/resistance to cetuximab.

Conclusion: We have established *in vivo* HNSCC mouse models with intact ADCC functionality for cetuximab resistance and sensitivity using the FaDu-R and FaDu-S cell lines, respectively. These models serve as valuable tools for investigating cetuximab resistance mechanisms and exploring novel drug combination strategies.

Keywords: HNSCC, cetuximab resistance, xenograft mouse model, immunodeficient mice

INTRODUCTION

Head and neck squamous cell carcinoma (HNSCC) is a type of cancer originating in the mucous membranes of the oral cavity, pharynx, and larynx. With over 800,000 patients being diagnosed every year^[1], HNSCC remains a challenging disease to treat. Over the years, novel treatment options have emerged targeting the tumor in a much more specific way, thereby reducing unwanted side effects associated with more conventional therapies, such as chemo- and radiotherapy. These novel immuno- and targeted therapies include the anti-programmed cell death-1 (PD-1) monoclonal antibody (mAb) pembrolizumab and the anti-epidermal growth factor receptor (EGFR) mAb cetuximab, which are now, respectively, first- and second-line therapy for the treatment of recurrent/metastatic (R/M) HNSCC^[2-4]. In addition, the PD-1 antibody nivolumab was already approved in 2016 for the treatment of patients with R/M HNSCC who have progressed on or after platinum-based chemotherapy^[5]. Although these therapies have proven their worth in terms of prolonging survival and tolerability, the development of therapeutic resistance, leading to a lack of durable efficacy, is a major roadblock in the search for effective treatment options in HNSCC. Finding a way to overcome this resistance might contribute to the much-needed progress in the field. Based on our own previous, extensive research on cetuximab resistance^[6-9] as well as preclinical and clinical studies reported in literature^[10-12], inhibition of the phosphatidylinositol 3-kinase (PI3K)/Akt pathway might be a promising therapeutic strategy to increase response to EGFR blockade with cetuximab. Recently, we demonstrated that the addition of the Akt inhibitor MK2206 to cetuximab treatment resulted in synergistic effects in both cetuximab-sensitive and acquired cetuximab-resistant HNSCC cell lines^[8]. However, *in vivo* validation of this combination strategy to overcome cetuximab resistance is yet to be investigated. Although cell lines grown in simple two-dimensional (2D) culture systems are useful and informative for initial screening of anti-cancer drugs, *in vivo* evaluation is essential for several reasons. Firstly, *in vivo* studies can provide information on the pharmacokinetics and toxicity of a drug, which cannot be accurately predicted by *in vitro* tests. Secondly, *in vivo* studies can reveal the efficacy of a drug in reducing tumor growth and metastasis, which is ultimately the most important factor in determining its clinical utility. Lastly, and maybe the most important reason of all, 2D culture systems do not accurately replicate the complex microenvironment of a tumor, including interactions with stromal cells, immune cells, endothelial cells, and the extracellular matrix (ECM). In this context, it has already been shown that cell polarity, nuclear organization, and gene expression in tumor cells are affected by their interaction with the ECM^[13]. In addition, tumor cells grown in three-dimensional (3D) culture systems exhibit clear differences in growth characteristics and response to chemotherapeutics compared to cells grown in conventional cell culture systems^[14-16]. Over the past few years, significant progress has been made

in developing more advanced culture systems that are able to more closely resemble the patient's original tumor. For example, 3D tumor organoid cell culture models co-cultured with autologous immune cells or stromal cells have already been demonstrated to be a useful tool for studying the interaction of tumor cells with the tumor microenvironment (TME)^[17,18]. Moreover, organ-on-chip technology has emerged as an innovative approach that integrates multiple cell types and can simulate the cellular and biochemical processes occurring in the TME^[19]. Furthermore, 3D organotypic co-culture models have proven effective in maintaining the architecture and cell composition of the original tumor^[20]. Interestingly, a 3D collagen-based scaffold model has been demonstrated to be a valuable tool for studying the TME and therapeutic resistance mechanisms in HNSCC^[21]. Despite these advancements, it is important to acknowledge that current cell culture systems still have limitations in fully capturing the complexity of tumors and their interactions with the TME. As such, *in vivo* evaluation remains a crucial step in the drug development process and is necessary to ensure the safety and efficacy of novel treatment combination strategies, including cetuximab, before they can be approved for clinical use. However, to date, the availability of adequate *in vivo* mouse models specifically designed to study cetuximab resistance and sensitivity remains limited.

Historically, the working mechanism of cetuximab has largely been attributed to the direct effects of EGFR inhibition. However, cetuximab is also involved in processes that stimulate the immune system^[22-24]. In this regard, cetuximab, being a chimeric human:mouse immunoglobulin G1 (IgG1), is able to mediate cellular immunity by inducing antibody-dependent cellular cytotoxicity (ADCC)^[25,26]. This is a biological process where the fragment crystallizable (Fc) region of the antibody can bind to CD16 Fc receptors located on natural killer (NK) cells, macrophages and granulocytes, with NK cells being the most potent effectors^[27]. This Fc-CD16 binding triggers the release of cytolytic proteins such as granzymes and perforin, leading to targeted destruction of tumor cells through apoptosis or lysis^[23,28]. Moreover, studies have demonstrated that cetuximab has the ability to promote cross-priming of cytotoxic T cells via antigen-presenting cells such as dendritic cells^[29]. This effect is primarily attributed to the induction of immunogenic cell death by cetuximab in tumor cells^[30]. As such, the immune-mediated effects of cetuximab play a significant role in its antitumor activity. Therefore, in this study, we aimed to optimize two mouse models, with different cetuximab resistance status and intact ADCC functionality, that are able to subcutaneously grow tumors from human cell lines proven to be cetuximab-sensitive and -resistant *in vitro* and *in vivo*. Preservation of ADCC functionality in these mouse models is crucial to ensure that cetuximab can still execute not only EGFR inhibition but also mediate ADCC as part of its antitumor effects. Although partially immunodeficient, these mouse models are more representative of the human situation, since they are capable of executing ADCC, potentially improving the translatability of cetuximab responses from mice to humans. These two mouse models can be used in the future to test the potency of novel combination strategies containing cetuximab with the goal of overcoming resistance to cetuximab and exploring cetuximab resistance mechanisms in an *in vivo* setting.

METHODS

Cell lines and cell culture

We included three sets of isogenic cetuximab-sensitive versus acquired -resistant HNSCC cell lines. The SC263 cell line was kindly provided by Prof. Dr. Sandra Nuyts (University Hospital Leuven, Leuven, Belgium), the SCC22b cell line was kindly provided by Prof. Dr. Olivier De Wever (Laboratory of Experimental Cancer Research, Ghent University Hospital, Ghent, Belgium) and the FaDu-S and FaDu-R cell lines were kindly provided by Prof. Dr. Cyril Corbet (Pole of Pharmacology and Therapeutics, Institut de Recherche Expérimentale et Clinique, UCLouvain, Brussels, Belgium). Acquired-resistant variants (suffix R) of the initially cetuximab-sensitive SC263 and SCC22b cell lines were generated by chronic exposure to cetuximab as described previously by us^[7]. In parallel, parental cell lines were exposed to the vehicle control,

i.e., phosphate-buffered saline (PBS), and used as a control for vehicle exposure and an increased culture period (suffix S). Before inoculation, acquired-resistant cell lines were exposed to a high dose of cetuximab for 7 days to ensure proper selection of resistant cells. All cell lines were human papilloma virus (HPV)-negative and cultured in Dulbecco's modified Eagle's medium (DMEM, Gibco™, 10938025), supplemented with 10% fetal bovine serum (FBS, Gibco™, 10270106), 1% penicillin/streptomycin (Gibco™, 15140122), and 2 mM L-glutamine (Gibco™, 25030024). Cells were grown as monolayers and maintained in exponential growth in 5% CO₂/95% air in a humidified incubator at 37 °C. Cell lines were confirmed free of mycoplasma infection through regular testing using the MycoAlert Mycoplasma Detection Kit (Lonza, LT07-118). The identity of each cell line was validated through short tandem repeat profiling.

Animal facilities and animals

All animal care and testing were approved by the Ethics Committee of the University of Antwerp (N° 2020-41 and 2021-39) and performed according to the European guidelines within the facilities of the University of Antwerp, Campus Drie Eiken.

Female C57BL/6NRj-Rag2tm1Ciphe/Rj [Rag2 knock-out (KO)] mice, aged 4-6 weeks, were obtained from Janvier Labs. Female BALB/cAnN.Cg-Foxn1nu/Crl (BALB/c nude) and CB17/lcr-PrkdcScid/lcrLcoCrl (CB17 Scid) mice, aged 4-6 weeks, were obtained from Charles River Laboratories (supplier of The Jackson Laboratory in Europe). After arrival, mice were allowed to acclimatize for at least 7 days before being used in experiments to reduce stress levels. All mice were housed in controlled, specific pathogen-free environments with 12-hour cycles of light and dark and provided with food and clean water ad libitum. Mice were monitored daily for humane endpoints (body weight, appearance, behavior, and comorbidities). The number of mice varied through the experiments, taking into account both feasibility and ethical considerations. Adjustments were made based on the outcome of previous experiments, ensuring meaningful conclusions while minimizing the use of animals. The principle of reduction, refinement, and replacement (3Rs) was followed, leading to the use of minimal numbers in all experiments.

Tumor kinetics and survival

Prior to injection, tumor cells were harvested using TrypLE (Gibco™, 12604021) and washed 3 times with sterile Dulbecco's phosphate-buffered saline (DPBS, Gibco™, 14190144). In all experiments, tumor cells were suspended in 100 µL sterile PBS and injected into the shaved hind flank of the mice. In each experiment, mice were injected subcutaneously with cetuximab-sensitive or -resistant HNSCC cells at different concentrations and with/without Matrigel or Geltrex according to the schematic overview in [Figure 1](#). When tumors reached a size of approximately 30 or 70 mm², mice were randomized based on tumor size and divided into different treatment groups. Tumor growth was monitored over time and measured two times a week using a digital caliper. Tumor size was calculated using the formula "length × width". Mice were sacrificed when a tumor size of 150 mm² was reached or when a humane endpoint was reached [[Figure 1](#)].

In vivo administration of cetuximab

Mice were treated twice per week (with an interval of 3 to 4 days) with a low (2.5 mg/kg), medium (10 mg/kg), or high (50 mg/kg) dose of the anti-EGFR-targeted mAb cetuximab (Merck) or PBS control through intraperitoneal (i.p.) injection at the contralateral abdominal side of the tumor for a total treatment duration of 3 weeks. The doses (2.5, 10, and 50 mg/kg) were determined based on literature^[31-34]. Iida *et al.* reported that no discernible toxicity was observed in mice treated with 50 mg/kg cetuximab twice a week for 10 consecutive weeks^[33]. Calculations of the required cetuximab concentration in mg/kg were made for each individual mouse based on the individual body weight.

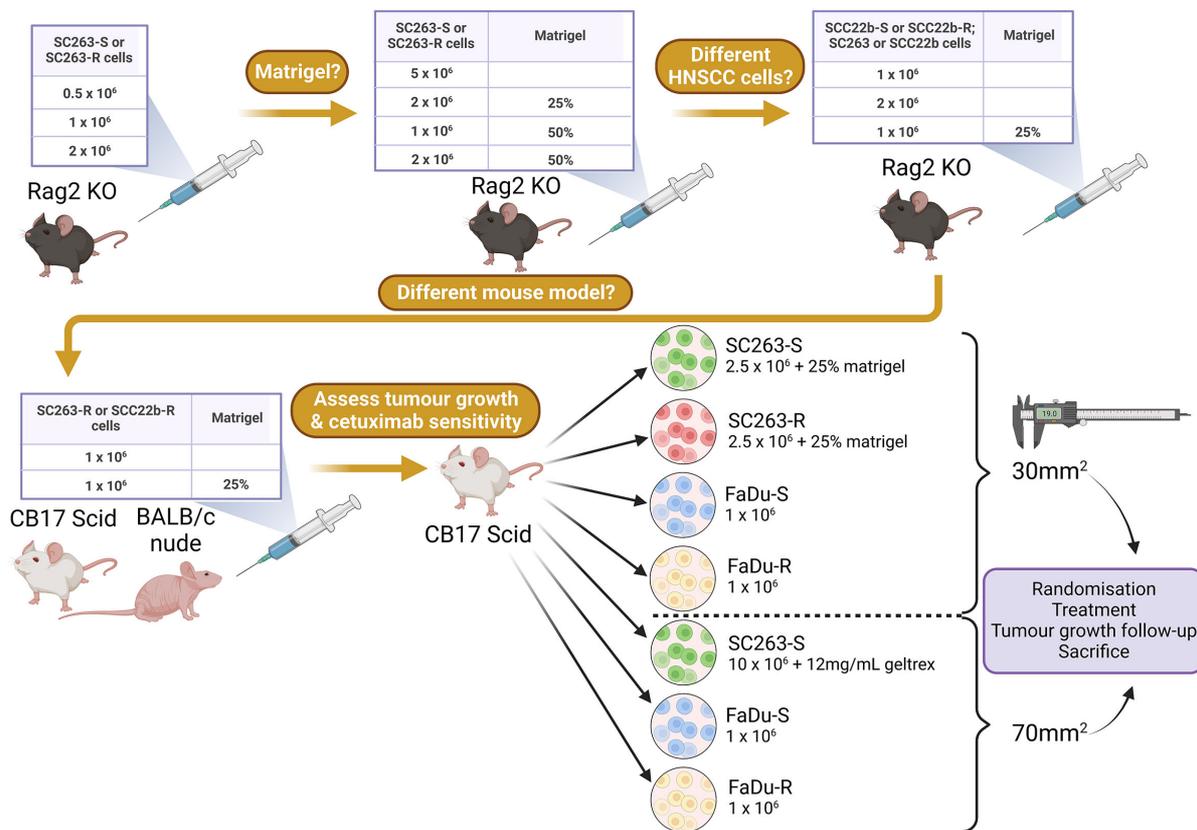

Figure 1. Schematic overview of performed experiments. This figure was created with Biorender.com. HNSCC: Head and neck squamous cell carcinoma; KO: knock-out; -R: cetuximab-resistant HNSCC cell line; -S: cetuximab-sensitive HNSCC cell line.

Immunohistochemical analysis

SC263-R, FaDu-S, and FaDu-R tumors were harvested directly after the last week of cetuximab treatment (or before tumors disappeared completely), whereas tumors originating from the SC263-S cell line were collected without prior treatment, since inducing a durable tumor growth was challenging with this cell line. Formalin-fixed paraffin-embedded (FFPE, 5 μ m thick) sections were prepared from tumor tissue blocks. Sections were incubated in a low pH buffer (pH6) for 20 min at 97 °C (PT-Link, DAKO) for heat-induced antigen retrieval. Peroxidase blocking buffer (3.5%, Acros Organics, 202465000) was used for 10 min to quench the endogenous peroxidase activity of the sections, followed by blocking with normal goat serum (for anti-F4/80, anti-Ki67 and cleaved caspase-3) or normal horse serum (for anti-NKp46). Subsequently, sections were incubated with primary antibodies: anti-NKp46 [1:50 for 60 min, NK cell marker, Bio-Techne (R&D Systems), polyclonal, AF2225-SP], anti-F4/80 (1:500 for 40 min, macrophage marker, Thermo Fisher Scientific, clone BM8, 14-4801-81), anti-Ki67 (1:400 for 35 min, proliferation marker, Cell Signaling Technology, clone D3B5, 12202S), and anti-cleaved caspase-3 (1:250 for 35 min, apoptosis marker, Cell Signaling Technology, polyclonal, 9661S). The ImmPRESSTM goat anti-rabbit peroxidase kit (for anti-Ki67 and cleaved caspase-3, Vector, MP-7451), the ImmPRESSTM goat anti-rat peroxidase kit (for anti-F4/80, Vector, MP-7444), or the ImmPRESSTM horse anti-goat peroxidase kit (for anti-NKp46, Vector, MP-7405) in combination with the liquid DAB+ substrate chromogen system (DAKO, K3467) were used for signal detection according to the manufacturer's instructions. All sections were counterstained with hematoxylin (0.1%, Merck, C.I.75290), dehydrated in a series of isopropanol baths (distilled water, 70%, 95%, 100%, Acros Organics, P/7490/FP21), cleared with xylene (MLS, ZY10020) and mounted with ExPert mounting medium (MLS, QC50082). Positive controls were included for each marker and consisted of mouse tissue of

spleen (for anti-Ki67, anti-F4/80, and anti-NKp46) and lymph node (for anti-cleaved caspase-3). Pictures were taken with a Leica ICC50 E camera on a Leica DM500 microscope.

Statistical analysis

Possible significant differences in tumor kinetics between treatment groups ($P < 0.05$) were evaluated with a linear mixed model by each time point with the treatment group as a fixed effect and the subject as a random effect using JMP Pro v16.0.0 software.

RESULTS

Rag2 KO mice prove to be ineffective as xenograft models for HNSCC tumor growth

Rag2 KO mice were selected as a suitable model for our first experiment, since this mouse strain has no mature B and T cells and is considered an excellent xenograft host for cancer cell lines. Importantly, the innate immunity is still intact in these mice. Thus, this model is highly suitable for testing the efficacy of therapeutic antibodies, such as cetuximab, as ADCC is still intact.

Rag2 KO mice were injected subcutaneously with a low (0.5×10^6), medium (1×10^6), and high (2×10^6) number of the cetuximab-sensitive SC263-S and acquired cetuximab-resistant SC263-R cells and tumor growth was followed up over time. The SC263-S and SC263-R cells were selected, as these cell lines showed the most promising responses in *in vitro* combination experiments. Unfortunately, after 4 weeks of follow-up, no mouse had developed a measurable subcutaneous (s.c.) tumor. Therefore, we tried to achieve tumor growth by varying several conditions. Firstly, we co-injected the tumor cells with Matrigel (25% and 50%) since, according to literature, Matrigel co-injection can increase the initiation and growth of tumor cells *in vivo*^[35]. In addition, a group of mice inoculated with 5×10^6 cells (without Matrigel) was included, as some HNSCC xenograft studies using such high cell numbers have been described in literature^[36-38]. After 2 weeks of follow-up, only the Matrigel groups showed measurable s.c. tumors that persisted for multiple measurements (≥ 3 , [Figure 2](#)). However, some tumors completely disappeared over time, while most tumors of both cell lines slowly regressed, reaching a plateau without further exponential growth, and tumor sizes never reached 30 mm^2 [[Figure 2](#)]. As a result, we decided to terminate this experiment, as it became evident that none of the groups would be appropriate for conducting further experiments.

Considering that the in-house developed SC263-S and SC263-R cell lines, as well as the parental SC263 cell line, have not been previously used in xenograft models to our knowledge, the results we obtained suggest that these cell lines may not be capable of initiating tumor growth *in vivo*. To further explore this hypothesis, we repeated the previous experiment with the SCC22b-S and SCC22b-R cell lines, with/without co-injection with Matrigel, as the parental SCC22b cell line has been employed in HNSCC xenograft studies before^[39-42], yet in other mouse models than Rag2 KO. Unfortunately, neither experimental group exhibited any sustainable tumor growth, indicating that these cell lines were also unsuitable as progressive HNSCC models in the Rag2 KO mouse strain. Although tumor growth was initially observed in mice injected with 2×10^6 SCC22b-S cells with 25% Matrigel, this was very limited (tumor sizes $< 17 \text{ mm}^2$) and tumor size decreased rapidly over time [[Figure 3](#)]. To eliminate the possibility that the increased passage numbers of these cell lines due to in-house development of acquired resistance were causing the issue, we tested the parental SC263 and SCC22b cell lines in the Rag2 KO mouse strain with/without Matrigel, but without any success. In conclusion, we attempted several methods, including co-injection with Matrigel, adjusting cell number, multiple cell lines and testing parental cell lines, but none of them proved effective. These results led to the conclusion that the Rag2 KO mouse strain is unsuitable for xenografting HNSCC cell lines, at least for our sets of isogenic cetuximab-sensitive versus acquired -resistant cell lines.

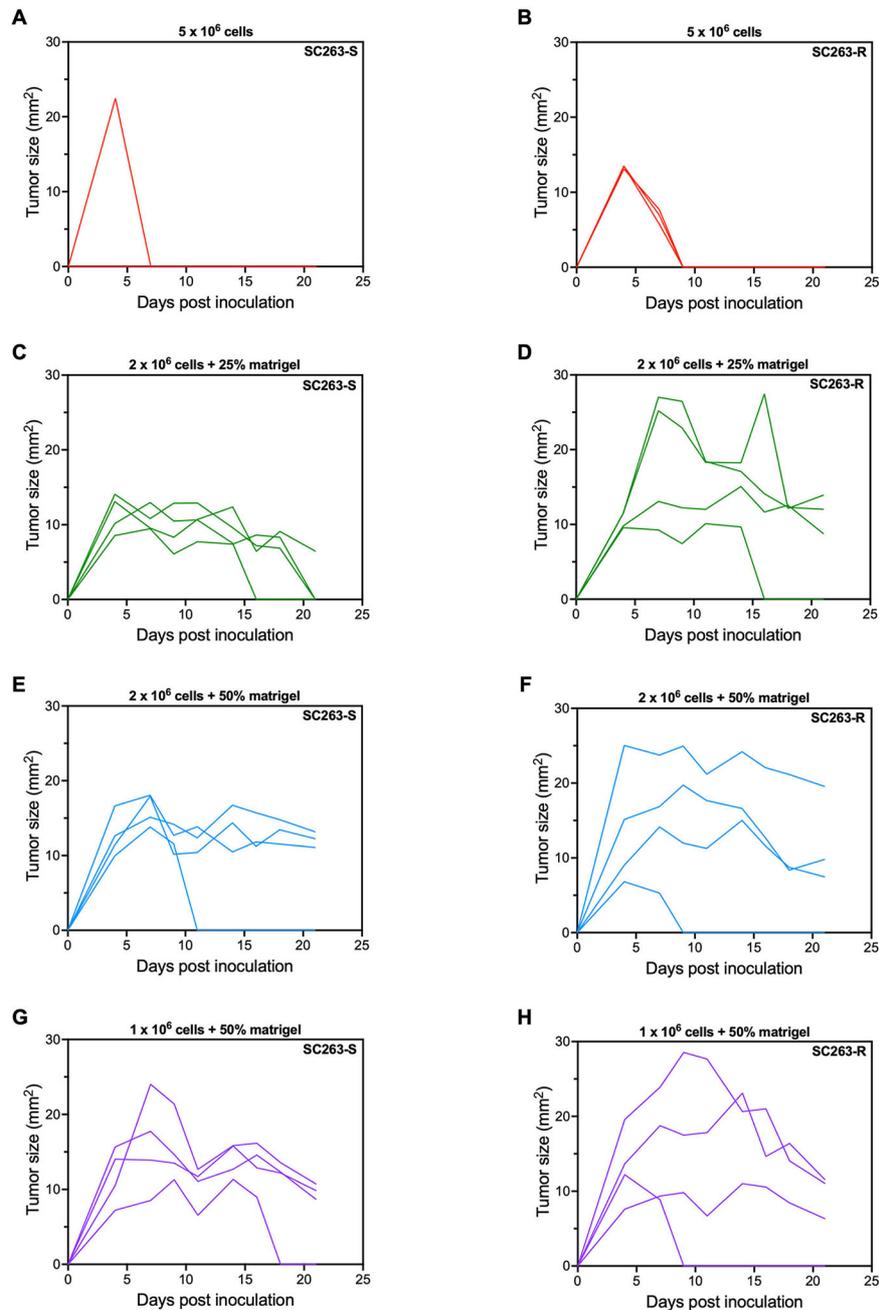

Figure 2. Co-injection of SC263 tumor cells with Matrigel in Rag2 KO mice did not result in sustained tumor growth. (A and B) Tumor kinetics after s.c. injection with 5×10^6 SC263-S: (A) and SC263-R cells; (B) ($n = 3$); (C and D) Tumor kinetics after s.c. injection with 2×10^6 SC263-S: (C) and SC263-R cells; (D) mixed with 25% Matrigel ($n = 4$); (E and F) Tumor kinetics after s.c. injection with 2×10^6 SC263-S: (E) and SC263-R cells; (F) mixed with 50% Matrigel ($n = 4$); (G and H) Tumor kinetics after s.c. injection with 1×10^6 SC263-S: (G) and SC263-R cells; (H) mixed with 50% Matrigel ($n = 4$). Each line represents the data of one individual mouse. KO: Knock-out; -R: cetuximab-resistant HNSCC cell line; -S: cetuximab-sensitive HNSCC cell line; s.c.: subcutaneous.

CB17 Scid mice prove to be a suitable host for resistant SC263-R HNSCC cells

In a subsequent pilot experiment guided by literature and advice from Janvier Labs, we evaluated the suitability of two different immunodeficient mouse models for xenografting human HNSCC cancer cell lines. More specifically, we injected BALB/c nude and CB17 Scid mice with SC263-R cells, both with and

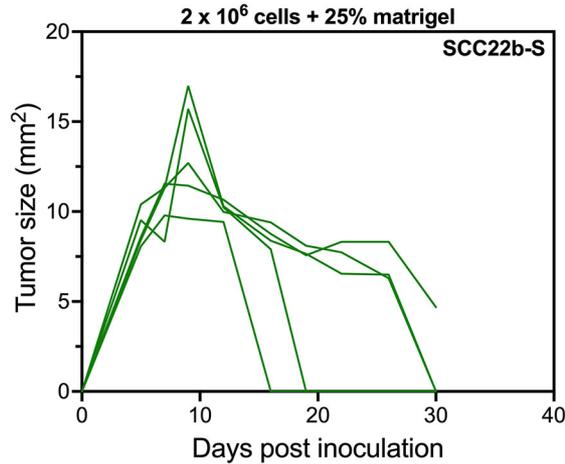

Figure 3. Tumor kinetics of SCC22b-S HNSCC cells with 25% Matrigel in a Rag2 KO mouse model. Tumor kinetics after s.c. injection with 2×10^6 SCC22b-S mixed with 25% Matrigel ($n = 5$). Each line represents the data of one individual mouse. HNSCC: Head and neck squamous cell carcinoma; KO: knock-out; -S: cetuximab-sensitive HNSCC cell line; s.c.: subcutaneous.

without 25% Matrigel, at a concentration of 1×10^6 cells per injection. CB17 Scid mice are genetically engineered to have no T and B cells, but still have intact innate immunity, including NK cells. The BALB/c nude mice lack T cells, but not B cells. In addition, NK cells are present at normal levels, and therefore, this model is also suitable to investigate NK cell cytotoxic responses such as ADCC. For this pilot experiment, we chose to only evaluate the resistant variants of our cell lines.

Only two out of three CB17 Scid mice injected with 1×10^6 SC263-R cells developed tumors, although very late in the experimental period, i.e., on days 31 and 45 post inoculation [Figure 4A]. In contrast, none of the BALB/c nude mice injected with only tumor cells showed any tumor growth [Figure 4B]. Interestingly, all CB17 Scid mice injected with 1×10^6 tumor cells mixed with 25% Matrigel exhibited sustainable tumor growth, which was already measurable as early as day 5 post inoculation. These mice reached their endpoint (tumor size = 150 mm^2) on days 61 and 91 [Figure 4C]. While two out of three BALB/c nude mice injected with tumor cells mixed with 25% Matrigel also developed tumors, growth was not sustained in this mouse strain [Figure 4D]. To maximize the information obtained from our pilot experiment and gain insight into the ability of SCC22b-R cells to grow in different mouse strains, mice that did not exhibit any tumor growth after injection with SC263-R cells were subsequently injected with SCC22b-R cells with Matrigel (for CB17 Scid mice) and with/without Matrigel (for BALB/c nude mice) at the opposite flank. However, none of the mice demonstrated sustainable tumor growth over time (data not shown). In conclusion, our pilot experiment suggested that the CB17 Scid mouse strain is an appropriate model for xenografting the human HNSCC SC263-R cell line in combination with Matrigel co-injection.

Resistant SC263-R cells do not maintain their cetuximab resistance in CB17 Scid mice

Now that we have identified an appropriate mouse model, we proceeded to the next phase of our study, which involved testing the effectiveness of cetuximab. Dose titration of the EGFR-targeting mAb cetuximab was performed in order to investigate whether xenografted HNSCC cells retained their cetuximab sensitivity in an *in vivo* setting. As tumor growth was rather slow, we increased the number of HNSCC cells to be injected from 1×10^6 to 2.5×10^6 with 25% Matrigel. CB17 Scid mice were injected with either SC263-S or SC263-R cells to generate a model that is sensitive and resistant to cetuximab, respectively. When tumors reached a volume of approximately 30 mm^2 , mice were randomized into four treatment groups (vehicle, cetuximab low dose, cetuximab medium dose, and cetuximab high dose). Unfortunately, mice inoculated

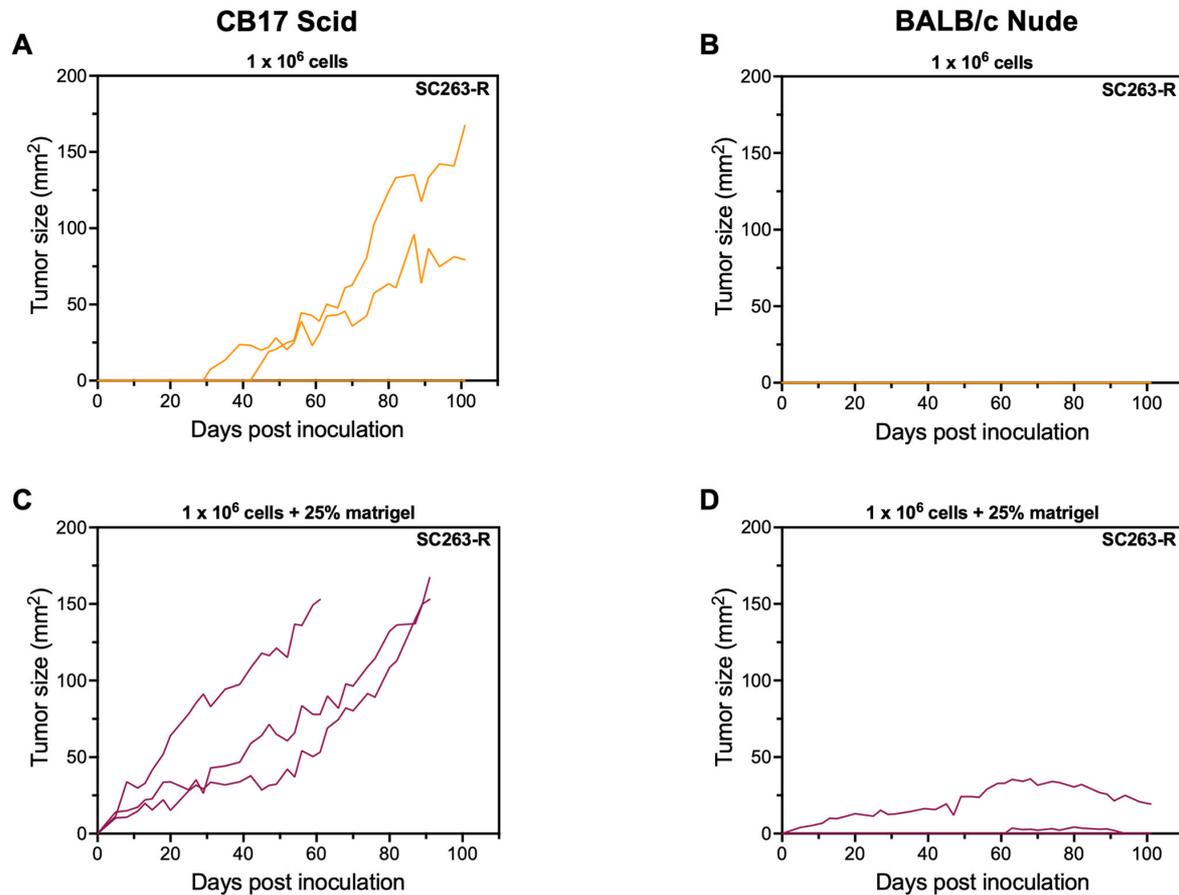

Figure 4. CB17 Scid mice are suitable hosts for SC263-R HNSCC cells when co-injected with 25% Matrigel. (A and B) Tumor kinetics over time after s.c. injection with 1×10^6 SC263-R cells in CB17 Scid: (A) and BALB/c nude; (B) mice ($n = 3$); (C and D) Tumor kinetics over time after s.c. injection with 1×10^6 SC263-R cells mixed with 25% Matrigel in CB17 Scid: (C) and BALB/c nude; (D) mice ($n = 3$). Each line represents the data of one individual mouse. HNSCC: Head and neck squamous cell carcinoma; -R: cetuximab-resistant HNSCC cell line; -S: cetuximab-sensitive HNSCC cell line; s.c.: subcutaneous.

with the SC263-S cell line reached an average tumor size of a maximum of 25 mm², after which the tumors spontaneously started to decrease in size for unknown reasons prior to treatment [Figure 5A]. In a final attempt to induce sustainable tumor growth of the SC263-S cell line in CB17 Scid mice, we remarkably increased the cell number and injected the mice with 10×10^6 SC263-S cells. Due to a global shortage of Matrigel, we used 12 mg/mL Geltrex instead to promote tumor growth. Geltrex has successfully been used in our lab to grow solid tumors from hematological cancer cell lines and is therefore a good alternative for Matrigel. Unfortunately, the results were similar to the previous experiment using 2.5×10^6 injected cells in CB17 Scid mice. Despite the tumors initially growing up to a maximum size of approximately 60 mm², they eventually began to regress spontaneously [Figure 5B]. Hence, while the tumors in this experiment achieved a larger size than in the previous one, we were still unable to induce durable tumor growth.

In contrast, in the mice injected with the SC263-R cells, treatment could be initiated at day 7. Mice in the vehicle group showed linear tumor growth, whereas tumors in the treatment groups started to decrease from the moment of treatment initiation. This shrinkage of tumor volume in the treatment groups continued until the mice showed no visible/palpable tumor anymore [Figure 5C].

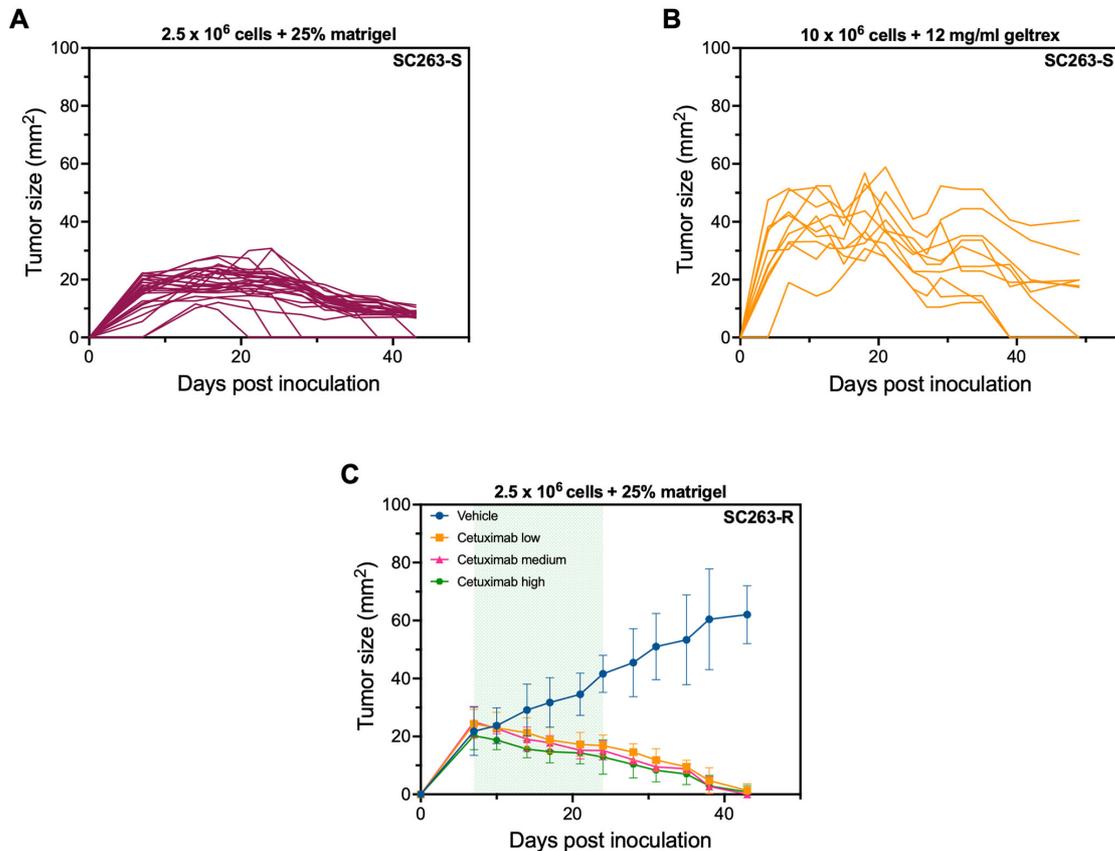

Figure 5. SC263 xenograft models in CB17 Scid mice are unsuitable for investigating cetuximab resistance. (A) Tumor kinetics after s.c. injection with 2.5×10^6 + 25% Matrigel SC263-S cells in CB17 Scid mice ($n = 27$); (B) Tumor kinetics after s.c. injection with 10×10^6 + 12 mg/mL Geltrex SC263-S cells in CB17 Scid mice ($n = 10$). Each line represents the data of one individual mouse; (C) Tumor kinetics of SC263-R tumor-bearing CB17 Scid mice following treatment with vehicle (PBS, $n = 6$), cetuximab low (2.5 mg/kg, $n = 7$), cetuximab medium (10 mg/kg, $n = 7$), and cetuximab high (50 mg/kg, $n = 7$). The green area in the graph represents the treatment period (starting from day 7). Data represent mean \pm SD. Immunohistochemistry demonstrates the high presence of macrophages in SC263-R tumors induced in CB17 Scid mice

As the CB17 Scid mouse strain has an intact innate immune system, the above-mentioned results might be explained by an activation of innate immune cells. To investigate this, we harvested tumors from both SC263-S and SC263-R tumor-bearing mice and performed immunohistochemistry [Figure 6 and Supplementary Figure 1]. Untreated SC263-S tumors were characterized by a low to moderate proliferation rate, little to no apoptotic cells, a moderate abundance of macrophages, and little to no NK cells. In contrast, Ki67 staining in vehicle-treated SC263-R-tumor-bearing mice indicated a high proliferation rate in these tumors. However, cetuximab treatment resulted in lower Ki67+ cells, indicating that cetuximab was inhibiting tumor cell proliferation in resistant cells. Although higher compared to SC263-S tumors, cleaved caspase-3 staining in SC263-R tumors was limited and slightly increased in the treatment groups. F4/80+ macrophages unexpectedly infiltrated the cetuximab-treated SC263-R tumors (particularly in the cetuximab low treatment group). This suggests that cetuximab may be altering the tumor microenvironment by increasing the infiltration of macrophages into the tumor, causing the *in vitro* resistant cells to lose their resistance *in vivo*. Little to no Nkp46+ cells were present in the vehicle group, but when tumors were treated with cetuximab, more NK cells appeared. However, this increase was not as pronounced as the infiltration

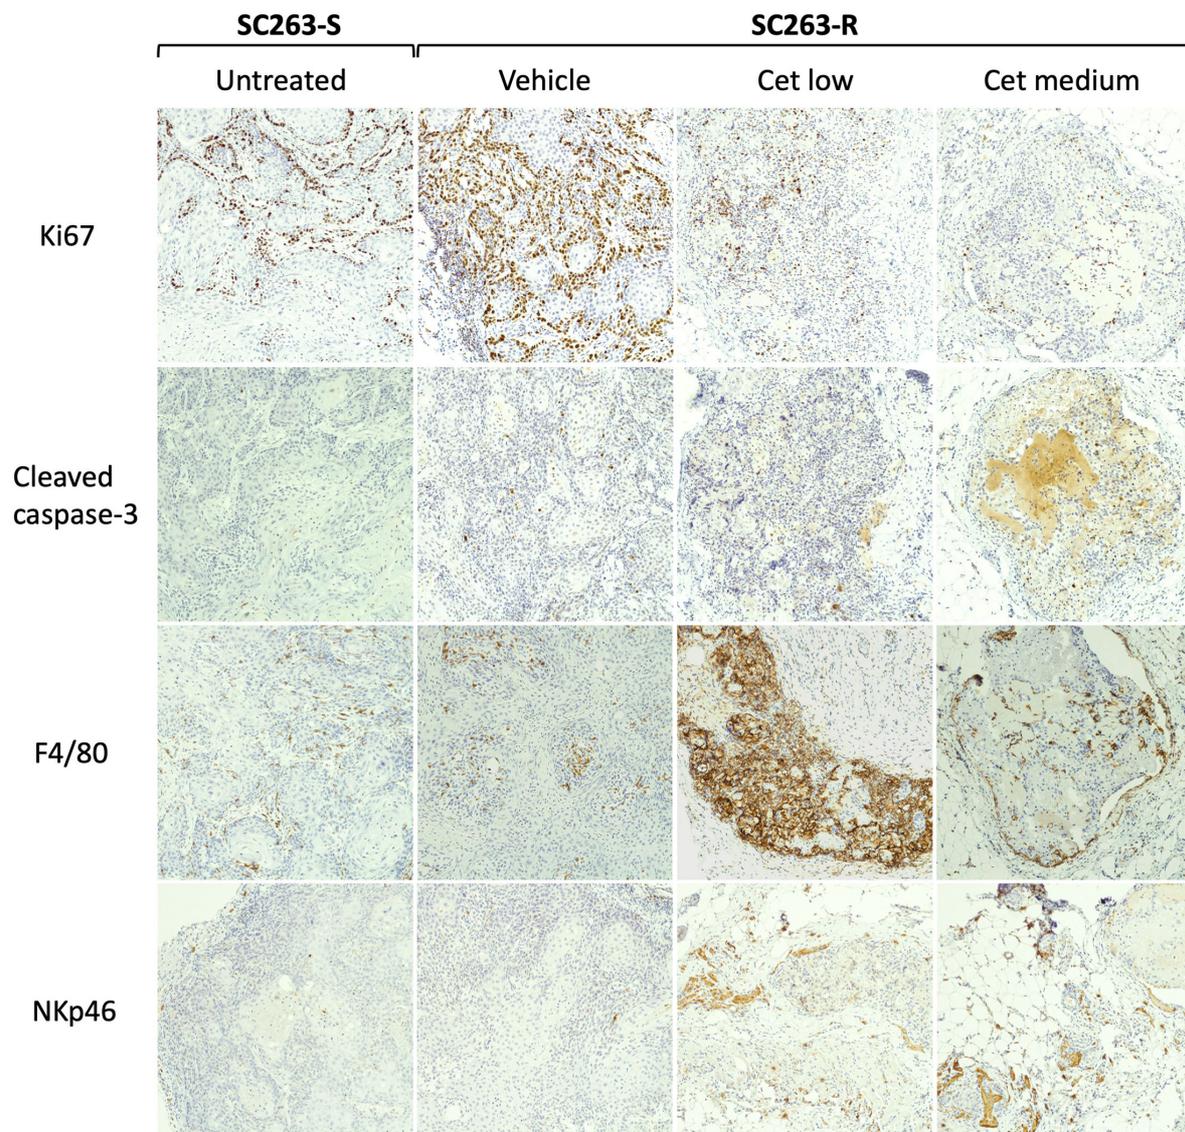

Figure 6. Infiltration of macrophages is likely compromising the growth of SC263-S tumors and the resistance to cetuximab of SC263-R tumors in CB17 Scid mice. Representative images of immunohistochemical staining for Ki67 (proliferation), cleaved caspase-3 (apoptosis), F4/80 (macrophages), and NKp46 (NK cells), shown at 100x. Vehicle: PBS; Cet low: 2.5 mg/kg cetuximab; Cet medium: 10 mg/kg cetuximab. NK: Natural killer; PBS: phosphate-buffered saline; -R: cetuximab-resistant HNSCC cell line; -S: cetuximab-sensitive HNSCC cell line.

of macrophages observed in treatment groups. Overall, these results suggest that there is a predominant presence of macrophages in both SC263-S and SC263-R tumor-bearing mice, which may be impairing the growth of SC263-S cells and the resistance of SC263-R to cetuximab *in vivo*.

FaDu cell lines retain their *in vitro* sensitivity status to cetuximab in CB17 Scid mice

In a final attempt to establish a reliable *in vivo* model for cetuximab resistance, we changed the HNSCC cell lines from SC263 to FaDu (sensitive and acquired resistant variant). In a pilot experiment with these cell lines in CB17 Scid mice, both the FaDu-S and FaDu-R cell lines exhibited robust tumor growth without the

need to add Matrigel or Geltrex [Supplementary Figure 2A and B]. This stands in contrast to the SC263-S cell line, which failed to demonstrate sustainable tumor growth in this mouse model [Figure 5A and B]. To investigate whether FaDu cells maintained their *in vitro* resistance status to cetuximab, mice were injected with 1×10^6 FaDu-S or FaDu-R cells. When tumors reached a size of approximately 30 mm², mice were randomized and treated with vehicle or a low dose of cetuximab (2.5 mg/kg). We opted to test only a low dose of cetuximab, since tumors already completely disappeared with this dosage in SC263-R tumor-bearing CB17 Scid mice [Figure 5C]. Treatment was initiated on days 13 and 9 post-inoculation for mice with FaDu-S and FaDu-R tumors, respectively. Treatment with cetuximab resulted in a significant delay in tumor growth in FaDu-S-bearing mice, while FaDu-R-bearing mice demonstrated persistent tumor growth upon cetuximab treatment [Figure 7A and B, Supplementary Figure 2C and D].

Since tumor size has been reported to be inversely correlated to response to EGFR inhibitors and chemotherapy^[43-45] in patients and CBA/lac mice, we next investigated the response to cetuximab in more established tumors in both models by delaying treatment initiation to a tumor size of approximately 70 mm². In these more established models, FaDu-S and FaDu-R tumor-bearing mice reached the treatment initiation point on day 18 post inoculation. Cetuximab treatment effectively reduced tumor growth exclusively in the FaDu-S tumor-bearing mice [Figure 7C and D], indicating that even in more established and advanced tumors, cetuximab resistance status is maintained. However, due to the study's implemented humane endpoints, the treatment window was too small to complete the intended three-week treatment period. To obtain more insight into the tumor and its microenvironment, immunohistochemistry was performed and demonstrated a remarkable decrease in Ki67+ cells and a slight increase in macrophages after cetuximab treatment in these tumors [Figure 7E]. The former confirms that cetuximab effectively reduced tumor proliferation in cetuximab-sensitive FaDu-S tumors but not in resistant FaDu-R tumors. Cetuximab treatment had no effect on the level of apoptosis or NK cell infiltration [Supplementary Figure 2E]. In conclusion, the FaDu-S and FaDu-R cell lines effectively maintain their *in vitro* resistance status to cetuximab *in vivo* in CB17 Scid mice, even when tumors are more established. As such, these robust and reliable models underscore the suitability and promise of using xenografts with both sensitive and acquired resistant FaDu HNSCC cell lines for investigating novel combination therapies aimed at overcoming cetuximab resistance in an *in vivo* setting.

DISCUSSION

Cetuximab resistance poses a significant challenge in the search for effective treatment options for HNSCC. To understand and address this problem, it is crucial to develop *in vivo* models that accurately depict cetuximab resistance. Such clinically relevant animal models are essential for studying and exploring novel combinations that have the potential to overcome resistance to cetuximab. Over the years, xenografts have become the gold standard for investigating novel cancer treatments, as they allow the use of human cell lines or even patient samples^[46]. However, the majority of studies addressing novel cancer treatments in HNSCC have primarily relied on xenograft models using human cell lines, without specifically focusing on resistance nor on retaining intact ADCC functionality *in vivo*. Studies specifically using an acquired cetuximab-resistant xenograft model in HNSCC are rather scarce and appear to be challenging to develop^[47,48]. As far as our knowledge extends, our research represents the first successful establishment of an acquired cetuximab-resistant HNSCC model derived from *in vitro*-generated acquired resistant cells. In addition to our work, there have been previous attempts to establish *in vivo* models of acquired cetuximab resistance by chronically treating tumor-bearing mice with increasing doses of cetuximab, however, without success for HNSCC^[47,48]. There has also been a study that established an HNSCC *in vivo* mouse model by utilizing cells with the EGFR-K521 polymorphism that are intrinsically resistant to cetuximab^[49]. However, our work specifically focuses on acquired resistance, making our study distinct and unique in the field. In

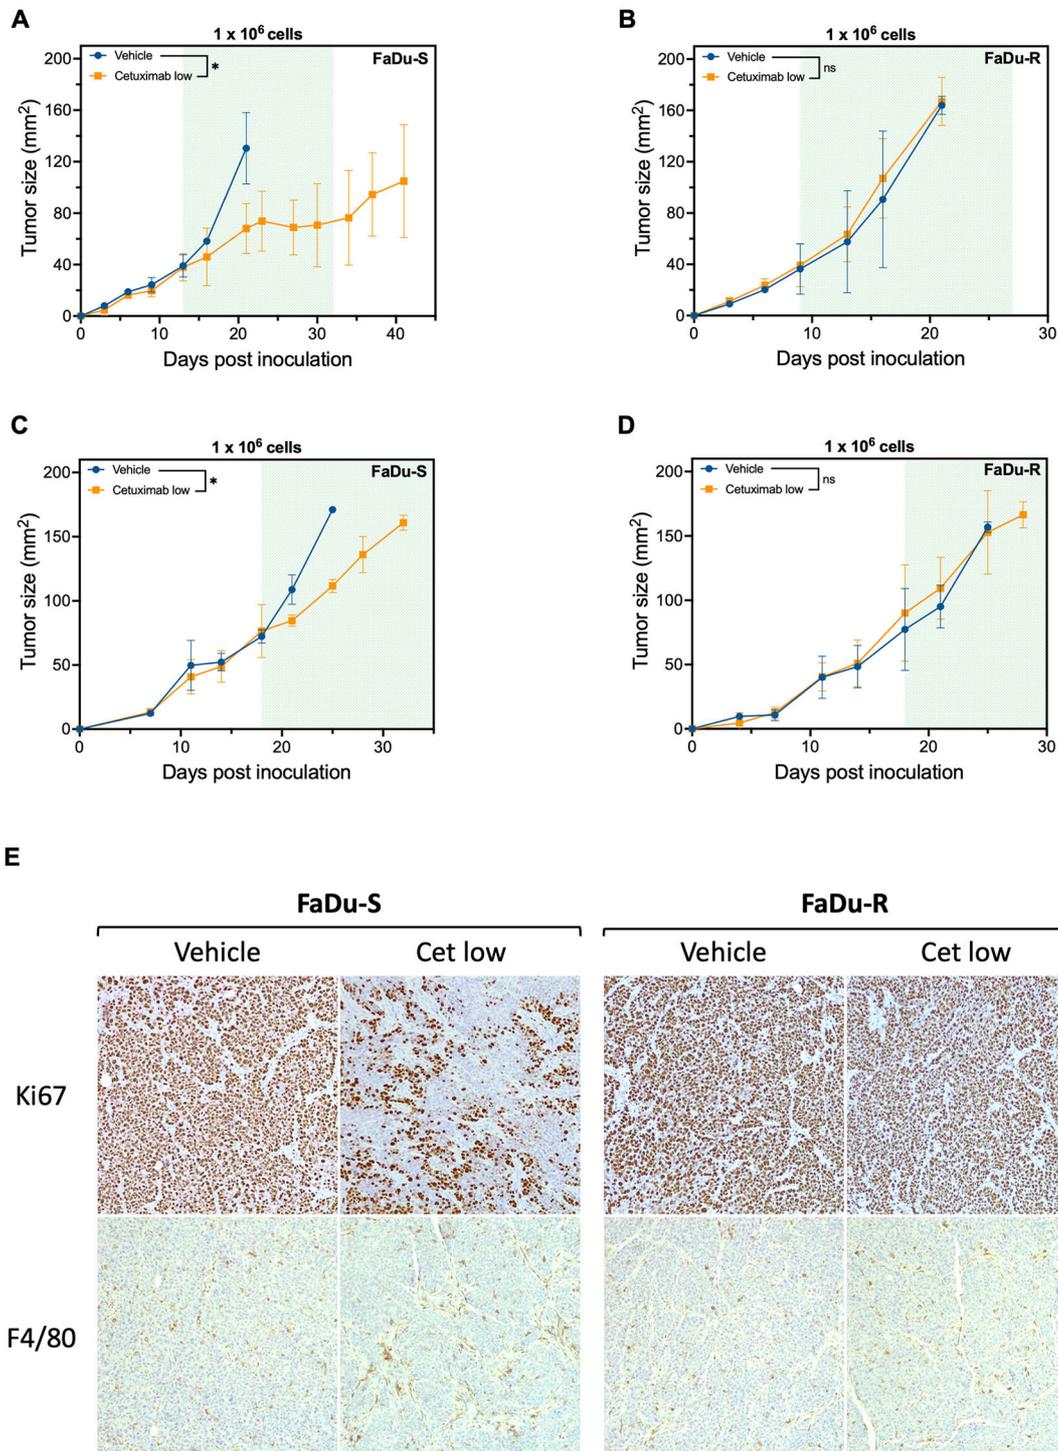

Figure 7. Cetuximab resistance status of isogenic FaDu cell lines is maintained in CB17 Scid mice. (A-D) Tumor kinetics of CB17 Scid mice inoculated with 1×10^6 cetuximab sensitive FaDu-S cells (A and C) or cetuximab resistant FaDu-R cells (B and D) following treatment with vehicle (PBS, $n = 2$) or cetuximab low (2.5 mg/kg, $n = 3$). The green area in each graph represents the treatment period [starting from (A) day 13, (B) day 9 or (C and D) day 18]. Data represent mean \pm SD. *P*-values were determined using a linear mixed model; (E) Representative images of immunohistochemical staining for Ki67 (proliferation) and F4/80 (macrophages), shown at 100x. **P* < 0.05. ns: Non-significant; PBS: phosphate-buffered saline; -R: cetuximab-resistant HNSCC cell line; -S: cetuximab-sensitive HNSCC cell line.

contrast, more success has been achieved with patient-derived xenograft mouse models for acquired cetuximab resistance, offering a valuable alternative and clinically relevant approach to study acquired cetuximab resistance *in vivo*^[50,51].

In the present study, we aimed to establish a xenograft model of acquired resistance using a human HNSCC cell line that was initially made resistant *in vitro* by chronically exposing it to increasing doses of cetuximab^[7]. Our attempts to generate a resistance model using the Rag2 KO mouse strain were unsuccessful, despite various attempts to optimize tumor growth induction by adjusting tumor cell number, cell lines and/or the addition of Matrigel. The finding that not even the SCC22b-S, which has only a larger passage number than its parental cell line, failed to induce sustainable tumor growth is particularly surprising, considering the extensive use of the parental cell line in numerous published xenograft studies^[39-42], yet in other mouse models than Rag2 KO and not focusing on cetuximab resistance. Initially, we chose the Rag2 KO mouse model, since this strain has been reported as a suitable host for tumor implantation studies of several cancers, including HNSCC^[52-55]. This is because the loss of Rag2 blocks the development of mature B and T cells, creating an immunodeficient mouse model that should be able to accept allogenic transplants^[55-57]. The C57BL/6N genetic background of the mouse strain employed in our study could potentially explain the unsuccessful tumor engraftment. C57BL/6N mice have a more robust and aggressive innate immunity in comparison to mice with a BALB/c background^[58-62]. This more robust immune activity could have triggered an amplified immune response against the implanted tumor cells, ultimately inhibiting their growth and engraftment in the Rag2 KO mouse strain.

Next, we conducted a pilot experiment using CB17 Scid and BALB/c Nude mice, two different mouse strains on a BALB/c genetic background with intact innate immunity that have been extensively used in HNSCC xenograft studies^[37,41,63-65], although not specifically in the context of cetuximab. Based on this experiment, the CB17 Scid mouse strain was selected as a suitable model for xenografting the SC263-R cell line. It is important to note that a limitation of this pilot experiment was the exclusion of the sensitive cell line (SC263-S), primarily due to the limited availability of mice, which was later found to be unable to grow in this specific mouse strain. Additionally, we observed that the acquired cetuximab-resistant variant SC263-R had lost its resistance phenotype in this specific *in vivo* model. This observation has been reported in literature before, although to a limited extent. In this regard, the study of Formelli *et al.* showed that doxorubicin-resistant B16 melanoma cells only maintained their resistance *in vivo* when the *in vitro* resistance index was greater than 100^[66]. Similarly, when the *in vitro*-derived cetuximab-resistant SCC1c8 HNSCC cell line was transplanted into an athymic nude mouse model, it unexpectedly lost its resistance phenotype^[48]. This mouse model lacks T cells but has functional B cells, NK cells and macrophages^[67], which may have been the reason for the observed loss of resistance *in vivo*. Similarly, an *in vitro* generated breast cancer cell line resistant to (ADCC-capable) trastuzumab failed to maintain its resistance status in an *in vivo* mouse model^[68]. These outcomes highlight the limitations of solely relying on *in vitro* drug exposure to generate resistant clones. To ensure more reliable *in vivo* models of drug resistance, it is suggested that *in vivo* selection or a combination of *in vivo* and *in vitro* selection methods should be employed^[69]. However, *in vivo* selection is still challenging and does not guarantee the successful generation of resistance models. This was demonstrated by Quesnelle *et al.*, who performed an *in vivo* selection of 10 different HNSCC cell lines, including SCC22b, with the goal of establishing much-needed *in vivo* models of cetuximab resistance. However, despite their efforts, none of the cell lines exhibited successful acquisition of cetuximab resistance in their *in vivo* setting^[47]. In addition, *in vivo* generated cetuximab-resistant cancer cells demonstrated to slowly lose their resistance phenotype after several *in vitro* passages^[70,71]. The cetuximab-resistant cell lines used in the present study were solely generated *in vitro*, but have proven to maintain their resistance phenotype even after 6 weeks of culture without cetuximab^[7,72], excluding the latter as a possible reason for the loss of resistance *in vivo*.

As immunohistochemical analysis revealed a high presence of macrophages in both SC263-S and SC263-R tumors, these macrophages might have impaired the growth of SC263-S cells and the resistance phenotype of SC263-R cells. The presence of macrophages in the tumor microenvironment may have exerted suppressive effects on tumor growth by contributing to an antitumor immune response or by directly influencing tumor cell behavior. Nevertheless, we acknowledge that our immunohistochemical findings warrant further validation with larger sample sizes to ensure robustness and reliability before drawing any definitive conclusions. In addition, factors such as oxygen levels, nutrient availability, cell-cell interactions and the presence of stromal cells, which are all different or even absent in *in vitro* cell cultures, may influence the behavior of tumor cells and potentially impact their response to cetuximab. In this regard, it has been shown that hepatocellular cancer cells cultivated *in vitro* in more native conditions exhibited an altered drug sensitivity compared to cells cultured in standard conditions^[73], highlighting the influence of the tumor microenvironment on drug sensitivity^[74].

In a final attempt to establish a cetuximab-resistant *in vivo* model from an *in vitro* generated resistant HNSCC cell line, we utilized acquired resistant FaDu-R cells. The parental FaDu cell line has already been used in HNSCC xenograft studies^[64,75-77], and both FaDu-S and FaDu-R have been demonstrated to induce robust tumor growth in CB17 Scid mice. Moreover, we showed that both FaDu-S and FaDu-R cell lines maintain their sensitivity/resistance status to cetuximab *in vivo*, in contrast to our other *in vitro*-proven cetuximab-resistant HNSCC cell lines.

Previous studies in mice have demonstrated that more advanced tumors have a lower response to EGFR inhibitors and chemotherapy^[43,44]. Together with the fact that larger gross tumor volumes have been linked to worse outcomes in HNSCC patients receiving cetuximab and radiotherapy^[73], we delayed treatment initiation until the tumor was more established, as it might lead to reduced responsiveness to cetuximab. Yet, FaDu-S and FaDu-R cells maintained their resistance phenotype when treatment was initiated at a larger tumor size. However, they exhibited rapid growth, failing to complete the intended three-week treatment period. Overall, this demonstrates that we have succeeded in establishing reliable and robust HNSCC mouse models, where the cetuximab resistance status of the tumor cells remains unaffected by larger tumor sizes.

It is important to mention that our models for cetuximab resistance have certain limitations. More specifically, we established tumor models using both cetuximab-sensitive and -resistant variants derived from only one HPV-negative cell line of hypopharyngeal origin, restricting our models to fully capture the heterogeneity and complexity of the HNSCC patient population. Indeed, one single HNSCC cell line may not fully capture the diverse molecular and phenotypic profiles observed in different patients. The choice to focus only on HPV-negative HNSCC can be justified by the fact that this patient population is in greater need of novel treatment options, as they have an inferior prognosis in terms of recurrence and survival compared to HPV-positive patients^[78]. In addition, HPV-positive HNSCC patients are, in the majority of cases, intrinsically resistant to cetuximab^[79,80], making an acquired cetuximab-resistant *in vivo* model for this patient population less clinically relevant. It is also worth mentioning that our established models are only validated for low doses (2.5 mg/kg) of cetuximab with a treatment period of three weeks. Further validation of the models with higher doses is still required. Furthermore, since our models are xenograft models, these mice lack a fully functional immune system, specifically the adaptive immunity component, which plays a crucial role in the evaluation of immunotherapeutic agents, such as pembrolizumab and nivolumab^[81]. However, previous studies in literature have utilized similar mouse strains with only ADCC induction

capability and no adaptive immunity to evaluate cetuximab-containing treatment combinations^[31,32,40,82-84], highlighting these models as valuable research tools. Although a syngeneic model would address the limitation of lacking adaptive immunity in our CB17 Scid mouse models, its use was not considered suitable for our study due to the inability of cetuximab to bind to murine EGFR^[85]. While there is a mouse variant of cetuximab known as 7A7, which was initially proposed as a valuable antibody for EGFR-based preclinical studies in mice^[86], a recent study failed to reproduce the earlier reported results^[87]. Furthermore, apart from the laboratory that initially reported 7A7, there are no other published studies in literature that have used this specific antibody, despite the first report dating back 20 years. Considering these factors, we opted against using a syngeneic model for our study, as it would not have provided the necessary compatibility with cetuximab and an accurate representation of its effects in mice. Alternatively, humanized mouse models could be a more optimal choice, as they possess a complete human immune system, including human NK cells^[81]. However, humanized mouse models can be costly to establish and maintain, making them a financial challenge for many research laboratories. Therefore, our models consider a robust and economical approach for cetuximab resistance and combination studies *in vivo*.

In conclusion, we have successfully established *in vivo* mouse models for cetuximab resistance and sensitivity using the FaDu-R and FaDu-S cell lines, respectively, in CB17 Scid mice with intact ADCC functionality. These models provide a useful tool for studying resistance mechanisms and novel drug combination strategies in a more clinically relevant setting.

DECLARATIONS

Acknowledgments

The authors would like to thank different donors, including Dedert Schilde vzw and Willy Floren, for funding some of the equipment used in this study. The authors would also like to acknowledge Sophie Rovers for helping to develop [Figure 1](#) using Biorender.com.

Abstract

The induction of cell death is recognized as a potent strategy for cancer treatment. Apoptosis is an extensively studied form of cell death, and multiple anticancer drugs exert their therapeutic effects by inducing it. Nonetheless, apoptosis evasion is a hallmark of cancer, rendering cancer cells resistant to chemotherapy drugs. Consequently, there is a growing interest in exploring novel non-apoptotic forms of cell death, such as ferroptosis, necroptosis, pyroptosis, and paraptosis. Natural compounds with anticancer properties have garnered significant attention due to their advantages, including a reduced risk of drug resistance. Over the past two decades, numerous natural compounds have been discovered to exert anticancer and anti-resistance effects by triggering these four non-apoptotic cell death mechanisms. This review primarily focuses on these four non-apoptotic cell death mechanisms and their recent advancements in overcoming drug resistance in cancer treatment. Meanwhile, it highlights the role of natural compounds in effectively addressing cancer drug resistance through the induction of these forms of non-apoptotic cell death.

Keywords: Drug resistance, cancer therapy, natural compound, non-apoptotic cell death

INTRODUCTION

Cancer, as a major global public health concern, poses a severe threat to people's well-being. In 2018, the World Health Organization reported that cancer ranked the second leading cause of death globally, resulting in approximately 9.6 million annual fatalities^[1]. Cell death is a fundamental process crucial for human health, playing a pivotal role in regulating cell division, facilitating organ development, and upholding tissue homeostasis^[2]. Nevertheless, the disruption and avoidance of cell death mechanisms facilitate malignant cell transformation and advance tumorigenesis^[3]. From a therapeutic perspective, conventional cancer treatments, such as chemotherapy and radiation, achieve their anticancer effects by inducing cell death^[2].

Over the span of several decades, there has been a growing comprehension of the diverse mechanisms governing cell death. This process can be classified into two primary categories: programmed cell death (PCD), which is genetically controlled, and unprogrammed cell death, which represents a passive response to both biotic and abiotic stress. Among the various forms of PCD, apoptosis has emerged as one of the earliest and most extensively explored pathways. For a significant duration, the development of anticancer drugs targeting apoptosis has been a focal point of research. Numerous drugs, such as cisplatin, oxaliplatin, and pirarubicin, have showcased their ability to elicit anticancer effects through this mechanism^[4,5]. However, recent studies have increasingly validated that cancer cells possess the capability to elude apoptosis through a range of mechanisms, including the overexpression of apoptosis-inhibiting proteins, the inhibition of apoptosis-inducing factors, and the activation of survival signaling pathways^[6]. This evasion of apoptosis directly contributes to chemoresistance, a phenomenon intricately associated with alterations in various aspects of cancer, encompassing angiogenesis, the tumor microenvironment, and oxidative stress^[7-10]. Ultimately, this leads to the failure of cancer treatment. To improve the efficacy of cancer treatment, the exploration of non-apoptotic cell death mechanisms has gradually emerged as a prominent priority. Over the last two decades, researchers have sequentially unveiled and extensively investigated novel different cell death mechanisms, including ferroptosis, necroptosis, pyroptosis, and paraptosis. These unique mechanisms, each with its distinct regulators and pathways, hold the potential to be activated within apoptosis-resistant cancer cells, offering novel strategies for the treatment of cancer and overcoming cancer drug resistance.

Throughout history, natural compounds derived from plants, animals, microorganisms, and minerals have consistently served as a valuable source for drug discovery^[11,12]. Unlike synthetic compounds, these substances are not artificially created and can be categorized into various forms, such as alkaloids, flavonoids, and terpenes, due to their diverse chemical structures^[13]. Many of these natural compounds exhibit significant potential in the realm of cancer treatment. In fact, certain natural compounds, such as paclitaxel (PTX), camptothecin, and vincristine, have already gained widespread acceptance as chemotherapeutic drugs in clinical practice^[14,15]. Moreover, an interesting aspect is that numerous natural compounds have been found to induce various non-apoptotic cell death pathways when administered to resistant cancer cells that evade apoptosis.

This review focuses on ferroptosis, necroptosis, pyroptosis, and paraptosis, providing a comprehensive overview of the latest research advancements in these mechanisms within the framework of cancer. We place specific emphasis on their relevance in the context of combatting cancer drug resistance. Additionally, this review compiles information on natural compounds with the capacity to induce these four modes of cell death in the context of addressing cancer resistance over the past two decades.

FERROPTOSIS

Overview of ferroptosis

Ferroptosis, a recently discovered form of PCD that is iron-dependent, was first proposed in 2012^[16]. Morphologically, ferroptotic cells exhibit intact nuclei without chromatin condensation. However, their mitochondria undergo significant changes, including reduced size, increased membrane density, reduced cristae, and outer membrane rupture^[17]. Interestingly, the discovery of ferroptosis inducers was earlier than its naming. Yang *et al.* discovered some new compounds as early as 2003 and 2008, including Erastin, RSL3, and RSL5, which induce cell death through a mechanism distinct from apoptosis^[18]. Erastin reduces cysteine uptake by inhibiting cysteine/glutamate transporter receptor, known as System X_c⁻, resulting in a decrease in glutathione (GSH) synthesis and an increase in iron-dependent lipid peroxidation (LPO), which finally leads cells to ferroptosis^[19]. Differently, RSL3 directly inhibits the activity of Glutathione Peroxidase 4 (GPX4), a GSH-utilizing enzyme that prevents the accumulation of toxic lipid hydroperoxide, thereby inducing ferroptosis^[20]. Additionally, Erastin also indirectly triggers ferroptosis through the inactivation of GPX4 via the inhibition of GSH synthesis^[21].

It is known that LPO and intracellular iron accumulation play pivotal roles in triggering ferroptosis. Polyunsaturated fatty acids (PUFAs) are the most susceptible lipids to peroxidation during ferroptosis. The regulation of PUFA synthesis may be influenced by enzymes such as Long-chain acyl-CoA synthetases (ACSLs) and lyso-phosphatidylcholine acyltransferase-3 (LPCAT3). Additionally, arachidonate lipoxygenases (ALOXs) and cytochrome p450s (POR) can directly or indirectly modulate PUFA peroxidation, resulting in ferroptosis^[22]. Additionally, iron metabolism is crucial for ferroptosis. As Fe²⁺ is released from the labile iron pool (LIP) into the cytoplasm, excess Fe²⁺ oxidizes PUFAs to hydroxyl radicals and leads to ferroptosis.

The mitochondria are responsible for cellular metabolism and also play an important role in the regulation of ferroptosis^[23]. Within the mitochondria, dihydroorotate dehydrogenase (DHODH) reduces ubiquinone (CoQ) to ubiquinol (CoQH₂), serving as a radical-trapping antioxidant with anti-ferroptosis activity. DHODH plays a significant role in mediating ferroptosis defense independent of the GSH pathway^[24]. Similarly, the plasma enzyme ferroptosis suppressor protein 1 (FSP1) inhibits lipid hydroperoxides by reducing ubiquinone to ubiquinol, operating in parallel with GPX4 to counteract ferroptosis^[25]. Obviously, the mechanisms of ferroptosis are complex and being explored constantly [Figure 1].

Ferroptosis pathways for chemotherapy resistance in cancer

In recent years, ferroptosis has been a hot topic in cancer development, treatment and cancer drug resistance. Several signaling pathways have been found to participate in promoting cancer development and drug resistance through the inhibition of ferroptosis. With multiple functions for proliferation, metastasis, and differentiation of cancer cells, the phosphatidylinositol 3-kinase (PI3K)/AKT/mammalian target of the rapamycin (mTOR) signaling pathway is responsible for ferroptosis prevention via sterol regulatory element-binding protein 1 (SREBP1)/stearoyl-CoA desaturase-1 (SCD1)-mediated adipogenesis^[26]. Hippo pathway activity is also responsible for cell growth and proliferation. Activating the Hippo pathway can suppress downstream YAP, leading cancer cells resistant to ferroptosis by downregulating acyl-CoA synthetase long-chain family member 4 (ACSL4) and TCP friendly rate control (TFRC)^[27]. Since RAS may regulate some processes to escape ferroptosis, RAS-mutated cells are always susceptible to ferroptosis. High-mobility group box 1 (HMGB1), a leukemia pathogenic gene, inhibits LPO via the RAS/MAP kinase (MAPK) pathway, promoting ferroptosis resistance^[28].

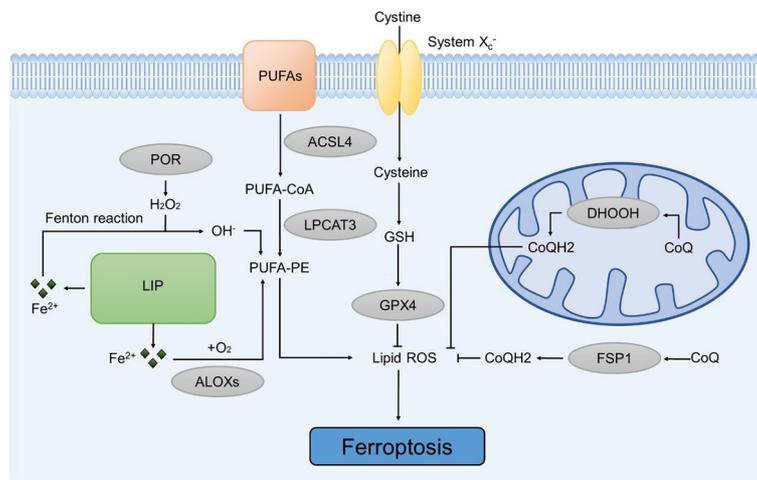

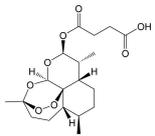

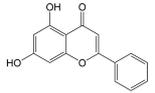

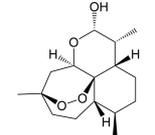

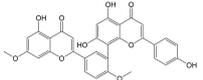

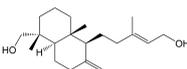

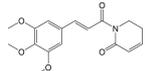

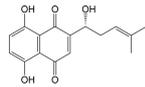

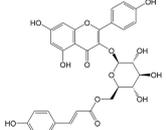

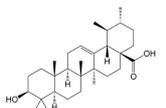

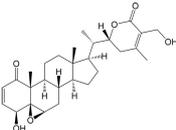

Figure 1. The mechanism of ferroptosis. Ferroptosis can be initiated by an increase in intracellular iron levels and the accumulation of iron-dependent lipid peroxidation. It can be induced through the SystemX_c⁻/GSH/GPX4 axis, the DHODH/CoQ10 axis, and the FSP1/CoQ10 axis. ACSL: Acyl-CoA synthetase; ALOXs: arachidonate lipoxygenases; CoQ: ubiquinone; FSP1: ferroptosis suppressor protein 1; GPX4: glutathione peroxidase 4; GSH: glutathione; LPCAT3: lyso-phosphatidylcholine acyltransferase-3; LIP: labile iron pool; POR: cytochrome p450s; PUFA: polyunsaturated fatty acid.

Additionally, several other pathways, including nuclear factor erythroid 2-related factor 2 (Nrf2), p53, and hypoxia-inducible factor (HIF), are also involved in chemotherapeutic resistance through ferroptosis regulation. Recent research highlights the significant impact of the Nrf2 signaling pathway on both organ protection and resistance to cisplatin (DDP) across various cancer types^[29]. For instance, in non-small cell lung cancer, Erastin and Sorafenib, either alone or in combination, induce ferroptosis by inhibiting the Nrf2/SLC7A11 (also known as xCT) pathway, thereby overcoming DDP resistance^[30]. The p53 gene, extensively studied in cancer research, influences metabolic pathways related to ferroptosis, such as enhancing ferroptosis by down-regulating xCT expression^[31]. According to this mechanism, Flubendazole and 5-fluorouracil (5-FU) demonstrate synergistic effects in treating castration-resistant prostate cancer^[32]. HIF serves a dual role in the regulation of ferroptosis in cancer cells. Lowering HIF- α levels has been found to increase LPO and enhance ferroptosis in clear cell renal cell carcinoma^[33]. Conversely, in temozolomide-resistant glioblastoma, activating HIF-1 α and HIF-2 α can induce ferroptosis, with HIF-2 α possibly promoting LPO as the primary mechanism^[34].

Natural compounds inducing ferroptosis for cancer treatment

Many natural compounds have been found to induce ferroptosis via single or combinational therapies, offering opportunities for cancer treatment and drug resistance [Table 1]. Here, we summarize those natural compounds that reverse drug resistance by inducing ferroptosis. Most of these compounds can synergize with chemotherapeutic drugs by regulating ferroptosis-related proteins and genes. Recent studies have revealed that sorafenib can induce ferroptosis in various types of cancer^[35]. However, sorafenib-induced ferroptosis can be suppressed, specifically through the activation of the PI3K/Akt signaling pathway or the NRF2/GPX4 axis^[36,37]. To overcome this challenge, drug combinations have proven to be effective strategies. Dihydroartemisinin, a derivative of artemisinin, shares similar mechanisms with sorafenib regarding ferroptosis-related proteins, such as GPX4, and has a stronger effect in liver cancer cells when combined with sorafenib^[38]. Ursolic acid, a pentacyclic triterpene compound, also exhibits synergistic anticancer effects with sorafenib by inhibiting xCT in many cancers^[39]. While DDP is considered a front-line chemotherapy drug for various cancers, including ovarian cancer, its resistance poses a significant impediment to achieving effective treatment outcomes^[40]. Inhibition of apoptosis plays a significant role in

Table 1. Natural compounds for anticancer drug resistance by inducing ferroptosis

Compounds	Origin	Structure	Cancer	Anti-drug resistant effects	Refs
Artesunate	<i>Artemisia annua</i> L.		Renal cell carcinoma	Increasing cytotoxicity in sunitinib-resistant renal cell carcinoma by triggering ferroptosis, increasing ROS generation, and decreasing metabolism.	[50]
Chrysin	<i>Oroxylum indicum</i> (L.) Kurz		Pancreatic cancer	Inhibiting CBR1 activity in gemcitabine-resistant pancreatic cancer to trigger ferroptosis through ROS accumulation.	[48]
Dihydroartemisinin	<i>Artemisia annua</i> L.		Hepatocellular carcinoma	Synergizing with sorafenib to induce ferroptosis by increasing the levels of L-ROS, LIP, and MDA and decreasing the level of GSH.	[38, 127-129]
Ginkgetin	<i>Ginkgo biloba</i> L.		Non-small cell lung cancer	Synergizing with DDP to induce ferroptosis by increasing ROS formation, decreasing the expression of xCT and GPX4, and inactivating the Nrf2/HO-1 axis.	[46]
Kayadiol	<i>Torreya nucifera</i> Sieb. et Zucc. (Taxaceae)		Extranodal natural killer/T cell lymphoma	Inducing p53-mediated ferroptosis through the xCT/GPX4 axis and exhibiting synergistic effects when combined with L-asparaginase and DDP.	[49]
Piperlongumine	<i>Piper longum</i> L.		Pancreatic cancer	Enhancing the antitumor effects of erastin by inducing ROS generation, GSH depletion and inhibiting TXNRD activity.	[43, 130]
Shikonin	<i>Lithospermum erythrorhizon</i> Sieb. et Zucc.		Ovarian cancer	Synergizing with DDP to induce ferroptosis through upregulation of HMOX1 and increased levels of ROS, LPO, and Fe ²⁺ .	[42]
Tiliroside	<i>Tribulus terrestris</i> L.		Hepatocellular carcinoma	Enhancing the antitumor effects of sorafenib by inducing ferroptosis via targeting TBK1 to promote Keap1-mediated Nrf2 ubiquitination and degradation.	[45]
Ursolic acid	<i>Ligustrum lucidum</i> W. T. Aiton		Colon cancer, gastric cancer, prostate cancer	Enhancing the antitumor effects of sorafenib by inducing xCT-dependent ferroptosis.	[39]
Withaferin A	<i>Withania somnifera</i> (L.) Dunal		Hepatocellular carcinoma	Enhancing the antitumor effects of sorafenib in sorafenib-resistant hepatocellular carcinoma cells by regulating Keap1/Nrf2-associated ferroptosis and EMT.	[44]

CBR1: Carbonyl reductase 1; DDP: cisplatin; EMT: mesenchymal transition; GPX4: glutathione peroxidase 4; GSH: glutathione; HMOX1: heme oxygenase 1; LIP: labile iron pool; LPO: lipid peroxidation; L-ROS: lipid reactive oxygen species; MDA: malondialdehyde; TBK1: tank-binding kinase; TXNRD: thioredoxin reductase.

contributing to DDP resistance, whereas the induction of novel forms of cell death, such as ferroptosis, has been shown to effectively kill DDP-resistant cancer cells that evade apoptosis^[41]. The combination of DDP with Shikonin, a hydroxy-1,4-naphthoquinone isolated from *Lithospermum erythrorhizon* Sieb. et Zucc. (Boraginaceae), promotes Fe²⁺ accumulation by upregulating heme oxygenase 1 (HMOX1), initiating ferroptosis in DDP-resistant ovarian cancer cells^[42]. Piperlongumine, an alkaloid derived from long pepper (*Piper longum* L.), exhibits anticancer activity in lung cancer cells by targeting the glutathione regeneration

enzyme, thioredoxin reductase 1 (TXNRD1). Although it does not induce ferroptosis, it can significantly enhance erastin-induced LPO^[43].

In addition to ferroptosis-related genes and proteins, some natural compounds induce ferroptosis via regulation of the Nrf2 signaling pathway. Withaferin A, a steroidal lactone isolated from the medicinal plant Ashwagandha [*Withania somnifera* (L.) Dunal], and Tiliroside, a flavonoid found in the herbs of *Tribulus terrestris* L., both modulate the Kelch-like ECH-associated protein 1 (Keap1)/Nrf2 pathway in hepatocellular carcinoma. Withaferin A enhances sorafenib sensitivity in sorafenib-resistant hepatocellular carcinoma cells by regulating the Keap1/Nrf2-associated epithelial-to-mesenchymal transition (EMT) and ferroptosis^[44]. Additionally, tiliroside synergistically combines with sorafenib to inhibit Tank-binding kinase (TBK1) activity, prompting Keap1-mediated Nrf2 ubiquitination and degradation, leading to ferroptosis in hepatocellular carcinoma cells^[45]. Ginkgetin, a natural biflavonoid isolated from the leaves of *Ginkgo biloba* L., has been found to induce ferroptosis in non-small cell lung cancer cells through decreased expression of xCT and GPX4, decreased GSH/glutathione disulfide (GSSG) ratio, and inactivation of the Nrf2/HMOX1 axis. Interestingly, it can promote DDP-induced anticancer activity, which is also a result of ferroptosis induction^[46].

As a key regulator of iron homeostasis, ferritin plays a vital role in storing intracellular free iron and is involved in ferritinophagy, a form of autophagic ferroptosis. In ferritinophagy, the autophagic cargo receptor nuclear receptor coactivator 4 (NCOA4) binds to ferritin heavy chains (FTH1) and delivers it to autophagosomes for degradation and iron release^[47]. Human carbonyl reductase 1 (CBR1) contributes to gemcitabine resistance in pancreatic cancer. The upregulation of CBR1 induced by gemcitabine inhibits the antitumor effects of the drug. Conversely, reducing CBR1 activity enhances the sensitivity of cancer cells to gemcitabine, thereby improving its therapeutic efficacy. Chrysin, a natural bioflavonoid compound, has been discovered to induce ferritinophagy, thus enhancing gemcitabine sensitivity in pancreatic cancer cells. In Chrysin-treated cells, there is a deregulation of FTH1 and an increase in intracellular free iron levels, followed by the inhibition of CBR1, which is involved in the induction of ferroptosis^[48].

The tumor suppressor protein p53 also plays an essential role in ferroptosis in certain cancers. As a diterpenoid extracted from *Torreya nucifera*, kayadiol exhibits anticancer properties through p53-mediated ferroptosis in NK/T lymphoma cells, and it could synergistically combine with L-asparaginase and DDP^[49]. Artesunate (AST), another derivative of artemisinin, was found to inhibit the growth of sunitinib-resistant renal cell carcinoma cells by both inhibiting cell cycle progression and inducing ferroptosis. Interestingly, the induction of ferroptosis was associated with its inhibitory effect only in renal cell carcinoma cells expressing p53, suggesting that AST induces p53-dependent ferroptosis^[50].

NECROPTOSIS

Overview of necroptosis

Necroptosis, first described in 2005, is a form of cell death characterized by morphological features similar to necrosis, including a lack of nuclear chromatin, organelle swelling, and cell membrane disruption^[51]. However, unlike necrosis, which is a passive and non-programmed form of cell death, necroptosis can be regulated by multiple signal transduction pathways^[52].

The classical form of necroptotic cell death is mediated by tumor necrosis factor- α (TNF- α). Initially, TNF- α binds to its specific receptor TNF receptor 1 (TNFR1), promoting its trimerization and facilitating the recruitment of several proteins including receptor-interacting protein 1 (RIP1) kinase, TNF- α receptor-associated death domain (TRADD), cellular inhibitor of apoptosis 1 (cIAP1), TNFR-associated factor 2 (TRAF2), and TNFR-associated factor 5 (TRAF5) to form complex I. Within complex I, RIP1 can

undergo polyubiquitination by TRAF2, TRAF5, cIAP1, and cIAP2. The ubiquitination status of RIP1 determines whether complex I activates the nuclear factor- κ B (NF- κ B) pathway to promote cell survival, or triggers cell death^[53].

When the ubiquitylation of RIP is impaired, complex I can transform into complex IIa and complex IIb, leading to cell death^[54]. Complex IIa can trigger caspase-8-dependent apoptosis in the absence of RIP1, whereas complex IIb depends on RIP1 for caspase-8 activation due to its deficiency in TRADD compared to complex IIa^[55]. Additionally, complex IIa can transform into complex IIb. When the levels of receptor-interacting protein 3 (RIP3) and mixed lineage kinase domain-like protein (MLKL) are sufficiently high and caspase-8 is blocked, complex IIb may develop into a necrosome. Following the phosphorylation of RIP1 and RIP3, two core components of the necrosome, the activated RIP3 can further recruit and phosphorylate MLKL, triggering its oligomerization. The oligomerized MLKL is then translocated to the plasma membrane, increasing its permeability and ultimately leading to necroptotic cell death^[56] [Figure 2]. In addition to TNF superfamily receptors, various other types of receptors, such as Toll-like receptors, T-cell receptors, and interferon receptors, also contribute to the activation of necroptosis^[57].

Regulation of necroptosis for anti-drug resistance in cancer

As independent of caspase activation and involving distinct components from apoptotic pathways, necroptosis is an effective mechanism to overcome apoptosis resistance in cancer. However, some necroptotic core components are always lacking in cancer cells, resulting in the evasion of this mechanism. RIP3 is silenced in numerous cancer types, and this silencing is likely ascribed to genomic methylation near the RIP3 transcriptional start site or driven by oncogenes BRAF and AXL^[58]. Current studies have revealed that demethylation treatment can activate necroptotic pathways by restoring the expression of RIP3. Moreover, upregulating RIPK3 expression can enhance the sensitivity of colon cancer cells to 5-FU and lung cancer cells to DDP through mediating necroptosis^[59,60].

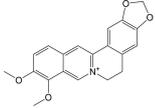

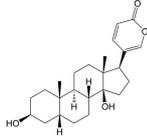

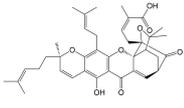

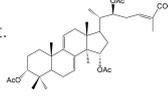

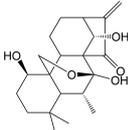

Furthermore, the low expression of MLKL appears to be associated with a poor patient prognosis in certain cancers, making it a potential novel potential prognostic biomarker for these cancers^[61]. In addition, some compounds can induce MLKL-mediated necroptosis without the phosphorylation of RIP1 and RIP3, which presents a very promising prospect for future studies^[62].

In addition to modulating necroptosis genes and proteins, increasing glycolytic metabolism may confer resistance to necroptosis in cancer cells under hypoxic conditions. The mechanism involves the suppression of RIP-dependent necroptosis through pyruvate scavenging of mitochondrial superoxide^[63]. Several studies have suggested that inhibiting glycolysis may be a potential mechanism for necroptosis induction. For instance, selenite-induced necroptosis in prostate cancer resulted from the inhibition of glycolysis through adenosine triphosphate (ATP) depletion and phosphofructokinase activity reduction^[64].

Natural compounds inducing necroptosis for cancer treatment

So far, many natural compounds can induce necroptosis in diverse cancer types, and some can also inhibit drug resistance [Table 2]. As mentioned above, modulating necroptosis core proteins is critical for necroptosis induction. By regulating the RIP1/reactive oxygen species (ROS)-mediated pathway, bufalin, an endogenous cardiotonic steroid, can induce necroptosis in adriamycin-resistant triple-negative breast cancer cell lines^[65]. Numerous studies have indicated that when 5-FU is in combination with other anticancer agents, its therapeutic efficacy can be effectively enhanced^[66]. Gambogic acid is one of the main components of Gamboge which can be used in combination with 5-FU to upregulate necroptosis-related proteins such as RIP1 in lung cancer cells, thereby inducing necroptosis^[67]. Piperlongumine can also activate RIP1 to produce excessive ROS, triggering necroptosis in DDP-resistant bladder cells^[68]. Berberine can

Table 2. Natural compounds for anticancer drug resistance by inducing necroptosis

Compounds	Origin	Structure	Cancer	Anti-drug resistant effects	Refs
Berberine	<i>Coptis chinensis</i> Franch		Ovarian cancer	Synergizing with DDP to induce necroptosis by activating the RIP3/MLKL pathway.	[69]
Bufalin	<i>Bufo bufo gargarizans</i> Cantor		Triple-negative breast cancer	Inducing necroptosis in adriamycin-resistant triple-negative breast cancer through mediating the RIP1/ROS pathway.	[65]
Gambogenic Acid	<i>Garcinia hanburyi</i> Hook. f.		Lung cancer	Synergizing with 5-FU to induce necroptosis by increasing the expression of RIP1.	[67]
Ganoderic acid T	<i>Ganoderma lucidum</i> (Leyss.ex Fr.) Karst.		Cervical cancer	Increasing the radiosensitivity of cervical cancer by inducing necroptosis via ROS generation and increased expression of RIP and MLKL.	[71]
Oridonin	<i>Isodon rubescens</i> (Hemsley) H. Hara		Renal carcinoma	Inducing necroptosis in renal carcinoma to enhance the antitumor effects of 5-FU via ROS generation, GSH depletion, and activation of p38, ERK, and JNK.	[70]

DDP: Cisplatin; ERK: signal-regulated kinase; FU: fluorouracil; GSH: glutathione; JNK: c-Jun N-terminal kinase; MLKL: mixed lineage kinase domain-like protein; RIP: receptor-interacting protein; ROS: reactive oxygen species.

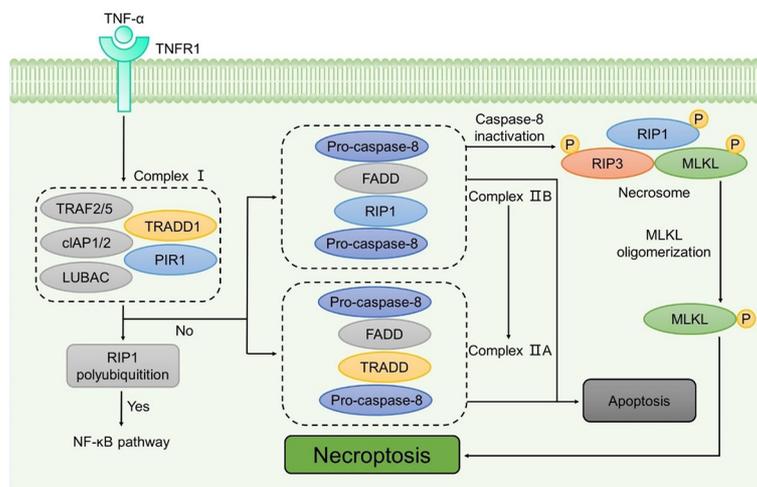

Figure 2. The classical pathway of necroptosis. The classical form of necroptosis begins with the binding of TNF- α to TNFR1, initiating the formation of complex I. If the ubiquitylation of RIP1 within complex I is inhibited, it undergoes a transition into complex IIA and complex IIB. When caspase-8 is inactive, complex IIB recruits RIP3 to form the necrosome. Once RIP3 is phosphorylated, it recruits and phosphorylates MLKL, leading to its oligomerization. The oligomerized MLKL is subsequently translocated to the plasma membrane, resulting in necroptosis. MLKL: Mixed lineage kinase domain-like protein; PIR1: receptor-interacting protein 1; RIP3: receptor-interacting protein 3; TNF: tumor necrosis factor; TNFR: TNF receptor; TRADD: TNF- α receptor-associated death domain TRAF: TNFR-associated factor.

effectively enhance the antitumor effect of DDP in ovarian cancer by increasing the expression and activation of RIP3 and MLKL, thereby inducing necroptotic cell death^[69]. In TNF- α induced necroptosis, MLKL is a key downstream component of RIP1 and RIP3. However, it is worth mentioning that tanshinol A, a phenolic compound extracted from *Salvia miltiorrhiza* Bunge, can trigger non-canonical necroptosis

mediated by MLKL in lung cancer independently of RIP1 and RIP3^[62].

MAPK signaling pathways also play a role in necroptosis induction. For instance, oridonin, a diterpenoid derived from *Isodon rubescens* (Hemsley) H. Hara, has been shown to enhance the cytotoxicity of 5-FU in renal cancer cells by inducing necroptosis. This process is associated with the activation of c-Jun N-terminal kinase (JNK), p38, and extracellular signal-regulated kinase (ERK)^[70].

Moreover, certain studies have demonstrated that the inhibition of caspases may cause a switch from apoptosis to necroptosis in specific cancer types. Ganoderic acid T (GAT) is a triterpene of *Garcinia hanburyi* Hook. f., inducing both necroptosis and apoptosis in cervical cancer cells. Interestingly, the percentage ratio of necroptosis is increased following the increase of GAT concentration, as GAT can reduce the matrix metalloproteinase (MMP) and ATP levels and caspase-8 expression under radiation conditions^[71].

Notably, glycolysis suppression has also emerged as an effective mechanism for necroptosis induction by natural compounds. Docetaxel is indeed a valuable chemotherapeutic agent utilized in the treatment of prostate cancer, primarily by inducing cell death^[72]. However, similar to DDP, the effectiveness of docetaxel-induced apoptosis can also be hindered through various pathways, including the p38/p53/p21 pathway, USP33-DUSP1-JNK pathway, and PI3K/Akt/NF- κ B pathway^[73-75]. Therefore, several studies are currently focused on identifying alternative cell death pathways, such as necroptosis, that can be induced in docetaxel-resistant cancer cells as well. Shikonin has been extensively studied as a natural necroptosis inducer in various cancer types, and it has been demonstrated to overcome drug resistance to docetaxel in prostate cancer and DDP in bladder cancer^[76,77]. Furthermore, shikonin can induce glycolysis suppression in glioma cells, which is closely associated with the accumulation of intracellular H₂O₂ triggered by the activation of RIP1 and RIP3^[78].

PYROPTOSIS

Overview of pyroptosis

Pyroptosis, a pro-inflammatory programmed cell death, was originally termed by Cookson *et al.* in 2001^[79]. The term derives from the Greek roots “pyro”, which relates to fire or fever, and “ptosis”, denoting a falling, reflecting its nature. Pyroptosis shares certain characteristics with apoptosis, such as DNA fragmentation, nuclear condensation, and caspase dependence. However, cells undergoing pyroptosis differ in that they retain intact nuclei and exhibit pore formation in the plasma membrane^[80]. An increasing understanding of pyroptosis has revealed that this type of cell death can be divided into classical and non-classical pathways.

The classical pyroptotic pathway is mediated by inflammasome assembly, which consists of pattern recognition receptors (PRRs), apoptosis-related speck-like protein (ASC), and pro-caspase-1^[81]. PRRs, functioning as inflammasome sensors, recognize pathogen-associated molecular patterns (PAMPs) and damage-associated molecular patterns (DAMPs)^[82]. Subsequently, they recruit the bridging protein ASC, which contains a pyrin domain (PYD) and a caspase activation and recruitment domain (CARD), through specific PYD-PYD interactions. After being recruited, ASC can interact with and activate pro-caspase-1 via CARD-CARD interactions^[83]. Some PRRs containing CARD can also directly bind to pro-caspase-1, forming inflammasomes without the participation of ASC^[84]. Activated caspase-1 facilitates the maturation of inflammatory cytokines interleukin (IL)-1 β and IL-18, as well as cleaves the pore-forming protein gasdermin D (GSDMD) to produce its N-terminal fragment (N-GSDMD)^[85]. N-GSDMDs then translocate to the plasma membrane and form pores, promoting the release of mature IL-1 β and IL-18. As the number of N-GSDMD pores increases, cells swell and rupture, resulting in pyroptotic cell death^[86].

In non-classical pathways, caspase-3/8 can also trigger pyroptosis by activating GSDMD or GSDME^[87,88]. Additionally, caspase-8 can induce GSDMC-dependent pyroptosis as well^[89]. The cleavage of GSDMD can also be mediated by caspase-4/5/11, which recognizes intracellular LPS to activate the non-canonical inflammasome^[90]. Notably, GSDMB can not only be cleaved by caspase-1 to directly initiate pyroptosis, but also enhance caspase-4 activity to promote this cell death mechanism^[91]. Recently, the cleavage of GSDMA has been found to be catalyzed by streptococcal pyrogenic exotoxin B (SpeB), a cysteine protease secreted by group A *Streptococcus*. This finding demonstrates that GSDMA can also play a role in pyroptosis by releasing the cleaved N-terminal fragments, which can bind to and disrupt specific acidic lipid-containing membranes^[92] [Figure 3].

Induction of pyroptosis for anti-drug resistance in cancer

In cancer treatment, the induction of pyroptosis is increasingly recognized as a promising strategy for overcoming drug resistance. NOD-like receptor family pyrin domain-containing 3 (NLRP3), a crucial inflammasome sensor in the NLR family, is recognized as a downstream target of multiple microRNAs (miRNAs) associated with cancer drug resistance. For example, by downregulating the expression of miR-556-5p in non-small cell lung cancer, NLRP3 inflammasome-mediated pyroptosis can be triggered, thereby enhancing DDP sensitivity^[93].

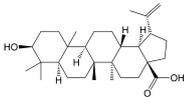

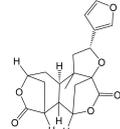

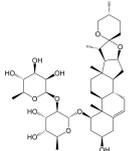

The pore-forming proteins GSDMD and GSDME, extensively studied in the GSDM family, are potential targets for combating drug resistance and contributing to the treatment and prognosis of various cancers. Some chemotherapeutic agents have been demonstrated to exert antitumor activity when used alone or in combination to induce GSDMD-dependent pyroptosis, enhancing the efficacy of chemotherapy. For instance, the co-administration of paclitaxel and ruthenium complexes can induce cell death in paclitaxel-resistant cervical cancer cells by mediating Caspase-1/GSDMD-dependent pyroptosis^[94]. GSDME-mediated pyroptosis has been observed to improve the sensitivity of various drugs across different cancer types, including increasing DDP sensitivity in esophageal squamous cell carcinoma cells and oxaliplatin sensitivity in colon cancer cells^[95]. Additionally, it can alleviate the side effects of DDP in patients with oral squamous cell carcinoma.

In recent years, programmed death-ligand 1 (PD-L1), known as an immune checkpoint, has emerged as a research hotspot in tumor immunotherapy. However, PD-L1 has an additional role as a non-immune checkpoint by regulating the non-classical pyroptosis pathway mediated by GSDMC/caspase-8^[96]. In this way, a variety of antibiotics can induce pyroptosis in cancer cells, indicating that it could be a novel strategy to combat antibiotic resistance in chemotherapy.

Natural compounds inducing pyroptosis for cancer treatment

Nowadays, the caspase-1/GSDMD and caspase-3/GSDME pathways have attracted significant attention in pyroptosis induction, and many natural compounds have been found to activate these pathways in cancers [Table 3]. Wedelolactone, an ingredient of *Eclipta prostrata* (L.) L., can simultaneously activate these two pathways by strongly increasing the activation of caspase-1, caspase-3, GSDME and GSDMD in retinoblastoma cells^[97]. Ophiopogonin B, derived from *Dioscorea bulbifera* L., can induce caspase-1/GSDMD-dependent pyroptosis in lung cancer cells, especially exhibiting a more significant suppression of growth in DDP-resistant cancer cells^[98]. As a pentacyclic triterpene compound of lupine, betulinic acid can induce caspase-1-dependent pyroptosis, thereby enhancing chemosensitivity to DDP in esophageal cancer cells^[99].

Table 3. Natural compounds for anticancer drug resistance by inducing pyroptosis

Compounds	Origin	Structure	Cancer	Anti-drug resistant effects	Refs
Betulinic acid	<i>Betula platyphylla</i> Suk.		Esophageal cancer	Enhancing the antitumor effects of DDP by inducing pyroptosis via increasing the levels of ASC and caspase-1 and decreasing the levels of Ki67, PCNA, SOX2, and OCT4.	[99]
Diosbulbin B	<i>Dioscorea bulbifera</i> L.		Gastric cancer	Increasing DDP-sensitivity in gastric cancer by inducing pyroptosis via regulating the PD-L1/NLRP3 pathway.	[106]
Ophiopogonin B	<i>Ophiopogon japonicus</i> (L. f.) Ker-Gawl.		Lung cancer	Increasing DDP-sensitivity in gastric cancer by inducing pyroptosis via regulating the caspase-1/GSDMD pathway.	[98]

ASC: Apoptosis-related speck-like protein; DDP: cisplatin; GSDMD: gasdermin D; NLRP3: NOD-like receptor family pyrin domain-containing 3; OCT4: octamer-binding transcription factor-4; PCNA: proliferating cell nuclear antigen; PD-L1: programmed death-ligand 1; SOX2: SRY-related high mobility group box protein-2.

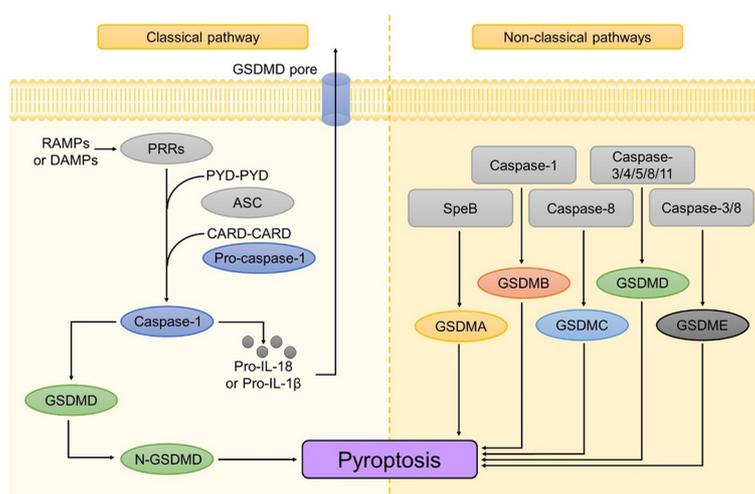

Figure 3. In the classical pathway, PRRs recognize PAMPs and DAMPs, initiating the recruitment of ASC and pro-caspase-1. The activation of caspase-1 results in cleavage of GSDMD, forming GSDMD pores that ultimately trigger pyroptosis. Furthermore, caspase-1 also results in the maturation of IL-1 β and IL-18, which are eventually released from the GSDMD pores. Alternatively, in the non-classical pathway, pyroptosis can be initiated by other members of the GSDM family. CARD: Caspase activation and recruitment domain; DAMPs: damage-associated molecular patterns; GSDMD: gasdermin D; IL: interleukin; PAMPs: pathogen-associated molecular patterns; PRR: pattern recognition receptor; PYD: pyrin domain.

By activating the caspase-3-dependent pathway, natural compounds such as curcumin, dihydroartemisinin, and germacrone can induce pyroptosis in different cancers^[100-102]. Some studies have reported that the activation of caspase-9 is also involved in caspase-3-mediated pyroptosis. For example, alantolactone, a terpenoid of *Inula helenium* L., can promote the cleavage of caspase-9 and caspase-3 to induce GSDME-mediated pyroptosis in anaplastic thyroid cancer^[103]. Some chemotherapeutic agents, such as DDP, 5-FU, and carboplatin, have been demonstrated to combat cancer drug resistance by inducing GSDME-dependent pyroptosis, while whether natural compounds can also suppress drug resistance through this pathway needs further investigation^[95,104,105].

In addition, by downregulating PD-L1 to activate NLRP3-mediated pyroptosis, Diosbulbin B extracted from *Dioscorea bulbifera* L. can sensitize DDP-resistant gastric cancer cells to DDP^[106]. At present, there are few reports on whether natural compounds induce pyroptosis via the regulation of other GSDM family proteins. This is partly because of their unclear functions in initiating pyroptotic cell death. Further elucidation of how the other members of the GSDM family contribute to pyroptosis induction in cancers may provide new insights for the search for natural compounds with anticancer and anti-drug resistance activities.

PARAPTOSIS

Overview of paraptosis

Paraptosis was first introduced as a form of programmed cell death by Sperandio *et al.* in 2000^[107]. It derives from “para”, meaning “next to” or “related to”, and “apoptosis”, suggesting that it is distinct from apoptosis. The main morphological features of paraptosis include cytoplasmic vacuolization, swelling of the endoplasmic reticulum and/or mitochondria, and the absence of nuclear fragmentation or apoptotic body formation. In this paradigm, caspases are not activated, and thus, cells undergoing paraptosis are resistant to caspase inhibitors^[108].

The MAPK pathways play a critical role in paraptosis, and research focusing on the ERK, JNK, and p38 pathways is particularly extensive. Notably, the protein AIP1/Alix was described as the first specific inhibitor of paraptosis, capable of restraining the insulin-like growth factor-I receptor (IGFIR)-induced paraptotic process mediated by the MAPK/ERK and JNK pathways^[109]. Furthermore, TrxR1 inhibition and GSH depletion have been observed to potentially activate the MAPK pathways by triggering the accumulation of cellular ROS^[110]. Paraptosis induction is also related to the homeostasis of intracellular Ca²⁺, which is mainly regulated by the endoplasmic reticulum and mitochondria. Intracellular Ca²⁺ can be released from the endoplasmic reticulum into mitochondria when paraptosis is initiated, resulting in the endoplasmic reticulum and mitochondrial dilation and ultimately leading to cell death. The voltage- and Ca²⁺-activated K⁺ (BKCa) channels are widely expressed in body and have the ability to link changes in intracellular calcium to outward hyperpolarizing potassium currents. The activation of these channels will disrupt the osmotic balance, initiating cell swelling and vacuolization^[111]. Additionally, proteasome inhibition may also promote paraptosis by inducing endoplasmic reticulum (ER) stress^[112] [Figure 4].

Paraptosis potential applications in cancer drug resistance

Paraptosis induction is a potential strategy for developing non-genetically modified tumor vaccines. In rat T9 glioma cells, the activation of BKCa channels promotes the overexpression of heat shock proteins and the translocation of HMGB1 from the nuclear region to the periphery, stimulating immune responses and initiating paraptosis. Rats injected with paraptotic T9 glioma cells, which are killed by prolonged BKCa channel activation, can develop specific immunity to T9 cells. This suggests the potential of using these treated cells as a functionally killed vaccine^[113].

Due to its unique molecular mechanism, paraptosis induction also contributes to enhancing the activity of proteasome inhibitors in cancer cells. Although many proteasome inhibitors have shown antitumor activities, their clinical efficacy is unsatisfactory as their effectiveness can be compromised by both primary and secondary resistance mechanisms. Therefore, combination therapy can be seen as an effective strategy to address proteasome inhibitor resistance. For instance, by triggering paraptotic cell death, bortezomib (Btz), a 20S core particle inhibitor of the proteasome, can be combined with loperamide, an anti-diarrheal agent, to enhance Btz sensitivity and reduce its side effects, effectively combating the colon cancer^[114].

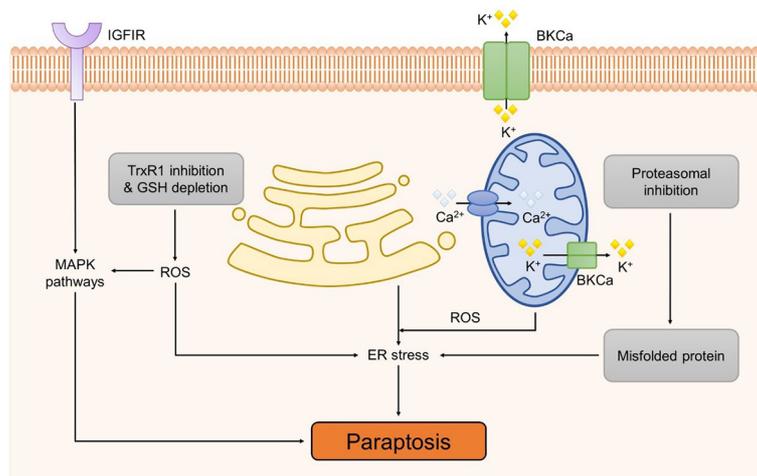

Figure 4. The mechanism of Paraptosis. Paraptosis was initially discovered to be induced by IGFIR and mediated through the MAPK pathways. Furthermore, it is intricately linked to various factors, including TrxR1 inhibition, GSH depletion, intracellular Ca²⁺ homeostasis, activation of BKCa channels, and proteasome inhibition. BKCa: Ca²⁺-activated K⁺; ER: endoplasmic reticulum; GSH: glutathione; IGFIR: insulin-like growth factor-I receptor; MAPK: MAP kinase; ROS: reactive oxygen species.

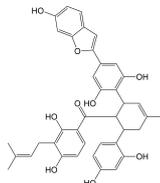

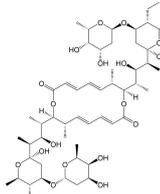

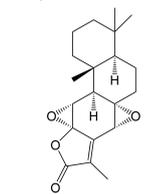

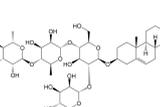

Natural compounds inducing paraptosis for cancer treatment

Currently, a number of natural compounds have shown potential in cancer treatment by inducing paraptosis [Table 4], with many of them modulating the MAPK signaling pathways to trigger ER stress. One such example is Paris Saponin II, derived from *Paris polyphylla* Smith, which effectively induces paraptosis by activating the JNK pathway and augmenting ER stress^[115]. Moreover, the activation of this paraptosis-associated pathway enhances the sensitivity of DDP in lung cancer. Jolkinolide B, an active abietane ent-diterpenoid, is also a noteworthy compound that induces paraptosis in both sensitive and DDP-resistant bladder cancer cells by activating the ERK pathway and enhancing ER stress^[110]. Additionally, Chalcomoracin, isolated from *Morus alba* L., has been discovered to enhance the sensitivity of non-small cell lung cancer to radiation by augmenting ER stress^[116]. Elaiophylin is a natural antibiotic derived from *Streptomyces melanosporus* that can also induce paraptosis through the hyperactivation of the MAPK pathway. This compound demonstrates notable efficacy in eliminating ovarian cancer cells that are resistant to multiple drugs, including platinum, taxane, and poly (ADP-ribose) polymerase inhibitor (PARPi)^[117].

Some natural compounds such as curcumin, morusin, and ophiobolin A can also induce paraptosis by affecting ion homeostasis. Curcumin can induce paraptosis in epithelial ovarian cancer mainly through mitochondrial Ca²⁺ overload, which subsequently contributes to mitochondrial swelling and dysfunction^[118]. Similarly, morusin, a prenylflavonoid, can also induce paraptosis in breast cancer by triggering mitochondrial Ca²⁺ overload^[119]. In glioblastoma cells, paraptosis induced by ophiobolin A, a sesterterpenoid phytotoxin from the genus *Bipolaris*, is linked to K⁺ homeostasis imbalance, primarily caused by the blockage of BKCa channels^[120].

Furthermore, natural compounds can induce paraptosis by disrupting sulfhydryl homeostasis and suppressing proteasome functions, both of which can be significantly inhibited by thiol antioxidants. In this way, plumbagin, extracted from *Plumbago zeylanica* L., can induce paraptotic cell death in different cancer types^[121]. Paraptosis can also be triggered in a p53-dependent manner. For instance, Ginsenoside Rh2, which is a bioactive product in *Panax ginseng* C. A. Meyer, can induce paraptosis in colorectal cancer via activating the p53 pathway as well as the NF- κ B survival pathway^[122].

Table 4. Natural compounds for anticancer drug resistance by inducing paraptosis

Compounds	Origin	Structure	Cancer	Anti-drug resistant effects	Refs
Chalcomoracin	<i>Morus alba</i> L.		Non-small cell lung cancer	Increasing the radiosensitivity of non-small cell lung cancer by inducing ER stress-mediated paraptosis via activation of the MAPK pathway.	[116]
Elaiophylin	<i>Streptomyces hygrosopicus</i>		Ovarian cancer	Inducing paraptosis to overcome platinum, taxane, and PARPi resistance in ovarian cancer by regulating the SHP2/SOS1/MAPK pathway.	[117]
Jolkinolide B	<i>Euphorbia fischeriana</i> Steud		Bladder cancer	Inducing ROS-mediated paraptosis to suppress the growth of DDP-resistant bladder cancer by targeting thioredoxin and glutathione systems.	[110, 131]
Paris saponin II	<i>Paris polyphylla</i> Smith		Non-small cell lung cancer	Enhancing the antitumor effects of DDP by regulating the JNK pathway.	[115]

DDP: Cisplatin; ER: endoplasmic reticulum; JNK: c-Jun N-terminal kinase; MAPK: MAP kinase; PARPi: poly (ADP-ribose) polymerase inhibitor; ROS: reactive oxygen species; SHP2: src homology 2 domain-containing tyrosine phosphatase 2; SOS1: son of sevenless homolog 1.

CONCLUSION

Numerous natural compounds possess the ability to elicit anticancer and anti-chemoresistance effects by triggering non-apoptotic cell death mechanisms such as ferroptosis, necroptosis, pyroptosis, and paraptosis. It is noteworthy that while these forms of cell death have unique regulators, some common pathways can also govern them. This implies that multiple cell death pathways may occur concurrently and be subject to simultaneous regulation. In 2019, Malireddi *et al.* introduced PANoptosis, an innovative form of cell death that amalgamates essential features of pyroptosis, apoptosis, and necroptosis yet defies a straightforward classification under any one of these categories^[123]. This discovery underscores the co-regulation and interplay among these cell death pathways, suggesting that drugs may possess multifaceted regulatory effects by modulating master factors within these pathways. Beyond the four aforementioned types of cell death, some other novel cell death mechanisms have surfaced in recent years, including parthanatos, disulfidptosis, and cuproptosis^[124-126]. These revelations open up new avenues for identifying targets in cancer treatment and provide additional strategies for combating cancer drug resistance. As such, ongoing exploration is essential to ascertain whether natural compounds can elicit anticancer effects through these emerging forms of cell death.

Abstract

Tumors survive by creating a tumor microenvironment (TME) that suppresses antitumor immunity. The TME suppresses the immune system by limiting antigen presentation, inhibiting lymphocyte and natural killer (NK) cell activation, and facilitating T cell exhaustion. Checkpoint inhibitors like anti-PD-1 and anti-CTLA4 are immunostimulatory antibodies, and their blockade extends the survival of some but not all cancer patients. Extracellular adenosine triphosphate (ATP) is abundant in inflamed tumors, and its metabolite, adenosine (ADO), is a driver of immunosuppression mediated by adenosine A2A receptors (A2AR) and adenosine A2B receptors (A2BR) found on tumor-associated lymphoid and myeloid cells. This review will focus on adenosine as a key checkpoint inhibitor-like immunosuppressive player in the TME and how reducing adenosine production or blocking A2AR and A2BR enhances antitumor immunity.

Keywords: Immunotherapy, adenosine, adenosine receptors, adenosine A2A receptors (A2AR), adenosine A2B receptors (A2BR), tumor cells, immune cells, tumor microenvironment

INTRODUCTION

Deadly tumors have the ability to resist the body's formidable immune defenses. They create protective micro-environments that limit antigen presentation, inhibit T and natural killer (NK) cell responses, and

induce T cell exhaustion, effectively escaping immune surveillance. These mechanisms allow some tumors to grow unchecked and resist conventional cancer therapies.

Checkpoint inhibitors that block immunosuppressive signaling molecules such as PD-1, T lymphocyte antigen 4 (CTLA4), and lymphocytic activation gene 3 protein (LAG-3) have ushered in a new era of cancer immunotherapy, offering hope for prolonged survival and enhanced quality of life for many patients. However, the beneficial effects of these therapies are not universal due to the ability of some tumors to maintain an immunosuppressive environment. The interplay between cancer cells and immune cells within the tumor microenvironment (TME) is a critical determinant of the therapeutic response.

A key driver of immunosuppression within the TME is extracellular adenosine (ADO), an adenosine triphosphate (ATP) metabolite. ADO formation and its immunosuppressive signaling play a pivotal role in maintaining the immunosuppressive state of the TME, promoting tumor growth, and facilitating resistance to other therapies. This review explores the role of ADO signaling in the TME. Inhibiting ADO receptors on immune cells reduces immunosuppression and, in some cases, has an additive antitumor effect when combined with other cancer treatments.

UNDERSTANDING NON-RESPONDERS TO IMMUNOTHERAPY IN SOLID TUMORS

Despite having antitumor effects, cancer immunotherapy often fails. One prominent reason is that most tumor proteins are recognized as self-proteins and fail to activate T cells, which serve as the frontline warriors of the adaptive immune response^[1]. To the extent that tumors are recognized by the immune system, their activation is muted by immunosuppressive signals like adenosine.

Antigen-presenting cells (APCs) such as macrophages and dendritic cells (DCs) also regulate the immune response to tumors^[2]. The function of APC is to recognize, engulf, and present tumor antigens on their surface. Their failure to optimally phagocytose and present antigens can undermine the initiation of adaptive immunity. The host's baseline immune response also significantly influences the success or failure of cancer immunotherapy. The baseline immune response is crucial in determining treatment efficacy, represented by the association between increased T cell infiltration into tumors and improved patient survival and immunotherapy response rates^[3]. However, the factors that dictate the extent of T cell infiltration into tumors, whereby an extensively infiltrated tumor is considered "hot", and a sparsely infiltrated tumor is considered "cold", are just beginning to be elucidated. The factors that influence infiltration vary across tumor types and subtypes due to immune cell heterogeneity^[4]. The complexity and dynamics of the immune system, in conjunction with the adaptability of tumor cells, create a challenging landscape for the successful deployment of cancer immunotherapy.

The complexity of the TME in solid tumors

The TME in solid tumors is complex, consisting of various immune cells, cytokines, chemokines, and metabolites. Specific features of the TME depend on the tumor type and the location within the patient. Some tumors develop an extracellular matrix (ECM) of fibrous proteins and stromal cells that define and isolate the TME from the surrounding tissue^[5,6]. Within "cold" solid tumors, very few antitumor CD8+ T cells, NK cells, and DCs are present, due to failure by immune cells to enter through the ECM^[7]. Immune cells that contribute to the immunosuppressive state are tumor-associated macrophages (TAMs) and myeloid-derived suppressor cells (MDSCs). Monocytes that enter tumors can polarize into M1 (proinflammatory) or M2 (immuno-suppressive) cells. In cancer, most become M2 and MDSC^[8] and function to secrete vascular endothelial growth factor (VEGF) and transforming growth factor β (TGF- β), which stimulates angiogenesis within the tumor^[9]. M2-TAMs and MDSCs also suppress CD8+ T cell

infiltration and increase regulatory T cell (Treg) differentiation from precursor CD4⁺ T cells^[10]. Tregs release suppressive cytokines such as interleukin-10 (IL-10) and TGF- β that inhibit CD8⁺ T cell function and enhance cancer cell escape from the immune attack^[11]. In some solid tumors, such as pancreatic ductal adenocarcinoma (PDAC), increased IL-10 is correlated with reduced survival^[12-14].

MDSCs are considered immature myeloid cells and secrete reactive oxygen species (ROS), IL-10, IL-13, TGF- β , arginase-I, inducible nitric oxide synthase (iNOS), and other immunosuppressive factors^[15-17].

The TME is usually hypoxic due to a poorly developed tumor vasculature. Most cytotoxic immune cells (CD8⁺ T cells and NK cells) function poorly in hypoxic states, while suppressive cells (M2 TAMs and Tregs) thrive^[18]. The hypoxic TME favors the production of ADO and the induction of immunosuppressive A2A receptors (A2AR) and A2B receptors (A2BR) in immune cells. A shift in tumor metabolism from oxidative phosphorylation to primarily glycolysis also suppresses immune cell infiltration due to increased lactate in the TME. The increase in lactate lowers tumor pH^[19]. This decrease in pH drives M2 polarization while inhibiting the nuclear factor of activated T cells (NFAT) within T cells^[20,21]. This suppression of NFAT inhibits chemotaxis into tumors and reduces T cell activation.

The role of immune checkpoint inhibitors (ICIs) in cancer immunotherapy

Immune checkpoint inhibitors (ICIs) have greatly advanced immunotherapy, especially in some hard-to-treat tumors. The two most studied checkpoints are CTLA4 and PD-1^[1,22,23]. Although antibodies that block these inhibitory signals have improved survival, most patients with solid tumors eventually develop either primary or secondary resistance to ICI. In primary resistance, tumors display early resistance to ICI and progress soon (within six months) after ICI treatment. In secondary resistance, patients respond to treatment initially but develop resistance later^[1]. Studies have demonstrated that the tumor mutational burden (TMB) influences the response to ICI^[24-26]. Reduced TMB within tumors treated with ICI can result in acquired resistance to ICI immunotherapy.

Contributions to therapy resistance by suppressive state and hypoxia

Suppressive immune cells within the TME contribute to checkpoint inhibitor resistance. Tregs, MDSCs, and M2-TAMs secrete immunosuppressive cytokines (TGF- β , CXCL8, CCL5, and IL-10) that prevent cytotoxic infiltrating immune cells from entering the tumor^[27-31]. An increase in VEGF due to the activation of the mitogen-activated protein kinase (MAPK) pathway can also stimulate tumor angiogenesis^[27-31] and inhibit immune cell infiltration^[32].

Hypoxia results from various physiological and pathological conditions, including solid tumors, ischemia-reperfusion injury, stroke, and chronic obstructive pulmonary disease (COPD)^[33]. A hypoxic TME contributes to an increase in extracellular ADO. The molecular mechanisms underlying hypoxia-driven responses include *Adora2a* and *Adora2b* via HIF-1 α and HIF-2 α ^[34,35]. HIFs also stimulate angiogenesis, vasodilation, and attenuation of inflammation^[34,36]. HIF-1 α induces CD73 and CD39 and increases the conversion of ATP into ADO, leading to T cell inhibition, metastasis, and increased angiogenesis^[37-40]. The accumulation of ADO within tumor suppresses cytotoxic immune cells and APCs, such as CD8⁺ T cells and DCs, while enhancing the accumulation of immunosuppressive cells^[41,42]. When ADO encounters its receptors, it can affect the activity of neutrophils and macrophages, reducing the release of IL-12, tumor necrosis factor-alpha (TNF α), and ROS^[43-45].

The role of cancer-associated fibroblasts (CAFs) in tumor development

Cancer-associated fibroblasts (CAFs) have a different morphology than other cells within the tumor. They lack epithelial, endothelial, and leukocyte markers, and do not have the same mutations as tumor cells^[46].

CAF development within tumors occurs when there is an increase in inflammatory markers such as IL-6 and TGF- β due to cancer cell DNA damage^[47,48]. When IL-6 and TGF- β are increased in the TME, they tend to reduce the number of T cells, limiting the extent of the antitumor response^[49]. These cytokines increase JAK-STAT signaling and ECM transition, promoting CAF formation^[50-52]. Breast cancers increase Notch signaling within the TME to increase CAFs^[53]. Patients who receive chemotherapy and radiation to treat solid tumors experience DNA breaks, and this stress can promote fibrosis or CAF accumulation and function. This change in CAF function causes resistance to therapy in various solid tumors^[54-56].

Solid tumor CAFs may exhibit different phenotypes depending on the TME. The different phenotypes exhibit different cell surface markers, but identifying these can be challenging^[46]. Breast cancers increase expression of fibroblast activation protein (FAP) to cause high immunosuppression through Treg activation^[57]. Pancreatic cancers express both myofibroblastic CAFs (myCAFs) and inflammatory CAFs (iCAFs) at different locations in the tumor. MyCAFs have high expression of TGF- β and α SMA and are located close to tumor cells, while iCAFs have high IL-6 secretion and are more distal in the TME^[58,59]. iCAFs can recruit TAMs and MDSCs to the TME to increase the immunosuppressive state^[13,60]. Targeting the MAPK/STAT pathways in iCAFs through inhibitors in combination with checkpoint inhibitor therapy (e.g., anti-PD-1) can lead to increased survival of patients with solid tumors like PDAC^[60]. McAndrews *et al.* discovered that in early-stage PDAC, iCAFs tend to be more abundant, while myCAFs have a higher abundance in late-stage cancer. When FAP+ CAFs were depleted, there was an increase in mouse survival. Conversely, when α SMA+ CAFs were depleted, there was a decrease in survival. In the TME, when FAP+ CAFs were depleted, there was a decrease in macrophages and B cells. However, α SMA+ CAF loss showed a decrease in effector T cells (Teff) and increased Tregs. A loss in IL-6 production in FAP+ CAFs increased responses in mice to gemcitabine therapy and combination therapy of gemcitabine + checkpoint inhibitors^[57].

THE ADENOSINE PATHWAY: A NEW APPROACH TO OVERCOMING THERAPEUTIC RESISTANCE TO CHECKPOINT INHIBITORS

Understanding the interaction between cells in the TME is crucial to overcoming therapeutic resistance. The concept of targeting ADO biosynthesis or inhibiting its receptors has garnered increased interest from the scientific community^[58]. Targeting extracellular ADO and its receptors opens opportunities for increasing the antitumor immune response in innate and adaptive immune cell populations normally suppressed within the TME^[59]. Since high ADO levels in the TME are predictive of immunosuppressive responses^[60], combining current immunotherapies with ADO blockade may help to overcome ICI resistance in solid tumors.

Chemotherapies and various cancer treatments result in elevated cell death and heightened ATP release^[61]. ATP is rapidly converted to ADO within solid tumors. This process is mediated by ectonucleotidases CD39 and CD73 and contributes to the formation of an immunosuppressive TME^[62]. CD39 acts on ATP to produce adenosine monophosphate (AMP), which is subsequently converted into ADO by CD73. The resulting extracellular ADO interacts with one of four G-protein-coupled receptors (A1R, A2AR, A2BR, and A3R) found in tumor cells, immune cells, and endothelial cells. This increase in ADO levels within the TME hinders the activity of effector immune cells and promotes the expansion of immunosuppressive regulatory T cells^[63]. Exosomes released into the TME during cell death also express CD73 and CD39^[62].

The A2AR is associated with elevated levels of checkpoint molecules like PD-1, CTLA4, and LAG-3 on T cells^[64]. Activation of this receptor tends to inhibit the antitumor functions of macrophages and the proliferation and cytokine production of cytotoxic T cells^[65]. However, increased expression of CD39 and

CD73 within the TME leads to an upsurge in MDSCs and Tregs^[59].

The influence of adenosine receptor expression in key immune cells

Innate immunity: the role of adenosine receptors in macrophages, dendritic cells, and natural killer cells

Innate immunity plays a critical role in the body's defense against cancer by providing the first line of protection against malignant cells [Figure 1]. This system, comprising various immune cells such as NKs, TAMs, DCs, and soluble factors like cytokines and chemokines, acts to identify and eliminate transformed cells. Recent studies have highlighted the dynamic interplay between innate immunity and cancer progression, shedding light on the delicate balance between tumor-promoting and tumor-suppressing functions of the innate immune system. An essential aspect of the innate immune system's interaction with cancer cells involves the A2BR, which modulates immune cell functions and significantly impacts the balance between tumor-promoting and tumor-suppressing activities.

Tumor-associated macrophages

TAMs exhibit substantial plasticity that can play a part in tumor progression and drug resistance^[66]. The two main classes of TAMs within the TME are activated M1 and alternatively activated M2^[67]. M1 is known to be the proinflammatory subset within the tumor, while M2 is considered to be suppressive. However, the classes are not static; the cells can change their state based on the cytokines present. There are also subsets of M2 within the TME, and each class plays a role in tumor formation and progression^[67,68].

The TME regulates M1 and M2 macrophages to regulate the immune response to tumors. TAM precursors are derived from embryogenic or bone marrow-derived monocytes^[66]. TAMs tend to differentiate primarily into M2-like phenotypes. These cells express high levels of VEGF (pro-angiogenic), mannose receptor (CD206), and scavenger receptor (CD163). They release suppressive cytokines such as IL-10 and promote immunosuppression within the tumor. M1 plays a key role in vaso-proliferation through the secretion of inflammatory cytokines such as IL-6, IL-8, TNF- α , and IL-1 β ^[67,69,70]. The presence of TAMs with high levels of IL-1 β within the TME contributes to neovascularization and is a predictor^[69].

Apoptotic cells phagocytosed by TAMs (aka efferocytosis) release ATPs into the extracellular space in tissues^[71]. ATP derivatives, specifically ADO, affect the immune activation of TAM through ADO receptors^[71-73]. The A2BR is upregulated on TAMs in response to interferon-gamma (IFN- γ). When activated, A2BR suppresses the production of TNF α in infiltrating TAMs, inhibiting their capacity to secrete cytokines that are crucial for antitumor immunity. This process ultimately promotes tumor growth^[71].

Dendritic cells

DCs are important APCs that present antigens to T cells on MHC proteins. T cells that recognize self-proteins abundant in tumors do not survive selection in the thymus. Intra-tumoral injections of DCs that initiate CD8+ T cell activation have been used to increase responses to immune checkpoint blockade immunotherapies^[74-76]. Damage-associated molecular patterns (DAMPs) are used to determine if an immune response needs to be stimulated or if there is immune tolerance to that antigen^[74,77]. DAMPs initiate a CD8+ T cell response within tumors but can also help re-prime effector CD8+ T cells to continue the adaptive immune response. However, when tumor cells overcome immune surveillance, DCs may have altered antigen processing and defective T cell activation^[78].

Within the TME, there are numerous subsets of DCs along with migratory/tissue-resident DCs^[79]. Classical DCs are derived from common myeloid progenitors that differentiate into common DC progenitors. Plasmacytoid DCs (pDC) are believed to be derived from lymphoid cells but can also be derived from

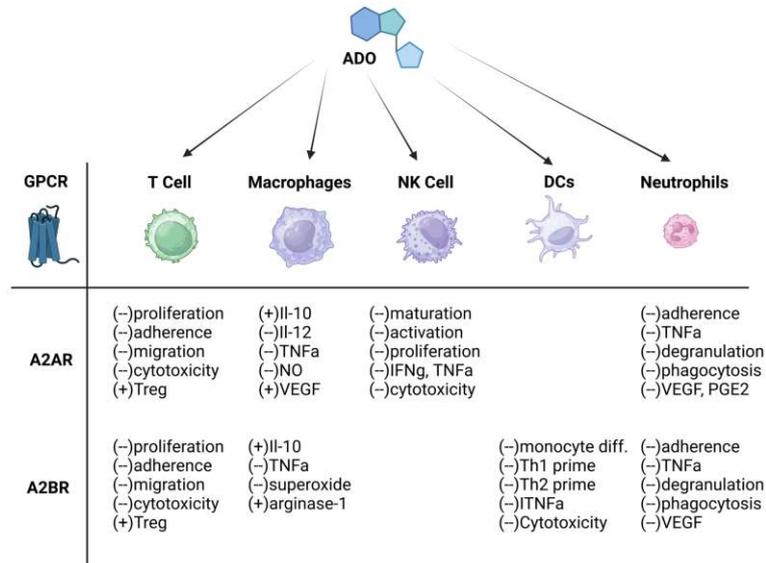

Figure 1. Adenosine's pleiotropic effects on immune cells. ADO facilitates the evasion of tumor cells from immune detection by restricting the activity of T cells, DCs, NK cells, macrophages, and neutrophils. Concurrently, adenosine amplifies the functionality of immunosuppressive cell types like MDSCs and Tregs. ADO: Adenosine; A2AR: A2A receptors; A2BR: A2B receptors; DCs: dendritic cells; MDSCs: myeloid-derived suppressor cells; NK: natural killer; TNF α : tumor necrosis factor- α ; Tregs: regulatory T cells; VEGF: vascular endothelial growth factor.

myeloid precursors. Common monocyte precursors differentiate into a third major subtype of DCs^[80]. Classical DCs have two major states: type 1 and type 2 (cDC1 and cDC2). cDC1 acts to recognize apoptotic and necrotic cell debris presented on its MHC-I receptors to activate CD8+ effector T cells. Their function helps to drive an antitumor response within the TME^[75]. cDC2 are more heterogeneous than cDC1 cells in tumors but are believed to play a role in recognizing exogenous tumor antigens and presenting them to CD4+ T cells on MHC-II^[81]. Within cDC2 populations, there are two further subtypes: anti-inflammatory (cDC2A) and proinflammatory (cDC2B). Classical DCs are now emerging as a potential target for PD-1/PD-L1 immune checkpoint blockade. It has been demonstrated that the proper functioning of checkpoint blockade requires cis interactions with CD80 and PD-L1, as well as PD-1 and PD-L1, between T cells and the DCs^[82,83].

DCs that have differentiated during exposure to ADO display diminished activity. Moreover, these DCs express high levels of angiogenic, immunosuppressive, proinflammatory, and tolerogenic factors, such as cyclooxygenase-2 (COX-2), indoleamine 2,3-dioxygenase (IDO), interleukin-6 (IL-6), interleukin-8 (IL-8), IL-10, TGF- β , and VEGF^[84,85]. These DCs depend on the upregulation of A2BR when producing these factors to promote ongoing tumor growth and increased angiogenesis for metastasis^[85]. As a result, blocking A2BR can preserve the activity of DCs to present neoantigens to T cells, thereby facilitating the process of tumor cell destruction.

NK cells

NKs are derived from CD34+ hematopoietic stem cell progenitors in bone marrow. These cells kill targets that express either no or extremely low MHC-I on their surface^[86,87]. NK cells have a specific killer immunoglobulin-like receptor (KIR) on their surface that recognizes MHC-I molecules. When the KIRs recognize MHC-I in self-cells, NK cells are downregulated to prevent an immune response^[86,88,89]. Tumor cells tend to have low MHC-I, which can stimulate suppressed NK cells to become activated^[90]. NK cells often recognize specific cancer ligands upregulated within tumors, such as MHC-I polypeptide-related

sequence A (MICA), MICB, UL-16 binding proteins, complement factor P, and platelet-derived growth factor DD^[91-93].

NK cells may have an important role in tumor immunosurveillance. In some cancers, such as colon cancer and gastrointestinal stromal tumors, low NK cell expression is associated with poor outcomes^[94,95]. NK cells can also kill circulating tumor cells that are implicated in metastasis^[96]. Tumors may become resistant to NK cell effects by suppressing immune cell activation. Like other immune cells, the hypoxic and low-nutrient environment in tumors can decrease NK cell activation^[97]. Tumors increase the interactions of activating ligands with their receptors on NK cells to stimulate later resistance to the cells. This increased stimulation can suppress the NK cell function^[98].

When NK cells are activated and encounter adenosine through the A2BR, it triggers the cyclic adenosine monophosphate (cAMP) pathway. This activation subsequently blocks cytotoxic activity and cytokine production, diminishing antitumor activity^[99,100]. NK cells can also increase CD73 on their surface after encountering mesenchymal stromal cells, thereby contributing to an increase in ADO and tumor growth^[101]. This increase in ADO associated with high levels of A2AR contributes to suppressing NK antitumor function^[102,103].

Adaptative immunity - the influence of adenosine receptors on t cell function

Adaptive immunity is the second line of defense in the immune system during infection or cancer. These immune responses are cytotoxic to tumor cells. The main two tumor-infiltrating lymphocyte (TIL) cell populations that mediate adaptive immunity are T cells (CD4+ and CD8+) and B cells. T cell infiltration within tumors depends on the tumor chemokine profile and how easily immune cells can enter through the tumor extracellular matrix. Over the last decade, improved methods have been developed to engineer T cells to be better at avoiding cancer immunosuppression. These techniques have resulted in clinical trials of blood-derived tumors and some sarcomas. Very little progress has been made for solid tumors. However, targeting the A2AR on T cells may help overcome the difficulties of T cell immunotherapies in solid tumors. Since ADO causes an increase in Tregs among infiltrating T cells, blocking A2AR can help maintain a high amount of CD4+ T cells in solid tumors. Relative to T cells, B cells have very low levels of A2BR, and limited studies have investigated its role in A2BR activation from ADO^[104]. A2AR are more abundant in human than mouse B cells, but their role in immunotherapy is unknown.

T cells

T cells have been the main target of immunotherapy. CAR T cells and immune checkpoint inhibitors have been used to enhance T cell-mediated tumor killing. Dangaj *et al.* demonstrated that CCL5 must be present within the TME for TILs to enter solid tumors. The macrophages and DCs within the tumor also need to produce CXCL9 to aid in T cell infiltration^[105]. Anti-PD-1 therapies have only shown limited success in solid tumors. In metastatic head and neck squamous cell carcinoma, only 15% of patients responded to anti-PD-1 treatment, and very few responses have been seen in microsatellite-stable colorectal cancer^[106,107]. Duhon *et al.* discovered a subset of CD4+ T cells in tumors that are double positive for PD-1 and inducible costimulator (ICOS)^[106]. These cells can have a tumor tissue-resident phenotype that allows them to recognize both tumor antigens and neoantigens on MHC-II. CD8+ TILs, on the other hand, are more heterogeneous in their response to tumor antigens^[108]. The presence of PD-1 and ICOS on CD4+ T cells may work in conjunction with CD8+ T cells to stimulate a robust antitumor response.

Co-expression of CD39 and CD103 on CD8+ TIL within solid tumors has shown promise in targeting tumor cells. CD8+ T cells that have high expression of CD39 and CD103 can be identified in both primary

tumors and metastatic sites but not in the periphery^[109]. The level of CD39 and CD103 double positive (DP) cells determines how well patients will respond to immunotherapy^[110,111]. However, tumors can still escape these DP TILs through exhaustion mechanisms. All DP TILs express high levels of PD-1 and other exhaustion markers^[112]. Checkpoint inhibitors may be useful, but there are also additional ADO pathways linked to CD39+ cells. Blocking the ADO pathway and using immune checkpoint inhibitors may help keep the DP CD8+ T cells active and prevent tumor growth.

Tumor cells increase their expression of CD39 to suppress both CD4+ and CD8+ T cell proliferation and cytotoxicity in the TME^[100]. Activation of A2AR in T cells causes increased CD4+ differentiation into Treg cells. There is also an increase in additional suppressive receptors such as PD-1, LAG-3, CTLA4, and T cell immunoglobulin and mucin domain-containing protein 3 (TIM3) on the T cells. Increases in ADO may have a negative effect on immunotherapies when checkpoint inhibitors are given to patients alone^[113].

The importance of ADO biosynthesis in the TME

Extracellular ADO is found at low levels in unstressed tissues^[114]. It is produced in response to the breakdown of adenine nucleotides and AMP outside injured cells [Figure 2]^[115]. In response to cancer initiation, ADO levels rapidly increase within tissues due to hypoxic, inflammatory, and/or ischemic conditions. Stressed cells release ATP into the extracellular space as a distress signal that transiently signals via P2 purinergic receptors. Ectoenzymes CD39 and CD73 can rapidly break down extracellular ATP on cell surfaces to produce extracellular ADO^[116,117]. Initially, CD39 converts ATP into adenosine diphosphate (ADP) and AMP, followed by CD73-mediated conversion of AMP into ADO^[118]. The accumulation of ADO in the TME helps create the suppressive niche.

Inhibition of critical immune mechanisms stimulates the formation of the pro-adenosine niche and fibrotic remodeling

The formation of solid tumors in tissues begins with an increase in cell death, inflammation, and hypoxia. This leads to an increase in extracellular ATP and ADO within the TME. When the proinflammatory metabolite extracellular ATP is cleaved into extracellular ADO and is recognized by the A2AR and A2BR within tumors, there is suppression of immune functions^[59]. Endothelial cells within the forming tumor and infiltrating immune cells express CD39 and CD73 on their surface. This allows for an increase in ADO within the TME. Endothelial and immune cells also express A2BR on their surface, and when activated by ADO, the tumor can suppress immune cell infiltration. Solid tumors become hypoxic, which feeds back to increase ATP, CD73, and CD39 in the TME to further suppress the immune infiltration^[115]. Tumor cells interact with suppressive immune cells to increase A2BR expression, leading to metastasis, proliferation, and VEGF production^[119].

CAF increases within solid tumors, forming a dense tumor stroma. These CAFs express high levels of CD39 and CD73 on their surface in various solid tumors such as ovarian, pancreatic, colorectal, and breast cancer, which contribute to ADO production^[120-122]. A dense fibrotic stroma allows ADO to remain in high concentration to drive immunosuppressive signaling throughout the tumor. An increase in A2BR on CAFs increases the secretion of IL-6 into the TME, which can convert epithelial cells to a more mesenchymal phenotype^[63]. This remodeling of the TME leads to increased metastasis and therapy resistance.

Increases in the ADO pathway cause resistance to immune checkpoint inhibitor therapies

Immune checkpoint inhibitors such as anti-PD-1 and anti-CTLA4 have shown great promise for improving the survival of patients with solid tumors. This form of therapy targets PD-1 and CTLA4 on CD8+ T cells. Tumor cells inhibit CD8+ T cell function by targeting these checkpoint molecules. By blocking PD-1 and

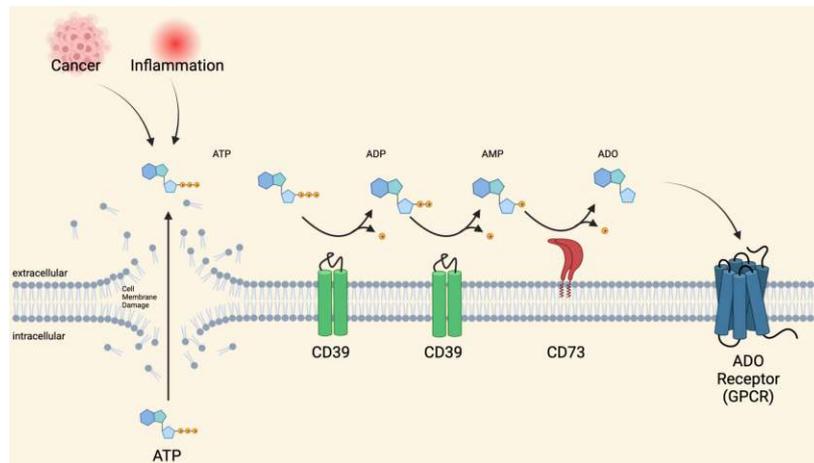

Figure 2. Adenosine Biosynthesis in Inflamed Tissues. The accumulation of extracellular ATP, driven by stress-induced conditions, stimulates extracellular ADO production by the enzymes CD39 and CD73. ADO binds four G protein-coupled receptors, A1, A2A, A2B, and A3. ADO: Adenosine; ADP: adenosine diphosphate; AMP: adenosine monophosphate; ATP: adenosine triphosphate.

CTLA4 from being recognized, the cytotoxic function of the CD8+ T cells is increased to clear the tumor cells^[113]. However, patients with solid tumors tend to relapse and become resistant to checkpoint therapy. Maj *et al.* discovered that when checkpoint therapy is given, there is an increase in the death of cancer cells and Tregs. The sudden death of these cells releases a high amount of ATP in the TME, which is then converted to adenosine by CD39 and CD73. This increase in ADO in the TME counteracts checkpoint therapy and suppresses the antitumor immune response^[123].

While an increase in CD73 and CD39 is associated with poor prognosis in patients, increasing A2AR and A2BR expression also contributes to an increased risk of resistance to checkpoint therapy. It has been found that having an increase in A2AR in non-small cell lung cancer (NSCLC) or A2BR in triple-negative breast cancer (TNBC) contributes to poor survival^[119,124]. Chalmin *et al.* showed that the adenosine pathway is involved in resistance to anti-PD-1 therapies. They demonstrated that when patients were given checkpoint therapy, there was an increase in CD73, leading to resistance^[125]. Combination therapies targeting CD73, and checkpoint inhibitors may help overcome early resistance in solid tumors. Studies have shown that targeting CD73 and PD-1 in murine colon tumors can inhibit tumor growth^[126]. The idea that targeting both the adenosine pathway and checkpoint inhibitors may overcome resistance in solid tumors gives promise to advancing immunotherapy.

Endothelial cells increase CD39 and CD73 levels during hypoxia in tumors, leading to angiogenesis

Hypoxia occurs in solid tumors and suppresses immune cell infiltration by activating hypoxia-inducible factor 1/2 (HIF1/2), IL-6, TGF β , and TNF. Under these conditions, endothelial, tumor, and various suppressive immune cells increase CD73 and CD39 to increase ATP conversion to AMP and ADO^[39,127]. Tumor cells that increase CD73 expression can generate ADO to interact with A2ARs on the tumor cells to stimulate an increase in VEGF secretion^[128]. VEGF works to increase angiogenesis within the tumor and provides nutrients and oxygen for growth and metastasis [Figure 3].

Endothelial cells express CD39 within tumors to degrade ATP and promote increased neovascularization and tumor growth^[129]. To have the ADO concentration needed to sustain the tumor-protective endothelial barrier, CD73 and A2BR are needed within the TME^[130]. Feng *et al.* and Sun *et al.* demonstrated that inhibiting CD39 on solid tumor endothelial cells decreased angiogenesis and tumor growth^[129,131]. CD39 on endothelial cells and the vascular is highly expressed within pancreatic and rectal carcinoma. High

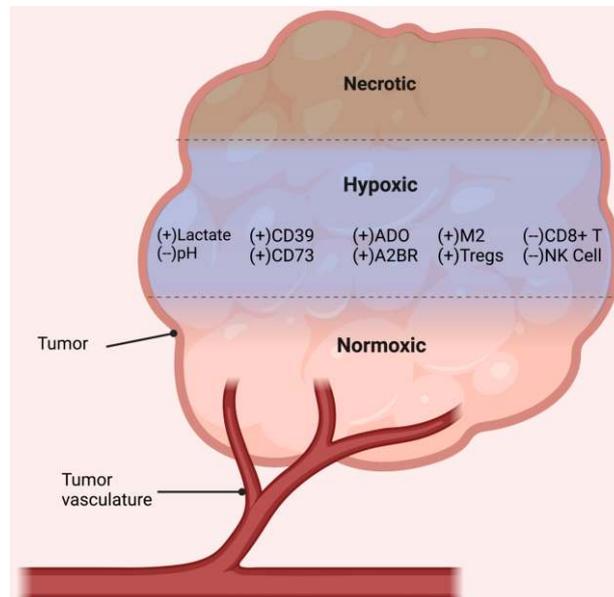

Figure 3. Hypoxia in the TME. This figure illustrates a region of a tumor devoid of vasculature, leading to an oxygen-starved environment. This hypoxic zone is characterized by low pH and a predominance of lactate. Within this environment, TAMs tend to adopt an M2 phenotype, and Tregs become the predominant T cell population. Hypoxic conditions also encourage the expression of the ectoenzymes CD39 and CD73, leading to a surge in extracellular ADO. This increase in adenosine, in turn, helps to sustain an immunosuppressive environment within the tumor. Note: this illustration does not depict the anatomical structure of the tumor, but rather represents the phenomena occurring at different levels of tumor oxygenation. ADO: Adenosine; A2BR: A2B receptors; NK: natural killer; TAM: tumor-associated macrophage; TME: tumor microenvironment; Tregs: regulatory T cells.

expression of these cells in these tumors is correlated with early TNM and better survival after tumor resection^[132,133]. Studies have shown that having high levels of CD73 in many solid tumors is associated with worse outcomes. High CD73 levels correlate with higher adenosine concentrations in the tumor, leading to a sustained immunosuppressive TME. With a high expression of both CD39 and CD73 within solid tumors, future combination therapies targeting CD39/CD73, PD-1/CTLA4, and A2BR may allow for better survival in patients.

ADO receptors play various roles in cancer growth

An increase in adenosine within the TME allows for immunosuppression that promotes tumor growth. Receptors for ADO on tumor cells, endothelial cells, and immune cells are drivers of tumor growth and metastasis. The ADO G-protein coupled receptors have four subtypes: A₁, A_{2A}, A_{2B}, and A₃ [Figure 4]. The A₁R, A_{2A}R, and A_{2B}R proteins are highly conserved, while the A₃R varies among species. These receptors interact with MAPK pathways to promote proliferation. A_{2A}R and A_{2B}R also increase activation of the mTOR and ERK pathways^[134]. However, receptor signaling is dependent on the concentration of extracellular ADO. This level of ADO is primarily dictated by ATP and ADP metabolism by CD39 and CD73 on cells to make AMP and then ADO. In the following, we will focus only on A_{2A}R and A_{2B}R, which appear to play major roles in tumor immunosuppression.

A_{2A}R and A_{2B}R increase immunosuppression in solid tumors

Both A_{2A}R and A_{2B}R are involved in ADO's immunosuppressive functions. A_{2A}R and A_{2B}R are expressed in most immune and tumor cells^[59,135]. A_{2B}R on myeloid cells normally has lower expression than A_{2A}R on other immune cells. However, this receptor increases in the presence of pathological responses such as infections or cancer^[136]. A_{2B}R upregulation and activation signal macrophages towards the

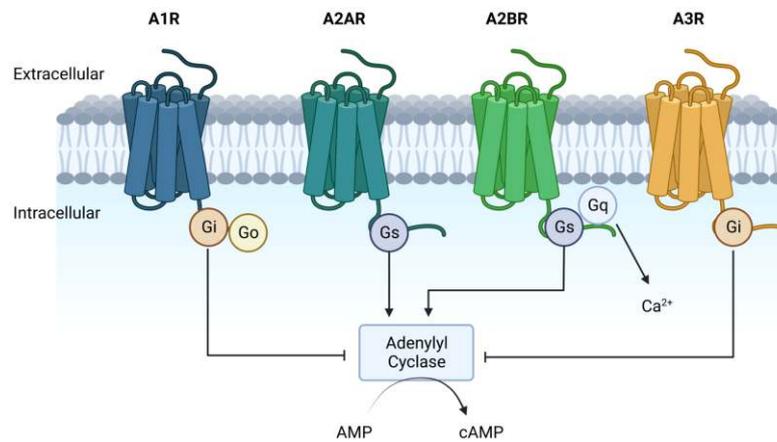

Figure 4. Adenosine receptors. Adenosine interacts with four distinct receptors - A1R, A2AR, A2BR, and A3R. Each of these receptors is linked to a G protein-coupled receptor. The A1R and A3R couple with the Gi protein to inhibit Adenylyl Cyclase. In contrast, the G protein coupled to A2AR and A2BR activates Adenylyl Cyclase, leading to an increased formation of intracellular cyclic AMP. A2BRs also couple to Gq which mobilizes Ca²⁺ upon activation. AMP: Adenosine monophosphate; A2AR: A2A receptors; A2BR: A2B receptors; cAMP: cyclic adenosine monophosphate.

suppressive M2-like phenotype and secrete IL-10 and VEGF to promote angiogenesis and tumor growth^[43]. A2ARs on infiltrating T cells within the TME are activated when ADO increases in the surroundings. This activation suppresses the effector CD8⁺ T cells in the TME while signaling CD4⁺ T cell differentiation into Tregs^[137-139]. IFN- γ production decreases in NK cells when the A2AR on these cells is activated by ADO^[99]. Decreases in antitumor cytotoxic cells and cytokines allow for increased suppressive factors that drive tumor growth and resistance to antitumor therapies.

A2BR activation due to TME hypoxia works to maintain the epithelial barrier of the tumor^[39]. Maintaining this barrier prevents antitumor immune cells from penetrating the tumor. A2AR and A2BR-mediated immunosuppression also allow for an increase in metastasis amongst solid tumors^[58].

A2BR is key for immunosuppression in solid tumors caused by ADO

Since A2BRs are expressed at low levels under normal conditions, this receptor may be key for triggering immunosuppression within solid tumors. The A2BR has the lowest potency for ADO under normal physiological conditions. However, during inflammation and sudden increases in apoptosis, the A2BR is activated to create an immunosuppressive niche. ADO drives immunosuppression in solid tumors by binding to the A2BR on immune and tumor cells. Once activated, the A2BR increases the secretion of VEGF and IL-8 into the TME^[140,141]. This secretion from immune cells comes mainly from monocyte-derived immune cells. When activated by ADO and A2BR interactions, these cells contribute major driving factors in tumor immunosuppression. Ben Addi *et al.* discovered that the A2BR, not the A2AR, on bone marrow-derived DCs decreased the production of IL-12p70 in mice^[84]. A2BR knock-out lung carcinoma cells produced lower VEGF levels in this model when stimulated with adenosine than wildtype controls^[140].

Hypoxia increases A2BR expression

As described earlier, hypoxia is a hallmark of solid tumors. Recent studies have expanded our understanding of the role of hypoxia in solid tumors, emphasizing its impact on angiogenesis and tumor growth and its influence on other aspects of tumor biology, such as immune evasion and therapy resistance^[18,142]. Hypoxia-driven upregulation of A2BRs and ADO signaling contributes to tumor progression, angiogenesis, and immune escape^[44,113].

The hypoxic response also modulates the immune system, affecting innate and adaptive immunity. Hypoxia can alter the functions of immune cells such as TAMs, neutrophils, DCs, T cells, and NK cells^[18,143]. Hypoxia-driven changes in the TME, for example, can create an immunosuppressive milieu, impairing the ability of immune cells to target and eliminate cancer cells^[144]. Novel therapeutic strategies targeting hypoxia and adenosine signaling pathways, including A2BRs, are currently being investigated to improve the efficacy of existing cancer treatments and overcome treatment resistance^[14].

The role of ADO and its receptors blockade to overcome resistance

ADO and its receptors are critical in maintaining immunosuppression in the TME, contributing significantly to immunotherapy resistance. Several clinical trials are exploring the potential of ADO receptor blockade as a novel strategy to counteract this resistance.

Several A2AR antagonists are currently being explored in clinical trials [Table 1], and two of the more advanced therapies are discussed further as part of this review: Corvus Pharmaceutical's ciforadenant and AstraZeneca's AZD4635^[145].

In a first-in-human Phase 1 dose-escalation study in patients with advanced refractory cancers (NCT02655822), ciforadenant (either monotherapy or in combination with atezolizumab) was administered to 502 patients. Of those, a cohort of 68 renal cell carcinoma (RCC) patients yielded clinical responses, including partial responses (PR) in 11% of patients treated with a combination of A2AR antagonists and anti-PD-L1 antibodies, and in 3% of patients treated with A2AR antagonists alone^[146]. Further, tumor regression was observed in an additional 24% of patients, although the regression was not significant enough to be classified as PR by RECIST criteria. These findings are noteworthy, especially considering that the patients involved in the study were not only resistant to PD-1 blockade but were also deemed untreatable prior to the trial.

According to Michail Sitkovsky^[147], the observed tumor regressions in patients with RCC, who were previously untreatable and refractory to PD-1 blockade, likely occurred in patients meeting specific criteria: their tumors were immunogenic, developed tumor-reactive effector T cells, retained a significant number of effector cells post-toxic cancer chemotherapies, and were protected by immunosuppressive extracellular ADO to A2AR signaling. Ciforadenant appears to have facilitated the invasion and tumor-rejecting functions of T and NK cells in these patients; however, the levels of antitumor immunity in responsive patients were not high enough to achieve a complete response. The major limitation appears to be the lack or low numbers of tumor-reactive T and NK cells in refractory patients, either due to the tumor's poor immunogenicity or past toxic chemotherapies.

A2AR antagonists are anticipated to be most efficacious in patients with sufficient aggressive, multifunctional tumor-reactive T cells. Without these cells, it could be expected that A2AR antagonists would only have antitumor effects when combined with cancer vaccines or T-cell transfers that increase the number of tumor-reactive T cells. Future treatments combining A2AR antagonism with adoptive cell transfer (ACT) are promising, especially for refractory patients, as ACT ensures the presence of sufficient T-cells and NK-cells in patients, enhancing the potential for A2AR antagonism as an immunotherapy.

These antagonists have been able to show, both *in vitro* and *in vivo*, that blocking the adenosine pathway at the A2AR increases cytotoxic T cells within the TME, increases cytokine production, and reverses T cell inhibition.

TT-4 (A2BR antagonist)	<ul style="list-style-type: none"> · TT-4, a small molecule, as a single agent 	1/2	GI cancers	69	NCT04976660	2023-09

Data obtained from ClinicalTrials.gov. A2AR: A2A receptors; A2BR: A2B receptors; CTLA4: T lymphocyte antigen 4; GI: gastrointestinal; H&N: Head & Neck; NSCLC: non-small cell lung cancer; RCC: renal cell carcinoma.

Another A2AR antagonist in development is AstraZeneca's AZD4635. In a monotherapy phase 1 trial (NCT02740985), observed adverse events included nausea, fatigue, and vomiting. In addition, one patient with colorectal cancer had sudden death 15 days after the last dose of AZD4635, which was considered treatment-related by the investigator. However, AZD4635 was well tolerated both as a monotherapy and in combination with durvalumab in all patients. There were patients with responses such as stable disease, partial response, and complete response and RNA analysis confirmed that in 5 of 7 patients, intertumoral adenosine signaling decreased. Four of these 7 patients also had increases in gene-expression signatures of cytolytic activity and IFN- γ signaling. These findings suggest that there were observable positive responses to the treatment in some patients.

A2BR antagonists are also under investigation in several clinical trials. Arcus' etrumadenant, a dual A2AR and A2BR antagonist, is being evaluated in several cancers and was recently discontinued in mCRPC due to a lack of efficacy (NCT05177770). Palofarma's PBF-1129, an A2BR antagonist, is being evaluated in metastatic NSCLC (NCT03274479) and EMD Serono's M1069 (NCT05198349), another A2AR and A2BR antagonist, is currently undergoing a first-in-human trial in patients with advanced malignancies. In addition, Portage is evaluating TT-4, an A2BR antagonist, as a single agent in gastrointestinal cancer (NCT04976660). Further investigation will likely provide more insights into the clinical potential of these promising strategies. Overall, compounds exhibiting the highest water solubility tend to possess increased bioavailability, making them more effective^[148]. With the advancement in the development of ADO receptor antagonists, enhancing the solubility of these promising compounds while preserving their selectivity emerges as an avenue for improvement.

CONCLUSION

In the complex battleground of cancer, it is necessary to understand the adaptations tumors employ to resist therapies. This review has emphasized the role of ADO, a significant player in the TME, in driving immunosuppression and fostering cancer drug resistance. The importance of ADO and its receptors, particularly the A2AR and A2BR subtypes, in promoting an immune-escaping environment was thoroughly explored.

Current research endeavors focus on various approaches to counteract immunosuppression, including monoclonal antibodies against CD73 and the blockade of ADO receptors. Ongoing clinical trials investigate combinations of these approaches with existing therapies, aiming to stimulate immune responses and improve patient outcomes.

The results of ongoing clinical trials will inform new ways of overcoming cancer drug resistance. However, further research is required to understand and fully exploit ADO's pathway. Targeting ADO could improve cancer treatments, providing hope for patients who previously had limited treatment options. This underscores the importance of ongoing research in this area, aiming to improve the prognosis for all cancer patients.

DECLARATIONS

Acknowledgments

The authors thank Schuyler Vinzant and Sara Adair for their critical feedback on the manuscript. All figures were created using Biorender.

Abstract

The use of immune checkpoint inhibitors (ICIs) has increased exponentially in the past decade, although its progress specifically for breast cancer has been modest. The first U.S. Food and Drug Administration approval for ICI in breast cancer came in 2019, eight years after the first-ever approval of an ICI. At present, current indications for ICIs are relevant only to a subset of patients with triple-negative breast cancer, or those displaying high microsatellite instability or deficiency in the mismatch repair protein pathway. With an increasing understanding of the limitations of using ICIs, which stem from breast cancer being innately poorly immunogenic, as well as the presence of various intrinsic and acquired resistance pathways, ongoing trials are evaluating different combination therapies to overcome these barriers. In this review, we aim to describe the development timeline of ICIs and resistance mechanisms limiting their utility, and summarise the available approaches and ongoing trials relevant to overcoming each resistance mechanism.

Keywords: Immunotherapy, immune checkpoint inhibitors, resistance mechanisms, breast cancer

INTRODUCTION

Breast cancer is the most common cancer worldwide, accounting for 12.5% of all new cancer cases globally, and is the leading cause of cancer mortality in women^[1]. In the year 2020, an estimated 2.3 million female breast cancers were diagnosed globally, and about 685,000 women died from their disease^[2]. This number is expected to grow to more than 3 million new cases diagnosed and 1 million deaths by the year 2040^[2].

With advances in our understanding of cancer biology, immuno-oncology has become an area of great interest and extensive research. Cancer immunotherapy employs the use of cutting-edge technologies, including immune checkpoint inhibitors (ICIs) such as those targeting Programmed Cell Death Protein-1 (PD-1), Programmed Cell Death Ligand-1 (PD-L1), and Cytotoxic T-Lymphocyte-Associated Antigen 4 (CTLA-4), and more recently, chimeric antigen receptor (CAR) T cell therapies. Other frontiers being pushed in the realms of immunotherapy include the use of cancer vaccines^[3], for cancer prevention, such as vaccines for Human Papilloma Virus and Hepatitis B^[4], as well as in cancer treatment, as in the case of Sipuleucel-T for prostate cancer^[5].

Since the first U.S. Food and Drug Administration (FDA) approval of ipilimumab, a CTLA-4 monoclonal antibody, in 2011 for the treatment of metastatic melanoma^[6], ICIs have transformed the treatment landscape across multiple tumour types^[7]. There are now eleven FDA approvals for ICIs: two CTLA-4 inhibitors (ipilimumab, tremelimumab), five PD-1 inhibitors (pembrolizumab, nivolumab, cemiplimab, dostarlimab, retifanlimab), three PD-L1 inhibitors (atezolizumab, avelumab, durvalumab), and one lymphocyte-activation gene 3 (LAG-3) blocking antibody (retatlimab)^[6-9]. However, amongst the numerous available approvals for ICIs, there are currently only two specific FDA approvals in the setting of breast cancer, both for pembrolizumab in the subgroup of triple-negative breast cancer (TNBC), given in combination with chemotherapy in the metastatic^[10] and neoadjuvant^[11] settings. Additional FDA approvals that are tumour agnostic and apply to breast cancer include pembrolizumab^[12] and dostarlimab^[13] in breast cancers displaying high microsatellite instability (MSI-H) or a deficiency in the mismatch repair protein (dMMR) pathway. While one of the hallmarks of treatment with ICIs is its durable response that translates to prolonged survival of these patients, admittedly, only a very small subset of patients benefit. In this review article, we will first describe the evolution of ICI in the TNBC subtype, focusing on its approved indications, before delving into the understanding of the resistance mechanisms towards ICIs, and how we can harness such knowledge to develop new combination strategies.

EVOLUTION OF ICIS IN BREAST CANCER

Monotherapy ICIs in TNBC

Evidence for the use of ICIs in breast cancer first came from single-agent immunotherapy trials in the metastatic setting, including the KEYNOTE-012 and KEYNOTE-086 studies. KEYNOTE-012 was a phase I study that aimed to evaluate the role of single-agent pembrolizumab in patients with various advanced solid tumours. In the cohort of TNBC who had progressed on a median of 2 lines of treatment, the objective response rate (ORR) was 18.5% and 6-month progression-free survival (PFS) was 24.4%, 6-month and 12-month overall survival (OS) were 66.7% and 43.1%, respectively^[14]. The investigators observed that there was a suggestion of response with increasing expression of PD-L1, albeit within a small sample size ($n = 32$).

KEYNOTE-086 was designed specifically to look at the role of pembrolizumab monotherapy in patients with metastatic TNBC. This phase II multicohort study included all comers with ≥ 1 prior systemic treatment for metastatic disease regardless of PD-L1 status (Cohort A)^[15], and also patients with no prior systemic treatment in the metastatic setting who had PD-L1 positive tumours defined as combined positive score (CPS) ≥ 1 based on the Dako PD-L1 IHC 22C3 platform (Cohort B)^[16]. Comparing across cohorts,

there was a suggestion of improved ORR in less heavily pre-treated patients (ORR 21.4% *vs.* 5.3%) in Cohort B *vs.* all-comers in Cohort A. This was consistent with other similar phase 1 trials evaluating avelumab (JAVELIN study)^[17] and atezolizumab (PCD4989g trial)^[18] as monotherapy in metastatic TNBC, suggesting clinical benefit when used in earlier lines of treatment and PD-L1 expressing tumours.

A subsequent KEYNOTE-119 randomised phase III trial compared pembrolizumab monotherapy *vs.* single agent physicians' choice chemotherapy in patients who progressed on 1 or 2 prior lines of treatment for metastatic TNBC^[19]. While the trial was negative for its primary endpoint of OS in all subgroups, there was a positive trend to survival benefit in patients with PD-L1 CPS ≥ 10 (12.7 *vs.* 11.6 months, HR 0.78; $P = 0.057$).

The limited efficacy of single-agent immunotherapy observed in breast cancer might be due to intrinsic tumour resistance due to its complex and enigmatic relationship with the immune system. Breast cancer was traditionally thought to be poorly immunogenic, also known as a "cold tumour". Immunogenicity, or the ability to elicit an antitumoural response by the body's immune system, is dependent upon the formation of neo-antigens that are derived from gene mutations, viral oncogenes alternative splicing, or gene rearrangement^[20-22]. It is assessed by the antigenicity of a cancer, which in turn is evaluated by its mutagenicity^[23]. One measure of the antigenicity of cancer is its mutational load or tumour mutational burden (TMB), which refers to the average number of somatic mutations per (Mb)^[23,24]. Cancers like melanoma and lung cancer are known to be "hot tumours", as observed in a study by Chalmers *et al.* who reported their median TMB levels to be 13.5 mut/Mb and 7.2 mut/Mb, respectively^[25]. In contrast, the TMB in breast cancer is generally much lower. In a study by Barroso-Sousa *et al.*^[26] of 3,969 patients with breast cancer, the median TMB reported was 2.63 mut/Mb, while another Chinese study of 196 breast cancer patients demonstrated a higher median TMB of 4.03 mut/Mb^[27]. Due to the poor efficacy observed with the use of single-agent immunotherapy treatment, further efforts were directed at exploring combination treatment.

Combining ICIs with chemotherapy in TNBC

The rationale for combination treatment with chemotherapy was that chemotherapeutic agents had been shown to have synergistic effects with ICIs by inducing immunogenic cell death, causing the release of tumour-associated neoantigens as well as its ability to stimulate immune surveillance^[28,29]. Indeed, this has proven to be an effective strategy in several subgroups of TNBC.

The initial results of several phase I studies evaluating this combination in the setting of metastatic TNBC were promising, reporting response rates ranging between 23.4%-39%^[30,31]. Several phase III trials confirmed these positive preliminary findings, leading to the first FDA-approved indication for an ICI for use in breast cancer treatment.

Atezolizumab

The first FDA accelerated approval of an ICI for breast cancer was with the anti-PD-L1 inhibitor atezolizumab, which was granted on 8 March 2019^[32] based on the IMpassion 130 trial^[33]. This phase III placebo-controlled randomised trial evaluated 902 patients with treatment naïve, unresectable locally advanced or metastatic TNBC. Patients were randomised to receive either atezolizumab or its placebo, in combination with albumin-bound paclitaxel (nab-paclitaxel). In patients whose tumours expressed PD-L1 based on the VENTANA PD-L1 SP142 assay, there was a significant median PFS benefit: 7.5 months in patients receiving atezolizumab *vs.* 5.0 months with placebo (HR 0.62, $P < 0.001$). The final approval of this combination was contingent upon the results of the IMpassion 131 trial evaluating atezolizumab with paclitaxel in TNBC in the same setting, which unfortunately failed to meet its primary endpoint of superior

PFS^[34]. This led to Genentech voluntarily withdrawing the previously granted accelerated FDA approval for atezolizumab on 27 August 2021. Eventually, when the final OS was read out for the IMpassion 130 trial, the addition of atezolizumab to nab-paclitaxel failed to meet statistical significance, precluding further testing^[35].

Pembrolizumab

Pembrolizumab is currently FDA-approved for use in TNBC in the first-line metastatic and neoadjuvant settings, both in combination with chemotherapy. It first received FDA approval on 13 November 2020 as combination therapy with chemotherapy for patients with unresectable locally-advanced or metastatic TNBC whose tumours have a PD-L1 CPS ≥ 10 based on the Dako 22C3 assay^[10]. This was based on KEYNOTE-355, a phase III randomised placebo-controlled study evaluating the role of pembrolizumab in combination with chemotherapy in patients in the above-mentioned setting. It reported a median OS (mOS) benefit of about 7 months in patients whose tumours expressed PD-L1 CPS ≥ 10 (mOS 23.0 vs. 16.1 months; HR 0.73, $P = 0.0185$). In patients whose tumours expressed PD-L1 CPS ≥ 1 or in the intention-to-treat population, there was no survival benefit shown.

In addition, pembrolizumab also has tumour-agnostic FDA approval for advanced unresectable or metastatic solid tumours that are dMMR or MSI-H^[12]. This was based on the combined results of 5 single-arm trials where a total of 149 patients with dMMR/MSH-H solid tumours achieved an ORR of 39.6%, with 78% of patients having responses lasting 6 months or more. It should be noted, however, that only 2 out of the 149 patients had breast cancer. They both achieved partial responses, with duration of response (DoR) of 7.6 and 15.9 months^[36].

Dostarlimab

Most recently, on 17 August 2021, dostarlimab also received accelerated FDA approval for recurrent or advanced solid tumours that are dMMR based on the GARNET trial^[13]. This was an open-label, non-randomised, multicohort phase I trial evaluating dostarlimab as monotherapy in the above-mentioned clinical setting. In these patients, there was an ORR of 41.6%, with 9.1% complete responses and 32.5% partial responses. The median DoR was 34.7 months, with 95.4% of patients still showing continued response at 6 months. In cohort F, which enrolled 106 non-endometrial solid tumours, 1 patient had dMMR breast cancer and reported a complete response^[37].

With the promising results of a combination of ICI therapy and chemotherapy in the metastatic setting, efforts were then shifted to study it in the earlier curative stages of breast cancer. One of these trials is the phase II I-SPY 2 trial, which adopted an adaptive trial design to evaluate various novel therapeutics in combination with chemotherapy, comparing that to standard treatment as in the neoadjuvant setting for early-stage breast cancer^[38]. Pembrolizumab was included in one of the study arms, where patients were randomised to receive 4 cycles of pembrolizumab given in combination with weekly paclitaxel vs. weekly paclitaxel alone, followed by doxorubicin/cyclophosphamide and then definitive surgery. Compared to standard chemotherapy alone, the addition of pembrolizumab improved pathologic complete response (pCR) rates in all breast cancer subtypes: 44% vs. 17% in HER2-negative breast cancers, 30% vs. 13% in HR-positive/HER2-negative breast cancers, and 60% vs. 22% in TNBC^[39].

Focusing on the TNBC subtype, the role of pembrolizumab in the neoadjuvant setting was proven in the confirmatory phase III KEYNOTE-522 trial, which subsequently led to pembrolizumab receiving its second breast cancer-specific FDA approval on 26 July 2021^[11]. In this phase III randomised controlled study, 1,174 patients with previously untreated stage II or III TNBC were randomised in a 2:1 ratio to receive pembrolizumab or a placebo, respectively, in combination with chemotherapy, before undergoing surgery.

Pembrolizumab or its placebo was continued post-operatively for up to 9 cycles. Both primary endpoints of the trial were met; there was a significant improvement in pCR of 64.8% *vs.* 51.2%; $P = 0.00055$, although this had reduced by the third interim analysis^[40] to 63.0% *vs.* 55.6%. There was also an improvement in 3-year event-free survival (EFS) 84.5% *vs.* 76.8%; $P < 0.001$ ^[41]. Interestingly, contrary to data in the metastatic setting, PD-L1 expression was not predictive of benefit^[11], and consequently the FDA approval in the neoadjuvant setting was granted irrespective of PD-L1 expression.

The benefit of ICIs in combination with chemotherapy in the neoadjuvant setting was also echoed in the IMpassion 031 study evaluating atezolizumab. In IMpassion 031, atezolizumab was evaluated in the neoadjuvant setting in patients with stage II-III TNBC treated for curative intent. This was a double-blind phase III randomised trial where patients received either atezolizumab or its placebo, in combination with nab-paclitaxel, followed by doxorubicin and cyclophosphamide. The investigators found an increase in pCR rates from 58% *vs.* 41% in the all-comers population; $P = 0.0044$, (significance boundary 0.0184), and 69% *vs.* 49% in PD-L1 positive patients; $P = 0.021$, (significance boundary 0.0184). As it did not hit the prespecified boundary of significance for its second co-primary endpoint, the study is not formally powered for further survival analyses^[42].

However, not all trials evaluating the addition of ICIs in combination with chemotherapy in the neoadjuvant setting for TNBC have yielded similar results. Both the NeoTRIP and GeparNeuvo evaluating atezolizumab and durvalumab, respectively, in the neoadjuvant setting were negative for pCR benefit. Patients in the NeoTRIP study were randomised to receive neoadjuvant carboplatin and nab-paclitaxel with or without 8 cycles of atezolizumab. Anthracyclines were given in the adjuvant setting after definitive surgery. The addition of atezolizumab resulted in numerically higher but nonsignificant pCR rates: 48.6% *vs.* 44.4%; $P = 0.48$ ^[43]. Similarly, the GeparNuevo trial studied the addition of durvalumab to neoadjuvant chemotherapy with paclitaxel followed by epirubicin and cyclophosphamide, which found a nonsignificant but numerically superior pCR rates of 53.4% *vs.* 44.2%; $P = 0.224$ ^[44]. Interestingly, a survival benefit with the addition of durvalumab compared to placebo was observed; 3-year invasive disease-free survival (iDFS) was 84.9% *vs.* 76.9% (HR 0.54; $P = 0.0559$) and 3-year OS 95.1% *vs.* 83.1% (HR 0.26; $P = 0.0076$)^[45].

While there is general consensus for the use of ICIs in combination with chemotherapy in the neoadjuvant setting for TNBC, its optimal duration is currently still widely discussed. In both KEYNOTE-522 and IMpassion 031, the ICI was continued post-operatively for a total of 1 year, while NeoTRIP and GeparNuevo only administered ICI in the neoadjuvant setting. GeparNuevo is the only study that has shown survival benefits with the use of ICI despite being administered only in the neoadjuvant context without continuation in the adjuvant setting, leading to questions of whether there is a need for continual ICI in the adjuvant setting. Additionally, the pCR benefit that was observed in the durvalumab group in GeparNuevo was exclusively seen in the cohort of patients who received a 2-week lead-in of durvalumab prior to chemotherapy, although the reason for this observation is currently unclear. We have summarised the trials evaluating the use of ICI both as monotherapy and in combination with chemotherapy in [Table 1](#).

In the adjuvant setting, there are ongoing trials such as the A-BRAVE trial^[46] investigating the use of avelumab in the treatment of high-risk TNBC, as well as the ALEXANDRA/IMpassion030 trial^[47] evaluating standard chemotherapy with or without atezolizumab in patients with early-stage TNBC. Additionally, the use of ICIs in early relapsing TNBC is also being investigated in the IMpassion 132 trial, a phase III randomised trial evaluating the role of combining atezolizumab with chemotherapy in patients with locally recurrent inoperable or metastatic TNBC within 12 months from receiving curative-intent treatment^[48].

Table 1. Summary of trials evaluating the use of ICI as monotherapy and in combination with chemotherapy

Trial name/ID	Phase	Population	Arms	Results
KEYNOTE-012 NCT01848834	I	Advanced TNBC, PD-L1 + ve; pre-treated	Pembrolizumab	ORR 18.5% 6-mo PFS 24.4% 6-mo OS 66.7%, 12-mo OS 43.1%
KEYNOTE-086 NCT02447003	II	Metastatic TNBC; pre-treated Cohort A: all-comers Cohort B: PD-L1 + ve	Pembrolizumab	Cohort A: ORR 5.3%, mPFS 2.0 mo, mOS 9.0 mo Cohort B: ORR 21.4%, mPFS 2.1 mo, mOS 18.0 mo
JAVELIN NCT01772004	I	Metastatic breast cancer; pre-treated	Avelumab	ORR: 3.0% (overall population), 5.2% (TNBC), 16.7% (PD-L1 + ve), 1.6% (PD-L1-ve)
PCD4989g NCT01375842	I	Metastatic TNBC; any-line	Atezolizumab	ORR 24% (1st line), 6% (\geq 2nd line) ORR 12% (1st line), 0% (\geq 2nd line) mOS 10.1 mo (PD-L1 + ve), 6.0 mo (PD-L1-ve)
KEYNOTE-119 NCT02555657	III	Metastatic TNBC; 1 or 2 prior lines	Pembrolizumab vs. chemotherapy	mOS 9.9 mo vs. 10.8 mo HR 0.97 (overall population) mOS 12.7 mo vs. 11.6 mo HR 0.78; $P = 0.057$ (PD-L1 CPS \geq 10)
IMpassion 130 NCT02425891	III	Metastatic TNBC; untreated	Nab-paclitaxel +/- atezolizumab	mPFS 7.2 mo vs. 5.5 mo, HR 0.79; $P = 0.002$ (ITT) mOS 21.0 mo vs. 18.7 mo HR 0.87; $P = 0.077$ (ITT) mPFS 7.5 mo vs. 5.0 mo HR 0.63, $P < 0.0001$ (PD-L1 + ve) mOS 25.4 mo vs. 17.9 mo HR 0.67; (PD-L1 + ve)
IMpassion 131 NCT03125902	III	Metastatic TNBC; untreated	Paclitaxel +/- atezolizumab	mPFS 6.0 mo vs. 5.7 mo, HR 0.82; $P = 0.20$ (PD-L1 + ve) mPFS 5.7 mo vs. 5.6 mo, HR 0.86 (ITT)
KEYNOTE-355 NCT02819518	III	Metastatic TNBC; untreated	Chemotherapy +/- pembrolizumab	mPFS 9.7 mo vs. 5.6 mo HR 0.66 (CPS \geq 10) mPFS 7.6 mo vs. 5.6 mo HR 0.75 mOS 23.0 vs. 16.1 mo HR 0.73; $P = 0.0185$ (CPS \geq 10) mOS 17.6 mo vs. 16.0 mo HR 0.86 $P = 0.1125$ (CPS \geq 1)
I-SPY 2 NCT01042379	II	High-risk stage II/III breast cancer	Chemotherapy +/- pembrolizumab	pCR 44% vs. 17% (ERBB2-negative), 30% vs. 13% (HR- + ve/ERBB2-ve), 60% vs. 22% (TNBC)
KEYNOTE-522 NCT03036488	III	Stage II/III TNBC	Chemotherapy +/- pembrolizumab	pCR 64.8% vs. 51.2%; $P = 0.00055$ 3yr EFS 84.5% vs. 76.8% HR 0.63; $P < 0.001$
IMpassion-031 NCT03197935	III	Stage II/III TNBC	Chemotherapy +/- pembrolizumab	pCR 58% vs. 41%; $P = 0.0044$ (all-comers) pCR 69% vs. 49% $P = 0.021$ (significance boundary 0.0184) (PD-L1 + ve)
NeoTRIP NCT002620280	III	Early high-risk and locally advanced TNBC	Chemotherapy +/- atezolizumab followed by surgery, then adjuvant anthracyclines	pCR 48.6% vs. 44.4% OR 1.18; $P = 0.48$
GeparNuevo NCT02685059	II	Non-metastatic TNBC	Chemotherapy +/- durvalumab *window phase included 2 weeks of durvalumab/placebo	pCR 53.4% vs. 44.2% OR 1.45; $P = 0.224$ 3yr iDFS 84.9% vs. 76.9% HR 0.54; $P = 0.0559$ 3yr OS 95.1% vs. 83.1% HR 0.26; $P = 0.0076$

CPS: Combined positive score; EFS: event-free survival; ICI: immune checkpoint inhibitor; iDFS: invasive disease-free survival; mOS: median OS; ORR: objective response rate; OS: overall survival; pCR: pathologic complete response; PD-L1: programmed cell death ligand-1; PFS: progression-free survival; TNBC: triple-negative breast cancer.

ICIs in other subtypes of breast cancer

While there have also been efforts to evaluate the use of ICIs in HER2-positive and hormone-positive/HER2-negative breast cancers, none of the studies have led to conclusive evidence for its use in these settings at present. In particular, HER2-positive breast cancer is thought to share certain similarities with TNBC that might suggest a benefit from ICI therapy. This includes the presence of higher tumour infiltrating lymphocytes (TILs) and PD-L1 expression. The presence of TILs in the tumour and its

surrounding microenvironment is thought to be a reflection of pre-existing antitumour immunity^[49,50], and its presence is thought to be predictive of response to systemic anti-cancer treatment^[50], as well as a prognostic biomarker^[24]. TNBC and HER2-positive breast cancers have been observed to have a higher number of TILs compared to hormone-positive breast cancers^[51,52]. PD-L1 expression has also been observed to be upregulated in HER2-positive breast cancer^[53], and be predictive of response to ICIs in the PANACEA and KATE2 studies^[54,55]. Further in-depth discussion of ICIs in HER2-positive and hormone-positive/HER2-negative breast cancers is beyond the scope of our current article, but has been extensively reviewed^[56-58].

UNDERSTANDING AND OVERCOMING RESISTANCE MECHANISMS TO ICIS

Given that the earliest approval for ICI use in breast cancer came on 8 March 2019 for atezolizumab in combination with nab-paclitaxel in metastatic TNBC based on the IMpassion 130 trial^[33], the experience and evidence available on resistance mechanisms specific to immunotherapy in breast cancer is scarce. In addition, discounting tumour agnostic approvals, which form a very small proportion of breast cancer patients as discussed above^[36,37], the approval for ICIs in breast cancer is now only limited to the TNBC subtype, which constitutes only 15%-20% of all patients with breast cancer^[59], and even so, only a subset of them with high risk early-stage and metastatic disease. Hence, much of our understanding of resistance to ICIs comes from the available data and research on ICI treatment as a whole from various other tumour types.

Resistance pathways to ICIs can be tumour-intrinsic, e.g., alteration of certain genes or signalling pathways within the tumour, or tumour-extrinsic, e.g., changes in components within the tumour microenvironment (TME) other than the tumour cell itself^[60]. This can happen either from the outset, conferring primary resistance whereby no response to treatment is noted, or after a period of observed response, highlighting the concept of acquired resistance. As previously mentioned, breast cancers are known to be immunogenically cold tumours, which contributes to their primary resistance to ICI. We will discuss the various mechanisms of resistance by looking at both tumour-intrinsic and tumour-extrinsic pathways, and how each of them might potentially be harnessed to overcome drug resistance [Figure 1].

TUMOUR INTRINSIC RESISTANCE MECHANISMS TO ICIS

Alteration of signalling pathways

There are several critical signalling pathways that control cell-cycle progression, apoptosis, and cell growth. Alterations in any of these pathways can sometimes be exploited by cancer cells to escape immune surveillance, leading to resistance to ICIs. Some of these pathways are known to be more commonly mutated in breast cancer, for example, the mitogen-activated protein kinase (MAPK) pathway, phosphatidylinositol 3-kinase (PI3K)/protein kinase B (AKT)/mammalian target of rapamycin (mTOR) pathway, Wnt/ β -catenin pathway and Janus kinase (JAK) and signal transducers and activators of transcription (STAT) pathway^[61]. Hence, various combination therapies of ICIs with other therapeutic agents to target each of these specific pathways are gaining traction and have shown promising preliminary activity.

MAPK pathway

Signalling via the MAPK pathway induces the expression of various proteins such as vascular endothelial growth factor (VEGF) as well as interleukin (IL)-8 that inhibit T cell recruitment and function^[62]. Inhibiting the MAPK pathway can also upregulate major histocompatibility complex (MHC)-I, MHC-II, and PD-L1 expression, and enhance infiltration of TILs^[63]. Loi *et al.* had confirmed this observation in an analysis of 111 patients with TNBC who had been treated with neoadjuvant chemotherapy, and demonstrated that

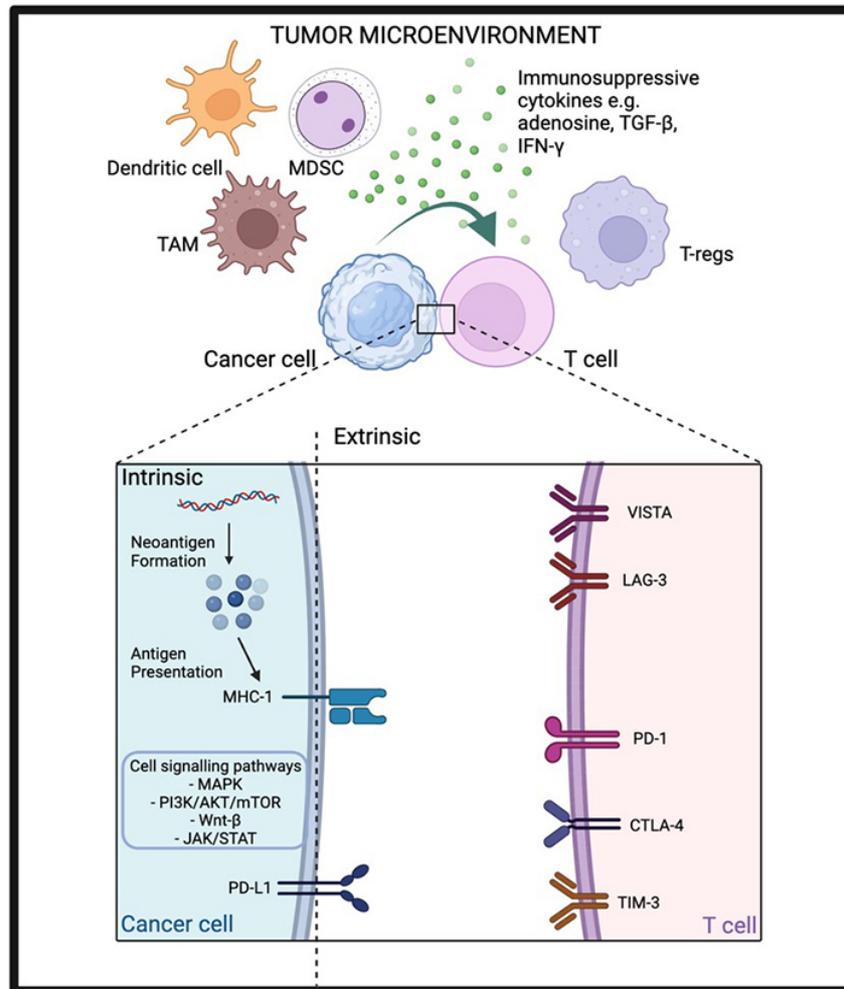

Figure 1. Tumour intrinsic and extrinsic resistance pathways to ICIs. Created with BioRender.com. AKT: Protein kinase B; CTLA-4: cytotoxic T-lymphocyte-associated antigen 4; IFN- γ : interferon- γ ; JAK: janus kinase; LAG-3: lymphocyte-activation gene 3; MAPK: mitogen-activated protein kinase; MDSC: myeloid-derived suppressor cell; MHC-I: major histocompatibility complex-I; mTOR: mammalian target of rapamycin; PD-1: programmed cell death protein-1; PD-L1: programmed cell death ligand-1; PI3K: phosphatidylinositol 3-kinase; STAT: signal transducers and activators of transcription; TAM: tumour-associated macrophage; TGF- β : transforming growth factor- β ; TIM-3: T-cell immunoglobulin, mucin domain-3 protein; T-reg: regulatory T cell; VISTA: V-domain immunoglobulin suppressor of T-cell activation.

alterations in the MAPK signalling pathway can suppress the expression of both MHC-I and MHC-II^[64].

Hence, trials evaluating the combination of mitogen-activated protein kinase kinase (MEK or MAP2K) inhibitors with ICIs are ongoing. The COLET trial^[65] was a phase II trial that investigated cobimetinib, a MEK inhibitor, in combination with atezolizumab and taxane chemotherapy in untreated metastatic TNBC. It demonstrated a numerical but nonsignificant increase in ORR of 34.4% and 29% in patients treated with paclitaxel vs. nab-paclitaxel, respectively. Exploratory biomarker analysis suggested that patients with PD-L1-positive disease (defined as IC \geq 1% by the SP142 IHC assay) had numerically higher ORR compared to those with PD-L1 negative disease (39% vs. 19%), as well as median PFS (7.0 vs. 3.7 months).

PI3K/AKT/mTOR pathway

Abnormalities in the PI3K/AKT/mTOR pathway are also another well-known mechanism of resistance in breast cancer^[66]. The protein phosphatase and tensin homolog (PTEN) tumour suppressor is a negative regulator of PI3K signalling and deletions in PTEN result in the enhancement of PI3K signalling^[66,67]. PTEN loss has also been associated with resistance to T cell-mediated immunotherapy by increasing the expression of immunosuppressive cytokines, particularly VEGF^[68]. VEGF can contribute further to immunosuppressive TME by recruiting suppressive immune cells such as myeloid-derived suppressor cells (MDSC) and regulatory T cells (Tregs)^[69].

Based on these preclinical findings, AKT inhibitors have been combined with ICIs to overcome this resistance pathway. The phase Ib study evaluating the triplet combination of ipatasertib, atezolizumab, and a taxane as first-line treatment for locally advanced/metastatic TNBC reported a promising ORR of 73% irrespective of their PD-L1 status or PIK3CA/AKT1/PTEN alteration status^[70]. The BEGONIA study (NCT03742102) is a phase Ib/II trial evaluating the combination of durvalumab with different novel oncologic therapies designed for immune modulation, with or without paclitaxel as first-line treatment in patients with metastatic TNBC. In arm 2^[71], the addition of capivasertib was studied, yielding an ORR of 53.3%. Importantly, there was a relatively high rate of G3/4 treatment-related adverse events of 73%, although only 6.7% discontinued treatment due to adverse events.

Wnt/ β -catenin pathway

The Wnt/ β -catenin pathway is an important oncogenic signalling pathway involved in many essential cellular processes^[72]. The activation of Wnt results in the accumulation of the transcriptional co-activator β -catenin to initiate the transcription of several cell cycle genes and oncogenes such as Myc^[73]. The high levels of β -catenin via the canonical pathway have also been shown in a murine study by Spranger *et al.* to decrease the presence of CD103+ dendritic cell (DC) by reducing the expression of chemokine that attracts CD103+ DC (CCL4), preventing the migration of DC into the TME^[74]. Consequently, this results in the blocking of adaptive antitumour immunity^[75]. A study of TNBC by Castagnoli *et al.* showed that TNBC stem cells are able to upregulate PD-L1 expression via the Wnt pathway^[75].

JAK/STAT pathway

Interferon γ (IFN- γ) is a cytokine produced by activated T cells and antigen-presenting cells (APCs) that is critical in immune cell activation via the Janus kinase 1 and 2 (JAK1/2) as well as signal transducers and activators of transcription-1 (STAT1) pathway^[76]. Any mutation or epigenetic silencing of molecules in this pathway allows tumours to escape its apoptotic or cytostatic effect^[77]. A study analysing melanoma patients who were treated with ICI therapy and subsequently developed resistance noted that resistance was associated with defects such as loss-of-function mutations in the JAK1/2 pathway^[78]. Another study of 16 melanoma patients observed that those who were non-responders to CTLA-4 inhibition harbor a much higher rate of genomic changes in the IFN- γ pathway genes compared to those who responded^[79].

Antigen presentation

A crucial feature of adaptive immunity is its ability to recognise antigens that are foreign or not “self”. Cancer cells generally harbour accumulated somatic mutations and genomic instability within DNA coding regions. Antigen peptide sequences that distinguish tumour cells are classified based on their unique cell expression patterns^[73]. Tumour-specific antigens (TSA) refer to novel peptide sequences, i.e., neo-antigens, that develop via mutations and are not present in normal healthy cells. Examples of mutations that result in TSAs usually involve oncogenic driver mutations, such as mutations in the *BRCA1/2* gene^[80]. The presentation of these neoantigens by APCs via MHC-I molecules is critical in priming specific cytotoxic

CD8+ T cells, thereby triggering an immune response towards the tumour. Indeed, studies have shown that increasing neoantigen formation helps to improve response to ICIs^[81-83].

Antibody-drug conjugates

Similar to the rationale for combining ICIs with chemotherapy which was discussed earlier, antibody-drug conjugates (ADCs) also increase tumour neoantigen formation via immunogenic cell death^[84]. An ADC consists of an antigen-specific monoclonal antibody bound to a cytotoxic payload via a molecular linker. The binding of an ADC via its antigen-binding portion induces its internalisation via endocytosis. Once inside the tumour cell, cleavage of its linker through proteolysis results in the release of the cytotoxic payload. This allows for target-dependent activation and selective cytotoxicity^[85]. Of note, two ADCs, namely trastuzumab deruxtecan (T-DXd) and sacituzumab govitecan, have received FDA approvals for the treatment of specific breast cancer subtypes. T-DXd is approved for unresectable or metastatic HER2-positive breast cancer based on the results of DESTINY-Breast 03, confirming significant PFS benefit (HR 0.28; $P < 0.0001$)^[86], as well as for unresectable or metastatic HER2-low breast cancer based on DESTINY-Breast 04 showing both promising PFS (HR 0.50; $P < 0.001$) and OS (HR 0.64; $P = 0.001$) benefit^[87]. Sacituzumab govitecan, on the other hand, has been approved both for unresectable or metastatic TNBC as well as hormone-positive, HER2-negative breast cancer based on the ASCENT and TROPiCS-02 trials, respectively, both confirming PFS and OS benefit^[88,89].

Preclinical data have suggested that the combination of ADCs with ICIs may improve the efficacy of ICIs via increasing neoantigen formation and presentation, as well as by activating DCs and increasing the expression of PD-L1^[85]. There are currently several ongoing trials evaluating the combination of different ADCs with ICIs. In the earlier described BEGONIA study, two ADCs, T-DXd and datopotamab deruxtecan (Dato-DXd), are being studied in arms 6 and 7 of the trial, respectively. Preliminary data for both arms were promising; ORR with the addition of T-DXd was 66.7%^[90] and 74% with the addition of Dato-DXd^[91]. Other ongoing trials in this space are summarised in [Table 2](#).

Poly(ADP-ribose) polymerase inhibitors

Poly(ADP-ribose) polymerase (PARP) inhibitors increase DNA damage, leading to more TSAs and also increased MHC-I expression, thereby causing increased antigen presentation^[92]. The increase in DNA damage associated with breast cancer patients who harbour the *BRCA1/2* mutation occurs via a process known as synthetic lethality^[93]. The use of PARP inhibitors blocks the repair of single-stranded DNA breaks via base excision repair. This allows single-stranded breaks to accumulate, leading to the generation of double-stranded breaks (DSBs). These DSBs can usually be restored by either the high-fidelity homologous repair pathway or the error-prone non-homologous end-joining method. As *BRCA1/2* mutant breast cancer patients already have existing defects in homologous repair, they are unable to effectively repair DNA damage, resulting in the generation of TSAs. In addition to increasing antigen presentation, PARP inhibitors have also been shown in preclinical studies to alter the TME by activating intra-tumoural dendritic cells and increasing CD8+ T cell infiltration via the STING (stimulator of interferon genes) pathway^[94]. It also enhances the upregulation of PD-L1 expression by reducing the PARylation of STAT3^[95]. The latter two mechanisms help to overcome tumour extrinsic mechanisms of resistance to immunotherapy that will be expounded upon later.

Consequently, there have been several studies evaluating the combination of PARPi together with ICIs. The TOPACIO/KEYNOTE-162 trial^[96] studied the efficacy of niraparib together with pembrolizumab in 55 patients with metastatic TNBC. In the subgroup of patients with *BRCA1/2* mutations, the ORR was 47% and mPFS 8.3 months. In contrast, patients who were non-*BRCA1/2* mutants had an ORR of 11% and mPFS of

Table 2. Summary of ongoing trials evaluating the addition of ADC to ICI therapy

Trial name/ID	Phase	Patients enrolled	ICI	ADC	Primary endpoint(s)
ASCENT-04 NCT05382286	III	Treatment naïve advanced/metastatic TNBC	Pembrolizumab	Sacituzumab Govitecan	PFS
NCT04448886	II	Metastatic HR+/HER2- breast cancer who have progressed on or within 12 months of adjuvant endocrine or ≥ 1 endocrine therapy in the metastatic setting	Pembrolizumab	Sacituzumab Govitecan	PFS
NCT03310957	I/II	Advanced/Metastatic TNBC	Pembrolizumab	SGN-LIV1A	ORR, DLT, adverse events
Morpheus-TNBC NCT03424005	Ib/II	Metastatic TNBC	Atezolizumab	Sacituzumab Govitecan or SGN-LIV1A	ORR, adverse events
InCITe NCT03971409	II	Metastatic TNBC	Avelumab	Sacituzumab Govitecan	ORR
Astefania NCT04873362	III	Patients with residual invasive disease in breast/axillary lymph nodes following neoadjuvant chemotherapy	Atezolizumab	Trastuzumab emtansine	Invasive disease-free survival
KATE3 NCT04740918	III	Metastatic PD-L1-positive cancer after progression on H +/- P and taxane	Atezolizumab	Trastuzumab emtansine	PFS, OS
NCT03032107	I	Metastatic breast cancer on progression on prior H and a taxane	Pembrolizumab	Trastuzumab emtansine	Safety and tolerability
NCT04042701	Ib	Metastatic HER2 positive or HER2 low breast cancer	Pembrolizumab	Trastuzumab deruxtecan	DLT and ORR
NCT03523572	I	Metastatic breast cancer progressed on ≥ 2 anti-HER2-based regimens	Nivolumab	Trastuzumab deruxtecan	DLT, ORR
DESTINY-Breast07 NCT04538742	Ib/II	Metastatic 2nd line and beyond (Part 1) and 1st line (Part 2)	Durvalumab	Trastuzumab deruxtecan	Safety and toxicity
DESTINY-Breast08 NCT04556773	I	Advanced or metastatic HER2-low breast cancer	Durvalumab	Trastuzumab deruxtecan	Safety and toxicity

ADC: Antibody-drug conjugate; DLT: dose-limiting toxicities; ICI: immune checkpoint inhibitor; ORR: objective response rate; OS: overall survival; PD-L1: programmed cell death ligand-1; PFS: progression-free survival; TNBC: triple-negative breast cancer.

2.1 months. The MEDIOLA trial^[97] studied the combination of olaparib and durvalumab as first or second-line therapy in germline *BRCA1/2* mutant metastatic TNBC, noting an ORR of 63%, mPFS of 8.2 months and mOS 21.5 months. Table 3^[96-101] summarises some of the available trials evaluating this combination.

Tumour cells can also evade immune surveillance by altering any step in the antigen presentation pathway, thereby conferring resistance to treatment with ICIs. Several studies involving patients with breast cancer have reported the downregulation of expression of the transporters TAP1, TAP2, and TAPBP, which are necessary for transporting antigens to be loaded onto MHC molecules^[102-104]. Other mechanisms that have been observed include loss of heterozygosity and epigenetic suppression of certain MHC-I molecules^[105] or alterations in the expression of beta-2-microglobulin (B2M) which is essential for the transport and subsequent expression of MHC-I on the cell surface^[105,106]. Luo *et al.* reported the potential use of DNA methyltransferase inhibitors to overcome resistance to immunotherapy in breast cancer patients^[107].

TUMOUR EXTRINSIC MECHANISMS OF RESISTANCE TO IMMUNOTHERAPY

Alteration of the tumour microenvironment

The TME comprises various components that are constantly evolving, with ongoing crosstalk between tumour and stromal cells, all of which can influence the immune response and drive resistance to ICIs^[73]. The presence of TILs in the tumour and its surrounding microenvironment is thought to be a reflection of pre-existing antitumour immunity^[49,50], and its presence is thought to be predictive of response to systemic anti-cancer treatment^[50], and a prognostic biomarker^[24]. TNBC and HER2-positive breast cancers have a

Table 3. Summary of ongoing trials evaluating the addition of PARPi to ICI therapy

Trial name/ID	Phase	Patients enrolled	ICI	PARPi	Primary endpoint(s)	Results (if any)
TOPACIO/ KEYNOTE-162 NCT02657889	I/II	Advanced or metastatic TNBC	Pembrolizumab	Niraparib	DLT and ORR	ORR 21%, 47%, 11% (overall, BRCA mutant, BRCA wild-type) ^[96]
NCT04683679	II	Metastatic TNBC or HR+/HER2- breast cancer	Pembrolizumab	Olaparib	ORR	
NCT03101280	Ib	Previously treated metastatic TNBC with BRCA mutation or BRCA-like molecular signature	Atezolizumab	Rucaparib	Number of dose modifications due to adverse events	
NCT02849496	II	Advanced or metastatic non-HER2-positive breast cancer with homologous DNA repair deficiency	Atezolizumab	Olaparib	PFS	
NCT04690855	II	Germline BRCA1/2 negative, PD-L1 positive metastatic TNBC	Atezolizumab	Talazoparib	ORR	
MEDIOLA NCT02734004	I/II	Germline BRCA mutated metastatic HER2-negative breast cancer	Durvalumab	Olaparib	DCR, safety, and tolerability	DCR at 12 weeks 80%, 28 weeks 50% ORR 63.3% ^[97]
DORA NCT03167619	II	Platinum-treated metastatic TNBC	Durvalumab	Olaparib	PFS	Combination arm: mPFS 6.1 mo, DCR 68.2% ^[98]
DOLAF NCT04053322	II	Advanced ER+, HER2- breast cancer with BRCA mutation, alteration in homologous recombination repair or MSI	Durvalumab	Olaparib	PFS

JAVELIN PARP Medley NCT03330405	Ib/II	Advanced/ metastatic TNBC or HR+/HER2- breast cancer	Avelumab	Talazoparib	DLT and ORR	ORR 18.2% and 34.8% (TNBC, HR+/HER2-) ^[99]
JAVELIN BRCA/ATM NCT03565991	II	BRCA or ATM mutant advanced or metastatic solid tumour	Avelumab	Talazoparib	ORR	ORR 26.4% (BRCA) 4.9% (ATM) ^[100]
TALAVE NCT03964532	I/II	Advanced breast cancer	Avelumab	Talazoparib	Safety and toxicities	
NCT03945604	Ib	Recurrent, metastatic TNBC	Camrelizumab (anti-PD-1)	Fluzoparib	DLT	mPFS 5.2 mo, 12 mo OS 64.2% ^[101]

DCR: Disease control rate; DLT: dose-limiting toxicities; ICI: immune checkpoint inhibitor; MSI: microsatellite instability; ORR: objective response rate; OS: overall survival; PARPi: poly(ADP-ribose) polymerase inhibitors; PD-L1: programmed cell death ligand-1; PD-1: programmed cell death protein-1; PFS: progression-free survival; TNBC: triple-negative breast cancer.

higher number of TILs^[51,52]. Other components of the TME include Tregs, MDSCs, tumour-associated macrophages (TAMs), and cytokines.

Tregs suppress effector T cells and APC via secretion of inhibitory cytokines, direct contact, and limiting inflammation^[108]. The increased infiltration of Tregs into tumour cells has been observed in several other tumour types^[109,110], and murine studies have demonstrated that depleting Tregs from the TME can help to restore antitumour immunity^[109].

The presence of MDSCs in the TME has also been shown to promote angiogenesis, immune evasion, tumour growth and metastasis^[108]. A study of patients with melanoma treated with CTLA-4 inhibitors

suggested that the increase in MDSCs was associated more often with non-responders^[111]. Interestingly, the γ isoform of PI3K has been noted to be highly expressed in MDSC cells in a study of several cancer types, including breast cancer^[112], and selectively inhibiting it can help to re-establish sensitivity to ICIs^[113].

Another important group of cells present in the TME that promote immunosuppression and play a role in resistance to immunotherapy are TAMs, which consist of M1 and M2 macrophages^[114]. M1 macrophages are mainly involved in antitumour immunity, while M2 macrophages are pro-tumourigenic. The accumulation of TAMs is regulated by cytokines, such as chemokine ligand 2 (CCL2), which was demonstrated by Qian *et al.* in their study using breast cancer-bearing murine model^[115], as well as colony-stimulating factor-1 (CSF-1). It was observed to be correlated with increased macrophage infiltration and more frequent metastases in breast cancer patients^[116]. Indeed, studies that evaluated CSF-1 receptor inhibition in combination with ICI treatment showed synergy of both agents and promising tumour regression, suggesting that CSF-1 receptor inhibitors can help to overcome tumour resistance to immunotherapy^[117,118].

Besides individual populations of cells, the make-up of various cytokines present in the TME is also important in immune cell recruitment, activation, and proliferation by its balance of both stimulatory and suppressive effects^[119]. For example, cytokines such as transforming growth factor β (TGF- β) induce immunosuppression by upregulating Tregs and inhibiting cytotoxic T lymphocytes^[120]. Tumour cells also express ecto-5'-nucleotidase (CD73), which is an enzyme that dephosphorylates adenosine monophosphate (AMP), forming adenosine^[121]. Adenosine is a potent immunosuppressor that binds to A2A receptors found on lymphocytes and suppresses its function^[122]. Breast cancer cells have been shown to express CD73^[123], and its expression appears to be regulated by the estrogen receptor (ER), whereby the loss of ER enhances the expression of CD73^[124]. A proof of concept study confirmed that anti-CD73 antibody therapy can trigger adaptive antitumour immunity and inhibit metastasis in breast cancer^[125].

Upregulation of other immune checkpoints

Resistance to ICIs can also be achieved via upregulation of other immune checkpoints such as T-cell immunoglobulin, mucin domain-3 protein (TIM-3), LAG-3, V-domain immunoglobulin suppressor of T-cell activation (VISTA), B and T lymphocyte attenuator (BTLA), and T-cell immunoreceptor tyrosine-based inhibition motif domain (TIGIT)^[108,126-128]. The co-expression of multiple immune checkpoints has been demonstrated to be associated with T cell exhaustion, and subsequently resistance to ICIs^[129]. Targeting these alternative pathways represents potential therapeutic options for overcoming drug resistance to ICIs. Although most studies evaluating such combination strategies have been in other tumour types such as melanoma and NSCLC^[130-132], these are still relevant in breast cancers as epigenetic modifications resulting in upregulation of multiple immune checkpoints such as PD-L1, CTLA-4, TIM-3, and LAG-3 have been observed, and correlated with poorer patient prognosis in a study of breast cancer patients^[133]. A study that specifically included breast cancer patients was a phase I study of LAG525, a monoclonal antibody blocking the binding of LAG-3 to MHC-II in combination with spartalizumab (an anti-PD-1 antibody) in patients with advanced malignancies, which showed durable responses^[134]. In particular, 2 out of 5 patients with advanced TNBC showed a response, and in TNBC tumour biopsies, a trend in the conversion of immune-cold to immune-activated biomarker profiles was reported^[134].

CONCLUSION: CHALLENGES AND FUTURE DIRECTIONS

Aside from resistance mechanisms to ICIs, there are also many unresolved and unanswered questions that have limited the use of ICIs in breast cancer. These include identifying the best predictive and prognostic biomarkers to guide treatment, evaluating the optimal duration of ICIs in the neoadjuvant/adjuvant setting,

and chemotherapy backbone in the metastatic setting, just to name a few. Recent review articles have discussed some of these topics^[135,136].

Further advancement in this field needs to be led by sound science with good preclinical evidence from appropriate murine tumour models that can reflect the human immune environment. While this has conventionally largely been restricted due to a limited selection of murine tumour models, novel syngeneic tumour murine models have been better able to mirror the genomic heterogeneity of human cancer, and recapitulate the TME so as to provide accurate results. It is hoped that the use of appropriate novel syngeneic tumour murine models will allow us to further study ICI combinations effectively and accurately^[137].

Lastly, studies looking beyond immunotherapy-based treatments are also being investigated. One such area is the study of the human gut microbiome, a host factor that influences not only the biology of tumour development but also the modulation of its response and resistance to immunotherapy^[138-140]. Consequently, there are ongoing studies looking at modifying the gut microbiota in order to increase the efficacy of immunotherapy treatment. These include interventions such as the use of antibiotics, probiotics, faecal microbiota transplantation, and diet and prebiotics^[141].

There is much to be anticipated in this evolving field of immunotherapy in breast cancer. While previously thought to be an immunologically “cold” cancer with limited responses to ICI, this is certainly set to change. The numerous ongoing trials evaluating ICIs in combination with novel therapies to overcome resistance and exploit the immune system, as well as the development of innovative immunomodulatory strategies, will allow us to further harness and expand the role of immunotherapy in breast cancer.

DECLARATIONS

Authors' contributions

Conceptualization: Wong RSJ, Ong RJM, Lim JSJ

Original draft writing: Wong RSJ, Ong RJM

Abstract

Drug resistance that affects patients universally is a major challenge in cancer therapy. The development of drug resistance in cancer cells is a multifactor event, and its process involves numerous mechanisms that allow these cells to evade the effect of treatments. As a result, the need to understand the molecular mechanisms underlying cancer drug sensitivity is imperative. Traditional 2D cell culture systems have been utilized to study drug resistance, but they often fail to mimic the 3D milieu and the architecture of real tissues and cell-cell interactions. As a result of this, 3D cell culture systems are now considered a comprehensive model to study drug resistance *in vitro*. Cancer cells exhibit an *in vivo* behavior when grown in a three-dimensional environment and react to therapy more physiologically. In this review, we discuss the relevance of main 3D culture systems in the study of potential approaches to overcome drug resistance and in the identification of personalized drug targets with the aim of developing patient-specific treatment strategies that can be put in place when resistance emerges.

Keywords: Drug resistance, 3D culture system, extracellular matrix, tumor microenvironment, personalized medicine

INTRODUCTION

One of the most significant challenges in cancer treatment is drug resistance. Cancerous cells can possess an intrinsic resistance to therapy or they can develop an acquired resistance to chemotherapy and other

targeted therapies, leading to treatment failure and disease progression^[1-3]. The development of drug resistance in cancer cells is a multifactor event and involves numerous mechanisms that allow these cells to evade the effect of treatments. Intrinsic drug resistance can be defined as the innate resistance to drugs that are present inside the cells prior to the administration of any kind of treatment. It can be caused by (i) inherent genetic mutations that impair the response of cancer cells to drugs; (ii) intratumoral heterogeneity characterized by the presence of subclones, including cancer stem cells, which are insensitive to drugs; (iii) activation of defense mechanisms against environmental toxins. On the other hand, acquired resistance is defined as the progressive reduction of the efficacy of a treatment after its administration, which can be due to: (i) the surge of secondary mutations in proto-oncogenes that could become the new driver genes; (ii) mutation or dysregulation of the expression of the target of the therapy; (iii) dynamic alterations in the tumor microenvironment (TME). The mechanisms underlying intrinsic and acquired drug resistance could co-exist during tumor progression^[3-5]. During the last decades, many different therapeutic approaches to overcome drug resistance have been tested. Combinatorial drug therapy (two or more drugs at the same time) has been used extensively and simultaneous multitargeting seems more effective in fighting drug resistance. It has been observed that cancers treated with the highest dosage of chemo- or targeted therapies rapidly become resistant to the treatment and new therapeutic approaches are based on “on and off” strategies. The intermittent treatment could interrupt the growth of resistant subpopulations inside the tumor^[6]. Unfortunately, this kind of approach has also shown limitations and researchers are working hard to find new strategies to tackle drug resistance^[3]. There is an urgent need to find new model systems to complement traditional 2D cell culture systems that are still the golden standard in the study of drug resistance. Researchers around the world are focusing on finding new systems to better model intrinsic and acquired resistance in tumors with the final aim of studying and tackling tumor drug resistance.

For years, cell culture systems have had an intense effect on the field of biomedical research for studying the molecular mechanisms of cancer progression and developing new therapies and treatments. Traditional 2D cell culture systems are the most commonly used preclinical models for different reasons: (i) easy to handle; (ii) relatively low costs; and (iii) suitable for high throughput analysis. Many anticancer drugs have been discovered thanks to the National Cancer Institute cancer cell line panel (NCI60), and the relevance of these models has been further supported by large pharmacogenomic screens such as the Genomics of Drug Sensitivity in Cancer, the Cancer Cell Line Encyclopedia, and the Cancer Therapeutics Response Portal^[7-10]. Drug-adapted cancer cell lines are easily handled and they allow the establishment of a large number of models in a given timeframe and at a given cost. Even if the procedure is quite long (several months), the protocol is quite straightforward and the rate of success in establishing these models pretty high^[11]. Clinically relevant mechanisms of resistance have been discovered using these models^[12]; however, they cannot mimic intra-tumor heterogeneity, the 3D milieu, and the architecture of real tissues and cell-cell interactions. As a result, 3D cell culture systems are nowadays considered a more comprehensive model to study drug resistance *in vitro*. For example, the heterogeneous traits of a tumor, such as hypoxia, genetic status, and altered gene expression, can be more genuinely analyzed in 3D models rather than in 2D models^[13,14]. Consequently, using 3D cell culture systems can find more reliable and accurate outcomes. However, the setting of protocols for 3D models is quite a time-consuming procedure and not successful for all kinds of tumors.

ADVANTAGES OF 3D CELL CULTURE SYSTEMS

3D cell culture systems have recently emerged as a better option than conventional 2D cell culture systems for disease modeling, drug screening, and cancer research. In the section below, we want to briefly discuss the advantages of 3D cell culture over 2D cell culture.

3D cell culture systems mimic the *in vivo* microenvironment in comparison to 2D cell culture systems since they contain a higher degree of cellular organization, cell-cell interactions, and extracellular matrix (ECM) components. 3D cell cultures show a well-defined geometry, which could be directly related to function. Furthermore, inside these cultures, proliferating, non-proliferating, and necrotic cells are present, as in intact human tumors. In 3D cell systems, multicellular and multi-layered systems can be created and exploited to study the interactions between different cell types^[15-17]. A wide variety of organoids, involving mini-brains, intestinal tissue, and liver tissue, can be generated and organoids made of various cell types can mimic the organization of an organ, making them ideal for drug screening and drug response^[18]. The cellular heterogeneity obtained in 3D cultures models mass transport limitations typical of solid tumors. This allows for the designing of more precise models of disease, which can help develop effective treatments^[19]. On the same line, 3D cell culture systems offer the potential for personalized medicine, enabling the production of patient-specific organoids for personalized drug screening and treatment^[20].

3D cell culture systems can potentially offer better predictive outcomes for patients' drug responses^[21]. They are more suitable for evaluating drug bioactivity since they simulate the impacts of treatments compared to 2D cell cultures more precisely^[22]. Additionally, they are a more biologically applicable system for toxicology screening, as 3D systems provide more tissue-like structures and better simulate patients' status, which can help predict the effects of toxins more accurately^[23]. They are ideal, for example, for studying the influences of nanoparticles on cells, providing a more realistic test environment for nanotoxicity studies^[24].

Cell shape and environment are recognized as crucial in determining cell behavior and gene expression of a cell. In epithelial tumors, for example, polarity is essential, together with the formation of tight junctions and desmosomes linked to cell proliferation and tumorigenesis. In a 3D context, cells acquire a "normal-like" architecture and gene expression profile, while 2D monolayers on artificial support fail to maintain the original epithelial cell characteristics^[25]. Cancer stem cells, which are crucial for treatment response, are strongly dependent on the niche for differentiation. Inducing stem cell differentiation and tissue-specific functionality is a challenging process in 2D cell culture systems, while 3D cell culture systems can be used for this purpose^[26,27]. An important feature of 3D cell cultures is the remarkable control over the growth and differentiation of cells in complex tissue or organ-like structures that could be achieved, aiding researchers in simulating multifaceted disorder organization or physiological environments^[21].

3D cell culture systems are better tools for studying cell migration and invasion. Cells in 2D cell culture systems often move in a flat 2D environment, while cells in 3D cultures can exhibit more natural 3D migration and invasion, allowing for more precise modeling of cancer metastasis^[28]. Moreover, 3D cell culture systems can be used to study the impacts of mechanical forces on cancer cell movement^[29]. In theory, 3D cell culture systems can also be used to create substantial quantities of functional tissue, which may be used for transplantation or tissue engineering. This is specifically useful for applications such as skin grafts and bone regeneration^[30].

Even though 2D systems have been extensively used to study drug resistance due to their easy handling and relatively low costs, in the last few years, 3D culture systems have attracted the interest of researchers. Acquired resistance relies on different mechanisms, such as secondary mutations of proto-oncogenes or mutations or dysregulation of the expression of the target of the therapy and alterations in the TME^[31]. 3D systems could help in the study of this phenomenon. For example, RNA editing levels are significantly correlated with drug sensitivity in cancer cell lines and can be heavily influenced by tumor environment^[31]. By studying RNA editing in 3D cell culture models, researchers are able to investigate the relationship between RNA editing and drug sensitivity/resistance in a more physiologically relevant context.

Table 1 briefly summarizes the main differences between 2D and 3D culture systems.

DIFFERENT TYPES OF 3D CELL CULTURE SYSTEMS

The most relevant components of the tumor stroma are ECM proteins and stroma cells. The ability of cancer cells to proliferate, migrate, adhere, differentiate and the activation of specific cell signaling pathways strongly rely on changes in ECM composition^[32] and on the interactions of tumor cells with stroma cells^[33]. Cancer-associated fibroblasts (CAFs) are the most representative component in the tumor stroma, and they enhance cancer cell survival and the ability of cell invasion. They are involved in ECM remodeling and tumor metabolic rewiring, and contribute to the onset of drug resistance^[34]. Mesenchymal stem cells (MSCs), which support the epithelial mesenchymal transition (EMT) of various cancer cells, alter the immunocompetence of the TME, inducing drug resistance in tumor cells. Various immune cells such as tumor-associated macrophages (TAMs), lymphocytes, natural killer (NK) cells, and dendritic cells (DCs) have pivotal roles in tumor control. Crosstalk between endothelial cells (ECs) and tumor cells during the formation of new blood vessels is crucial in providing the required nutrients and oxygen for the growth of tumors^[33] [Figure 1]. Considering all these important interactions within the TME, cell-based 3D models have emerged as models which could closely recapitulate physiological tumor organization *in vitro*.

Essential cell-ECM interactions can be recapitulated by biomimetic scaffolds, where tumor cells are seeded inside a 3D platform made of a porous biomaterial where they attach, start to grow, rearrange, and secrete ECM. After this process, called “scaffold maturation”, the entire scaffold is completely covered by cells [Figure 2A]. Biomaterials present in scaffolds can be synthetic polymers, i.e., polyethylene glycol (PEG), polycaprolactone (PCL), poly(hydroxyethylmethacrylate) (PHEMA), poly(lactic-co-glycolic acid) (PLGA), and ceramics (i.e., hydroxyapatite or bioglass), which are often preferred over natural polymers because their properties can be more easily controlled^[35] and they can be functionalized by the addition of peptides which can modulate protein adsorption as well as cell adhesion^[36]. As far as natural biomaterials are concerned, collagen, fibrin, alginate, and chitosan can be derived from tissue and cells^[35]. Decellularized native tissues potentially allow for an easier recapitulation of tumor tissue and ECM architecture being closer to the *in vivo* condition; however, the decellularization process can be challenging since various steps (i.e., detergent and enzyme digestion) may affect tissue architecture.

Hydrogels are crosslinked networks formed by hydrophilic polymers connected through physical, ionic, or covalent interactions that highly resemble ECM^[37] and allow cells to behave and communicate in an *in vivo* setting^[35]. At first, cells are mixed with a precursor hydrogel, and then the hydrogel is crosslinked in order to obtain a cell-laden hydrogel. Cells start to grow and rearrange in the mature hydrogel, where they form cell clusters and secrete ECM, while the original hydrogel architecture remains intact [Figure 2B].

Scaffolds that are used to create complex 3D models can be obtained by 3D bioprinting, with the advantages of well-defined architecture, composition, and high reproducibility^[38]. A cell-laden bioink made of a precursor hydrogel and cells is prepared and deposited in a preprogrammed pattern using a 3D bioprinter; hydrogel is then crosslinked to form the final structure [Figure 2C]. Printing may be obtained through extrusion, inkjet, and stereolithography, as well as laser-assisted and electrospinning-based bioprinting^[39]. Scalability is one of the interesting features of 3D printed models. Indeed, it is possible to take into consideration 4D variables. Time, for example, is crucial for assessing the kinetics of growth factors, drugs or for following tumor cell dissemination over time^[40]. Prominent issues in the use of 3D printing techniques could be damaging pressure and excessive heating during the printing of living cells, as well as slow printing speeds and the continuous need for new biocompatible and printable bioinks^[41]. At the moment, however, insufficient reproducibility to create reference models is the main limitation. Despite

Table 1. Comparison of the main features of 2D and 3D culture systems

Aspect	2D cell culture	3D cell culture
Cell arrangement	Cells grow in a monolayer on a flat surface	Organoids, hydrogels, and other three-dimensional structures, such as scaffolds, allow cells to grow in a more natural spatial environment.
Cell-cell interactions	Limited	Improved, allowing for direct interaction between cells, cell signaling, and sophisticated cellular actions.
Cell-matrix interactions	Limited	An ECM that mimics the <i>in vivo</i> microenvironment interacts with cells, managing cell adhesion, migration, and differentiation.
Phenotypic expression	Changed compared to <i>in vivo</i> conditions	Provides a more accurate representation of <i>in vivo</i> environments, including tissue-specific gene expression, protein synthesis, and cellular responses.
Cellular functions	Basic, absent of tissue-specific functions and complex cell-cell interactions	It is possible to accomplish more intricate and organotypic processes, such as cell polarization, differentiation, barrier function, and the creation of tissue-specific substances.
Spatial organization	Homogeneous distribution of cells	Cells are capable of spatial organization, resulting in multicellular structures, gradients, and tissue-like structures.
Drug response	Useful to study different drug sensitivities in comparison to <i>in vivo</i> conditions	Improved cellular responses and interactions across various cell types provide better predictive capability for drug screening, enabling assessment of medication efficacy and toxicity.
Disease modeling	Limited capability to recapitulate intricate diseases and tissue interactions	Enables the creation of disease models that are more accurate, making it easier to research disease progression, find new drugs, and practice personalized treatment.
High-throughput screening	Well-suited for high-throughput analyses and screening purposes	Due to 3D culture's intricacy and additional experimental requirements, it is typically less suitable for high-throughput screening.

ECM: Extracellular matrix.

Tumor Heterogeneity and Drug Resistance

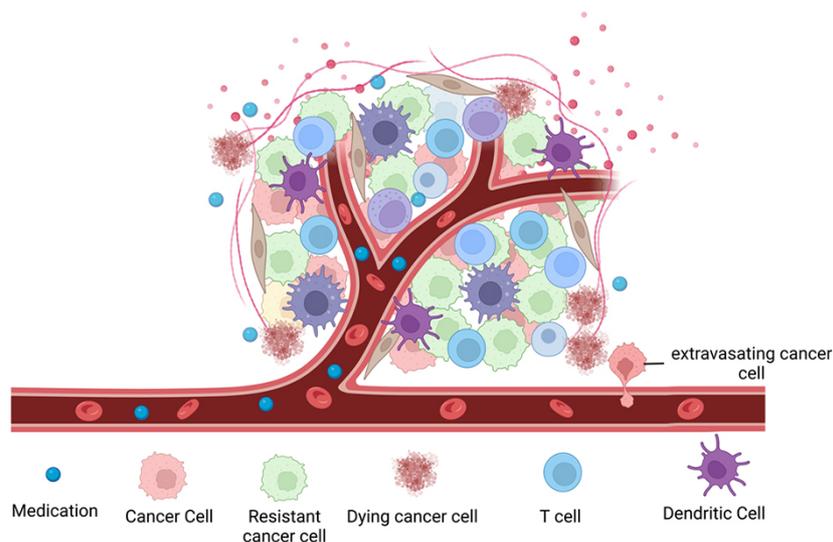

Figure 1. Tumor heterogeneity and drug resistance. Primary tumors are heterogeneous. Subpopulations of cancer cells showing partial or full resistance to therapy are present. The activation of resistance mechanisms can be due to the activation of genetic or epigenetic mechanisms that could be caused by the therapy itself and by the interaction of tumor cells with the microenvironment. This figure is generated with [Biorender.com](https://biorender.com).

these drawbacks, 3D bioprinting is a powerful technique since cancer and stroma cells are embedded in a complex microenvironment where tumor-stroma cell interactions, tumor-ECM contacts, and self-organization of the tissue could be deeply studied.

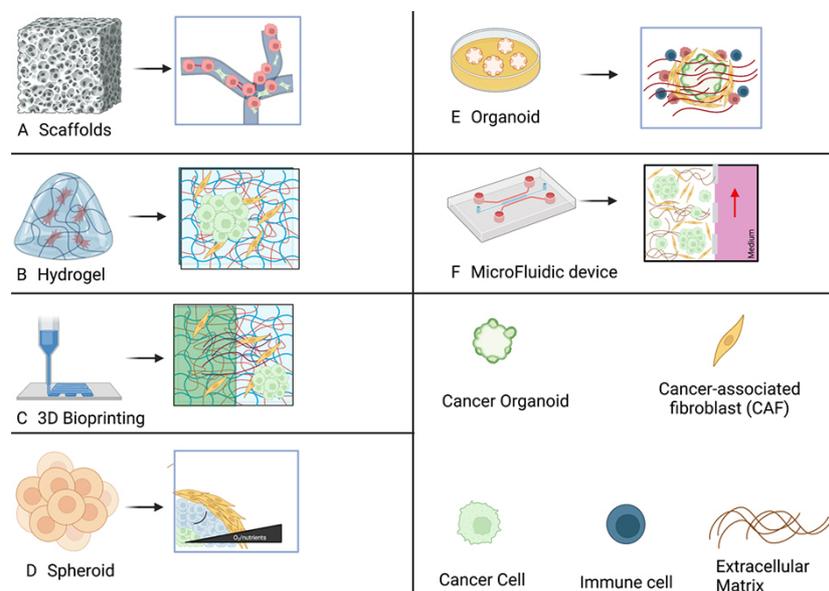

Figure 2. Schematic drawing of different 3D culture systems describing the main features of each system. (A) Scaffold. Cells, including immune cells, adhere to the scaffold, where they can proliferate and produce ECM, which coats the entire scaffold; (B) Hydrogel. Cells are combined with a hydrogel solution, which produces a sturdy framework that can support the cells. Cells divide and reorganize themselves; (C) 3D bioprinting. Cells are combined with hydrogel to produce bioink, a substance that can be printed using a 3D bioprinter. Depending on the type of bioink used, multiple cultures, including scaffold-based, scaffold-free, and semi-scaffold-free cultures, can be obtained; (D) Spheroid. Cells with significant cell-cell interaction are allowed to aggregate. As cells multiply, they rearrange themselves, and dense spheroids with oxygen or nutrition gradients could develop. Different kinds of cells can be combined in the spheroid; (E) Organoid. Cells are cultured in a hydrogel environment utilizing materials like Matrigel. Organoids are produced and are surrounded by other cells that replicate and produce natural ECM. Immune cell penetration can be simulated by adding immune cells to the culture; (F) Microfluidic device. Cells, spheroid, or organoids are plated onto the ready platform together with hydrogel, and then a medium containing nutrients can flow and perfuse the cells. Different kinds of cells can be added to the culture. This figure is generated with [Biorender.com](https://biorender.com). ECM: Extracellular matrix.

Spheroids [Figure 2D] contain important features that characterize tumors, such as cellular heterogeneity, gene expression variations, cell signaling pathway alterations, cell-cell, cell/ECM interactions, and multicellular layer organization, thus mimicking *in vivo* tumor morphology^[42]. For these reasons, they are widely used to study tumor biology and to evaluate anticancer drugs. Spheroids can be generated easily by hanging drop methods or spontaneous cell aggregation of cells grown on low-attachment surfaces; however, more sophisticated techniques, such as 3D bioprinting or magnetic levitation, are applied to obtain more homogenous spheroid populations both in size and number^[43]. Bigger spheroids (500 μm in diameter) can be used to recapitulate the milieu where micro-metastases develop since nutrients and oxygen are limited in those big structures^[44]. Spheroids are useful models to study cancers that form tumor embolus or cancers characterized by packed tumor cell clusters such as inflammatory breast cancers^[45,46]. In recent years, spheroid models have been implemented by the combination of different cell types in the same spheroids, i.e., tumor cells, monocytes, and CAFs, taking advantage of a particular technique utilizing spinner flasks^[47]. In order to evaluate the role of pancreatic stellate cells (PSCs) in pancreatic ductal adenocarcinoma (PDAC) cells resistance to gemcitabine and c-MET inhibitors, 3D-spheroid co-cultures of primary human PDAC cells and PSC (heterospheroids) were generated and compared with spheroids containing only PDAC cells (homospheroids). While heterospheroids were more resistant to gemcitabine compared to homospheroids, no difference was observed for c-MET inhibitor treatment, suggesting that the choice of 2D or 3D systems to study drug resistance is strongly dependent on the kind of drug under investigation^[48]. The main limitations of the use of spheroids are the poor uniformity in size/morphology of the obtained spheroids and often the difficulty in retrieving the cells for further molecular analysis^[46].

Spheroids are formed by forcing cell aggregation^[49], whereas organoids are obtained from progenitor cells that can proliferate, differentiate, and self-organize, thus closely recapitulating the 3D structure of the *in vivo* tissue/tumor from which they originate. As a result of this natural process, organoids preserve cancer cell heterogeneity as well as genetic and phenotypic properties of the tumor of origin [Figure 2E]. The significant feature of organoids is that they can be obtained from the patient's cells and represent a potential alternative to patient-derived tumor xenografts (PDX) and animal models in many aspects, i.e., they are less laborious and expensive^[50]. However, it has been observed that organoids could be helpful in predicting the responsiveness to therapy for some kinds of drugs but not for all. Ooft *et al.* developed patient-derived organoids (PDOs) from metastatic lesions of colorectal cancer (CRC) to identify non-responders to CRC standard therapy. While PDOs were able to predict the response in more than 80% of patients treated with irinotecan-based therapies, they failed to predict the response to 5-fluorouracil plus oxaliplatin, underlying once again the relevance of the choice of the system to study drug resistance^[51]. To implement organoid models, co-culture of PSCs and PDAC tumor organoids has been established, thus allowing the differentiation of PSCs into myofibroblast-like and inflammatory CAFs^[52]. More sophisticated organoid cultures can be obtained by 3D bioprinting^[53]. The main drawback of organoids is that, in some kinds of tumors, they are unable to reach *in vivo*-like levels, and often, the variability can be high between experiments. Lastly, organoids lack vasculature and stroma^[18].

Both cell-ECM and cell-based 3D models described so far have an important limitation: cells cannot be perfused inside the 3D organization. Microfluidics devices have been introduced in tumor modeling to overcome this issue. They consist of a network of channels that allows the control and modification of various parameters, for instance, mechanical forces, cell localization, and chemical gradients [Figure 2F]. Spheroids or organoids can be grown inside these platforms and thanks to the control of several factors, microfluidics can model tumor tissues and organs so these systems are called organ-on-a-chip devices. Another important point is that a small volume of reagents can be used due to miniaturization, thus reducing the costs of these kinds of cultures compared to the other 3D-culture methods^[54]. High-throughput screenings can be performed with increased controllability in microfluidics. The advent of 3D bioprinting has speeded up the process and reduced the costs. However, there is an urgent need for new materials to produce the chips, since the most common material used for this, polydimethylsiloxane (PMDS), can absorb small molecules in a nonspecific way. Microfluidics can be used to study tumor-stroma cell interactions because different cell types can be cultured in a chip^[54]. The possibility to tightly control multiple gradient candidates makes microfluidics the model of choice to analyze the effects of growth factors or drugs in a biomimetic microenvironment. The main limitation of microfluidics is that the fabrication of these devices requires specialized skills.

Table 2 highlights the main characteristics of the different 3D systems described above.

APPLICATIONS OF 3D CULTURE SYSTEMS IN DRUG RESISTANCE RESEARCH

3D cell culture systems have drawn substantial attention in the study of various aspects of drug resistance. Drug response and the mechanisms of drug resistance can be assessed using 3D cell culture models in a setting that is more physiologically suitable. Altered cell signaling, genetic variations, and tumor microenvironment interactions contribute to lower drug sensitivity due to tumor heterogeneity^[55,56].

3D cell culture platforms can be used for the screening and identification of new therapeutic agents that can overcome drug resistance. Through the use of these models, compound libraries may be tested in a more accurate tumor microenvironment, which helps researchers find new treatment combinations that are more effective at eliminating cancer cells that show intrinsic or acquired resistance. Ultimately, organoids and

Table 2. Comparison among the different 3D-culture techniques

Technique	Description	Advantages	Disadvantages	Ref.
Scaffolds	Cells are grown on or inside a three-dimensional scaffold structure	Mimics the structure of tissue and encourages cell differentiation	Limited control over the characteristics of the scaffold	[37]
3D bioprinting	A bioprinter is used to deposit cells layer by layer to produce intricate three-dimensional structures	Precise cell placement control; customizable	High-priced; limited scalability	[40]
Spheroids	Without an external scaffold, cells self-assemble into 3D spherical structures	Easy and inexpensive to produce; repeatable	Limited scalability, limited nutrient, and oxygen diffusion	[54]
Organoids	Three-dimensional self-organizing cell formations that resemble the functions and structures of organs	Reflects the complexity of the organ and models disease	Variability, complexity, and time-consuming generation	[18]
Microfluidics	Microscale channels that simulate <i>in vivo</i> tissue settings are used to cultivate cells, giving researchers great control over the culture environment.	High-throughput screening and accurate gradient control	Required technical knowledge; restricted scalability	[53]

tumor explants are examples of patient-derived 3D cell culture models that can be used to assess how each patient responds to a particular treatment. With the use of this strategy, precision oncology techniques can be guided by the discovery of individualized treatment plans and the prediction of patient-specific drug responses^[55].

3D cell culture systems to overcome drug resistance

Intratumor heterogeneity poses a significant obstacle to effective cancer therapy. Tumor subpopulations may respond differently to therapeutic interventions due to intrinsic drug resistance or the emergence of acquired drug resistance. Therefore, innovative research models to comprehend and address this complexity are needed.

CRC exhibits distinct subpopulations within clonal organoids: cells generating large spheroids (D-pattern) and cells generating small spheroids (L-pattern). S-pattern spheroids display chemotherapy resistance, but modulation of Notch signaling can push them towards the D-pattern, offering a potential therapeutic target to reverse chemoresistance^[57]. The nuclear tyrosine-protein kinase receptor 3 (TYRO3) receptor tyrosine kinase has been identified as an inducer of drug resistance and metastasis in CRC organoid culture and mouse models. TYRO3 function requires matrix metalloproteinase-2 (MMP-2) and bromodomain-containing protein 3 (BRD3), making selective inhibition of MMP-2 or BRD3 activity a potential strategy to ameliorate CRC malignancy^[58]. In understanding drug resistance mechanisms, mutational status plays a crucial role. For instance, KRAS codon G12 (KRASG12) mutations in metastatic CRC (mCRC) patients have been associated with increased resistance to trifluridine/tipiracil chemotherapy. This observation was paralleled in isogenic cell lines and PDOs, highlighting the relevance of 3D systems in studying drug resistance^[59]. In microsatellite instability-high (MSI-H) CRC, inflammation plays a pivotal role in disease progression and immunosuppression. *In silico* investigation highlighted a correlation between inflammatory conditions and poor response to programmed cell death-1 (PD-1) blockade. Cultures of paired T cells and organoid cells from patients confirmed this hypothesis, and single-cell RNA sequencing revealed the involvement of neutrophils in the suppressive immune microenvironment. An elevated neutrophil/lymphocyte ratio was associated with an impaired immune status and a poor response to immunotherapy, suggesting it could potentially serve as an indicator for clinical decision-making^[60]. In MSI-H CRC, resistance to immune checkpoint blockade has been observed in a specific subtype characterized by peritoneal metastases and ascites formation. To study the mechanism of immune checkpoint blockade, PDOs were transplanted into the cecum of humanized mice. It was found that immune checkpoint blockade led to reduced tumor masses and liver metastasis, driven by the formation of tertiary lymphoid structures (TLS) containing B cells, T cells, and an activated interferon- γ signaling pathway. However, peritoneal metastases lacked B cells and TLS, and T cells displayed a dysfunctional phenotype^[61].

3D cell culture systems, such as organotypic tumor spheroids and matched PDOs, have been instrumental in identifying effective treatment strategies to overcome resistance to cancer immunotherapy in other cancers. For instance, Sun *et al.* identified TANK-binding kinase 1 (TBK1) as a potent therapeutic target to enhance the response to PD-1 blockade in melanoma and other cancers. Inhibition of TBK1 reduced the cytotoxicity threshold to effector cytokines, thereby empowering the response to PD-1 blockade^[62].

Resistance to common chemotherapy treatments, such as 5-fluorouracil and cisplatin (5FU + CDDP), remains a major challenge. As mentioned above, RNA editing is correlated with the emergence of resistance^[31]; organoid lines from resistant patients with the intestinal subtype of gastric cancer (GC) showed upregulation of JAK/Src-signal transducer and activator of the transcription (STAT) signaling and adenosine deaminases acting on RNA 1 (ADAR1), along with hyper-edited lipid metabolism genes due to A-to-I editing on the 3'UTR of stearoyl-CoA desaturase (SCD1). SCD1 favored lipid droplet formation, reducing chemotherapy-induced ER stress and enhancing self-renewal in resistant GC lines^[63]. In another subset of GC known as stem-like/Epithelial-to-mesenchymal transition/Mesenchymal (SEM-type) GC, resistance to glutaminolysis inhibition was observed due to a stem-like population in the tumor. SEM tumors displayed high glutaminase (GLS) levels and upregulation of the 3-phosphoglycerate dehydrogenase (PHGDH)-mediated mitochondrial folate cycle pathway to produce NADPH. A potential treatment strategy to combat chemotherapy resistance in SEM-type GC involves the combined inhibition of GLS and PHGDH to eliminate stemness-high cancer cells^[64].

Chemoresistance in PDAC is quite common, and there is an urgent need to identify new targets and compounds to improve treatment outcomes. A biobank of human PDAC organoid models was established and used to screen FDA-approved compounds, leading to the discovery of irbesartan, an angiotensin type 1 (AT1) receptor antagonist. Irbesartan inhibits the Hippo/YAP1 pathway, reducing c-Jun expression and enhancing chemotherapy effectiveness in killing PDAC cells. High c-Jun expression in PDAC patients was associated with poor response to the standard chemotherapy regimen (gemcitabine plus nab-paclitaxel)^[65]. Loss of cyclin dependent kinase inhibitor 2A (CDKN2A) (encoding p16INK4A) and activation of KRAS play crucial roles in PDAC development and malignant growth. Restoration of p16INK4A with CDK4/6 inhibitors (CDK4/6i) alone has shown limited efficacy in clinics. However, combinatorial treatment with a CDK4/6i and an ERK-MAPK inhibitor synergistically suppresses tumor growth through blocking CDK4/6i-induced compensatory upregulation of ERK, PI3K, antiapoptotic signaling, and MYC expression in PDAC cell lines and organoids^[66]. Neoadjuvant chemotherapy (neoCTx) is used to treat PDAC, but its effects vary among patients. PDOs generated from PDAC tissues allowed researchers to evaluate differential responses to FOLFIRINOX or Gem/Pac regimens. This approach could help personalize poly-chemotherapy regimens, avoiding severe side effects and increasing the number of patients who benefit from complete neoadjuvant treatment^[67].

TME strongly influences the treatment outcome and new therapies targeting the cells of the TME are emerging. PDAC and cholangiocarcinoma (CCA) progression and chemoresistance are influenced by CAFs. In co-cultures of primary PDAC organoids and patient-matched CAFs, CAFs displayed a pro-inflammatory phenotype, while organoids showed increased expression of genes associated with EMT and drug resistance. This suggests that targeting CAFs could improve treatment sensitivity in PDAC and CCA^[68]. CAFs also contribute to drug resistance in CCA. In PDOs consisting of epithelial and matched CAFs, CAFs were relatively resistant to bortezomib treatment due to an overexpression of CXCR4. However, the addition of a CXCR4 inhibitor reversed the resistance to bortezomib in CAFs and sensitized CCA to anti-PD1 treatment, offering a promising triple treatment strategy for CCA patients^[69].

Pyroptosis is a gasdermin-driven lytic programmed cell death triggered by inflammatory caspases that can be put to good use to kill cancer cells, including those exhibiting chemo- or targeted therapy resistance. Su *et al.* have demonstrated that pyroptosis can be reactivated in resistant pancreatic and lung cancer cell lines and organoids by administering a Src or ceramidase inhibitor. In resistant cancer cells, the β 5-integrin protein plays a crucial role in controlling chemotherapy-induced pyroptosis, leading to chemoresistance. This effect is mediated through the upregulation of the sphingolipid metabolic enzyme ceramidase (ASAH2) expression, which is regulated by the STAT3 signaling pathway. The increased ceramidase expression results in a reduction of the metabolite ceramide concentration and subsequent suppression of reactive oxygen species (ROS) production, effectively blocking chemotherapy-induced canonical pyroptosis^[70].

In conclusion, intratumor heterogeneity presents a significant obstacle to the development of effective cancer therapies. There are now more ways to understand and deal with this complexity thanks to the use of sophisticated models such as organoids and 3D cultures. These models have highlighted possible treatment targets and drug combinations to potentially overcome drug resistance.

3D cell culture systems to investigate drug resistance mechanisms

Inhibitors of receptor tyrosine kinases (RTKs) are commonly used in cancer treatment. However, in head and neck squamous cell carcinoma (HNSCC), despite the high expression of epidermal growth factor receptor (EGFR), RTKI treatment often fails to show therapeutic efficacy in clinical trials, questioning their inclusion in standard therapy regimens. To understand the reasons behind these failures, researchers evaluated the response of HNSCC cell lines to RTK inhibitors under both 2D and 3D cell culture conditions. Interestingly, the HNSCC cells displayed strong resistance to lapatinib, an RTKI, when cultured in 3D conditions. However, in a 2D setting, the same cells responded to the lapatinib treatment. This resistance was associated with an overexpression of HER3. These results indicate that the increased cell-to-cell contacts and enhanced communication between cells due to higher cell density, as well as the augmented concentration of receptors and intracellular signaling molecules of the EGFR family in 3D systems, could impact drug response. Moreover, in 3D systems, cells live in hypoxic and nutrient-poor conditions and behave as dormant cells that are less susceptible to cytostatic treatment, leading to increased resistance. This finding indicates that the culture conditions can alter cell signaling pathways, potentially leading to different drug resistance mechanisms in cancer therapy^[71].

Glioblastoma (GBM) is a challenging cancer with poor patient prognosis and frequent tumor recurrence. Due to the resistance of certain subpopulations, such as mesenchymal and glioma stem cells, to the standard chemotherapy drug temozolomide (TMZ). Small protein kinase inhibitors have also been extensively studied for GBM treatment, but their benefit for patients has been limited compared to standard therapy regimens. Fabro *et al.* investigated the effects of prolonged treatment with TMZ, enzastaurin, and imatinib on patient-derived GBM 2D and 3D organotypic multicellular spheroid models. They observed a heterogeneous inter-patient response to the different drugs, with minor changes in kinase activation, primarily associated with the ErbB signaling pathway. Additionally, they identified a new resistance mechanism to imatinib treatment in one 3D sample, resulting in a more invasive behavior. The authors suggest the stroma cell interactions present in 3D structures could exert a protective effect on tumor cells against TMZ action^[72]. In other studies, using 3D collagen scaffold culture and 3D Ca-alginate scaffolds, researchers analyzed the gene expression profiles of GBM cells. Glioma cells cultured in 3D collagen scaffolds exhibited increased colony and sphere formation and increased drug resistance compared with 2D cultures. The hub genes involved in 3D collagen-induced drug resistance (AKT1, ATM, CASP3, CCND1, EGFR, PARP1, and TP53) were predicted by bioinformatics and their expression was verified by Western Blot analysis^[73].

Glioma cells cultured in 3D Ca-alginate scaffolds exhibited significant changes in gene expression compared with 2D cultures, with upregulation of genes related to mitogen-activated protein kinase signaling, autophagy, drug metabolism through cytochrome P450, and ATP-binding cassette transporter, and downregulation of genes related to the cell cycle and DNA replication. This altered gene expression could be due to the fact that the 3D-collagen culture may enhance the stemness traits of glioma cells compared to 2D conditions^[74]. These findings provide valuable insights into the differences in gene expression between 2D and 3D culture systems and their potential implications for drug resistance in GBM.

Biomimetic collagen scaffolds have been used as models to study the tumor hypoxic state and may be valuable tools in predicting chemotherapy responses in breast cancer (BC). Triple negative (TN) and luminal A BC cells were treated with doxorubicin in 2D cultures, 3D collagen scaffolds, or orthotopically transplanted murine models. In 3D culture conditions, TN cells displayed impaired drug uptake, increased drug efflux, and drug lysosomal confinement, contributing to drug resistance. Luminal A cells, on the other hand, were found to be insensitive to DNA damage due to deregulation of the p53 pathway. Transcriptome analysis identified a signature of deregulated genes that were validated in BC patients, showing their potential as predictive biomarkers. Transporter associated with antigen processing 1 (TAP1) and tumor protein p53-inducible protein 3 (TP53I3) showed high expression and were associated with shorter relapse in ER+ breast tumor patients, while high expression of lysosomal-associated membrane protein 1 (LAMP1) was associated with the same clinical outcome in TNBC patients. Resveratrol treatment with subsequent hypoxia inhibition partially re-sensitized cells to doxorubicin treatment, highlighting the relevance of these 3D preclinical models in the study of resistance mechanisms. Conversely, data obtained in monolayers were not able to recapitulate *in vivo* conditions and efficacy was overestimated when tested in a 2D context^[75]. To investigate recurrence mechanisms in ER+ BC, tumor organoids were generated from needle biopsy, surgical excision, and cerebrospinal fluid samples. Next generation sequencing (NGS) analysis revealed detrimental mutations in PIK3CA and TP53 genes and mutations of unknown functions in BAP1, RET, AXIN2, and PPP2R2A. Drug screening in BC organoids allowed for the evaluation of drug toxicity and showed dynamic changes in tumor progression, reflecting the heterogeneity of BC and demonstrating their reliability as models for personalized medicine development^[76]. In ER+ positive BC cells, the recurrent deletion of 16q12.2 affects AKTIP, which governs tumorigenesis, specifically in ER+ positive BC cells. Its deletion is linked to ER α protein level and activity and triggers JAK2-STAT3 activation, an alternative survival signal in the absence of ER α activation. Consequently, ER α -positive PDOs become more resistant to ER α antagonists, but this resistance can be overcome by co-inhibition of the JAK2/STAT3 signaling pathway^[77].

These papers show the applications of 3D cell culture platforms in the study of the mechanisms behind treatment resistance in various cancers in comparison with 2D systems. In order to design targeted therapies, it is now possible to identify specific molecular pathways and cellular interactions that contribute to resistance through the use of 3D models.

Potential use of 3D cell culture systems to identify individual drug response

In recent years, personalized medicine has made considerable progress, allowing tailored treatments for each patient. One of the potential advancements in personalized medicine is the development of 3D cell culture models, which could hold the potential for addressing individual drug resistance.

Anderle *et al.* pioneered the creation of a 3D system of epithelial ovarian cancer (EOC) comprising patient-derived microtumors and autologous tumor-infiltrating lymphocytes (TILs). By employing reverse-phase protein array (RPPA) analysis of over 110 total and phospho-proteins on these models, they measured

patient-specific sensitivities to standard platinum-based therapy and predicted individual treatment responses. The inclusion of autologous TILs in 3D cultures facilitated testing patients' responses to immune checkpoint inhibitors (ICIs). The therapeutic sensitivity predictions obtained through 3D systems hold clinical relevance post-surgery for patients' treatment. Ongoing follow-up studies in larger cohorts aim to validate the effectiveness of this platform for guiding clinical decision-making^[78].

A significant milestone was achieved by Senkowski *et al.*, who leveraged viably biobanked tissues to establish organoids from high-grade serous ovarian cancer (HGSC). These organoids faithfully recapitulated the original tumors in terms of both genetics and phenotype, as evidenced by genomic, histologic, and single-cell transcriptomic analyses. Furthermore, when cultured in a human plasma-like medium, organoid drug responses correlated with clinical treatment outcomes, highlighting the potential of these models for predicting patient responses to therapy^[79].

The significance of 3D systems in predicting drug responses and the development of resistance has led to the establishment of international consortia conducting multicenter studies to validate the clinical relevance of these models.

The INFORM program, an international precision oncology initiative, enrolled 132 pediatric cancer patients with relapsed or refractory conditions. In a two-year pilot study, fresh tumor tissue spheroid cultures were exposed to a library of clinically relevant drugs. The drug sensitivity profile (DSP) results from the multicellular tumor tissue spheroid cultures correlated with known molecular targets (BRAF, ALK, MET, and TP53 status). Remarkably, drug vulnerabilities were identified in 80% of cases, and the correlation between clinical outcomes and DSP results in selected patients suggests the potential advantage of this platform in predicting individual treatment responses^[80].

3D models are also proving useful in predicting individual responses to radiotherapy (RT) in various tumor types. For instance, Lee *et al.* cultured HNSCC patient tumor cells in a 3D pillar/well array culture system, exposing them to standard radiation protocols and evaluating their RT response. This approach allowed the quantification of the radioresponse index in HNSCC patients^[81]. Similarly, a HNSCC organoid biobank comprising 110 models, including 65 tumor models, was established. Organoids exposed to chemo-radiotherapy and targeted therapies demonstrated drug response correlations with patient clinical outcomes. Notably, *in vitro*, organoid response to RT closely mirrored patients' clinical responses^[82].

In the context of mCRC, which often develops resistance and has limited therapeutic options, tumor-derived organoids are being used to assess individual drug sensitivity and explore new treatment avenues. In a phase 2 study involving 90 mCRC patients with progression after standard therapy, organoids derived from metastatic biopsies were cultured and evaluated for sensitivity to a panel of drugs. Patients were treated with the drug demonstrating the highest relative activity, resulting in a 50% progression-free rate at two months^[83]. Another study generated organoids from 40 mCRC patients and performed drug screenings, associating the results with patients' responses. In the future, these findings may support the potential use of organoids to generate functional data and to aid in clinical decision-making^[84]. The integration of PDO drug response with multi-omics data could likely lead to the identification of proteomic and gene expression signatures capable of predicting treatment response or resistance in advanced CRC. Drug sensitivity tests coupled with mass spectrometry and RNA-seq analysis revealed differential responses to oxaliplatin and palbociclib. Oxaliplatin resistance was linked to t-RNA aminoacylation processes, while high palbociclib responses were associated with MYC activation and T-complex protein ring complex (TriC) chaperonin protein enrichment^[85].

The complexity of protocols to generate PDOs has posed a challenge, prompting efforts to standardize these procedures. A novel microfluidics-based system known as the Pu-MA System has been introduced, coupled with high-content imaging and metabolite analysis, for the processing and multi-functional profiling of tumoroid samples from metaplastic BC subtype patients. High-content imaging and multi-parametric profiling revealed tumoroid sensitivity to specific drugs, closely mirroring primary tumor responses^[86]. In inflammatory BC, a living organoid biobank was established from locally advanced patients undergoing neoadjuvant chemotherapy. Organoids treated with neoadjuvant drugs demonstrated a response pattern that closely matched patients' clinical responses, suggesting that PDOs could predict neoadjuvant therapy outcomes in BC patients^[87].

Predicting clinical treatment responses in locally advanced or metastatic lung cancer (LC) patients using tumor organoids has also been explored. Wang *et al.* generated 212 LC organoids and conducted drug sensitivity tests for chemotherapy and targeted therapy. Organoids successfully predicted clinical treatment responses^[88]. In another study by Mazzocchi *et al.*, 3D LC organoids were fabricated from pleural effusion aspirate, a rare cell source. These organoids recapitulated lung tissue anatomy and exhibited lung-specific behavior compared to 2D cultures. While 2D cultures were more sensitive to chemotherapy, organoids better reflected the *in vivo* situation, underlining the relevance of 3D systems in studying drug responses and resistance emergence^[89].

In the context of GBM, the need for assays that predict drug responses prompted the establishment of a high-density 3D primary cell culture model from resected GBM tissue. These cultures accurately modeled GBM heterogeneity, including tumor and surrounding cells, and replicated histopathological traits of parent tumors. These 3D cultures effectively predicted chemotherapy responses within a brief period and correlated with patients' responses to TMZ therapy^[90]. Metabolic imaging based on NAD(P)H fluorescence lifetime imaging microscopy (FLIM) was applied to GBM organoids to predict anticancer treatment responses. This technique identified TMZ Responder and Non-Responder tumors shortly after surgery, with metabolic stratification aligning with molecular levels, demonstrating its potential for patient stratification^[91].

PDOs have also proven valuable in predicting responses to neoadjuvant chemotherapy (NAT) in PDAC patients. A PDO biobank was generated from patients receiving NAT and untreated patients. The response to NAT correlated with PDO chemotherapy response (oxaliplatin), highlighting the feasibility of rapid PDO drug screening shortly after tissue resection for optimal patient NAT regimen selection^[92].

Through standardization and integration with multi-omics data, 3D cell culture models offer improved patient outcomes across various cancer types, enabling precise prediction of drug reactions, therapeutic outcomes, and personalized treatment options.

CONCLUSION

Overall, 3D cell culture models may be of help in understanding the general and the patients' specific mechanisms of drug resistance by providing more physiologically relevant systems for disease modeling and drug screening. These models could allow for the identification of personalized drug targets and the potential development of patient-specific treatment strategies. However, standardization of culture protocols, characterization methods, and outcome metrics is essential for maximizing the clinical value of 3D cell culture models. For example, the choice of bio-materials used to generate 3D cultures is critical for the successful generation of organoids and the prediction of drug response. The comparison among patient-derived BC cells encapsulated in bioprinted PEG-derived hydrogels and gelatin-derived hydrogels (GelMA

and GelSH) showed that GelSH increased organoid formation ability and a better response to doxorubicin, EP31670, and paclitaxel treatments compared to 2D cultures and other matrices^[36]. To ensure repeatability among laboratories, efforts are being made to create standards and quality control procedures^[93]. Integrating 3D cell culture models with multi-omics data (genomics, transcriptomics, and proteomics) can provide a thorough understanding of disease causes and treatment responses. The combination of these datasets can enable the identification of molecular signatures and biomarkers for patient stratification and therapy choice^[94]. However, the fact that the 3D models cannot be used for all drugs without distinction needs to be considered. It has been shown, for instance, that organoids fail to predict the response to 5-fluorouracil plus oxaliplatin, while they are able to predict the response in more than 80% of patients treated with irinotecan-based therapies^[51]. Therefore, for some kinds of drugs, 2D culture models remain the elective systems to study the mechanisms of drug resistance^[12]. Despite this, 3D cell culture models hold tremendous potential for improving therapeutic approaches and ultimately enhancing patients' outcomes.

DECLARATIONS

Abstract

Cancer drug resistance has become one of the main challenges for the failure of chemotherapy, greatly limiting the selection and use of anticancer drugs and dashing the hopes of cancer patients. The emergence of supramolecular host-guest nanosystems has brought the field of supramolecular chemistry into the nanoworld, providing a potential solution to this challenge. Compared with conventional chemotherapeutic platforms, supramolecular host-guest nanosystems can reverse cancer drug resistance by increasing drug uptake, reducing drug efflux, activating drugs, and inhibiting DNA repair. Herein, we summarize the research progress of supramolecular host-guest nanosystems for overcoming cancer drug resistance and discuss the future research direction in this field. It is hoped that this review will provide more positive references for overcoming cancer drug resistance and promoting the development of supramolecular host-guest nanosystems.

Keywords: Supramolecular nanosystems, host-guest interaction, cancer drug resistance

INTRODUCTION

With the number of cancer cases increasing each year, cancer has become the second leading cause of death worldwide^[1]. Although chemotherapy remains the primary method of cancer treatment, its effectiveness is severely limited by cancer drug resistance^[2-5]. The occurrence of cancer drug resistance is associated with

multiple factors, including the overexpression of multidrug resistance gene (MDR1), anti-apoptotic protein (BCL-2), multidrug resistance-associated protein (MRP), and the enhanced activity of glutathione S-transferase (GST) and DNA repair enzyme^[6-8]. These factors can lead to decreased drug uptake, increased drug efflux, DNA damage repair, abnormal drug metabolism, and dysfunctional apoptosis, resulting in cancer drug resistance^[9,10]. Nanosystems have been widely used to overcome cancer drug resistance due to their ability to alter the way drugs enter cells, increase drug uptake, and improve drug stability^[11,12]. Common nanosystems used to overcome cancer drug resistance include liposomes, polymeric nanoparticles, and metal nanoparticles. However, there are still some problems in the application of these nanosystems. For example, drugs loaded in liposomes tend to leak in the circulatory system before reaching the tumor; polymeric nanoparticles have a high burst release effect; and metal nanoparticles have poor biocompatibility. These problems have led to the limited role of these nanosystems in overcoming cancer drug resistance^[13,14]. Therefore, it is urgent to develop a class of novel nanosystems to reverse cancer drug resistance.

Supramolecular chemistry is “chemistry beyond the molecule”^[15]. Supramolecules generally refer to organized aggregates formed by non-covalent interactions of two or more molecules, including electrostatic interaction, hydrogen bond, van der Waals force, and π - π interaction^[16-21]. By introducing supramolecules into the nanosystem, it is possible to construct a more promising new drug delivery system, supramolecular host-guest nanosystem, which provides a potential solution for cancer drug resistance^[22-28]. Compared with traditional nanomaterials constructed by covalent interactions, supramolecular host-guest nanomaterials constructed by non-covalent interactions have excellent dynamic reversibility and responsiveness to various stimuli (such as weak acidity, specific enzymes, and different redox environments)^[29-33]. Based on these advantages, supramolecular host-guest nanosystems can increase drug uptake, accurately release drugs, inhibit drug efflux, and protect the activity of drugs, which provide great possibilities for eliminating cancer drug resistance and promoting the progress of cancer treatment^[34-37].

In this review, we summarize the research progress of supramolecular host-guest nanosystems for overcoming cancer drug resistance over the past few years, including cyclodextrins, calixarenes, cucurbiturils, and pillararenes [Scheme 1]. Moreover, the challenges and prospects of supramolecular host-guest nanosystems for overcoming cancer drug resistance are discussed extensively. This review aims to provide valuable insights and contribute to the development of more effective ways to reverse cancer drug resistance.

CYCLODEXTRINS-BASED HOST-GUEST NANOSYSTEMS FOR OVERCOMING CANCER DRUG RESISTANCE

Cyclodextrins (CDs), a class of natural oligosaccharides obtained from the degradation of starch, are linked by glucopyranose units through α -1,4-glycosidic bonds [Figure 1]^[38,39]. The most common CDs contain six, seven, and eight glucopyranose units, respectively, known as α , β , and γ -CDs^[40,41]. CDs have hydrophobic cavities, which can encapsulate hydrophobic drug molecules to form host-guest complexes^[42-45]. In addition, these complexes can self-assemble into nanoparticles, greatly improving the efficiency of the drug (such as good water solubility, high stability, and low physiological toxicity)^[46-48]. Therefore, CDs-based host-guest nanosystems have the potential to reverse cancer drug resistance by increasing drug uptake and decreasing drug efflux^[49-51]. For example, Yang *et al.* constructed three nanomedicines based on β -CDs that enhanced the drug uptake and the toxicity of drug-resistant cells^[52]. Das *et al.* prepared a dual-responsive nanocarrier by embedding carbon nanotubes into β -CDs-based polymers, enabling the combination of cocktail chemotherapy with photothermal therapy, which was conducive to multidrug resistance reversal^[53].

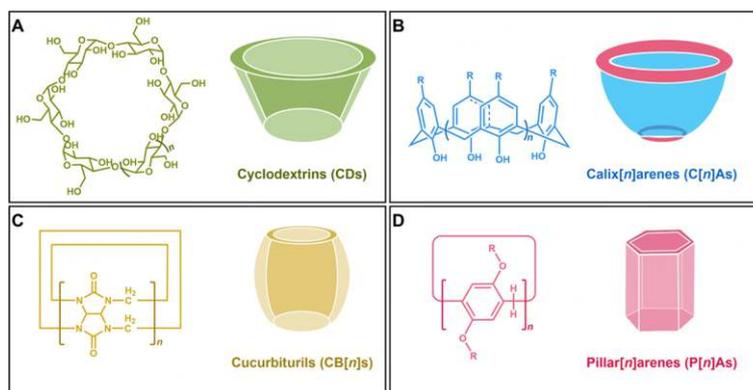

Figure 1. Schematic illustration of structures of (A) CDs; (B) calixarenes (C[n]As); (C) cucurbiturils (CB[n]s); and (D) pillararenes (P[n]As).

P-glycoprotein (P-gp) is an energy-dependent efflux pump located on the cell membrane^[54,55]. P-gp depends on the energy produced by ATP hydrolysis within the mitochondria to keep intracellular drug concentrations low by transporting drug molecules outside the cell, resulting in drug resistance^[56-58]. Therefore, drug resistance can be effectively reversed by inducing mitochondrial dysfunction. Wang *et al.* constructed a nanosystem (Aa-DOX + ADD@PC) based on a pH-sensitive graft copolymer (PBAE-g- β -CD) to achieve co-loading of the anticancer drug doxorubicin (DOX) and mitochondrial inhibitor (ADD) [Figure 2A]^[59]. When Aa-DOX + ADD@PC was endocytosed by tumor cells, DOX and ADD were released in the acidic environment for combined chemotherapy. Western blot assay was used to study the expression

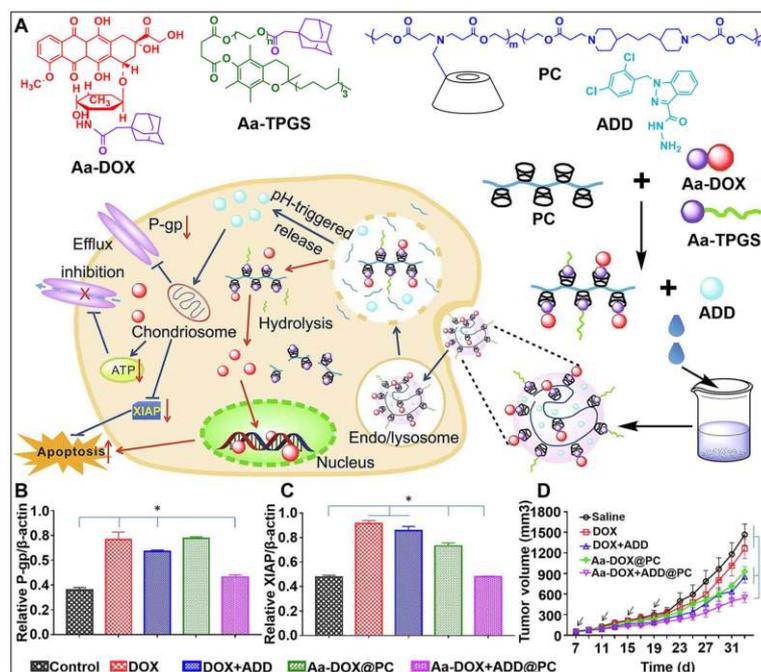

Figure 2. (A) Schematic illustration of dual-drug co-loaded nanoparticle (Aa-DOX + ADD@PC) for overcoming cancer drug resistance; The expression levels of (B) P-gp and (C) XIAP in MCF-7/ADR cells with different treatments; (D) Tumor growth inhibition curves of tumor-bearing mice after various formulations. levels of P-gp and X-linked inhibitor of apoptosis protein (XIAP), and it was found that Aa-DOX + ADD@PC showed the best inhibitory effect on P-gp and XIAP [Figures 2B and C]. Moreover, the therapeutic effect of Aa-DOX + ADD@PC was better than that of free DOX, significantly inhibiting the growth of drug-resistant tumors [Figure 2D]. In this work, the effective loading of mitochondrial inhibitors by CDs was used to successfully reverse drug resistance by decreasing drug efflux, providing a new therapeutic platform for overcoming multidrug resistance (MDR).

Furthermore, compared with free drugs, tumor cells can effectively take up nanomedicine, which is conducive to the reversal of drug resistance caused by low intracellular drug concentration^[60,61]. Liu *et al.* developed pH/redox dual-responsive DOX delivery nanosystems (DOX@RPMSNs) based on cationic β -cyclodextrin-PEI (PEI- β -CD) to overcome drug resistance of tumor cells [Figure 3A]^[62]. The poly (ethylene glycol) amine derivative shell (PEG-b-PLLDA) of DOX@RPMSNs could protect DOX@RPMSNs from safely reaching the vicinity of tumor cells, increasing the absorption of drugs by tumor cells. PEI- β -CD and DOX were sequentially released in response to the action of acid and glutathione (GSH) in tumor cells. DOX was used to kill tumor cells, and PEI- β -CD acted as an inhibitor to downregulate the expression of drug resistance-related P-gp by reducing ATP [Figure 3B]. Compared with other formulations, DOX@RPMSNs significantly inhibited tumor growth [Figures 3C and D]. These results indicated that DOX@RPMSNs successfully improved drug resistance reversal.

Histone-acetyltransferase (GCN5) is a silencing protein closely related to drug-resistance genes. Drug resistance caused by efflux can be reversed by down-regulating the expression of GCN5^[63,64]. RNA interference (RNAi) is a therapeutic technique that specifically targets mRNA and regulates the expression of silencing proteins^[65-67]. Yuan *et al.* exploited a nanosystem (DOX/siRNA@HPMSNs) to combine RNAi and DOX, which could knockout drug-resistance genes (Figure 3E)^[68]. The hyaluronan (HA) shell of DOX/

Figure 3. siRNA@HPMSNs could prolong the circulation time of DOX/siRNA@HPMSNs *in vivo* and target tumor cells, which promoted the accumulation of antitumor drugs. In the microenvironment of tumor cells, the effective release of siRNA could downregulate the expression of GCN5 to reduce the efflux of DOX caused by P-gp [Figure 3F]. Additionally, the inhibition rate of DOX/siRNA@HPMSNs on the growth of drug-resistance tumors was higher than DOX by evaluating the chemotherapeutic effects of different drug delivery systems [Figure 3G]. The two pH/redox dual-responsive nanosystems reduced drug efflux caused by the overexpression of P-gp in different ways, providing more possibilities for reversing MDR.

The acidic tumor microenvironment commonly found in solid tumors can reduce the endocytosis of free drugs and dissociate drug molecules^[69,70]. Therefore, pH-responsive supramolecular host-guest nanosystems have been widely developed to enhance cell internalization and protect drugs from dissociation^[71-73]. He *et al.* prepared a pH-responsive nanoparticle (Ac- α -CD NP) based on acetylated α -CD (Ac- α -CD), which

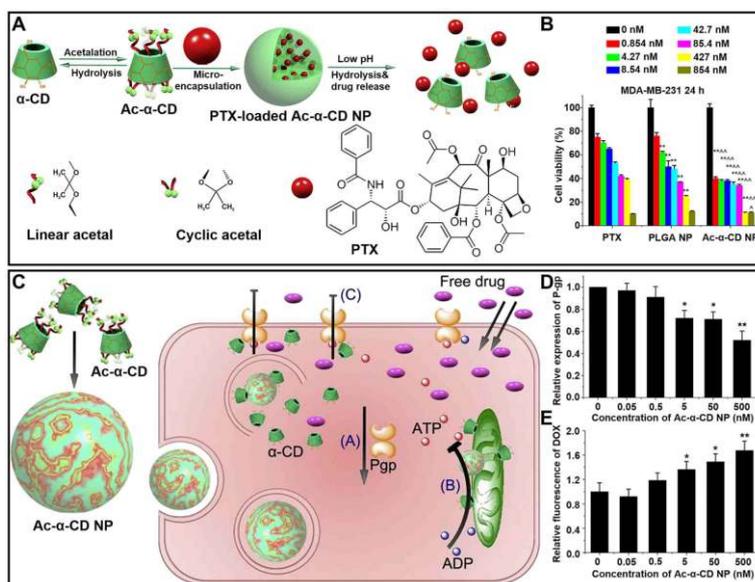

Figure 4. (A) Schematic illustration of the formation of pH-sensitive nanosystems (Ac- α -CD NP); (B) The cell viability of MDA-MB-231 cells treated with different doses of PTX, PLGA NP, and Ac- α -CD NP ($^*P < 0.01$). This figure is quoted with permission from He *et al.*^[74]; (C) Schematic illustration of the antitumor progress of Ac- α -CD NP in MCF-7/ADR cells; (D) The P-gp expression level; and (E) the accumulation of DOX with different doses of Ac- α -CD NP in MCF-7/ADR cells ($^*P < 0.05$, $^{**}P < 0.01$). This figure is quoted with permission from Shi *et al.*^[75]. CD: Cyclodextrin; DOX: doxorubicin; NP: nanoparticle; PTX: paclitaxel.

could stably encapsulate paclitaxel (PTX) [Figure 4A]^[74]. Ac- α -CD NP had a stronger inhibitory effect on the viability of breast cancer drug-resistant cells (MDA-MB-231) compared with free PTX and PLGA NPs [Figure 4B]. Moreover, Ac- α -CD NP exhibited good drug activity at a low concentration (0.854 nM), indicating its potential to kill drug-resistant cells.

Additionally, further studies showed that Ac- α -CD NP could also enhance the uptake and sensitivity of drug-resistant cells to DOX [Figure 4C]^[75]. α -CD was released by pH-induced hydrolysis of Ac- α -CD NP to inhibit the expression of P-gp and decrease the activity of ATPase, eliminating drug resistance caused by drug efflux [Figure 4D]. The changes in drug concentrations indicated that the downregulation of P-gp expression directly increased the accumulation of DOX in drug-resistant cells, thus achieving the purpose of inhibiting cancer drug resistance [Figure 4E]. Such pH-responsive supramolecular nanoparticles could not only inhibit the viability of drug-resistant cells at low concentrations but also increase the uptake and sensitization of drug-resistant cells to DOX, successfully reversing drug resistance from multiple angles.

Various star-shaped polymers can be obtained by modifying β -CD with different polymer chains^[76,77]. These polymers can further self-assemble into stable supramolecular host-guest nanoparticles after loading anticancer drugs^[78-80]. Compared with free drugs, nanoparticles are more easily internalized by tumor cells, reducing the efflux of drugs^[81-83]. These factors work together to eliminate cancer drug resistance^[84,85]. Chen *et al.* constructed a cationic β -CD-based nanocarrier that co-delivered PTX and Nur77 gene (an orphan nuclear receptor) to eliminate cancer drug resistance^[86]. In addition, they reported a nanoparticle based on a PEGylated star-shaped copolymer successfully reversed MDR1-induced drug resistance^[87].

Subsequently, they designed a new type of thermosensitive star-shaped polymer β -CD-g-(PEG-*v*-PNIPAAm), with “V”-shaped arms, which encapsulated PTX through the cavity of β -CD [Figure 5A]^[88]. The drug-loaded polymer further self-assembled into a stable supramolecular host-guest nanomedicine at

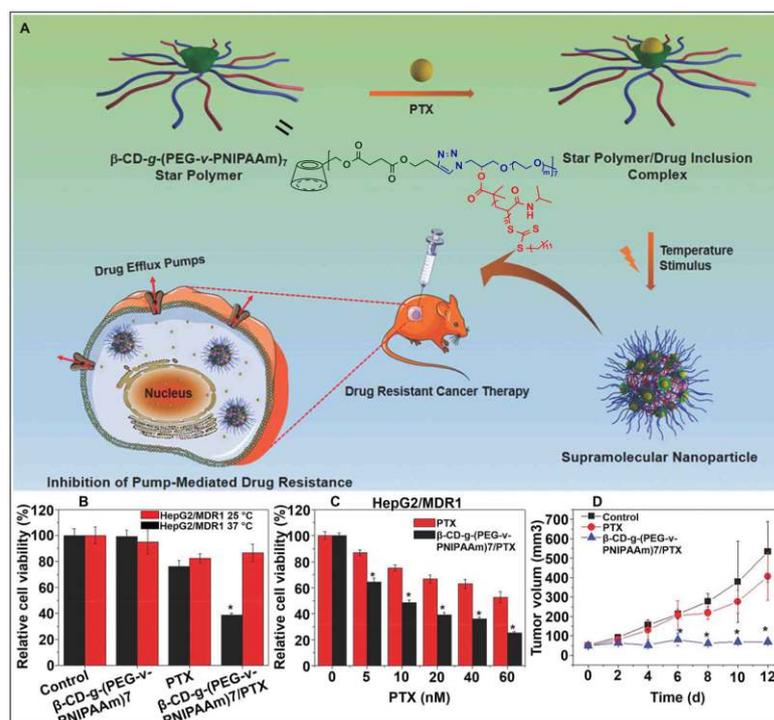

Figure 5. (A) Schematic illustration of supramolecular nanoparticle for inhibiting pump-mediated drug resistance; (B) Cell viability of HepG2/MDR1 cells treated with β -CD-g-(PEG-v-PNIPAAm)₇, PTX, and β -CD-g-(PEG-v-PNIPAAm)₇/PTX at different temperatures; (C) Changes in cell viability of HepG2/MDR1 cells treated with different doses of PTX and β -CD-g-(PEG-v-PNIPAAm)₇/PTX; (D) Tumor growth inhibition curves of tumor-bearing mice after various treatments ($P < 0.05$). This figure is quoted with permission from Fan *et al.* [88]. CD: Cyclodextrin; MDR1: multidrug resistance gene; PEG: poly (ethylene glycol); PTX: paclitaxel.

37 °C, greatly enhancing the retention of drugs in cells. Compared with other drugs, this supramolecular host-guest nanomedicine was more sensitive to the change of temperature, causing a sharp decline in cell viability at 37 °C [Figure 5B]. When the drug-resistance tumor was transplanted into mice and treated with PTX and nanomedicine, respectively, β -CD-g-(PEG-v-PNIPAAm)₇/PTX was more prominent in reducing cell viability [Figure 5C]. Additionally, there was no obvious change in tumor volume after treatment with β -CD-g-(PEG-v-PNIPAAm)₇/PTX [Figure 5D]. These results indicated that β -CD-based temperature-responsive nanomedicine had a good therapeutic efficacy against drug-resistant tumors.

Moreover, Li *et al.* constructed a unimolecular micelle based on a star-shaped polymer (β -CD-g-PCL-SS-PEG-FA) that stably encapsulated DOX [Figure 6A] [89]. The folic acid (FA) in the unimolecular micelle could target and penetrate tumor cells to increase the accumulation of DOX, inhibiting the cancer drug resistance caused by decreased drug uptake. The drug loaded in the unimolecular micelle could be released in response to GSH. MTT assay analysis indicated that β -CD-g-PCL-SS-PEG-FA had a better inhibitory effect on cell viability compared with free DOX [Figure 6B and C]. In addition, the overexpression of folate receptors on cervical cancer drug-resistant cells (HeLa/MDR1) accelerated the uptake of β -CD-g-PCL-SS-PEG-FA, enhancing the therapeutic effect of DOX on drug-resistant cells. Such β -CD-based stimuli-responsive supramolecular host-guest nanoparticles showed exciting results in overcoming cancer drug resistance due to the precise targeting, effective uptake, and controlled release of drugs.

CALIXARENES-BASED HOST-GUEST NANOSYSTEMS FOR OVERCOMING CANCER DRUG RESISTANCE

Calixarenes are a class of cyclic oligomers formed by methylene-bridging ortho-phenolic hydroxyl groups

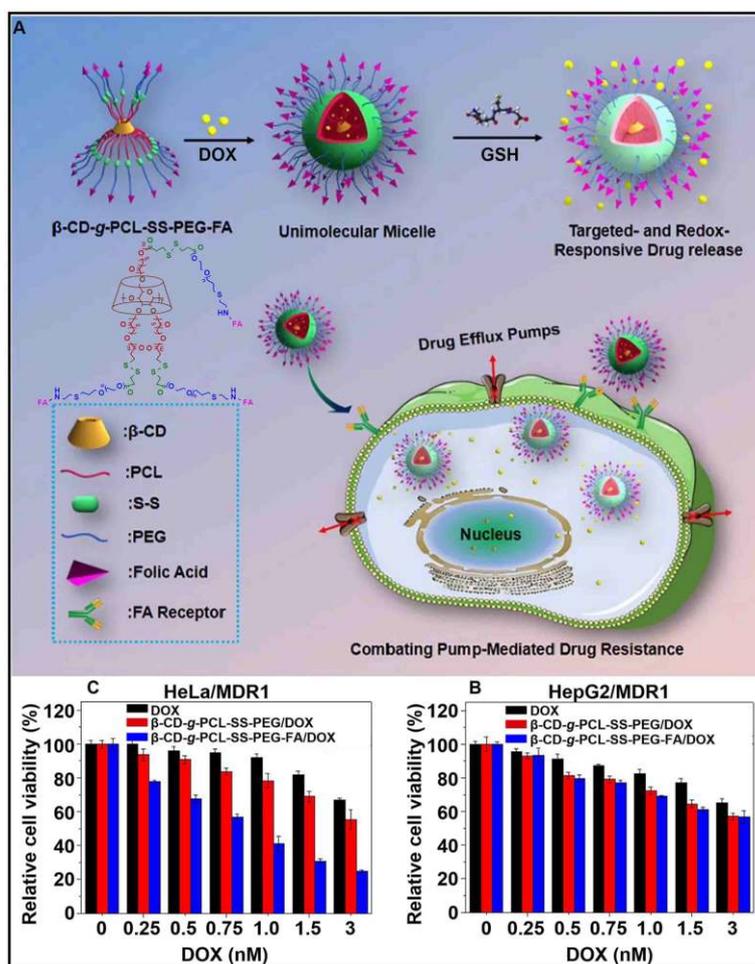

Figure 6. (A) Schematic illustration of a unimolecular micelle for inhibiting pump-mediated drug resistance; Cell viability of (B) HepG2/MDR1 cells and (C) HeLa/MDR1 cells treated with different doses of DOX, β -CD-g-PCL-SS-PEG/DOX, and β -CD-g-PCL-SS-PEG-FA/DOX. This figure is quoted with permission from Li *et al.*^[89]. CD: Cyclodextrin; DOX: doxorubicin; FA: folic acid; GSH: glutathione; MDR1: multidrug resistance gene; PEG: poly (ethylene glycol).

[Figure 1B]^[90-92]. Due to their molecular shapes similar to the Sangreal, they are named calix[n]arenes (C[n]As) by Gutsche^[93]. By introducing hydrophilic and hydrophobic groups at the upper and lower rims of C[n]As, respectively, amphiphilic C[n]As can be designed, which are easy to self-assemble into vesicles, nanoparticles, or other aggregates^[94-99]. Host-guest nanosystems based on C[n]As have low toxicity and good biocompatibility, becoming a new research hotspot in the field of cancer drug resistance^[100-102].

The close coordination between GSH and GST can initiate detoxification mechanisms within tumor cells, leading to the formation of drug resistance^[103-105]. For example, GST can catalyze the binding of GSH to electrophilic antitumor drugs, accelerating the degradation of drugs^[106-108]. Therefore, drug resistance can be reversed by regulating the GST. Recently, Dai *et al.* designed a nanomedicine (Pt-cCAV_{5-FU}) based on sulfonatocalix[4]arene for overcoming GST-induced cancer drug resistance [Figure 7A]^[109]. The GST regulator (5-FU) was encased into the hydrophilic core of Pt-cCAV_{5-FU} self-assembled from a host-guest complex of sulfonatocalix[4]arene with cisplatin. Pt-cCAV_{5-FU} actively released cisplatin and 5-FU during the hydrolysis process caused by esterase. 5-FU could downregulate GST activity, prompting cisplatin to damage DNA rather than binding to GSH [Figure 7B]. In addition, the endocytosis of cisplatin resistance cells A549/CDDP against Pt-cCAV_{5-FU} was stronger than that of A549, which increased the accumulation of

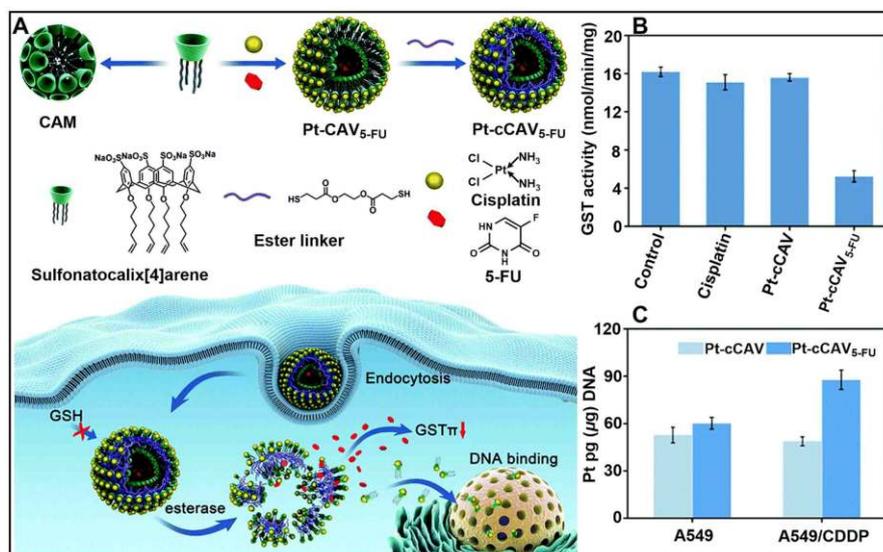

Figure 7. (A) Schematic illustration of Pt-cCAV_{5-FU} for overcoming cisplatin resistance in A549/CDDP cells; (B) The GST activity of A549/CDDP cells with different treatments; (C) Platinum content in the genomic DNA of A549 and A549/CDDP cells after incubation with Pt-cCAV and Pt-cCAV_{5-FU} for 12 h. cisplatin in cancer cells [Figure 7C]. All of these factors ultimately made Pt-cCAV_{5-FU} more toxic to drug-resistance cells. This work developed a novel nanomedicine, laying the foundation for C[n]As-based host-guest nanosystems to reverse cisplatin resistance.

Furthermore, although free DOX can kill the nuclear DNA (n-DNA) of tumor cells, the undamaged mitochondrial DNA (Mt-DNA) can trigger drug resistance^[110-112]. Therefore, the design of a drug to destroy synchronously n-DNA and Mt-DNA can promote the reversal of drug resistance^[113]. Nair *et al.* constructed a gold nanotherapy platform (TTNDV) based on sulfonatocalix[4]arene [Figure 8A]^[114]. The nanoplatform could encapsulate DOX and mitochondrion-targeted analogue (Mt-DOX) in an optimal ratio of 1:100 to reverse cancer drug resistance caused by mitochondrial escape. *In vitro* and *in vivo* experiments showed that TTNDV had less toxic side effects than free DOX. In addition, TTNDV had a stimulating response to temperature. Under near-infrared irradiation, drugs embedded in TTNDV were released simultaneously to kill n-DNA and Mt-DNA, successfully overcoming DOX resistance and improving the chemotherapeutic effect of DOX [Figure 8B]. This work solved the problem of DOX resistance by killing Mt-DNA to induce

apoptosis, providing a feasible strategy for reversing cancer drug resistance.

CUCURBITURILS-BASED HOST-GUEST NANOSYSTEMS FOR OVERCOMING CANCER DRUG RESISTANCE

Cucurbiturils (CB[*n*]s) are a kind of macrocyclic hosts constructed by condensation of glycoluril with formaldehyde under acid conditions, which are the fourth macrocyclic hosts after crown ethers, cyclodextrins, and calixarenes [Figure 1C]^[115-117]. According to the different number of glycoluril units, different types of CB[*n*]s can be obtained, and common cucurbiturils include CB[6], CB[7], and CB[8]^[118,119]. Due to their unique structures of hydrophobic cavity and hydrophilic port, CB[*n*]s are easy to form host-guest complexes with drug molecules and are promising materials for reducing side effects and enhancing the stability of antitumor drugs^[120-124]. In addition, CB[*n*]s-based supramolecular nanosystems can be used to effectively reverse cancer drug resistance^[125-128].

Cancer drug resistance is closely related to the inhibition of tumor apoptosis^[129,130]. Mitochondria serves as the center for regulating tumor cell apoptosis^[131,132]. Therefore, the destruction of mitochondria is also an effective way to overcome cancer drug resistance^[133-135]. Recently, Dai *et al.* synthesized a multivalent supramolecular polymer (HABMitP) by modifying HA with mitochondrial targeting peptide and 4-bromophenylpyridium [Figure 9A]^[136]. The combination of HABMitP, cisplatin, and CB[8] could promote mitochondrial aggregation, which led to the deterioration of mitochondria to release apoptosis-inducing factor (cytochrome C), thereby activating the apoptosis of tumor cells [Figure 9B and C]. Moreover, cisplatin-resistant tumors did not grow treated with CisPt + HABMitP + CB[8] for 14 days, indicating that assembly-induced mitochondrial aggregation significantly improved the antitumor efficacy of cisplatin [Figure 9D]. This study showed that the regulation of mitochondrial behavior was beneficial to the reversal of drug resistance, which provided a broad prospect for overcoming tumor drug resistance.

The inhibition of P-gp expression by reducing ATP concentration can reduce drug resistance in tumor cells^[137,138]. Wang *et al.* reported nanoparticles (SCC-NPs) based on CB[7], which encapsulated the anticancer drug oxaliplatin (OxPt) and mitochondria-targeting peptide (N-Phe-KLAK) by the excellent host-guest properties of CB[7] [Figure 10A]^[139]. Due to the special acid responsiveness and competitiveness of the polymeric shell, SCC-NPs were used for self-motivated supramolecular combination chemotherapy. In acidic tumor environments, the amidomethyl phenylamine moieties on the polymeric shell were restored to form host-guest complexes with CB[7], competing to replace and release OxPt and N-Phe-KLAK. The released N-Phe-KLAK could effectively inhibit the production of ATP, resulting in the damage of energy-dependent drug efflux pump [Figure 10B]. Additionally, the accumulation of OxPt in cells directly led to an increase in the number of apoptotic cancer cells, which successfully inhibited the viability of drug-resistance cells [Figure 10C and D]. Self-motivated supramolecular combination chemotherapy provided a new strategy for addressing the issue of cancer drug resistance.

The *Fusobacterium nucleatum* (*F. nucleatum*) with apoptosis-inhibiting effect can trigger drug resistance in colorectal cancer (CRC) cells^[140-143]. To address this issue, Yan *et al.* constructed a CB[7]-based nanomedicine (PG-Pt-LA/CB[7]) by multiple assemblies to overcome drug resistance [Figure 11A]^[144]. PG-Pt-LA/CB[7] targeted and penetrated cancer cells and released OxPt in response to the GSH. The efficient uptake and stable release of drugs increased the accumulation of OxPt in CRC cells. In addition, PG-Pt-LA/CB[7] showed the best inhibition effect on *F. nucleatum* compared to OxPt and PG-Pt-LA, successfully overcoming the drug resistance of CRC cells caused by *F. nucleatum* [Figure 11B]. A negligible growth in tumor volume was observed after 18 d of incubating tumors with PG-Pt-LA/CB[7], showing that PG-Pt-LA/CB[7] improved the chemotherapeutic effect of OxPt on CRC cells [Figure 11C]. PG-Pt-LA/CB[7] was

expected to be a good material for improving the effect of OxPt on CRC cells.

PILLARARENES-BASED HOST-GUEST NANOSYSTEMS FOR OVERCOMING CANCER DRUG RESISTANCE

Pillararenes (P[n]As) are a new type of macrocyclic hosts that bridge hydroquinone units through methylene discovered by Ogoshi *et al.* [Figure 1D]^[145]. These hydroquinone units are generally 5-10, with P[5]A and P[6]A being the most common^[146-151]. P[n]As are widely used in various fields such as drug delivery, ion recognition, adsorptive separation, sensors, and optoelectronic materials due to the characteristics of symmetrical rigid skeleton, adjustable electron-rich cavity, and easy functionalization^[152-154]. In addition, because of the highly attractive host-guest properties of P[n]As, more and more attention has been paid to the construction of P[n]As-based host-guest nanosystems to overcome cancer drug resistance^[155-157]. Liu *et al.* prepared a novel carboxylatopillar[5]arene-based supramolecular quaternary ammonium nanoparticle to overcome the drug resistance generated during the chemotherapy of CRC^[158]. Chang *et al.* constructed a redox-responsive cationic vesicle based on amphiphilic pillar[5]arene, successfully overcoming the drug resistance of tumors^[159].

The water-soluble pillar[6]arene (WP6) not only forms stable host-guest complexes with a variety of guest molecules but also exhibits good biocompatibility and stimuli-responsiveness, which offers the possibility for constructing supramolecular host-guest nanoplateforms to reverse cancer drug resistance^[160-166]. Shao *et al.* reported a host-guest complex (AWP6⊃G) containing anionic WP6 (AWP6) and prodrug (G), which further self-assembled to form nanovesicles for inhibiting cancer drug resistance [Figure 12A]^[167]. The nanovesicles released camptothecin (CPT) and chlorambucil (Cb) under the action of GSH to achieve combination chemotherapy. The dual-drug co-loaded nanovesicles showed a better inhibition effect on drug-resistance cells compared to the single drug [Figure 12B]. This study showed that P[n]As-based supramolecular host-guest nanosystems were expected to be ideal materials for inhibiting MDR.

Subsequently, Liu *et al.* prepared a nanosponge (NS) based on AWP6 using a “bottom-up” template preparation technique [Figure 12C]^[168]. Through the host-guest interaction, antitumor drugs and dyes were stably encapsulated in AWP6 to overcome MDR. The IC₅₀ of DOX@NS (3.4 μM) was significantly lower than that of free DOX (34.4 μM) when different doses of free DOX and DOX-loaded NS were incubated in drug-resistance cells [Figure 12D]. Mechanistic studies indicated that the effective loading and stable

This figure is quoted with permission from Yu *et al.*^[170]. AWP6: Anionic WP6; CPT: camptothecin; DOX: doxorubicin; FA: folic acid; GSH: glutathione; MDR: multidrug resistance; NS: nanosponge; PEG: poly (ethylene glycol); PIC: polyion complex.

encapsulation of DOX based on host-guest interaction were the main reasons for overcoming MDR. This work showed that the delivery of anticancer drugs through host-guest interaction was a promising way to overcome MDR.

Additionally, cationic WP6 (CWP6) can encapsulate ATP, blocking the energy of drug efflux^[169]. Yu *et al.* prepared a polyion complex (PIC) micelle by modifying CWP6 with functionalized diblock copolymer (FA-PEG-b-PAA) [Figure 12E]^[170]. PIC micelles could specifically target and penetrate cancer cells overexpressed with FA receptors. The decrease in extracellular fluorescence intensity indicated that CWP6 successfully blocked the energy source of calcein (model drug) efflux [Figure 12F]. In addition, PIC micelles significantly enhanced the inhibitory effect of DOX-HCl on cell viability compared with free DOX-HCl [Figure 12G]. These results suggested that the supramolecular nanomicelle endocytosed by drug-resistance cells and

released CWP6 to selectively form a host-guest complex with ATP, which provided a new method for blocking the energy of drug efflux and was expected to become an ideal material for overcoming cancer drug resistance.

In addition to blocking the energy source of P-gp expression, nitric oxide (NO) can also downregulate the expression level of P-gp, reversing the drug resistance of cancer^[171-173]. To achieve stable delivery and selective release of NO in tumor cells, Ding *et al.* designed supramolecular peptide nanomedicine (BPC/DOX-ICG) based on the host-guest complexation of anionic water-soluble [2]biphenyl-extended-pillar[6]arene (AWBpP6) with pyridinium-terminal-modified polypeptide (PPNC) [Figure 13A]^[174]. DOX and indocyanine green (ICG) loaded in BPC/DOX-ICG were used to simultaneously treat cancer cells with chemotherapy and photothermal therapy. S-nitrosothiol on PPNC released NO to downregulate the expression level of P-gp after near-infrared (NIR) irradiation. Western Blot analysis showed that the P-gp level in MCF-7/ADR cells was significantly reduced to 24.9% when treated with NIR irradiation and BPC/DOX-ICG [Figure 13B]. The reduced P-gp could greatly enhance the efficacy of chemotherapeutic drugs, inhibiting tumor growth [Figure 13C]. Therefore, P[n]As-based nanocarriers could effectively deliver NO to downregulate P-gp expression, providing a promising approach to eliminate cancer drug resistance.

Chloride channel protein is highly expressed in various cancer cells and has a significant correlation with tumor drug resistance^[175,176]. Yang *et al.* reported a supramolecular nanoprodruge (DOX@GP5⊃Pro-NFA) based on the host-guest complexation between galactose-modified pillar[5]arene (GP5) and chloride channel inhibitor prodrug (Pro-NFA) to reverse drug resistance [Figure 14A]^[177]. DOX@GP5⊃Pro-NFA was hydrolyzed under the action of esterase to release DOX and NFA, which could effectively block chloride ion channels, and reverse cancer drug resistance. Additionally, the inhibitory effect of DOX@GP5⊃Pro-NFA on tumor cells, especially drug-resistance cells, was significantly higher than that of free DOX [Figure 14B]. Moreover, poly(ADP ribose)polymerase (PARP) can repair DNA to directly lead to drug resistance^[178,179]. Yang *et al.* designed a nanoparticle (DOX@GP5⊃Pro-ANI) based on GP5 to load PARP inhibitor prodrug (Pro-ANI) that could inhibit DNA repair [Figure 14C]^[180]. DOX@GP5⊃Pro-ANI overcame tumor drug resistance by inhibiting the expression of PARP, effectively reducing the viability of drug-resistance cells [Figure 14D]. These studies showed that P[n]As could effectively load anticancer prodrugs, which opened up broad prospects for inhibiting the expression of proteins associated with drug resistance.

CONCLUSION

In summary, we reviewed the application of supramolecular host-guest nanosystems based on cyclodextrins, calixarenes, cucurbiturils, and pillararenes in overcoming cancer drug resistance. Compared with traditional small molecule drugs, nanosystems can effectively reduce the side effects of drugs and improve the accumulation of drugs in tumors. However, traditional nanosystems also have some drawbacks, such as lack of stimuli-responsiveness, difficulty in preparation and synthesis, and slow degradation *in vivo*. The emergence of supramolecular nanosystems complements the drawbacks of these traditional nanosystems. Due to their dynamic and reversible host-guest interactions, supramolecular nanosystems are endowed with rich stimuli-responsiveness to release drugs within tumors. Furthermore, supramolecular host-guest nanosystems have some advantages, such as high drug loading, low side effects, and good biocompatibility, which can co-deliver multiple drugs to inhibit cancer drug resistance by damaging mitochondrial function, blocking the energy source, inhibiting DNA repair, and reducing the level of GSH. However, supramolecular host-guest nanosystems still face some challenges in overcoming cancer drug resistance:

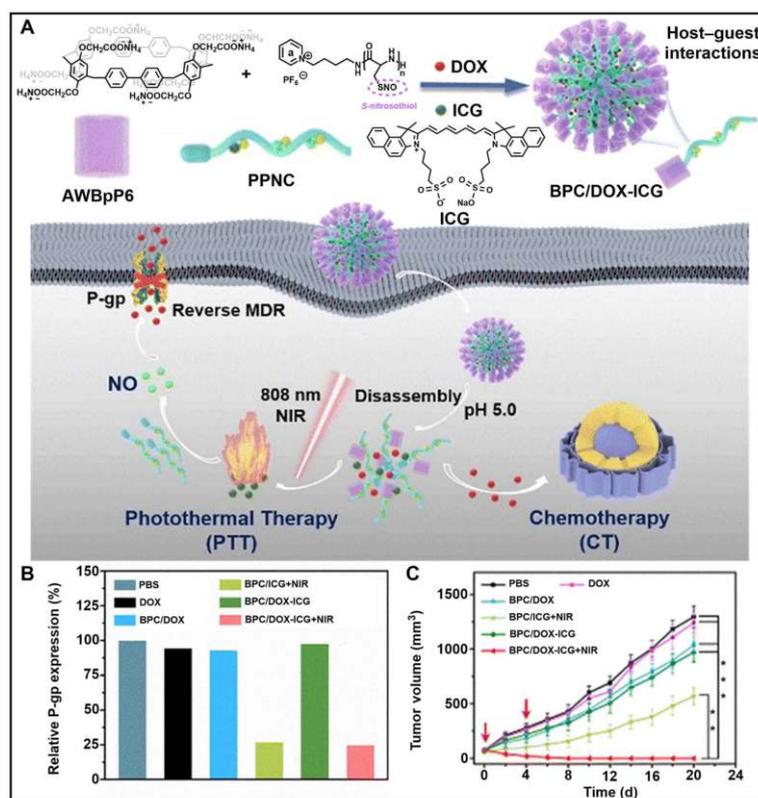

Figure 13. (A) Schematic illustration of synergistic PTT and CT using supramolecular polypeptide nanomedicine (BPC/DOX-ICG); (B) The P-gp expression levels in MCF-7/ADR cells with different treatments; (C) Changes of tumor volume in tumor-bearing mice with different formulations ($^{**}P < 0.01$, $^{***}P < 0.001$). This figure is quoted with permission from Ding et al.^[174]. DOX: Doxorubicin; ICG: indocyanine green; MDR: multidrug resistance; NIR: near-infrared; PPNC: pyridinium-terminal-modified polypeptide.

- (i) Further improve the targeting. Tumor cells differ from healthy cells in many ways, such as acidity, hypoxia, and metabolism. Thus, more specific supramolecular host-guest nanosystems should be developed by focusing on the tumor microenvironment to target and penetrate tumor cells, reversing cancer drug resistance caused by drug uptake;
- (ii) Optimize drug loading strategy. Although multidrug-loaded supramolecular host-guest nanosystems can inhibit drug resistance, their effects are difficult to predict due to the different pharmacokinetics of each drug. Therefore, it is necessary to optimize the combination and dosage of loaded drugs and design supramolecular host-guest nanosystems with excellent performances;
- (iii) Improve stability. Supramolecular host-guest nanosystems have rich stimuli-responsiveness, but at the same time, there are problems of poor stability. In future studies, the stimuli-responsiveness of supramolecule and the stability of macromolecule can be better combined to prepare supramolecular polymeric nanosystems to overcome cancer drug resistance;
- (iv) Promote the development of cancer synergistic therapy. At present, most supramolecular host-guest nanosystems used to overcome drug resistance of tumors remain at the level of drug delivery, which greatly limits the inhibitory effect on drug-resistance cells. Introducing other therapeutic methods (such as photodynamic therapy, gene therapy, and immunotherapy) into supramolecular host-guest nanosystems will help establish more accurate and personalized strategies to combat cancer drug resistance;
- (v) Enhance the clinical translation. While some preliminary studies have shown that supramolecular host-guest nanosystems can be used to overcome drug resistance in cancer, there is still a long way to go before clinical translation. Firstly, the pharmacokinetics, biodistribution, metabolic behavior, and toxicological

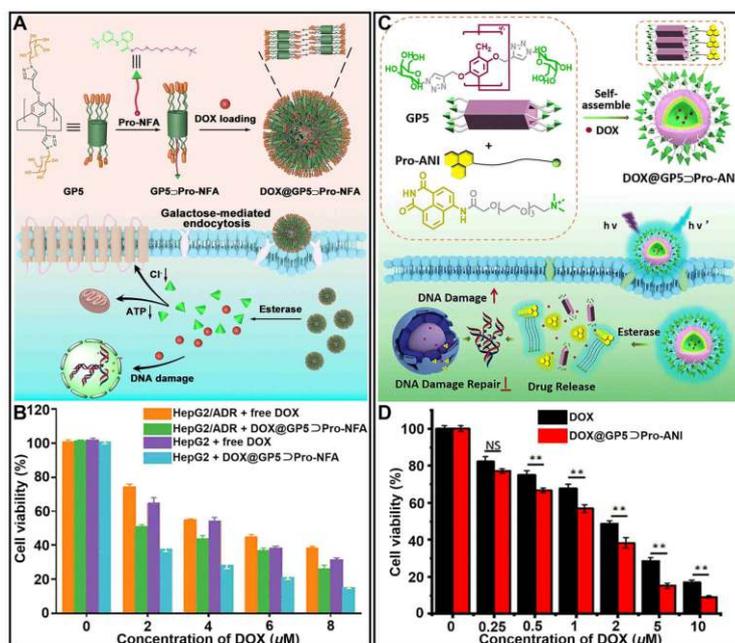

Figure 14. (A) Schematic illustration of the preparation of supramolecular nanoprodrugs DOX@GP5-Pro-NFA and their applications in overcoming cancer drug resistance; (B) Cell viability of HepG2 cells and HepG2/ADR cells treated with free DOX and DOX@GP5-Pro-NFA, respectively. This figure is quoted with permission from Yang et al.^[177]; (C) Schematic illustration of the preparation of supramolecular nanoprodrugs DOX@GP5-Pro-ANI and their applications in overcoming cancer drug resistance; (D) Cell viability of HepG2/ADR cells treated with free DOX and DOX@GP5-Pro-ANI ($P < 0.01$). characteristics of supramolecular host-guest nanosystems are still in the research stage, and there are still unpredictable risks to their safety. Secondly, *in vitro* and *in vivo* experiments of supramolecular host-guest nanosystems cannot completely mimic the complex microenvironment of tumors in the body, resulting in lower clinical therapeutic effects than expected. Thirdly, the large-scale production of supramolecular host-guest nanosystems is a bottleneck in clinical applications, and small changes in the manufacturing process can cause significant changes in their physicochemical properties, which will affect their safety and biological effects. Therefore, more basic research and clinical trials are needed to assess their safety, efficacy, and feasibility.

The development of supramolecular host-guest nanosystems offers new hope to alleviate drug resistance in cancer, although innovation and progress are still required in many aspects. We believe that with continued research efforts, supramolecular host-guest nanosystems will make further progress in reversing cancer drug resistance, and bring new breakthroughs for cancer treatment and even human health.

DECLARATIONS

Authors' contributions

Abstract

Chronic lymphocytic leukemia (CLL) is common amongst leukemic malignancies, prompting dedicated investigation throughout the years. Over the last decade, the treatment for CLL has significantly advanced with agents targeting B-cell lymphoma 2 (BCL2), Bruton's tyrosine kinase, and CD20. Single agents or combinations of these targets have proven efficacy. Unfortunately, resistance to one or multiple of the new treatment targets develops. Our review investigates various mechanisms of resistance to BCL2 inhibitors, including mutations in BCL2, alterations in the Bcl protein pathway, epigenetic modifications, genetic heterogeneity, Richter transformation, and alterations in oxidative phosphorylation. Additionally, the review will discuss potential avenues to overcome this resistance with novel agents such as bispecific antibodies, Bruton's tyrosine kinase (BTK) degraders, non-covalent BTK inhibitors, and chimeric antigen receptor T (CART).

Keywords: BCL-2 inhibitors, apoptosis, CLL, resistance, tumor microenvironments, cell cycle regulation, genetic mutations, epigenetics, richter transformation

INTRODUCTION

Chronic lymphocytic leukemia (CLL) has been the most common form of Leukemia in the developed world for the last decade, according to the Surveillance epidemiology and end result database^[1]. Treatment and,

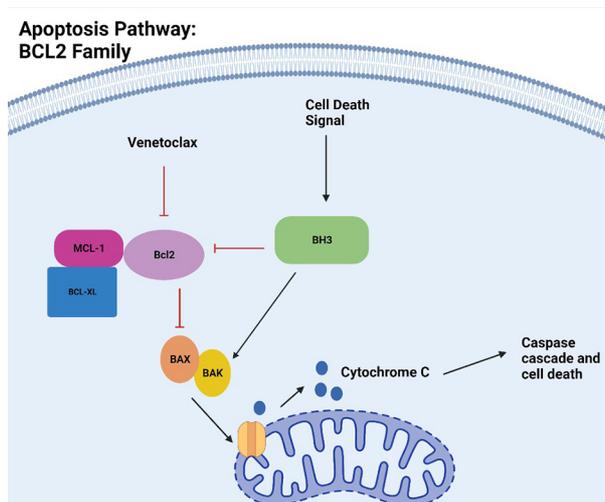

Figure 1. Apoptosis Pathway: BCL2 Proteins. Made with Bioreader with data from the following publications: Roy et al.^[11]; Youle et al.^[12]. BCL2: B-cell lymphoma 2.

therefore, overall prognosis have improved significantly during this time. Investigation into the pathophysiology of CLL allowed for the development of targeted agents, including Burton's tyrosine kinase (BTK) inhibitors, anti-CD20 monoclonal antibody, and B-cell lymphoma 2 (BCL2) inhibitors^[2]. Ibrutinib, a BTK inhibitor, proved to be an effective treatment of CLL in the first line^[3]. Venetoclax, a BCL2 inhibitor, was first utilized in relapsed disease alone and then in combination with rituximab [Table 1]^[4-10]. More recently, the combination of ibrutinib and venetoclax was approved for front-line treatment of CLL in Europe after findings from the GLOW trial [NCT03462719] and CAPTIVATE trials [NCT02910583]^[6,7] [Table 1].

Widespread use of venetoclax in hematologic malignancies prompted further research into the BCL2 apoptosis pathway, allowing for the identification of the key agents involved. From extensive research, we have found that in non-cancerous cells, after receiving a pro-apoptotic signal, the BH3-only proteins will activate additional proteins, BAX and BAK, by binding directly or by binding to anti-apoptotic proteins, BCL2, BCL-XL, MCL-1, thereby freeing these pro-apoptotic proteins to travel to the mitochondrial membrane forming pores, releasing cytochrome c which stimulates the caspase cascade for apoptosis^[11,12] [Figure 1]. Venetoclax promotes apoptosis by binding to BCL2, enabling the release of the pro-apoptotic proteins to trigger apoptosis^[13] [Figure 1]. Unfortunately, resistance to venetoclax develops by several distinct mechanisms, including mutations in BCL2, epigenetic pathways, alterations in oxidative phosphorylation, alterations in BCL2 pathway, tumor microenvironment, genetic heterogeneity, and Richter's transformation. We will discuss each of these mechanisms, focusing on the contributions to resistance in this review. Additionally, we will propose various methods to overcome the various resistance pathways.

BCL2 INHIBITOR RESISTANCE MECHANISMS

Genetic mutations in BCL2

Alterations in the substrate or target thereby conferring resistance is a common theme in biology and venetoclax resistance is no exception. A recent analysis of CLL patients who progressed on venetoclax found that 7 of the 15 patients developed a mutation, Gly101Val, in BCL2, which decreases the affinity of BCL2 for venetoclax by overcrowding the BH3 binding groove, thereby preventing venetoclax from displacing the pro-apoptotic proteins [Table 2]^[14-18]. Of note, the mutation was not detected prior to starting treatment but

Table 1. Venetoclax trials in CLL

Drug	Line of treatment	Target	Trial	Duration of treatment	Rate of Richter's transformation
Venetoclax + Ibrutinib	First line	BCL2 + BTK	GLOW ^[6]	Fixed	3 patients (2.8%) vs. 2 patients (1.9%) in control arm
Venetoclax + Ibrutinib	First line	BCL2 + BTK	CAPTIVATE ^[7]	Fixed	Not documented
Venetoclax + Ibrutinib	Relapsed/Refractory	BCL2 + BTK	CLARITY ^[8]	Fixed	0 patients
Venetoclax	Refractory, 17p mutated	BCL2	Phase II ^[9]	Till progression	11 patients (10.3%)
Venetoclax + Rituximab	Refractory	BCL2 + CD20	MURANO ^[5]	Fixed	6 patients (3.1%) vs. 5 patients (2.65%) in control arm
Venetoclax + Obinutuzumab	First line	BCL2 + CD20	CLL14 ^[10]	Fixed	2 patients (0.94%) vs. 1 patient (0.46%) in control arm

BCL2: B-cell lymphoma 2; BTK: Bruton's tyrosine kinase; CLL: chronic lymphocytic leukemia.

Table 2. Venetoclax resistance: mutations in BCL2

Mutation	Mutation type	Mutation site	Found in	Frequency in patients
Gly101Val ^[14]	Point	BH3 binding groove	CLL	7/15 (46.6%)
Phe104Ile ^[16]	Point	BH3 binding groove	Follicular lymphoma	1/1 (100%)
Gly101Ala ^[18]	Point	BH3 binding groove	CLL	1/11 (9%)
Asp103Tyr ^[15]	Point	BH3 binding groove	CLL	1/4 (25%)
Ala113Glu ^[18]	Point	Non-binding	CLL	1/11 (9%)
Phe104Cys ^[17]	Point	BH3 binding groove	Murine human-like MCL cell lines	NA

BCL2: B-cell lymphoma 2; CLL: chronic lymphocytic leukemia.

rather was detected after 19-42 months of treatment^[14]. Mutations that also confer resistance due to the impact on binding include Phe104Ile located at the venetoclax binding site of BCL2 and Asp103Tyr, an essential part of hydrogen binding of venetoclax which have been identified in follicular lymphoma and CLL, respectively^[15,16] [Table 2]. In mantle cell lymphoma cell lines, Phe104Cys and Phe104Leu missense mutations have also been found to alter the BH3 domain and therefore binding affinity^[17] [Table 2]. From a retrospective analysis of CLL patients whose disease was refractory to ibrutinib and resistant to venetoclax, multiple mutations including point mutations in Gly101Ala, Ala113Glu, Leu119Val, Asp113Glu and in-frame insertion of Arg107_Arg110 were observed^[18] [Table 2]. Of note, the BCL2 mutations were noted to be sub-clonal with a varying percentage of cells (from 7%-70%, vast majority < 50%), indicating multiple resistance patterns are likely involved^[14-18]. This finding would argue against these mutations representing so-called "driver mutations", but there is not enough evidence to definitively determine this. As the general CLL population is not tested for the above mutations given their rarity, it is impossible to give an overall frequency. From the original study identifying the G101V mutation, 21 out of 67 patients had progression on venetoclax, of which 15 samples were analyzed and roughly 50% (7 patients) developed the mutation after venetoclax as the mutation was not present prior^[14]. With further analysis into venetoclax-resistant patients, additional mutations conferring various changes in the structure of the BCL2 will likely be identified and methods to overcome these mutations will follow.

Epigenetic modifications

For the last decade, scientists investigated modifications of translation with gene activation or deactivation and the corresponding downstream effects. In the case of the BCL2 pathway, these epigenetic alterations may play a larger role in resistance than direct mutations in the BCL2 protein. A recent study used advanced molecular techniques including CRISPR, whole-exome sequencing, and methylated DNA immunoprecipitation sequencing to identify a regulatory CpG island within the PUMA (a BH3-only protein) promoter site which was shown to be methylated and therefore silenced gene expression (favoring oxidative phosphorylation and cell survival) after the administration of venetoclax, indicating resistance^[19]. This data was obtained from both CLL patients (6 patients) and VEN/S63845 resistant cell lines. Further proof of this concept was demonstrated by the restoration of venetoclax function (cell death) after inhibition of methyltransferases^[19].

Non-coding RNAs, including microRNA (miRNA) and long non-coding RNA (lncRNA), have been investigated extensively in the last two decades in CLL due to their involvement in cell cycle regulation among other cellular mechanics, thereby promoting resistance^[20-22]. Additionally, RNA cytosine methyltransferases NSUN1 and NSUN2 have been shown to induce venetoclax resistance in leukemic cells via interactions with RNA polymerase II extension complex, knocking down NSUN1 or NSUN2 returned sensitivity to venetoclax^[23]. Much is still not fully understood regarding these complex epigenetic regulations, as this is an area of future research and investigation.

Alterations in BCL2 pathway

As the BCL2 pathway is complex, alterations or upregulation of other components have also been the subject of investigation. Mutations in the effector proteins BAX/BAK may be venetoclax specific as one analysis found mutations in BAX followed venetoclax treatment in 30% of the patients but not after treatment with ibrutinib^[24]. Further, a mutation in the C terminal transmembrane domain (G179E) of BAX prevents the anchoring of BAX to Mitochondria, thereby blocking venetoclax-induced apoptosis^[17,25].

In a 2011 study of the novel agent ABT-737, which inhibits BCL2, BCL-XL, and BCL-w, the levels of MCL-1 and BFL-1 were significantly higher than BCL2 in the population resistant to the drug, while the sensitive population had the highest levels of BCL2 comparatively^[26]. Conversely, in some tumor models, cells express low levels of BCL2 but are still highly sensitive to BCL-2 inhibition, indicating that the BCL2 protein is a small part of a more intricate process^[17]. Other anti-apoptotic proteins, such as MCL-1 and BCL-XL, are not directly inhibited by venetoclax but appear to have a role in resistance, with BCL-XL appearing to have the strongest impact^[27]. The overexpression of BCL-XL is associated with venetoclax resistance and the upregulation of NF- κ B signaling (cell survival); the addition of BCL-XL inhibitors can restore cell sensitivity to venetoclax^[27].

Likewise, MCL-1, involved in the sequestration of BIM and binding of BAK which prevents apoptosis is commonly overexpressed in venetoclax-resistant patients^[13,28]. MCL-1 has been the subject of interest as there are various efforts at utilizing its inhibition as a potential therapeutic option, occasionally in conjunction with venetoclax^[29]. Yet still, the matter is more complicated as additional proteins involved in this pathway were also found to have interactions with MCL-1 and BCL-XL, namely BFL-1^[30]. Research into the detailed interactions between the pro-apoptotic and anti-apoptotic protein signaling balance is warranted, as any number of these proteins could be targeted for treatment.

Tumor microenvironment

For added complexity, tumor microenvironment including alterations in cell metabolism and signaling may also contribute to resistance. When CLL and MCL cells were preincubated with anti-apoptotic/pro-growth

signaling factors from outside the direct BCL2 pathway, namely sCD40L, IL-10, CpG-ODN, B-cell-activating factor (BAFF), CXCL3, the combination of sCD40L, IL-10, and CpG-ODN had the lowest level of ibrutinib/venetoclax induced cytotoxicity indicating resistance^[31]. Even high levels of ibrutinib and venetoclax did not achieve an adequate level of cytotoxicity, but when NF-κB signaling was inhibited by the addition of proteasome inhibitors, bortezomib and carfilzomib, sensitivity to ibrutinib/venetoclax returned^[31]. Further research into this topic may reveal potential therapeutic targets for patients experiencing relapse/resistance.

Genetic heterogeneity

The extensive variation in the genetics of CLL patients has been noted, and the most common alterations include deletions of chromosomes 13q, 11q, 17p, and trisomy 12^[32]. This heterogeneity may also play a role in resistance, as seen with the 17p deletion, which is not only associated with advanced disease/poor prognosis but also correlated with resistance, as one study found 7 out of 11 venetoclax-resistant CLL patients harbored the *TP53* aberration^[18,32]. Further, trisomy 12 contributes to increased expression of MCL-1 which also has been associated with venetoclax resistance^[33]. In addition to chromosomal alterations, other genetic alterations have been associated with resistance; in a study of 8 venetoclax resistance patients, 2 patients were found to have potential targetable mutations (BRAF and PD-L1), both thought to be involved in MCL-1 upregulation^[34]. Additionally, a homozygous mutation in *CDKN2A/B*, a cell cycle regulator, was also identified in the resistant patient population^[34]. A combined analysis of several CLL studies found *TP53*, *SF3B1*, *MYD88*, *NOTCH1*, and *ATM* were the most mutated genes with varying rates of mutation across the studies^[32]. Interestingly, there was variation across the mutations, as certain mutations arise continuously throughout disease (*TP53*, *ATM*), others arise after treatment initiation (*NOTCH1*), while others remain in the same frequency throughout the disease course (*MYD88*)^[35].

Abnormal oxidative phosphorylation

As the BCL2 pathway ultimately involves mitochondria, there has been consideration of the role of oxidative phosphorylation in resistance. In other cancerous cell lines, increased levels of oxidative phosphorylation and reactive oxygen species are associated with resistance to chemotherapeutic agents^[36]. Investigation into CLL cell lines in vitro found that the resistant cells had significantly higher levels of both basal and maximal oxygen consumption from ATP production by oxidative phosphorylation as well as increased mitochondrial membrane potential^[37]. Additionally, after the cell lines were treated with venetoclax, a decline in oxygen consumption was observed, but this was dependent on the ability of pore formation (BAX/BAK) as knockout cell lines did not have the same response to venetoclax^[37]. Additional research into cell metabolism may further elucidate details regarding these complex interactions and potential treatment targets.

Richter transformation

Transformation of CLL contributing to venetoclax resistance is one of the less well-studied mechanisms of resistance. Recent analysis has shown that increased genetic instability during transformation can result in the development of mutations related to venetoclax resistance^[27]. While the more common BCL2 mutation, Gly101Val, was not seen in the transformed population, a rarer mutation, Arg110dup, was seen in a low percentage (< 0.5%)^[18]. Rates of Richter's transformation vary by trial but were generally low [Table 1]. Currently, data on Richter transformation in CLL remains limited, but it is an area of ongoing investigation.

METHODS TO OVERCOME RESISTANCE

While the first action after resistance to treatment is to alter treatment to another agent, researchers have identified several other avenues to combat resistance, including other formulations of bcl2 inhibitors, chimeric antigen receptor T (CART), BTK degraders, non-covalent BTK inhibitors, phosphoinositide 3-

kinase inhibitors, and novel bispecific antibodies. Additionally, duration of treatment, fixed *vs.* continuous, may be instrumental in the development of resistance. An investigation into relapsed CLL patients treated with venetoclax and rituximab followed by venetoclax monotherapy found that among the durable responses (33 patients of which 14 remained on monotherapy and 19 stopped venetoclax), five-year estimates of ongoing response rate were similar, 71% (95%CI, 39-88) in continuous treatment *vs.* 79% (95%CI, 49-93) in the fixed duration group^[38]. However, an analysis of single-agent venetoclax in CLL patients with prolonged follow-up found ongoing venetoclax treatment may be a driver of resistance, as activation of NF- κ B with associated MCL1 expression was increased in all relapsed samples while on venetoclax therapy compared to off therapy^[39]. This concept is further supported by a patient who achieved minimal residual disease on venetoclax with fixed treatment duration, and did not have increased NF- κ B or other cell survival signaling^[39]. Further, analysis of the MURANO trial with fixed duration combination treatment did not identify any mutations in *BCL2*, a known mechanism of resistance as discussed above^[40].

BCL2 inhibitors/BH3 mimetic

Since the discovery of the BCL2 family of proteins involved in apoptosis, there has been an evaluation of BCL2-targeted agents. Obatoclax, a BH3 mimetic that antagonizes Mcl-1/Bcl-xL and Bcl-w but not BCL2, was evaluated in a phase I/II with bortezomib in relapsed refractory mantle cell lymphoma, but ORR was modest at 31% with myelosuppression and fatigue as the most common grade 3/4 adverse events^[41]. Additionally, navitoclax, another BH3 mimetic, demonstrated 55% ORR when used with Rituximab for 12 weeks and 70% when used with Rituximab continuously until progression or intolerance compared to 35% ORR with rituximab alone in previously untreated CLL patients^[42]. Unfortunately, significant thrombocytopenia limited widespread use as it was often dose-limiting^[43,44]. Recently, Lisoftoclax, which selectively binds Bcl2 and prevents BCL2:BIM complexes allowing pore formation in mitochondria, demonstrated significant antitumor activity in preclinical trials^[45]. This prompted progression to a phase I/II clinical trial in relapsed/refractory CLL patients with an ORR of 65% in the monotherapy group, 98% ORR in combination with acalabrutinib, and 87% in combination with Rituximab^[46]. The average number of previous treatments was 2, with 12% of the patients progressing on BTK inhibitors and/or venetoclax^[46].

Novel agents

In addition to BH3 mimetics, there has been an investigation into alternative targets with Bispecific antibodies/BiTE. As with venetoclax, the novel agents are explored across B-cell malignancies. Mosunetuzumab, a bispecific T cell engager targeting CD20/CD3, is under evaluation in Non-Hodgkin's lymphoma (NHL) and CLL refractory to at least two lines of treatment in a phase I/II trial [NCT02500407] after promising results of a 60% CR in follicular lymphoma^[47]. Other bispecific antibodies targeting CD20/CD3 are currently in various stages of clinical trials, namely odronextamab, glofitamab, epcoritamab, and plamotamab^[48-51]. The most common serious adverse event across this drug class remains cytokine release syndrome^[48-51]. At this time, these studies consist of mostly large B-cell lymphoma and follicular lymphoma patients, but in the future, the trials could be expanded to include refractory CLL patients.

Since the last decade, the implementation of CART has greatly impacted hematology and the treatment of hematologic malignancies. Initial evaluation of CART in CLL over a decade ago had a small sample size (2 patients), but on long-term follow-up, the patients continued to have a durable remission^[52,53]. An analysis of several studies (15 studies, 160 patients) found decreased efficacy of CART in CLL patients with an average CR rate of 30% (0% to 67%) and suggested T-cell dysfunction as a potential rationale for the less robust response^[54]. However, a large multicenter study of lisocabtagene maraleucel has recently shown rapid, deep, and durable responses in relapsed/refractory CLL patients after BTKi and venetoclax use^[55].

Additionally, there are ongoing clinical trials evaluating novel agents such as BTK degrader (NX-2127) and non-covalent BTK inhibitor (Pirtobrutinib) in relapsed/refractory patients^[56,57]. Initial data on pirtobrutinib demonstrated promising results in BTK inhibitor refractory patients, with an ORR of 79% in patients (100 patients) who were refractory to both BTK inhibitors and *BCL2* inhibitors^[54]. This success prompted a large phase III trial evaluating pirtobrutinib in the first line in CLL/SLL vs. ibrutinib and bendamustine + rituximab^[58,59]. The combination of pirtobrutinib and venetoclax is currently in a phase II study in CLL patients in the first line with the primary endpoint of minimal residual disease after 15 cycles [NCT05677919]. Other non-covalent BTK inhibitors such as fenebrutinib and nemtabrutinib have also been investigated, but as both had limited success in phase I trials, their use in B cell malignancies was stopped^[60,61]. Phosphoinositide 3-kinase inhibitors have some proven efficacy in CLL, namely idelalisib and duvelisib, with many others under various stages of investigation^[62-64]. Combination treatments instead of single-agent therapy may be a method to overcome resistance, as previous CLL studies found that 50% of the patients became refractory to single-agent venetoclax after 2-3 years^[4,9].

CONCLUSION

Since the widespread use of venetoclax, more and more has been discovered about intrinsic and extrinsic mechanisms of resistance. Genetic mutations in Bcl-2 are the most common form of venetoclax resistance but have only been reported in approximately 50% of resistant patients, although small sample size (15 patients)^[14]. The less well-known forms of resistance, such as epigenetic modifications, alterations of oxidative phosphorylation, and Richter's transformation, may play a larger role in resistance than we know and may become essential in future research of relapsed disease. Given this heterogeneity in resistance in both mechanisms and timeline of development, testing for resistance prior to venetoclax initiation is not warranted. However, there is some data supporting NF-κB expression as a potential biomarker for venetoclax resistance^[39], but more investigation is needed to determine its validity prior to widespread application.

Despite the extensive modes of venetoclax resistance, treatment is effective with both monotherapy and combination therapy^[4-10]. Even refractory/relapsed CLL patients with poor prognostic factors, like 17p deletion, had durable responses to venetoclax in a phase 2 trial with 54% PFS at 24 months^[9]. Interestingly, in a post-hoc analysis of the MURANO trial, dose reduction of venetoclax did not have a significant impact on PFS as long as treatment was not terminated^[65]. The implication of dose reduction on resistance was not examined, but it would be beneficial to determine whether lower doses contribute to resistance as this would change management. Additionally, we need further analysis on fixed versus continuous treatment on the development of resistance as initial investigation supports fixed duration treatment in preventing at least certain types of resistance. Research into continuous vs. fixed treatment in combination treatments, particularly combination oral agents, could provide clarification.

Novel treatments like bispecific antibodies, BTK degraders, non-covalent binding BTK inhibitors, phosphoinositide 3-kinase inhibitors, and CART may provide the solution for relapsed/refractory patients, but their sequencing order in treatment remains to be determined, especially in CLL where the treated patient population is small. Given the relative novelty of bispecific antibodies, BTK degraders, non-covalent BTK inhibitors, and CART, we do not have long-term data on the impact on resistance. Retrospective analysis of the various clinical trials may provide some insights and should be an area for further research. Regardless of the potential resistance, we can conclude that venetoclax remains a cornerstone in the treatment of CLL.

Abstract

Multiple myeloma (MM) is a type of hematological cancer that occurs when B cells become malignant. Various drugs such as proteasome inhibitors, immunomodulators, and compounds that cause DNA damage can be used in the treatment of MM. Autophagy, a type 2 cell death mechanism, plays a crucial role in determining the fate of B cells, either promoting their survival or inducing cell death. Therefore, autophagy can either facilitate the progression or hinder the treatment of MM disease. In this review, autophagy mechanisms that may be effective in MM cells were covered and evaluated within the contexts of unfolded protein response (UPR), bone marrow microenvironment (BMME), drug resistance, hypoxia, DNA repair and transcriptional regulation, and apoptosis. The genes that are effective in each mechanism and research efforts on this subject were discussed in detail. Signaling pathways targeted by new drugs to benefit from autophagy in MM disease were covered. The efficacy of drugs that regulate autophagy in MM was examined, and clinical trials on this subject were included. Consequently, among the autophagy mechanisms that are effective in MM, the most suitable ones to be used in the treatment were expressed. The importance of 3D models and microfluidic systems for the discovery of new drugs for autophagy and personalized treatment was emphasized. Ultimately, this review aims to provide a comprehensive overview of MM disease, encompassing autophagy mechanisms, drugs, clinical studies, and further studies.

Keywords: Autophagy, multiple myeloma, unfolded protein response, bone marrow microenvironment, drug resistance, hypoxia, DNA repair and transcriptional regulation, apoptosis

INTRODUCTION

Multiple myeloma (MM) is associated with the proliferation of a single plasma B cell variant in the bone marrow and the secretion of monoclonal immunoglobulins^[1]. MM is the second most common type of hematological malignancy worldwide, which accounts for approximately 10% of cases^[2]. The mean age of diagnosis is 69 years, and the disease diagnosis is based on the monoclonal M protein produced by malignant B cells^[3]. Myeloma cells are plasma cells that secrete immunoglobulins and usually synthesize IgG or IgA^[4]. As plasmacytomas increase, monoclonal gammopathy of undetermined significance (MGUS), a premalignant and painless disease, emerges. Subsequently, asymptomatic smoldering myeloma (SMM) and eventually symptomatic MM appear. 1% of cases with MGUS and 10% of cases with SMM might convert to MM^[5]. Rapidly accumulating malignant B cells cause bone destruction, anemia, hypercalcemia, and renal failure^[6]. In the clinical treatment of the disease, proteasome inhibitors, steroids, monoclonal antibodies, DNA damage, and immunomodulatory compounds are used in combination^[7]. Most of these therapies focus on killing MM cells. Commonly, there are three different death mechanisms in cells: apoptosis (type 1), autophagy (type 2), and necrosis (type 3). Apoptosis eliminates irreparable cells and prevents damage from spreading. Nuclear fragmentation, chromatin condensation, and apoptotic bodies commonly crop up in cells during apoptosis^[8]. Autophagy is a process of cellular self-degradation that helps the body repair itself by breaking down damaged materials under conditions of starvation or stress. In the autophagic mechanism, gathered proteins in the cell, wrecked organelles or microorganisms are digested in large vesicles with the help of the lysosome^[9]. Necrosis is a critical condition that occurs when living tissue is damaged beyond repair, leading to cell death. An exogenous factor such as injury provokes necrosis formation in cells, which causes disruption of cell morphology and damage to organelles^[10]. Currently, it was reported that cell death types can be converted into each other through different gene expressions^[11]. For example, caspase-8 has a critical function as a bridge between the apoptosis and necrosis pathways^[12]. Additionally, inhibition of autophagy was associated with necrosis, inflammation, and accelerated tumor growth^[13]. This review extensively delves into the mechanisms of autophagy related to MM disease progression or regression. We clarified how signaling pathways and genes in autophagy mechanisms may affect the disease. Additionally, we elucidate how the drugs used to regulate autophagy affect the regulation of these genes. Finally, we offer valuable insights into specific mechanisms that should be targeted with appropriate drugs to leverage autophagy for the treatment of MM disease.

The mechanisms of autophagy

Autophagy is a recycling activity that is employed to maintain the survival of other cells and to maintain body homeostasis in case of stress such as nutrient deficiency and reactive oxygen compounds (ROS)^[14]. In tumorigenesis, autophagy can work in a bidirectional manner by increasing disease progression or causing cancer cell death^[15]. In addition, differentiations in autophagic balance might lead to drug resistance in cancer cells. Commonly autophagy-related genes are under-expressed or contain deletions in cancer cells^[16]. In recent years, it has been declared that the loss of PTEN, a tumor suppressor, leads to a decrease in autophagy and thus plays a key role in shaping the fate of tumor cells^[17]. The formation of autophagosomes primarily serves as a recycling process, not exclusively aimed at cancer cells. However, it works in tandem with the immune system in its specific function related to cancer^[18]. Many autophagy-related proteins (ATG) are involved in the regulation of autophagy. The mechanisms of autophagy can be summarized into five items^[19], as shown in [Figure 1](#).

The initiation of phagophore formation is determined by the interaction between Beclin1 and Bcl-2, which is triggered by the phosphorylation of Bcl-2 by JNK-1. This results in the dissociation of Bcl-2 from Beclin1, which allows for the initiation of autophagy by the Beclin1/Vps34 complex. Recently, the role of Beclin1 and UV radiation resistance-associated gene (UVRAG) as a tumor suppressor and autophagy trigger in cancer was emphasized^[20]. mTOR plays a pivotal role in regulating autophagy by inhibiting ATG1/ULK1-2 from

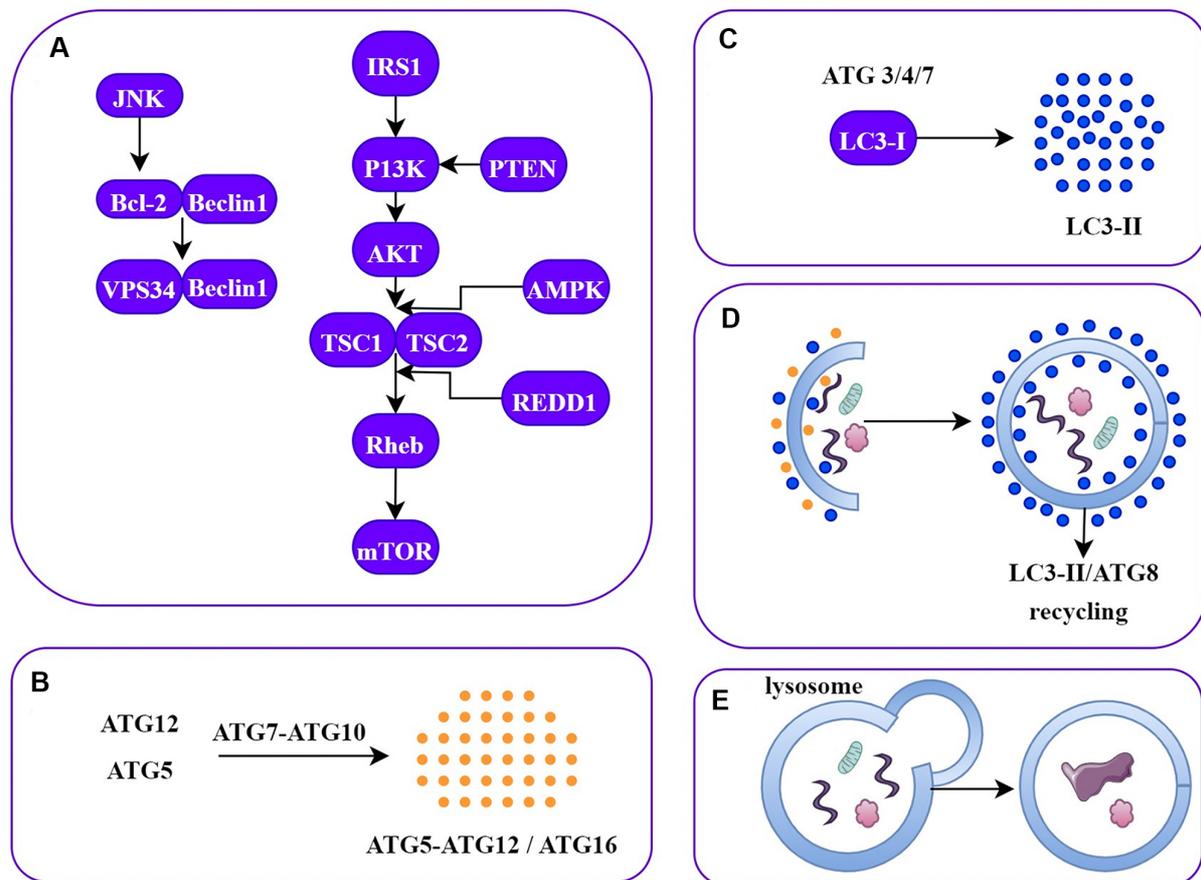

Figure 1. Schematic of the stages of autophagy. ATG: Autophagy-related proteins.

the early stages. mTOR interacts with various proteins to form mTORC1/2 complexes, which activate different transduction pathways. Essentially, mTOR serves as the linchpin governing the balance between cell growth and the induction of autophagy. mTOR is inhibited by REDD1 and AMPK through Rheb under conditions of hypoxia or low ATP [Figure 1]. In addition, mTOR is activated via the IRS1, PI3K/AKT, TSC1/TSC2, and Rheb signaling pathways. Although three variants of autophagy have been proposed so far [microautophagy, chaperone-mediated autophagy (CMA), and macroautophagy], degradation by lysosomal fusion is inevitable. Macroautophagy is characterized by the formation of an autophagosome, which consists of lipid bilayers so that large proteins and organelles can be broken down and recycled by the lysosome^[19]. In microautophagy, the cell membrane spontaneously folds inwards to form a tube. The end of the tube buds and connects with the lysosome through vesicles^[16]. Unlike others, CMA is the selective degradation of misfolded proteins by lysosomes via chaperones. The KFERQ motif in misfolded proteins is recognized by Hsc70 and forms a complex^[21]. This complex is pulled in and destroyed by LAMP-2A in the lysosome membrane without the need for vesicles. Finally, they are degraded into the fundamental units by lytic enzymes (protease, lipase, and hydrolase) in the lysosome and are released to the cytoplasm for synthesizing new complex molecules.

Autophagy is a crucial factor in the circumstance of the disease, as MM cells are plasma cells that synthesize a large amount of immunoglobulin. Therefore, it is important to assess how autophagy functions, considering its dual impact as both a suppressor and supporter of the tumor^[15]. ATG5, an important autophagy-related indicator, is cleaved upon exposure to Bortezomib and initiates autophagy in MM cells^[22]. It is known that inhibiting autophagy in conjunction with proteasome inhibitors, which are effective in treating MM, presents a promising therapeutic avenue. Therefore, it is necessary to elucidate the fundamental mechanisms of autophagy at the forefront of MM research. In this review, autophagy mechanisms and autophagy modulators in MM disease were comparatively reviewed. This review emphasizes the significance of incorporating autophagy alongside appropriate medications and timing as a strategy to significantly extend the lifespan of MM patients.

AUTOPHAGY-RELATED MECHANISMS IN MM

MM cells use multiple mechanisms to evade cell death, including proteasome, unfolded protein response (UPR), and autophagy. MM cells that can escape from death develop resistance to drugs, which makes available therapies useless. The viability of MM cells is based on the proteasome-mediated degradation of misfolded proteins and non-functional newly synthesized proteins^[23]. Therefore, autophagy can maintain the continuity of MM cells by averting the toxic stack of misfolded proteins. A basal level of autophagy is essential for the life cycle of MM cells. When these mechanisms collapse, apoptosis is finally induced by immune cells for the integrity and health of the organism^[18]. Autophagy may be involved in the progression of MM from malignant plasma cells. Exemplarily, the enhancement of autophagy in plasma cells of MGUS and MM patients was only in the direction of MM^[24]. A study conducted with biopsies of 89 patients with MM reported that patients with Beclin1 and LC3 biomarkers had a longer life expectancy^[25]. It was revealed that elevated IFN γ in neutrophils isolated from MGUS and MM patients triggers JAK2/STAT3 signaling to form an autophagic survival system^[26]. Recently, CD46, IKBKE, PARK2, ULK4, ATG5, and CDKN2A were considered in a three-cohort meta-analysis study that investigated the contribution of polymorphisms in autophagy-related genes to MM disease risk^[27]. Considering all these, autophagy is related not only to MM progression or regression but also to MM development at the beginning. We can examine the mechanisms thanks to the fact that autophagy is effective in MM under the headings of UPR, bone marrow microenvironment (BMME), drug resistance, hypoxia, DNA repair and transcriptional regulation, and apoptosis.

UPR

The folding of proteins takes place in the endoplasmic reticulum (ER). Misfolded proteins are ubiquitinated by a system including ER chaperones and are degraded by the proteasome^[28]. Besides contributing to the degradation of p62/SQSTM1 aggregated proteins via proteasomes, it is known that p62 can sustain cell survival by inducing autophagy^[29]. Additionally, recent studies have shown that SQSTM1/p62 plays a crucial role in supporting proteostasis and is not just involved in working with the proteasome to degrade Ub-protein aggregates^[30,31]. SQSTM1/p62 is a vital component of the autophagic reserve that helps the cell adapt to proteasome stress induced by proteasome inhibitors with the modification of the interactome^[30]. In this sense, it can be interpreted that p62 functions in the regulation of autophagy. Autophagy plays a significant part in the transformation of B cells into plasma cells, and ATG5 mediates these tasks^[32]. Mice with *Atg5^{fl/fl}* were observed to have a higher ER stress with increased immunoglobulin synthesis compared to wild type^[33]. Therefore, autophagy plays a role in guiding plasma cells to the bone marrow for adaptive immune responses. Myeloma cells are under constant ER stress due to the high content of immunoglobulins they synthesize and can easily induce the UPR^[34]. Inhibition of the proteasome with chemotherapeutics makes the damaged proteins roll up, turn toxic, and trigger UPR^[35]. UPR restores homeostasis and performs in conjunction with autophagy. Thus, autophagy is upregulated and initiates a survival mechanism to eliminate UPR.

The UPR proteolytic system is controlled by the signaling mechanism of IRE1/XBP-1, PERK/ATF4, and ATF6/cleaved ATF6. IRE1, PERK, and ATF6 are separated from GRP78, to which they are attached when UPR is triggered, which accounts for a signal transduction cascade^[36]. The PERK signaling pathway conduces to the UPR system by suppressing protein synthesis. IRE1 participates both by augmentation of misfolded protein impairment and by enhancement of protein folding together with ATF6. The function of XBP-1 is of great importance in the autophagy mechanism in UPR and MM cells. IRE1 fulfills the cell viability role of autophagy by regulating itself and XBP-1 at the mRNA level^[37]. Directing the maturation of plasma cells, XBP-1 is involved in autophagy through ATG5^[38]. However, XBP-1 facilitates IRE1 binding to the BiP chaperone to downregulate the UPR function in B cells^[39]. IRE1a/XBP-1 balance is critical in MM cells as it reduces ER stress^[40]. Furthermore, it was reported that inhibition of XBP-1 splicing by IRE1 may be a treatment modality for MM cells^[41]. Additionally, it was demonstrated that there is a correlation between elevated spliced XBP-1 levels and Bortezomib resistance^[35]. XBP-1 is also involved in the regulation of ATG5 and Beclin1 via eIF2AK3 for the activation of autophagy^[42]. Moreover, XBP-1 functions as a transcription factor in the signaling cascade between IRE1 and ATF6 cleavage in UPR^[43]. XBP-1 influences the expression of genes grave in B cell differentiation, such as BAFF, APRIL, BCMA, and TACI^[44]. In addition, these genes also affect NF- κ B expression. In MM cells, the NF- κ B pathway leads to the expression of cytokines, cell adhesion molecules, and cell growth and survival factors. NF- κ B, which also mediates XBP-1 expression, contributes to the induction of UPR and autophagy in cancer cells^[45]. It was previously mentioned that Beclin1 and LC3 work together in autophagosome formation. NF- κ B raises the possibility of autophagy by augmenting Beclin1 expression^[46]. PERK obstructs the phosphorylation of eIF2B, which leads to a significant reduction in the production of ATF4 and protein synthesis^[47]. This mechanism serves as a crucial intervention point for regulating protein synthesis in cells. PERK can operate to diminish the oxidative stress response that may be motivated by unfolded proteins by activating NRF2^[48]. In this sense, it plays a binary part in up or down-regulating UPR in autophagy. PERK labors with ATF4/6 to activate the transcription factor CHOP and to reduce ER stress^[49]. From this point of view, PERK primarily functions to sustain cell life, but it can also operate cell death mechanisms in response to the strong signals it receives. In an experiment study where IRE1, ATF6, and PERK were individually knocked out using RNAi, it was indicated that PERK functions as a sensor of autophagy in MM cells^[50]. An inhibitor that targets the PERK pathway via eIF2AK3 in MM cells holds great potential in inducing cell death and providing effective therapy^[51]. This approach must be further explored to unlock its full potential in treating MM.

BMME

The BMME consists of cells and supporting elements. BMME stimulates a reputable part in the differentiation of B cells and their transformation into cancer^[52]. As a result of the interaction of MM cells with stromal cells, IL-6, VEGF, and IGF-1 are secreted, and signaling pathways that cause tumor aggression, such as PI3K/AKT/mTOR, MEK/ERK, JAK/STAT3, and NF- κ B, are activated [Figure 2]. Intercellular interactions between stromal cells and MM cells in the bone marrow and relationships with extracellular matrix (ECM) elements determine the fate of MM cells. Furthermore, adhesion molecules such as TNF- α , ICAM-1, LFA-1, and VLA-4 generated by stromal cells are responsible for the interaction of MM cells and bone marrow stromal cells (BMSCs). Stimulation of adhesion molecules for expression is mediated by NF- κ B^[53] and ultimately contributes to the development of drug resistance in MM cells. As another factor, IL-6 is an interleukin released from stromal cells and contributes to the clinical prognosis, apoptosis, drug resistance, and metastasis processes of MM^[54]. Elevated IL-6 levels induce XBP-1 generation, which results in the enhancement of UPR and autophagy^[24]. APRIL and BAFF ligands, which bind to BCMA secreted from B cells, promote XBP-1-mediated autophagy via NF- κ B, assisting in the survival of MM cells^[55]. It is argued that there may be crucial mechanisms for cancer-associated fibroblasts (CAFs) in autophagy in cancer cells^[56]. CAFs from Bortezomib-resistant patients were observed to protect MM cells from apoptosis in the co-culture^[56]. Because autophagy is induced by the inhibition of TGF- β in Bortezomib-resistant CAFs,

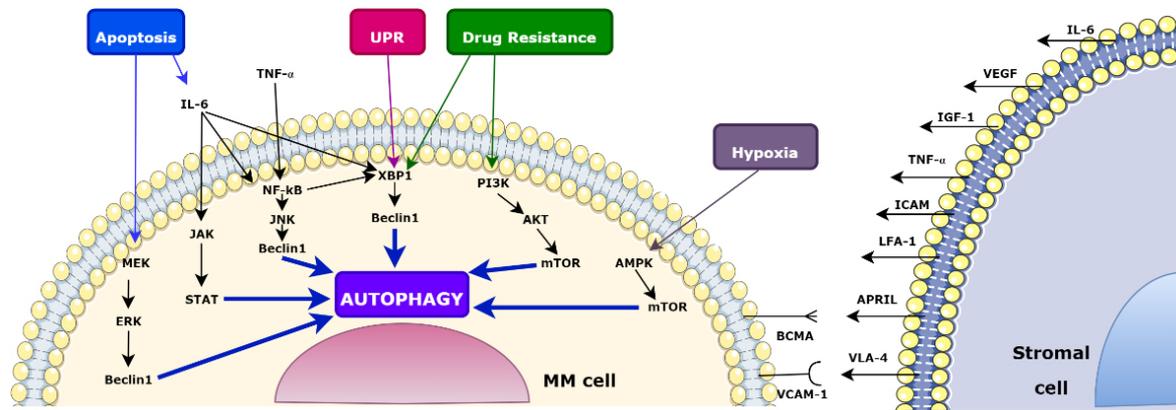

Figure 2. Causes and consequences of autophagy in MM cells within BMME. In the bone marrow, stromal cells secrete IL-6, VEGF, and IGF-1 due to intercellular interactions with MM cells. IL-6 stimulates UPR and autophagy through XBP-1. Apoptosis triggers autophagy via the JAK/STAT3 and MAPK/ERK pathways or IL-6. Autophagy and survival are promoted by the interaction of BCMA and APRIL through NF- κ B and XBP-1. Adhesion molecules such as TNF- α , ICAM-1, LFA-1, and VLA-4 develop drug resistance by inducing autophagy via NF- κ B. PI3K/AKT/mTOR inhibition promotes autophagy in drug-resistant cells. UPR upregulates HIF1- α through XBP-1 processing, which triggers autophagy through AMPK and mTOR. BMME: Bone marrow microenvironment; MM: multiple myeloma; UPR: unfolded protein response.

apoptosis is prevented by reducing ER stress^[57]. Moreover, it was stated that mature adipocytes in BMME contribute to the induction of autophagy by MM cells to avoid apoptosis and to the development of drug-resistant phenotypes^[58]. Autophagy also supports the immune system by taking part in the phagocytosis of microbes. LC3, IFN1, MHC class 2, and IL-6 aid in this process^[5]. Apart from these, cancerous cells necessitate a higher nicotinamide adenine dinucleotide (NAD⁺) cycle and rely on the Nampt enzyme for regulation. The Nampt inhibitor FK866 suppresses the protective effects of BMME and demonstrates its effect in both resistant MM cell lines and MM patients^[59]. Moreover, FK866 induces autophagy in MM through inhibition of mTORC1 and ERK1/2^[59]. The involvement of the WNT signaling pathway in the self-renewal abilities and metastasis processes of MM cells has also been proven in another study^[60]. Furthermore, it was found that exposure of MM cells to UV triggers the WNT pathway and induced autophagy^[61].

Angiogenesis is an important element in the transition of the disease from MGUS to MM^[62]. Although it is a distinguishing fact that angiogenesis occurs only in MM, various cytokines play a significant role in the process^[63]. Pro-angiogenic cytokines are released by interactions among MM cells, stromal cells, and endothelial cells. Studies reported that MM cells secrete higher levels of bFGF, HGF, and VEGF than plasma cells, which promotes angiogenesis^[64]. In a recent study, it was concluded that endothelial cells from patients with MM expressed higher levels of EGFR and its ligand HB-EGF than those from MGUS patients^[65]. When EGFR is activated, it promotes blood vessel growth and assists endothelial cells in surviving. Blockade of HB-EGF-EGFR signaling limited the angiogenic potential of bone marrow endothelial cells and hampered tumor growth in an MM mouse model^[65]. These findings suggest that HB-EGF-EGFR signaling could be a potential target in anti-angiogenic therapy for MM. Another study aimed to investigate the effect of combining Bortezomib and Hydroxychloroquine on plasma and endothelial cells isolated from patients with MM and MGUS^[66]. The results showed that the combined treatment had different effects on MM cells and endothelial cells^[66]. LC3B and p62 expressions induced autophagy in MM cells^[66], and it was suggested that Bortezomib should be used in combination with an anti-angiogenic drug to enhance its effectiveness. Considering the dual role of autophagy in MM, it initially acts as a tumor suppressor, but may also promote tumor growth, survival, and therapy resistance. The relationship between EGFR and autophagy is intricate. In fact, inhibiting EGFR could trigger autophagy as a survival mechanism. Thus, by gaining a deeper understanding of the connection among EGFR, autophagy, and bone marrow angiogenesis, we can

potentially develop novel treatments for MM.

Drug resistance

Drug resistance is one of the major issues in MM and causes relapse and refractory of the disease. MM cells can avoid the toxic effects of chemotherapeutics via autophagy and thus develop drug resistance^[14]. Bortezomib, which is frequently used in the treatment of MM and ratified by the FDA, triggers autophagy via UPR by inhibiting proteasomes^[67]. Bortezomib resistance occurs frequently in MM, and different approaches are sought for treatment. Caspase-10 endorses the survival and resistance of MM cells by regulating autophagy^[15]. Through induction of IRF4 in MM, caspase-10 cleaves BCLAF1, which competes with Beclin-1 for binding to Bcl-2 and inhibits autophagy^[68]. Therefore, the sensitivity of MM cells to Bortezomib can be restored by developing caspase-10 inhibitors. The association of Bortezomib resistance with P-gp and drug resistance-related proteins in MM cells was demonstrated^[69]. The increase in ATF4 expression after Bortezomib treatment in breast cancer cells^[70] suggests that Bortezomib resistance can be overcome by combined suppression of autophagy and proteasomes. In a recent study on Bortezomib-resistant MM patients and cell lines, it was mentioned that upregulation of CMA may be a mechanism leading to resistance formation and targeting this mechanism could be a therapeutic target^[71]. It was revealed that the CMA pathway was induced due to the ER stress caused by Bortezomib, and the expression of LAMP2A, which is an indispensable part of this pathway, was boosted^[71]. However, it was stated that inhibition of the CMA pathway restored Bortezomib sensitivity, and the dual combination was more cytotoxic^[71]. It was revealed that the Profilin-1 gene contributes to Bortezomib resistance in MM by boosting autophagy through Beclin1^[72]. The combination of anti- β 2M monoclonal antibodies with Bortezomib in MM cells promoted cellular death even in resistant cells by inhibition of autophagy^[73]. Bortezomib response decreased in MM cells as a result of suppression of NEDD4L, which induced autophagy by binding the 19S proteasome^[74]. A mechanism for the NEK2/USP7/Beclin-1 complex was identified in autophagy-induced Bortezomib resistance in MM patients^[75]. As a result of Bortezomib treatment applied to MM cells, autophagy was incited by GRP78 in cells^[76]. Furthermore, it was displayed that HSPA5 expression was upregulated in Bortezomib-resistant cells^[76]. It was declared that transfection of mir145-3p into MM cells suppresses HDAC4 and mTORC1 and causes sensitivity to Bortezomib due to autophagy^[77].

Autophagy functions in the development of resistance to many chemotherapeutics used in the treatment of MM. In a related study, by using primary patient samples and Dexamethasone-resistant MM cell lines, Beclin1 and LC3/ATG8 expressions were found to be inversely proportional to the p62 level^[78]. In this case, the authors claimed that autophagy leads to drug resistance in MM, and Beclin1/p62 is a biomarker. Additionally, antiestrogen binding site ligands regulated the cholesterol mechanism via the PI3K/AKT/mTOR pathway, inducing autophagy and overcoming Dexamethasone resistance^[79]. The relationship of Carfilzomib resistance with autophagy in MM cells and the contribution of the KLF4 transcription factor were obvious^[80]. KLF4 attaches to the p62 gene promoter and upregulates its expression. It was emphasized that Doxorubicin-induced resistance in MM cells is mediated by DEPTOR, and autophagy plays a main role in this resistance^[81].

Hypoxia

Tumor cells have a high metabolic rate and require large amounts of nutrients and oxygen. The needs of the rapidly growing tumor mass cannot be met at the same rate through the vessels, and a hypoxic environment develops. Cancer cells can continue to proliferate by inducing HIF1- α and adapting to these unfavorable conditions. HIF1- α triggers autophagy by inhibiting Bcl-2/Beclin1 and upregulating ATGs through BNIP3 and its ligand^[82]. However, tumor cells can initiate autophagy independently of HIF1- α through the activation of mTOR or AMPK^[83]. Since BMME has a low pO₂ level compared to blood, MM cells can easily

adapt to the hypoxia environment^[84]. The hypoxia state around the MM cell provokes the induction of UPR and autophagy due to the aggregation of the unfolded protein^[85] because many proteins need O₂ in order to be folded properly. Due to hypoxia-induced O₂ deficiency, sufficient ATP cannot be produced from glucose. In this case, MM cells can also induce starvation-induced autophagy^[86]. It was reported that upregulation of Hexokinase-2 in hypoxia conditions intensifies autophagy in MM cells and introduces it as an antiapoptotic feature^[87]. UPR initiates hypoxia by upregulating the expression of HIF1- α and VEGF via XBP-1^[88]. In addition, activation of mTORC1, an autophagy-related factor, was found to increase susceptibility to hypoxia in MM cells^[89].

DNA repair and transcriptional regulation

Dysfunctional DNA repair pathways facilitate the progression and metastasis of MM disease from its initial stages to the development of drug-resistant phenotypes, because autophagy can be induced through DNA repair mechanisms^[90]. The activation of autophagy via the mTORC1/TSC2/ULK1 pathway is triggered by the ATM-mediated phosphorylation of AMPK^[91,92]. Additionally, ATM enables the inhibition of mTOR through the activation of Che-1 via REDD1 and DEPTOR^[93]. Furthermore, stress-induced Sestrin2 binds to GATOR2, thereby suppressing mTORC1^[94]. NF- κ B, also activated by ATM, leads to the activation of Beclin1 and induction of autophagy^[95]. ROS-induced DNA damage assists in the suppression of AMPK and triggering of autophagy by activation of PARP1^[96]. ATM can also induce autophagy through the regulation of p53. p53 induces the initiation of autophagy through the upregulation of PTEN and AMPK^[97]. Moreover, DAPK regulated by p53 facilitates autophagy through its connection with Beclin1 phosphorylation and VPS34 activation^[98].

Histone deacetylases (HDACs) are crucial transcription regulators and can control functional proteins in signaling pathways. HDAC6 is critical in MM due to its connection with UPR. Because of its deficiency, autophagy can be induced by forming aggresomes. Therefore, it is a promising target for patient treatment. HMGB1 is a DNA-binding protein that contributes to the functionality of nucleosomes and causes tumor progression. HMGB1 expression is increased during the treatment of various cancers with different chemotherapeutics^[99]. HMGB1 is involved in autophagy and DNA damage repair, and the knockdown of HMGB1 in MM cells restores mTOR-mediated Dexamethasone sensitivity^[100]. Additionally, it was reported that HMGB1 expression increased in Bortezomib-resistant MM cells, and the combination of Bortezomib and Lycorine reversed the resistance^[101]. Furthermore, it was emphasized that MALAT1, a lncRNA, caused the upregulation of HMGB1 in MM cells, and the knockdown of MALAT1 caused a decrease in the expressions of Beclin1 and LC3B together with HMGB1 in MM^[102]. In light of these findings, it is clear that targeting HMGB1 in drug-resistant MM patients is an essential and promising therapeutic approach.

Apoptosis

Apoptosis against cellular stress is the first type of cell death pathway and is used to eliminate situations where autophagy cannot be overcome. Depending on the stress state of the cell, these death mechanisms can block or trigger each other. Apoptosis in MM cells can be induced by IL-6, VEGF, IGF1, SDF1, and FGF factors via the JAK/STAT3 and MAPK/ERK pathways^[16]. It was reported that drug-resistant MM cells induce apoptosis via the Apo2L/TRAIL pathway^[103]. The expression of Mcl-1, a proliferation marker of MM cells, increased by JAK/STAT3 and VEGF, resulting in resistance to apoptosis^[104]. The importance of the Bcl-2/Bax ratio in MM apoptosis is indisputable^[105], and the increase in Bcl-XL protein leads to the inhibition of apoptosis via IL-6. NF- κ B's involvement in MM cell apoptosis, metastasis, and drug resistance was investigated^[106]. Autophagy helps to alleviate metabolic stress, but when apoptosis and autophagy are both impaired, it can lead to necrotic cell death^[13]. Therefore, autophagy plays a role in suppressing tumors by reducing metabolic stress and preventing necrotic cell death, along with apoptosis^[13].

The similarity of proteins in the apoptosis and autophagy pathways is a well-known phenomenon in MM, which highlights the complex interplay between these cellular processes^[18]. As an example, Beclin1 executes its function as a tumor suppressor through regulation by AMBRA1, Bif1, and UVRAG. Both siRNA-mediated inhibition of Beclin-1 and autophagy inhibition by 3-methyladenine and Chloroquine resulted in apoptosis of MM cells^[107]. Furthermore, inhibition of autophagy with 3-methyladenine augmented Oridonin-dependent apoptosis by regulating ROS and SIRT1 in MM cells^[108]. Beclin1 inhibition extinguishes both autophagy and apoptosis, because Bcl-2 inhibits apoptosis by MOMP inhibition and stops autophagy by tethering Beclin1 or AMBRA1^[109]. It was claimed that HMGB1 disturbs the equilibration between Beclin1 and Bcl-2 in the resistance to Bortezomib in MM^[101]. AMBRA1 induces autophagy and suppresses apoptosis^[110]. UVRAG induces autophagy by activating Beclin1, while Bif1 induces tumor suppression via autophagy^[111]. In addition, a high expression of p38/MAPK engenders autophagy, while a low expression causes apoptosis^[112]. STAT3 regulates many autophagy-related genes, such as FOXO1/3, by sequestering eIF2AK2 to fulfill this function^[113]. It was suggested that the nutritional status marker mTORC1 could be responsible for drug resistance in MM via the AKT/ERK signaling pathway^[114]. In a study with MM patients and cell lines, it appeared that gene expressions related to the PI3K/AKT/mTOR pathway and autophagy were higher in resistant groups^[115]. Additionally, it was also unveiled that inhibition of PI3K/AKT/mTOR signaling promotes autophagy and apoptosis^[115]. Autophagy can also induce apoptosis by aggregation of caspase 8^[116]. Although p53 is an important biomarker in cancer, its role in the control of cell cycle and apoptosis in MM was clarified^[105].

Recent studies reveal that MM cells can reshape cellular traffic mechanisms to combat ER stress. FAM46C, which is mutated in more than 10% of MM patients, is frequently emphasized. In a study on MM cells, it was reported that reactivation of FAM46C triggered apoptosis and ER stress by forming a complex with FNDC3A, an ER-associated protein^[117]. The FAM46C and FNDC3A complex increases the exocytosis of lysosomes, which causes changes in cellular traffic and secretion^[117]. This leads to aggregate accumulation and negative regulation of autophagy in MM cells^[117]. Eventually, MM cell-specific FAM46C/FNDC3A-mediated tumor suppression occurs by induction of apoptosis^[117]. Another study highlights the tumor suppressor and therapeutic role of FAM46C^[118]. FAM46 interaction with FNDC3 proteins stabilizes ER-targeted protein mRNAs and increases ER growth and Ig secretion^[118]. However, when the proteasomal balance is disrupted, p62 associates with FAM46C and prevents its interaction with FNDC3 proteins^[118]. The p62/FAM46C/FNDC3 ensures the survival of MM cells, and targeting this pathway with proteasome inhibitors appears as a mechanism that enables selective cell death.

THERAPEUTICS FOR AUTOPHAGY IN MM

Autophagy plays a crucial role in the development of MM, a disease where plasma cells produce large quantities of immunoglobulin. Combining autophagy inhibition with proteasome inhibitors is an effective MM treatment. Since autophagy can work in both directions, strategies to induce or inhibit autophagy could be helpful in the treatment of MM. Benefits can be obtained by inhibiting the tumor mass-preserving effect of autophagy or by directly triggering autophagy in MM cells. Therefore, suppressing the PI3K/AKT/mTOR signaling pathway to induce autophagy in MM cells may be a therapeutic option. The PI3K/AKT/mTOR signaling pathway is associated with p38/MAPK, PTEN, p53, SIRT1, IGF-1 and ROS. Since the MAPK/ERK signaling pathway is in connection with mTOR, its suppression in MM may inhibit autophagy. JNK may have a tumor suppressor task due to its capacity to regulate the function of Beclin1. Ca²⁺ itself, as a signaling molecule, can trigger autophagy through its ability to activate Beclin1 and AMPK. The above-mentioned signaling pathways can be regulated with drugs to achieve the desired autophagy benefit in MM. For this reason, [Table 1](#) lists drugs that can inhibit or induce autophagy by various mechanisms, especially in MM. [Table 2](#) provides an overview of the most promising autophagy modulators clinically tested in MM patients.

Table 1. Autophagy modulators and functioning mechanisms in MM

Mechanism	Drug	Effect	Ref.
AMPK activators	Metformin	Activation	[119-121]
	Spermidine		[122]
AMPK and mTOR inhibitors	Resveratrol	Activation	[123,124]
Autophagy flux inhibitors	Elaiophylin	Inhibition	[125]
	4-Acetylanthroquinonol B		[126]
Autophagy inducer	Tat-Beclin1 peptide	Activation	[127]
BTK inhibitors	Ibrutinib	Activation	[128]
Ca ²⁺ -ATPase inhibitors	Thapsigargin	Inhibition	[129,130]
Class I PI3K inhibitors	CH5132799	Activation	[131]
	GDC-0941		[132]
Class III PI3K inhibitors	3-Methyladenine	Inhibition	[107,108,133,134]
	Wortmannin		[135]
	LY294002		[136]
HDAC inhibitors	Vorinostat	Activation	[137,138]
Lysosomal alkalizers	Chloroquine	Inhibition	[107,139,140]
	Hydroxychloroquine		[66,134]
	Lys05		[141]
Lysosome membrane permeabilization	Thymoquinone	Inhibition	[142]
mTORC1/2 inhibitors	Rapamycin	Inhibition	[124,134]
	Everolimus		[143,144]
	Deforolimus		[145]
	Temsirolimus		[146]
	AZD8055	Activation	[147]
	Torin1	[148]	
	PP242	[149]	
PI3K/AKT inhibitors	Perifosine	Activation	[150]
PI3K/mTOR inhibitors	Apitolisib	Activation	[151]
Protease inhibitor	Pepstatin A	Inhibition	[152]
	E64d		[68,153]
Vacuolar H-ATPase inhibitors	Bafilomycin A1	Inhibition	[140,154]
	Concanamycin A		[155]
VPS34 kinase inhibitors	Paclitaxel	Inhibition	[156,157]

MM: Multiple myeloma.

Lysosomal alkalizers

Lysosomes are important organelles of autophagy, and changes in pH levels prevent the activity of lysosomal enzymes and the fusion of autophagosomes with lysosomes. As mentioned before, the life of MM cells is dependent on the protein synthesis cycle. Therefore, the combination of lysosomal alkalizers and proteasome inhibitors or alkylating agents is a powerful therapeutic option for the selective killing of MM cells. It is known that Hydroxychloroquine, which is widely used in the treatment of malaria, can inhibit autophagy in cancer cells^[162]. The combination of Bortezomib and Hydroxychloroquine increased cellular cytotoxicity via autophagy in MM patient samples^[66]. In the Phase 1 study of MM patients, the same treatment combination not only improved disease symptoms but also reduced side effects^[158]. In Phase II trials, whose Chloroquine was administered in combination with Bortezomib and Cyclophosphamide, a curative effect was shown for relapsed and refractory MM patients^[139].

Table 2. Summary of autophagy therapeutics in MM clinical trial

Title	Therapeutics	Phase	Publication	Identifier
A pilot study of infusional Cyclophosphamide and pulse Dexamethasone with Rapamycin or Hydroxychloroquine in patients with relapsed or refractory multiple myeloma	Hydroxychloroquine Rapamycin	Early phase 1	-	NCT01396200
A Phase I/II trial of Hydroxychloroquine added to Bortezomib for relapsed/refractory myeloma	Bortezomib Hydroxychloroquine	Phase 1	[158]	NCT00568880
A Phase I dose escalation study of Hydroxychloroquine with infusional Cyclophosphamide, pulse Dexamethasone, and Rapamycin in patients with relapsed or refractory multiple myeloma	Cyclophosphamide Dexamethasone Hydroxychloroquine Sirolimus	Phase 1	-	NCT01689987
A Phase II, trial of Chloroquine in combination with VELCADE and Cyclophosphamide in patients with relapsed and refractory myeloma	Velcade Cyclophosphamide Chloroquine	Phase 2	[139]	NCT01438177
A Phase 1B/2 multicenter, open label, dose-escalation study to determine the maximum tolerated dose, safety, and efficacy of ACY-1215 (RICOLINOSTAT) in combination with Pomalidomide and low-dose Dexamethasone in patients with relapsed and refractory multiple myeloma	Ricolinostat Pomalidomide Dexamethasone	Phase 1 Phase 2	-	NCT01997840
A Phase 1/2, open-label, multicenter study of ACY-1215 administered orally as monotherapy and in combination with Bortezomib and Dexamethasone for the treatment of relapsed or relapsed/refractory multiple myeloma	Ricolinostat	Phase 1 Phase 2	[159]	NCT01323751
A Phase 1/2, open-label, multicenter study of ACY-1215 (Ricolinostat) in combination with Lenalidomide and Dexamethasone for the treatment of relapsed or relapsed/refractory multiple myeloma	Ricolinostat Lenalidomide Dexamethasone	Phase 1	[160]	NCT01583283
An open-label phase I study of the safety and efficacy of RAD001 in combination with Lenalidomide in the treatment of subjects with relapsed and relapsed/refractory multiple myeloma	Everolimus Lenalidomide	Phase 1	[161]	NCT00729638
Phase II trial of RAD001 in relapsed/refractory multiple myeloma	Everolimus	Phase 2	-	NCT00618345
An open-label phase 1 study of Metformin and Nelfinavir in combination with Bortezomib in patients with relapsed and/or refractory multiple myeloma	Bortezomib Metformin Nelfinavir	Phase 1	-	NCT03829020
Phase II trial, open label, clinical activity of Metformin in combination with high-dose of Dexamethasone (HDdexa) in patients with relapsed/refractory multiple myeloma	Metformin Dexamethasone	Phase 2	[120]	NCT02967276

MM: Multiple myeloma.

HDAC inhibitors

The performance of the HDAC6 inhibitor Panobinostat added to the MM treatment protocol in Phase 3 trials is clear^[163] because HDAC6 inhibitors work together with UPR in toxic protein aggregation to promote autophagy. Additionally, HATs and HDACs can control the acetylation status of autophagy-related genes. An example of HDAC inhibitors inducing autophagy is the inactivation of mTOR by Vorinostat. Autophagy is suppressed by phosphorylating ULK1 through mTOR. The HDAC inhibitor Vorinostat triggers autophagy in tumor cells through the production of ROS^[164]. The combination of Suberoylanilide hydroxamic acid (Vorinostat), 17-allylamino-17-demethoxy-geldanamycin (Tanespimycin), and Clonazepam overcame the complication of peripheral neuropathy by inducing autophagy via HSP70 or LAMP-2A^[165]. Moreover, the efficacy of the combination of Clarithromycin, a high-spectrum antibiotic, in MM and various cancers has been previously reported^[166]. Clarithromycin's suppression of autophagy by reducing cytokines such as IL-6, which is an important factor in MM development and drug resistance, makes it a possible candidate. It was shown that the combination of Bortezomib, Lenalidomide, and Clarithromycin would also be suitable for therapy without Dexamethasone in MM patients with diabetes^[167]. The combination of Vorinostat, Bortezomib, and Clarithromycin in MM cells causes cell death and upregulation of CHOP genes that stimulate ER stress^[137]. In this sense, combinations of proteasome inhibitors and next-generation HDAC6 inhibitors may serve as therapeutic options to increase autophagy in MM cells.

Vacuolar H-ATPase inhibitors

Vacuolar type H-ATPases are pumps responsible for regulating intracellular organelle pH. Inhibiting these pumps with specific inhibitors blocks autophagy and prevents cell metastasis. The combined effect of Bortezomib and Bafilomycin A1 in MM cells is more cytotoxic than their use alone, which reveals the link between UPR, autophagy, and ER stress^[154]. Furthermore, a combination of Ixazomib and autophagy inhibitors Bafilomycin A and Chloroquine increases cytotoxicity and cell death via JNK^[140]. Therefore, the combination of vacuolar-type H-ATPase inhibitors with proteasome inhibitors stands as a potential therapeutic option. Additionally, inhibition of autophagic flux is also a treatment option. In a recent study, the treatment of p53 mutant MM cells with Elaiophylin suppressed autophagy and resulted in cell death by apoptosis^[125].

AMPK activators and mTOR inhibitors

AMPK plays a critical role in responding to stress caused by metabolic disorders. It helps in maintaining the balance between anabolic and catabolic reactions, which is crucial for the stability of the cell and energy preservation. In cancer treatment, AMPK activators are used to trigger autophagy and cell death. In peripheral neuropathy, one of the best-known side effects of Bortezomib treatment in patients, pathological changes occur in Schwann cells. Metformin, which is used as an antidiabetic drug, in combination with Bortezomib, suppressed GRP78 and promoted autophagy^[120]. Furthermore, Metformin was recently shown to induce apoptosis and necrosis in MM cells and mouse models^[119]. Additionally, Metformin applied to MM cell lines and mouse models promoted cell proliferation arrest and autophagy by AMPK and mTORC1/2 regulation^[121]. Thus, AMPK activators are a promising option for inducing autophagy by selectively targeting MM cells.

mTOR plays a cornerstone role in autophagy by regulating proliferation and metabolism. Resveratrol induces cell cycle arrest, apoptosis, and autophagy. In a study conducted to prove this, it was emphasized that Resveratrol induces autophagy and apoptosis in MM cells by inhibiting AMPK and mTOR^[123].

PI3K/AKT/mTOR inhibitors

The PI3K/AKT/mTOR signaling pathway promotes the survival and proliferation of tumor cells. Therefore, inhibition of one or more proteins on the signaling pathway causes tumor regression. A report on testing autophagy-regulating drugs in MM cells stated that Rapamycin can induce apoptosis and autophagy, Hydroxychloroquine can inhibit autophagy and induce apoptosis, and 3-methyladenine can only inhibit autophagy^[134]. Furthermore, the combination of 3-methyladenine and VEGF inhibitor Bevacizumab in MM cells promoted apoptosis^[133]. In a recent study, NVP-BEZ235 was discovered to induce autophagy through the mTOR2-Akt-FOXO3a-BNIP3 signaling pathway in MM cell lines, mouse models, and primary samples^[168]. Targeting the PI3K/AKT/mTOR signaling pathway, which is central to cell life and death choices, is a good strategy and a powerful therapeutic option for clinicians.

Other drugs or compounds

Glycosphingolipids located outside the cell membrane are important in cell adhesion, cell-cell interactions, and oncogenesis. In MM and MGUS preclinical models, it was shown that Eliglustat can inhibit autophagy through the glycosphingolipid mechanism, thereby maintaining osteoclastogenesis and preventing bone loss^[169]. The tumor burden-reducing effect of the combination of hexokinase-2 inhibitor 3-bromopyruvate and Bortezomib was published^[87]. It was reported that Solamargine alone induces autophagy, and its combination with Bortezomib may be a good treatment strategy^[170]. The induction of autophagy in MM cells by inhibitors of the isoprenoid biosynthesis pathway is a potential target for developing new therapeutic drugs^[171].

Dihydroartemisinin induced autophagy and apoptosis via WNT/ β -catenin and P38/MAPK in MM cell lines and mouse models^[172]. Hsp90 inhibitor 17-dimethylaminoethylamino-17-demethoxygeldanamycin triggered autophagy over mTOR inhibition in MM cells^[173]. Clioquinol engendered autophagy by causing mTOR downregulation in MM and leukemia cells^[174].

Trifluoperazine, an antipsychotic drug, caused the inhibition of autophagy by NUPR1 overexpression in MM cells and led to the induction of apoptosis^[175]. Betulinic acid performs its cytotoxicity in MM cells by inducing autophagy or apoptosis via the PP2A switch^[176]. It was reported that Fingolimod regulates apoptosis by inducing autophagy in MM cells^[177].

Drug discovery

Currently, there is no known treatment option to be considered definitive for targeting autophagy in cancer. This is because traditional cell cultures do not fully describe the complex interaction between cancer cells, other cells, and the microenvironment. However, 3D cell cultures are more effective in depicting the tumor microenvironment than traditional cultures, and they better reflect the differentiation and proliferation of tumor cells^[178]. Microfluidic systems are biomedical platforms that enable the controlled distribution of small amounts of liquids, which facilitates the simultaneous execution of multiple tests^[179]. These devices allow for more accurate and quicker studies of the tumor microenvironment, metastasis, and drug resistance^[1]. They also enable drug screening to be carried out rapidly and precisely, which assists in identifying new drug candidates with more efficiency^[180].

CONCLUSION

MM is a disease of plasma cells and is very sensitive to protein turnover processes. Autophagy, a mechanism linked to cell death, contributes to the progression of the disease by activating the UPR system in MM cells. Proteasome inhibitors, commonly employed in MM, induce UPR and ER stress. However, inhibiting proteasomes not only triggers autophagy but also leads to drug resistance. Therefore, there is a close interplay among UPR, autophagy, apoptosis, and drug resistance. The combination of proteasome inhibitors such as Bortezomib and Carfilzomib, which are frequently used in the treatment of MM, and autophagy inhibitors can effectively induce cell death. Additionally, agents that inhibit heat shock proteins also show therapeutic potential in MM by initiating autophagy. Furthermore, as in all cancer processes, autophagy in MM is affected by BMME, DNA repair, and transcriptional regulation, crucial aspects in the development of MM disease. The addition of autophagy inhibitors to agents that cause DNA damage will prevent MM cells from evading death. The widespread use of HDAC6 inhibitors in treating MM cells deactivates the UPR protection and induces autophagy. Clinically, PI3K/AKT/mTOR inhibitors prove effective by restricting MM cell growth, making cell death inevitable. Furthermore, even in normal cells, stress-causing starvation and hypoxia conditions trigger autophagy. Consequently, VEGF and EGFR inhibitors, which will prevent MM cells from feeding, and HIF1- α inhibitors, which will cause oxygen deprivation, become beneficial. Moreover, small molecules that target genes involved in the autophagy mechanism also have a therapeutic potential. There is a considerable volume of both completed and ongoing clinical trials exploring this avenue. However, a clinically promising drug has not yet been released, and there is no standardized autophagy treatment yet. In this regard, leveraging 3D and microfluidic systems holds the potential to develop disease models. These platforms have the capability to generate results more rapidly than traditional clinical trials. Additionally, reconstructing disease models with 3D models and microfluidic systems can lead to the identification of new autophagy modulators^[1,178]. Moreover, it is possible to conduct tests on new agents before administering them to the patient and to develop appropriate strategies that can be tailored according to the patient's needs. This enables the utilization of autophagy, similar to apoptosis, in halting or even eradicating the progression of MM.

DECLARATIONS

Authors' contributions

Conceptualized, did the literature review, designed the review, and drafted the manuscript: Kozalak G
Edited the manuscript, supervised the process, and critically revised the article: Koşar A
Both authors read and agreed with the published version of the manuscript.

Availability of data and materials

Not applicable.

Financial support and sponsorship

This research was funded by TUBITAK (Turkish Scientific and Technological Council) grant number 121C417.

Conflicts of interest

Both authors declared that there are no conflicts of interest.

Ethical approval and consent to participate

Not applicable.

Consent for publication

Abstract

Renal cell carcinoma (RCC), the most prevalent type of kidney cancer, is a significant cause of cancer morbidity and mortality worldwide. Antiangiogenic tyrosine kinase inhibitors (TKIs), in combination with immune checkpoint inhibitors (ICIs), are among the first-line treatment options for patients with advanced RCC. These therapies target the vascular endothelial growth factor receptor (VEGFR) tyrosine kinase pathway and other kinases crucial to cancer proliferation, survival, and metastasis. TKIs have yielded substantial improvements in progression-free survival (PFS) and overall survival (OS) for patients with advanced RCC. However, nearly all patients eventually progress on these drugs as resistance develops. This review provides an overview of TKI resistance in RCC and explores different mechanisms of resistance, including upregulation of alternative proangiogenic pathways, epithelial-mesenchymal transition (EMT), decreased intracellular drug concentrations due to efflux pumps and lysosomal sequestration, alterations in the tumor microenvironment including bone marrow-derived cells (BMDCs) and tumor-associated fibroblasts (TAFs), and genetic factors such as single nucleotide polymorphisms (SNPs). A comprehensive understanding of these mechanisms opens the door to the development of innovative therapeutic approaches that can effectively overcome TKI resistance, thereby improving outcomes for patients with advanced RCC.

INTRODUCTION

Kidney cancer is the 6th most common cancer in men and the 9th most common cancer in women in the United States, and there will be an estimated 82,000 new cases and 15,000 deaths in 2023^[1]. Renal cell carcinoma (RCC) is the most common type of kidney cancer, accounting for over 90%-95% of all cases^[2]. With an annual incidence rate of 17.1 per 100,000 individuals and a mortality rate of 3.6%, RCC has become a significant public health concern, resulting in substantial morbidity and mortality^[3]. RCC originates from renal tubular epithelial cells and comprises a diverse and heterogeneous group of pathologies^[4]. RCC is categorized into multiple subtypes, the most common of which is clear cell RCC (ccRCC), accounting for approximately 75% of all cases and 85% of metastatic cases^[5,6]. Other subtypes include papillary, chromophobe, collecting duct, and renal medullary carcinomas. Risk factors for RCC include age, male sex, tobacco use, hypertension, and genetic syndromes such as von Hippel-Lindau (VHL)^[7,8].

Management of RCC varies based on disease stage and characteristics. For localized disease, treatment strategies encompass active surveillance, nephrectomy, radiofrequency ablation, and cryotherapy^[9,10]. Adjuvant systemic therapies including antiangiogenic targeted therapies have thus far failed to demonstrate a benefit in overall survival, although there are several ongoing trials in this space^[11]. The management of metastatic disease, predominantly ccRCC, is more complicated. Until the mid-2000s, systemic cytokines including interleukin-2 (IL-2) and interferon-alpha (IFN- α) were commonly used, but response rates to these therapies were poor^[12]. The initial breakthrough in targeted therapy for RCC occurred in 2005 with the approval of sorafenib, a tyrosine kinase inhibitor (TKI) against vascular endothelial growth factor (VEGF). In 2009, bevacizumab, a monoclonal antibody against VEGF, was approved in combination with IFN- α . Subsequently, other multitargeted small molecule antiangiogenic TKIs emerged as treatment options and significantly improved progression-free survival (PFS) and overall survival (OS)^[13]. Another class of agents, the mammalian target of rapamycin (mTOR) inhibitors, were introduced during the same period. In recent years, the addition of immune checkpoint inhibitors (ICIs) to TKIs in the frontline setting has reshaped the treatment landscape of advanced RCC^[14].

TKIs are competitive inhibitors that bind to the kinase domain of their target receptor tyrosine kinase (RTK). RTKs are transmembrane proteins possessing an extracellular ligand-binding domain and an intracellular kinase domain, enabling them to transmit signals across the plasma membrane. Upon ligand binding, RTKs undergo dimerization and autophosphorylation, leading to kinase domain activation. This provides a docking site for proteins, enabling them to direct a cascade of intracellular events that regulate cellular proliferation, differentiation, survival, and migration [Figure 1]^[15]. Dysregulation of RTK signaling via constitutive autophosphorylation resulting in ligand-independent kinase activity has been implicated in many cancers, making RTKs attractive therapeutic targets^[16]. In RCC, the signaling pathways initiated by overactive VEGF receptor (VEGFR) lead to enhanced endothelial cell migration, proliferation, permeability, survival, and lymphangiogenesis^[17]. Antiangiogenic TKIs have been developed to mute this response by binding at or adjacent to the ATP-binding site, preventing autophosphorylation^[18,19]. These drugs target various kinases, including VEGFR, platelet-derived growth factor receptor (PDGFR), c-Kit, FMS-related receptor tyrosine kinase 3 (FLT-3), and rearranged during transfection tyrosine-protein kinase (RET)^[20]. The majority of TKIs are multitargeted and have activity against several kinases with varying potency. Importantly, all TKIs commonly used in the treatment of advanced RCC possess activity against VEGFR^[21]. These include sunitinib, sorafenib, pazopanib, axitinib, cabozantinib, and lenvatinib.

Despite the success of these targeted agents, antiangiogenic TKI resistance is common and poses significant obstacles to achieving durable responses in the treatment of RCC. For instance, the majority of RCC patients who start on sunitinib will develop resistance within 6 months of treatment^[22]. In this review, we

aim to explore the molecular mechanisms underlying TKI resistance in RCC and shed light on potential strategies to overcome this phenomenon. By elucidating the complexities of TKI resistance, we hope to pave the way for the development of novel therapeutic approaches that can improve outcomes for patients with advanced RCC.

RATIONALE FOR ANTIANGIOGENIC TKIS IN RCC

The treatment of RCC stems from the underlying molecular and genetic alterations that drive tumorigenesis and progression. Almost all hereditary and most sporadic cases of RCC involve mutations leading to loss of tumor suppressor gene function. The most common mutation in ccRCC is the loss of the VHL via loss of chromosome 3p, seen in over 90% of sporadic cases^[23]. This leads to the loss or impaired function of VHL tumor suppressor protein (pVHL). Normally, pVHL targets the alpha subunits of hypoxia-inducible factor (HIF) for proteasomal degradation through prolyl hydroxylases. In the absence of pVHL, HIF, particularly HIF-2 α , accumulates and acts as a transcription factor to trigger the overexpression of hypoxia-inducible genes such as VEGF, platelet-derived growth factor-BB (PDGF-BB), transforming growth factor- α (TGF- α), c-Met, cyclin D1, and CXCR4^[24]. These genes play a crucial role in angiogenesis, cell proliferation, and tumor growth. HIF-2 α also upregulates the production of c-Myc, a transcription factor implicated in the progression of various cancers^[25]. Antiangiogenic TKIs disrupt this aberrant molecular cascade by specifically targeting the dysregulated signaling pathways driven by HIF-2 α and its downstream targets, thereby inhibiting tumor angiogenesis and growth in RCC.

TKI RESISTANCE

Resistance to a targeted agent develops when either the agent is no longer able to inhibit specific signaling pathways or when a tumor's ability to survive becomes independent from those pathways. Various mechanisms contribute to drug resistance, such as alterations in drug targets, activation of alternative signaling pathways, enhancement of drug efflux, and evasion of apoptotic cell death^[26].

Resistance to antiangiogenic targeted therapies can be categorized as intrinsic (primary) or acquired (secondary)^[27]. Intrinsic resistance is characterized by an inherent insensitivity of cancer cells to TKIs and a lack of response to the drug. By contrast, acquired resistance arises when cancer cells initially respond to TKI treatment but eventually relapse as the drug loses efficacy over time due to the acquisition of various resistance mechanisms. Multiple *in vitro* and *in vivo* models involving cell lines, patient-derived xenografts (PDX), organoids, and genetically engineered mouse models (GEMMs) have been developed to assess the mechanisms, dynamics, and progression of drug resistance^[28]. These models help elucidate the complex interplay between cancer cells and their microenvironment, offering valuable information for developing strategies to overcome resistance and improve treatment outcomes. In the following section, we summarize the numerous mechanisms of TKI resistance identified to date in RCC.

ACQUIRED MECHANISMS OF TKI RESISTANCE IN RCC

Alternative proangiogenic pathways

Successful antiangiogenic TKI therapy suppresses the production of proangiogenic factors such as VEGF and PDGF and inhibits angiogenesis. This eventually leads to tumor hypoxia, which then triggers the upregulation of alternative proangiogenic pathways, contributing to eventual drug resistance. This process is also known as angiogenic escape or angiogenic switch.

One such pathway involves the increased expression of interleukin-6 (IL-6). IL-6 activates the STAT3 pathway, leading to the upregulation of HIF-2 α and subsequent increased production of VEGFR^[29]. IL-8 is also upregulated as a response to hypoxia and contributes to angiogenesis by promoting endothelial cell proliferation, survival, and migration via VEGF mRNA transcription and autocrine VEGFR-2 activation^[30,31]. High levels of IL-6 and IL-8 have been correlated with significantly shorter PFS and OS in metastatic RCC patients treated with sunitinib and pazopanib^[32,33].

Angiopoietin 1 and 2 (Ang 1/2) are critical regulators of angiogenesis, acting as ligands for the Tie2 receptor tyrosine kinase on endothelial cells^[34]. When Tie2 is activated, it promotes vessel stabilization, survival, and maturation, thereby boosting the VEGF pathway's effectiveness in improving perfusion to RCC tumors^[35]. Wang *et al.* followed Ang 2 levels as RCC patients were treated with sunitinib and found that Ang 2 decreased as patients responded to therapy, but then increased as patients became resistant and developed advanced disease^[36].

C-Met, a tyrosine kinase encoded by the MET proto-oncogene, binds hepatocyte growth factor (HGF) and initiates an alternative proangiogenic pathway to VEGFR. Type 1 papillary RCC is commonly associated with activating MET alterations and has an unfavorable prognosis^[37]. Inhibitors against c-Met have emerged as important treatment options for this disease in recent years. In the phase 2 CREATE trial by Schöffski *et al.*, patients with type 1 papillary RCC were categorized by MET mutation status and treated with crizotinib, a TKI against c-Met and ALK. Patients with MET alterations or amplifications were found to have a higher objective response rate, as well as increased PFS and OS compared to patients without MET alterations or amplifications^[38]. High c-Met expression in ccRCC has been identified as an independent risk factor for higher tumor grade, aggressive phenotype, increased metastasis, and decreased overall survival^[39].

C-Met activation and overexpression have been identified in ccRCC cells previously treated with anti-VEGFR TKIs, likely conferring resistance to these therapies^[40]. Increased c-Met expression in patients previously treated with sunitinib has been correlated with shorter PFS and OS^[41].

Other proangiogenic factors including fibroblast growth factors 1 and 2 (FGF 1/2) and ephrin A1 and A2 (EFNA 1/2) have also been found to be upregulated following VEGFR inhibition, likely as a result of tumor hypoxia^[42]. The FGF receptor (FGFR) pathway regulates and activates alternative proangiogenic pathways such as mitogen-activated protein kinases/extracellular signal-related kinases (MAPK/ERK) and phosphoinositide-3-kinase/Akt strain transforming signaling pathway (PI3K/Akt)^[43].

Increased pericyte coverage

Pericytes are mural cells that surround the endothelial cells of blood vessels and promote vascular stability and angiogenesis^[44]. PDGF-BB is secreted by vascular endothelial cells and binds to PDGFR- β on pericytes, activating signaling that leads to increased pericyte production of VEGF which promotes endothelial cell proliferation^[45]. Increased pericyte activity in the tumor microenvironment has been associated with more aggressive ccRCC^[46], and resistance to antiangiogenic TKIs has been observed in tumors with an increased number of pericytes^[47]. A proposed mechanism of resistance is the inhibition of an important negative feedback loop. High VEGF levels lead to the formation of a VEGFR/PDGFR- β complex that suppresses PDGFR- β signaling, preventing the production of excessive VEGF^[48]. In the setting of TKI therapy against VEGFR, this mechanism may be less effective, leading to overactive pericyte activity. Thus, all antiangiogenic TKIs induce resistance via this mechanism.

Multi-drug resistance via lysosomal sequestration and efflux transporters

Sunitinib is a small, hydrophobic, weak base, which allows it to easily pass through the cellular membrane, accumulate intracellularly, and bind to the kinase domain of VEGFR^[49]. However, this structure also lends itself to efficient passage into lysosomes, where a more acidic environment encourages protonation of the drug, conferring a positive charge and effectively sequestering it for degradation^[50]. Although sunitinib is particularly susceptible due to its chemical properties, lysosomal sequestration has been identified as a contributor to multi-drug resistance (MDR) in cancer cells via a variety of mechanisms. Cancer cells have been found to upregulate PI3K, which promotes lysosomal activity and stability. Further, cancer cells have been found to abolish lysosomal membrane permeabilization (LMP), a process that normally induces apoptosis, via upregulation of cytosolic protease inhibitors and via increased translocation of Hsp70 to the lysosomal lumen, which stabilizes lysosomal membranes^[51]. Following exposure to sunitinib, RCC cells exhibit a rise in lysosomal mass, facilitating enhanced sequestration^[52]. Zhitomirsky *et al.* demonstrated that exposure of human carcinoma cells to sunitinib leads to an increase in the number of lysosomes per cell, as well as the number of lysosomes accumulating high levels of sunitinib^[53].

Sunitinib exposure has also been associated with increased expression of ATP-binding cassette (ABC) transporters such as P-glycoprotein (P-GP), which are present both on the lysosomal and cell membranes and promote both lysosomal sequestration and extracellular efflux^[54]. Thus, lysosomal sequestration and efflux transporter proteins work synergistically to promote the development of resistance^[55].

Bone marrow-derived cell recruitment

Bone marrow-derived cells (BMDCs) are a pool of progenitor cells, including hematopoietic stem cells, endothelial progenitor cells, tumor-associated macrophages, mesenchymal stromal cells, VEGFR1-positive hemangiocytes, and more^[56]. Myeloid-derived suppressor cells (MDSCs) are a subpopulation of BMDCs that most commonly express CD11b and serve an immunomodulatory role in the tumor microenvironment, suppressing the activity of infiltrating cytotoxic T lymphocytes^[57]. MDSCs produce

nitric oxide, which reacts with superoxide, generating peroxynitrite (PNT). PNT nitrates both T-cell receptors, reducing their responsiveness to antigen major histone compatibility (MHC) complexes, and T-cell specific chemokines, blocking T-cell migration^[58]. MDSCs also produce proangiogenic proteins such as IL-8, MMP8, and MMP9^[59]. MDSCs and other BMDCs are recruited to RCC tumors by various chemokines, promoting tumor angiogenesis and progression^[60,61]. Sunitinib has been shown to reduce MDSCs in the peripheral blood of mRCC patients who had the local tumor resected^[62]. However, persistently high levels of MDSCs have been found in cases of resistant RCC. This may be due to the increased production of granulocyte-macrophage colony-stimulating factor (GM-CSF), which protects MDSCs from sunitinib-induced apoptosis^[59]. Recruitment of MDSCs and other BMDCs to the tumor microenvironment is likely due to hypoxia induced by TKI therapy. Therefore, though this effect of sunitinib is well-known, all approved antiangiogenic TKIs are thought to contribute to this process.

Tumor-associated fibroblasts

Tumor-associated fibroblasts (TAFs) are activated fibroblasts that have undergone phenotypic and functional changes in response to tumor-derived signals^[63]. Unlike regular fibroblasts, TAFs remain chronically activated and continue to carry out their work indefinitely within the tumor microenvironment. They support tumor survival and growth by secreting various growth factors, cytokines, and chemokines, such as interleukins, HGF, and stromal cell-derived factor 1 alpha (SDF-1 α)^[64]. TAFs promote the deposition of a dense extracellular matrix, creating a physical barrier that hampers drug penetration into the tumor and supporting cell adhesion-mediated drug resistance^[65,66]. Moreover, the role of TAFs in supporting cell adhesion-mediated drug resistance (CAM-DR) is well-defined. TAFs also play a part in reprogramming tumor metabolism, making cancer cells less dependent on glucose, and increasing the lactate upload to drive anabolic pathways^[64]. Platelet-derived growth factor-C (PDGF-C) mediates the angiogenic properties of TAFs and has been found to be upregulated in tumor cells resistant to anti-VEGF antibodies^[67].

Epithelial-mesenchymal transition

Epithelial-mesenchymal transition (EMT) is an embryonic development process that can be hijacked by cancer cells to promote invasion, metastasis, and resistance to therapy. During EMT, epithelial cells lose characteristics such as cell-to-cell adhesion and apical-basal polarity, and acquire mesenchymal features including increased motility, invasiveness, and resistance to cell death^[68]. This phenotypic switch is achieved by changes in gene expression, such as the downregulation of epithelial markers (E-cadherin) and upregulation of mesenchymal markers (N-cadherin, vimentin), as well as by epigenetic modifications^[68]. EMT in cancer is largely driven by tumor hypoxia and resultant HIF-1 α activation, as well as by inflammatory cytokines IL-6, IL-8, IL-15, and tumor necrosis factor- α (TNF- α)^[20,69].

EMT is frequently discussed in the context of cancer stem cells (CSCs), which are subpopulations of cells within tumors that are capable of self-renewal and multi-lineage differentiation^[70]. Because heterogeneous tumors contain many phenotypically distinct cells with varying degrees of response to chemotherapeutics, CSCs enhance drug resistance and tumor relapse. Processes associated with EMT, such as suppression of E-cadherin, have been shown to generate increased CSCs in tumors^[71]. A specific side population of CSCs has been identified in RCC, and many RCC tumors express diverse markers associated with CSCs^[72].

Acquired resistance to sunitinib via EMT has been demonstrated in patient-derived xenograft models. In a study by Hammers *et al.*, tumor tissue from skin metastases of a sunitinib-resistant ccRCC patient was implanted into nude mice, and these mice were treated with sunitinib or vehicle for 90 days. The average tumor volume was less than 200 mm³ in mice treated with sunitinib and more than 800 mm³ in mice treated with the vehicle, which suggests renewed sensitivity to sunitinib. The histology of the skin metastases indicated sarcomatous differentiation with a fibroblast-like appearance, indicating EMT. However, the cells

in the xenograft returned to normal ccRCC histology^[73].

Pharmacogenomic factors

Single nucleotide polymorphisms (SNPs) are variations in a single nucleotide within the DNA sequence, which achieve an allelic frequency of at least 1% in a population, and they can affect gene expression, protein function, and drug metabolism^[3]. Specific SNPs in drug-metabolizing enzymes, drug transporters, or drug targets can impact the efficacy of TKIs.

CYP3A4 and CYP3A5 are two of the principal enzymes responsible for sunitinib metabolism, converting the drug to its active metabolite, N-desethyl sunitinib (SU12662)^[74]. SU12662 has a longer half-life than sunitinib, resulting in increased drug exposure^[75]. The CYP3A4 SNP rs4646437G>A has been associated with an increased incidence of hypertension in mRCC patients treated with sunitinib. This is presumably due to enhanced sunitinib metabolism leading to increased concentrations of SU12662^[76]. The expression of CYP3A4 is negatively regulated by two ligand-activated nuclear receptors, NR112 and NR113^[77]. SNPs present in the genes encoding NR112 and NR113 have been associated with decreased patient PFS and OS, likely due to enhanced NR112 and NR113 activity leading to decreased CYP3A4 expression and lower SU12662 concentrations^[78]. SNPs in CYP3A5, such as the CYP3A5*1 allele, have been associated with sunitinib toxicity and the need for dose reduction, likely due to enhanced CYP3A5 activity leading to increased concentrations of SU12662^[79].

Additionally, SNPs in genes coding for ABC transporters have been found to affect the uptake and efflux of TKIs, altering drug concentrations within tumor cells. The presence of CGT in the ABCB1 haplotype is associated with improved PFS, likely due to decreased clearance of sunitinib and its active metabolite SU12662^[79]. On the other hand, certain variants such as the TT-genotype in ABCB1 rs1125803 or the TT/TA-variant in ABCB1 rs2032582 have been found to promote drug efflux, resulting in increased intracellular clearance of sunitinib, increased time-to-dose reduction, and decreased PFS^[80].

MicroRNAs

MicroRNAs (miRNAs) are small non-coding RNA molecules that play a significant regulatory role in gene expression. miRNAs are known to contribute to cancer progression by silencing tumor suppressor genes via destruction or decreased expression of mRNA^[81]. Multiple miRNAs have been implicated in mediating TKI resistance in RCC by targeting key signaling pathways involved in cell proliferation, survival, and drug response. For example, miR-15b has been found to be overexpressed in sunitinib-resistant cell lines after incubation with the drug. *In vivo* models have produced similar results^[82]. Other notable miRNAs overexpressed in sunitinib-resistant RCC cells include miRNA-575, miRNA-642b-3p, and miRNA-4430 (all studied *in vitro*), as well as miRNA-942, miRNA-133a, miRNA-628-5p, and miRNA-484 (all studied *in vivo*)^[83,84]. Additionally, miR-144-3p overexpression in ccRCC has been found to enhance cell proliferation, clonogenicity, migration, invasion, and resistance via repression of the tumor suppressor gene, ARID1A^[85].

In contrast, miR-200b and miR-141 have been found to be downregulated in ccRCC compared to benign tissue, and their expression may represent an independent prognostic factor for increased PFS and OS^[86]. [Figure 2](#) illustrates the wide array of known acquired mechanisms of TKI resistance in RCC.

INTRINSIC MECHANISMS OF TKI RESISTANCE IN RCC

Methylation of tumor suppressor genes

Enhancer of zeste homolog 2 (EZH2) is an enzyme that functions as the catalytic subunit of the polycomb

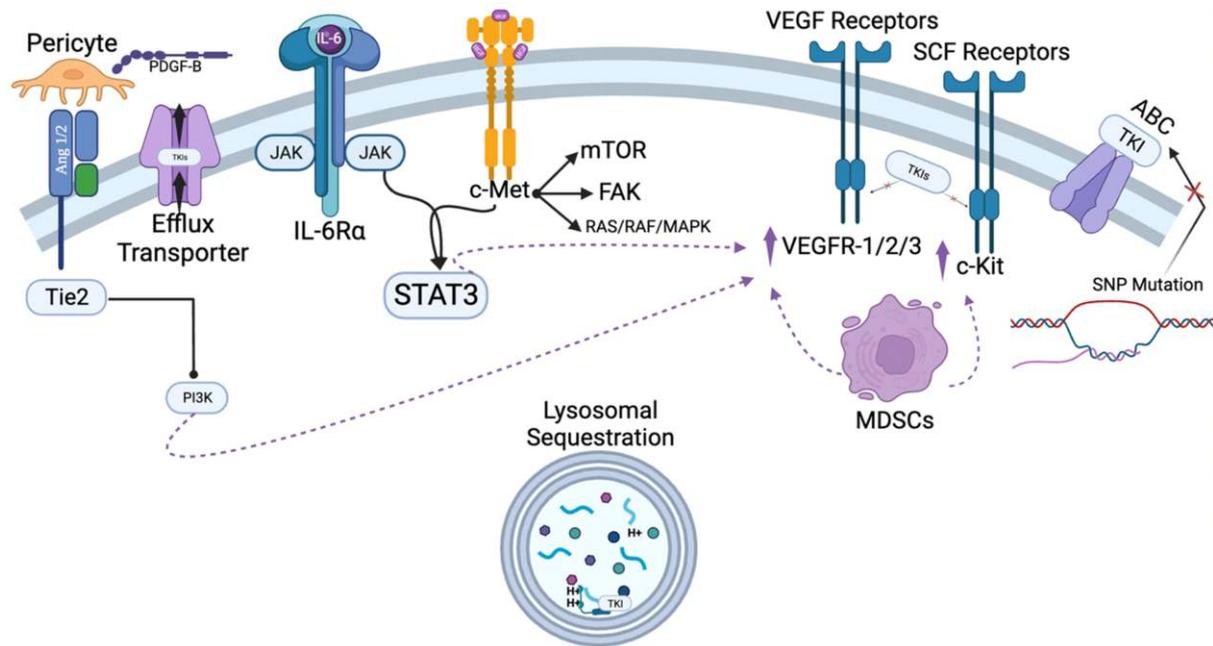

Figure 2. Common acquired mechanisms of resistance to tyrosine kinase inhibitors in RCC. ABC: ATP-binding cassette; IL-6: interleukin-6; MAPK: mitogen-activated protein kinases; MDSCs: myeloid-derived suppressor cells; mTOR: mammalian target of rapamycin; PDGF: platelet-derived growth factor; PI3K: phosphoinositide-3-kinase; RCC: renal cell carcinoma; SNP: single nucleotide polymorphism; TKIs: tyrosine kinase inhibitors; VEGF: vascular endothelial growth factor; VEGFR: vascular endothelial growth factor receptor.

repressive complex 2 (PRC2). Its primary function is to methylate lysine 27 on histone H3, resulting in gene silencing and transcriptional repression^[87]. Intrinsic increased expression of EZH2 can lead to aberrant methylation of specific tumor suppressor genes, rendering them inactive. Methylation of these genes can disrupt critical cellular pathways involved in growth control and DNA repair, leading to the promotion of tumorigenesis. The dysregulation of EZH2-mediated methylation can confer resistance to TKIs and other antineoplastic agents by circumventing the inhibitory effects of these drugs on oncogenic signaling pathways. The overexpression of EZH2 has been reported in RCC and is associated with poor prognosis^[88,89].

Inhibition of apoptosis

B cell lymphoma-2 (Bcl-2) and B cell lymphoma-extra large (Bcl-xL) are proteins within the Bcl-2 family and play a key role in inhibiting apoptosis. These are known to be upregulated in many cancers, contributing to proliferation and metastasis^[90]. There is limited evidence that overexpression of these proteins may confer intrinsic resistance to TKIs and other antineoplastic agents in RCC via inhibition of apoptosis, though further study is needed^[91]. **Figure 3** demonstrates known intrinsic mechanisms of resistance to TKIs in RCC.

OVERCOMING TKI RESISTANCE IN RCC

Effective mitigation of TKI resistance plays a vital role in improving outcomes for patients with advanced RCC. Undoubtedly, this is a significant challenge due to the diverse range of mechanisms through which RCC can develop resistance. However, the multitude of mechanisms also offers numerous avenues for

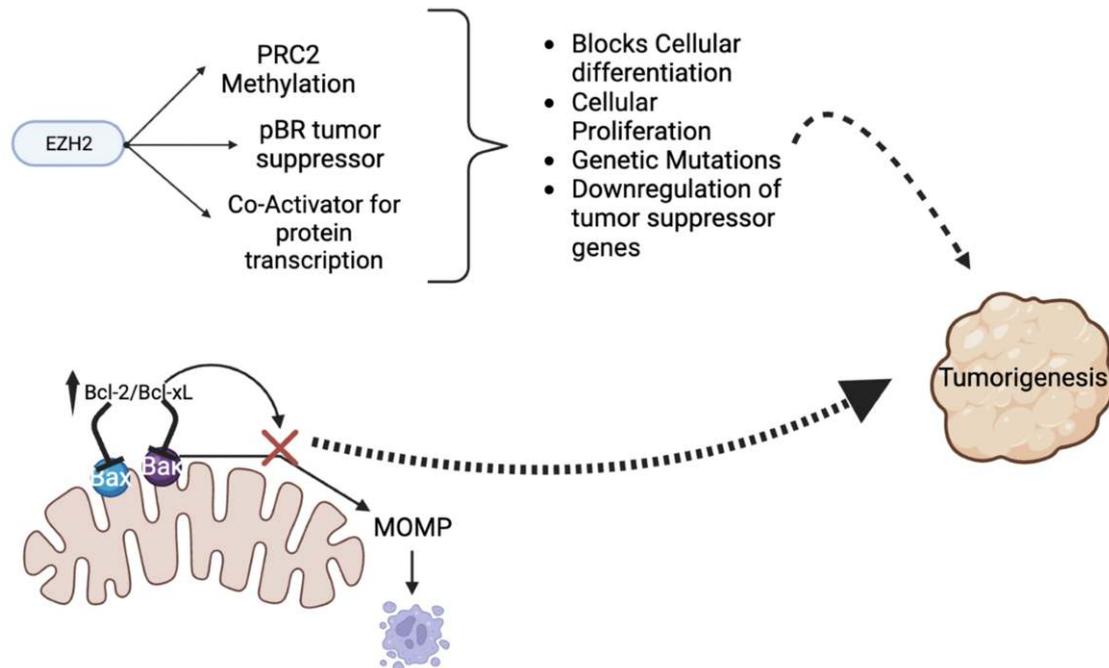

Figure 3. Intrinsic resistance mechanisms affecting tyrosine kinase inhibitor activity in RCC. Bcl-2: B cell lymphoma-2; Bcl-xL: B cell lymphoma-extra large; EZH2: enhancer of zeste homolog 2; PRC2: polycomb repressive complex 2; RCC: renal cell carcinoma.

intervention, enabling the targeting of various processes to minimize resistance. [Table 1](#) summarizes the many resistance mechanisms herein described, as well as potential approaches for overcoming these mechanisms.

One strategy is to target processes upstream from VEGF/VEGFR, such as HIF-2 α . In hypoxic conditions, HIF-2 α promotes the expression of multiple hypoxia-inducible genes, including VEGF and PDGF-BB. As previously discussed, in VHL syndrome, the negative regulatory protein pVHL is lost, leading to the accumulation of HIF-2 α and excessive angiogenesis^[24]. HIF-2 α inhibitors act by inhibiting the dimerization of HIF-2 α and its partner protein, ARNT1, thereby inhibiting HIF-2 α mediated transcription^[92]. The HIF-2 α inhibitor, belzutifan, was approved by the FDA for the treatment of germline VHL-mutated RCC after a phase 2 trial demonstrated promising efficacy in this population^[93]. Other studies examining belzutifan in sporadic (non-VHL associated) RCC are also encouraging^[94]. In a phase 1 expansion cohort, belzutifan in combination with nivolumab was administered to patients with advanced ccRCC, and patients with therapeutic exposure to the drug had a median PFS of 10.0 months compared to just 4.7 months for patients with subtherapeutic exposure^[95]. An ongoing trial evaluating the combination of belzutifan and cabozantinib is currently underway^[96].

Directly targeting the alternative proangiogenic pathways upregulated during resistance development may also be effective. IL-6 and IL-8, both upregulated in the setting of tissue hypoxia following effective antiangiogenic therapy, are prime examples^[47]. These cytokines can induce a cascade of immunologic changes that promote angiogenesis. Interestingly, co-administration of IL-8 neutralizing antibody has shown promise in re-sensitizing xenograft tumors to sunitinib treatment^[97]. Administration of the anti-IL-6 antibody, tocilizumab, given in combination with interferon, has also slowed RCC xenograft proliferation^[29]. The Ang/Tie signaling pathway, which augments the VEGFR pathway and promotes blood vessel stabilization, survival, and maturation, can be directly targeted with the TKI trebananib^[98]. In

Table 1. Acquired and intrinsic mechanisms of tyrosine kinase inhibitor resistance in RCC

Process	Mechanism	TKIs affected	Potential therapies	Ref.
Alternative proangiogenic pathways	Multiple; tumor hypoxia induces upregulation of interleukins, c-Met/HGF, angiopoietins, and growth factors	Sunitinib, pazopanib, sorafenib, axitinib, tivozanib	HIF-2 α inhibitors; anti-IL-6 and IL-8 antibodies; TKIs against Ang 1 and 2, c-Met, and FGFR	[29-43, 92-104]
Increased pericyte coverage	Increased tumor endothelial stability and production of VEGF	Sunitinib, pazopanib, sorafenib, axitinib, tivozanib	Unknown	[44-48]
Lysosomal sequestration	Drug sequestered; subtherapeutic intracellular concentrations; ineffective inhibition of receptor tyrosine kinases	Sunitinib	Alkalizing agents; drugs against lysosomal membrane proteins	[49-53, 55,108]
Efflux pumps	Subtherapeutic intracellular concentrations	Sunitinib known, but other TKIs possible	P-GP inhibitors	[54,55, 109-113]
Bone marrow-derived cell recruitment	Bone marrow-derived cells accumulate around tumor; immunomodulatory effects including suppression of cytotoxic T cells	Sunitinib, pazopanib, sorafenib, axitinib, tivozanib	Immune checkpoint inhibitors to rejuvenate immune response in the tumor microenvironment	[56-62]
Tumor-associated fibroblasts	Overactive fibroblasts secrete interleukins, hepatocyte growth factor, and more in tumor microenvironment; increased extracellular matrix deposition hampers drug penetration and supports cell adhesion	Unknown, but all TKIs possible	Histone deacetylase inhibitors	[63-67, 105,107]
Epithelial-mesenchymal transition	Tumor hypoxia drives epithelial cells to acquire features such as increased motility, invasiveness, and resistance to cell death	Sunitinib, pazopanib, sorafenib, axitinib, tivozanib	Drugs with activity against EMT in combination with antineoplastic agents	[20,68 -72,105, 106]
Pharmacologic Factors	Single nucleotide polymorphisms in genes related to sunitinib metabolism lead to decreased concentrations of active metabolite	Sunitinib	Unknown	[3,74-80]
miRNAs	Silencing of tumor suppressor genes via destruction or decreased expression of mRNA	Sunitinib	Unknown	[81-86]
Methylation of tumor suppressor genes	EZH2 overexpression leads to aberrant methylation of tumor suppressor genes, rendering them inactive	All antineoplastic and targeted drugs	EZH2 inhibitors; hypomethylating agents	[87-89, 114]
Inhibition of apoptosis	Bcl-2 and Bcl-xL overexpression inhibits tumor cell apoptosis	All antineoplastic and targeted drugs	Bcl-2 inhibitors	[90,91, 115]

Bcl-2: B cell lymphoma-2; Bcl-xL: B cell lymphoma-extra large; EMT: epithelial-mesenchymal transition; EZH2: Enhancer of zeste homolog 2; FGFR: fibroblast growth factors receptor; HGF: hepatocyte growth factor; IL-6: interleukin-6; IL-8: interleukin-8; miRNAs: MicroRNAs; P-GP: P-glycoprotein; RCC: renal cell carcinoma; TKIs: tyrosine kinase inhibitors; VEGF: vascular endothelial growth factor.

xenograft mouse models, treatment with trebananib in combination with sunitinib slowed tumor progression compared to treatment with sunitinib plus control^[36]. However, other results have been less promising. A phase 2 trial examined the efficacy of trebananib with or without continued anti-VEGF therapy in RCC patients who had previously progressed on anti-VEGF therapy and observed poor outcomes in both treatment arms^[99]. Targeting c-Met in cells that have become resistant to TKI's against VEGF may also be effective. Studies have shown that the growth of sunitinib-resistant tumors can be slowed with a combination of sunitinib and a c-Met inhibitor^[39]. Likewise, Zhou *et al.* found that treatment with cabozantinib, a TKI against VEGFR and MET, can rescue acquired sunitinib resistance in xenograft mouse models^[100]. Finally, fibroblast growth factor (FGF) overexpression, specifically FGF2, has been associated with a poor RCC prognosis and contributes to TKI resistance through suppression of antiangiogenic activity^[42,101]. There are several multitargeted TKIs that inhibit FGFR, such as lenvatinib, but these drugs are themselves susceptible to resistance^[102]. *In vitro* studies have suggested that combining FGFR inhibitors with other TKIs such as PI3K inhibitors may help mitigate this resistance and inhibit RCC cell metabolic activity^[103]. PI3K inhibitors have also demonstrated strong *in vitro* anti-tumor activity when co-administered with sunitinib^[104].

Targeting proangiogenic changes in the tumor microenvironment may be useful in combatting TKI resistance. The process of EMT, which promotes resistance to therapy and metastases, is associated with a host of metabolic changes. Although there are no direct inhibitors to EMT, multiple metabolism-inhibiting drugs have shown indirect activity against EMT changes through various complex biochemical mechanisms^[105]. There are multiple ongoing clinical trials examining the combination of these drugs with antineoplastic agents, although none of these trials include RCC patients^[106]. Additionally, TAFs may serve as a target for overcoming resistance. Histone deacetylase inhibitors offer a promising approach to diminish the activation of TAFs and eradicate their infiltration within the tumor stroma, as demonstrated by a study in patients with relapsed or refractory lymphoma or multiple myeloma^[105,107].

Lysosomal sequestration of TKIs is another potentially reversible mechanism of resistance. Combination therapies incorporating alkalinizing treatments have been explored, creating a toxic environment that counteracts the sequestration process^[51]. Drugs targeting various lysosomal membrane proteins have shown promise in destabilizing the lysosomal membrane, leading to membrane permeabilization^[55]. Interestingly, Gotink *et al.* showed that sunitinib efficacy in RCC cells that had developed resistance via lysosomal sequestration can be restored by culturing resistant cells with sunitinib-free media^[108]. This supports lysosomal sequestration as an acquired, transient, and reversible resistance mechanism.

Additionally, RCC has been shown to overexpress the ABC transporter P-glycoprotein (P-GP) in response to hypoxia from antiangiogenic therapy. P-GP is predominantly found in the cell membrane and exports drugs, contributing to multi-drug resistance^[109,110]. P-GP is also commonly found in enterocytes and contributes to resistance via drug export into the GI lumen, limiting drug oral bioavailability^[111]. Several studies have examined the co-administration of inhibitors to P-GP with anticancer drugs in various malignancies, but this strategy has been limited by severe toxicity and unwanted side effects^[112]. Despite evidence of *in vitro* anti-tumor activity, there are currently no P-GP inhibitors approved for cancer treatment^[113].

Intrinsic mechanisms may also be targeted to overcome resistance. EZH2 overexpression in RCC contributes to hypermethylation, and ultimately inactivation, of tumor suppressor genes. The efficacy of EZH2 inhibitors and hypomethylating agents is currently not defined in many solid tumors, including RCC, but investigative studies are underway^[114]. Antiapoptotic proteins such as Bcl-2 and Bcl-xL also confer intrinsic resistance. There is limited evidence regarding the use of Bcl-2 inhibitors in RCC. However, one preclinical study has demonstrated a potential synergistic effect of the Bcl-2 inhibitor, venetoclax, when given sequentially prior to sunitinib^[115].

In recent years, ICIs targeting programmed cell death protein 1 (PD-1), programmed cell death ligand 1 (PD-L1), and cytotoxic T lymphocyte-associated antigen 4 (CTLA-4) have emerged as a cornerstone in the treatment of advanced RCC. These therapies block interactions between immune checkpoint proteins, thereby triggering immune activation against various cancers^[116]. ICIs are frequently combined with TKIs to leverage their synergistic effects resulting from complementary mechanisms of action. Notably, all TKI resistance mechanisms share a common thread of promoting angiogenesis. Proangiogenic molecules like VEGF impede both the innate and adaptive immune systems by hindering precursor cell differentiation, upregulating PD-1, PD-L1, and CTLA-4 on immune cells, and recruiting MDSCs^[117]. ICI therapy rejuvenates the immune response, counteracting these immunosuppressive effects and mitigating resistance.

CONCLUSION

TKIs have significantly improved the outcomes of patients with advanced RCC by targeting key pathways involved in cancer proliferation, survival, and metastasis. However, treatment with VEGF-targeted TKIs is almost always characterized by the eventual development of resistance and subsequent disease progression. Mitigating drug resistance is challenging due to the diverse mechanisms underlying TKI resistance, including upregulation of alternative proangiogenic pathways, EMT, efflux pumps reducing intracellular drug concentrations, lysosomal sequestration, alterations in the tumor microenvironment, and genetic factors.

Understanding these mechanisms is crucial for the development of innovative therapeutic approaches to overcome TKI resistance. Notably, the combination of TKIs with other agents, particularly ICIs, has made significant strides towards accomplishing this aim, solidifying ICIs as a cornerstone in the treatment of advanced RCC. Additionally, strategies to reverse or inhibit specific resistance mechanisms hold the potential to restore TKI efficacy. The continued exploration of combination therapies, comprehensive understanding of the tumor microenvironment, and identification of additional genetic biomarkers will pave the way for more effective treatments, ultimately improving outcomes for patients with advanced RCC.

AUTHOR INSTRUCTIONS

1. Submission Overview

Before you decide to publish with *Cancer Drug Resistance (CDR)*, please read the following items carefully and make sure that you are well aware of Editorial Policies and the following requirements.

1.1 Topic Suitability

The topic of the manuscript must fit the scope of the journal. Please refer to Aims and Scope for more information.

1.2 Open Access and Copyright

The journal adopts Gold Open Access publishing model and distributes content under the Creative Commons Attribution 4.0 International License. Copyright is retained by authors. Please make sure that you are well aware of these policies.

1.3 Publication Fees

The publication fee for each submission is \$2000. There are no additional charges based on color, length, figures, or other elements. OAE provides expense deduction for authors as appropriate. For more details, please refer to OAE Publication Fees.

1.4 Language Editing

All submissions are required to be presented clearly and cohesively in good English. Authors whose first language is not English are advised to have their manuscripts checked or edited by a native English speaker before submission to ensure the high quality of expression. A well-organized manuscript in good English would make the peer review even the whole editorial handling more smoothly and efficiently.

If needed, authors are recommended to consider the language editing services provided by OAE to ensure that the manuscript is written in correct scientific English before submission. An extra charge is required to enjoy this service. Please visit https://www.oaepublish.com/index/author_services or contact English-Editing@oaepublish.com for more details.

1.5 Work Funded by the National Institutes of Health

If an accepted manuscript was funded by National Institutes of Health (NIH), the authors may inform Editors of the NIH funding number. The Editors are able to deposit the paper to the NIH Manuscript Submission System on behalf of the authors.

2. Submission Preparation

2.1 Cover Letter

A cover letter is required to be submitted accompanying each manuscript. It should be concise and explain why the study is significant, why it fits the scope of the journal, and why it would be attractive to readers, *etc.*

Here is a guideline of a cover letter for authors' consideration:

In the first paragraph: include the title and type (e.g., Original Article, Review, Case Report, *etc.*) of the manuscript, a brief on the background of the study, the question the author sought out to answer and why;

In the second paragraph: concisely explain what was done, the main findings and why they are significant;

In the third paragraph: indicate why the manuscript fits the Aims and Scope of the journal, and why it would be attractive to readers;

In the fourth paragraph: confirm that the manuscript has not been published elsewhere and not under consideration of any other journal. All authors have approved the manuscript and agreed on its submission to the journal. Journal's specific requirements have been met if any.

If the manuscript is contributed to a special issue, please also mention it in the cover letter.

If the manuscript was presented partly or entirely in a conference, the author should clearly state the background information of the event, including the conference name, time and place in the cover letter.

2.2 Types of Manuscripts

The journal publishes Original Article, Review, Meta-Analysis, Case Report, Commentary, *etc.* For more details about paper type, please refer to the following table.

Manuscript Type	Definition	Word Limit	Abstract	Keywords	Main Text Structure
-----------------	------------	------------	----------	----------	---------------------

Author Instructions

Original Article	An Original Article describes detailed results from novel research. All findings are extensively discussed.	5000 max	Structured abstract including Aim, Methods, Results and Conclusion. No more than 250 words.	3-8 keywords	The main content should include four sections: Introduction, Methods, Results and Discussion.
Review	A Review paper summarizes the literature on previous studies. It usually does not present any new information on a subject.	7000 max	Unstructured abstract. No more than 250 words.	3-8 keywords	The main text may consist of several sections with unfixed section titles. We suggest that the author include an "Introduction" section at the beginning, several sections with unfixed titles in the middle part, and a "Conclusion" section in the end.
Case Report	A Case Report details symptoms, signs, diagnosis, treatment, and follows up an individual patient. The goal of a Case Report is to make other researchers aware of the possibility that a specific phenomenon might occur.	2500 max	Unstructured abstract. No more than 150 words.	3-8 keywords	The main text consists of three sections with fixed section titles: Introduction, Case Report, and Discussion.
Meta-Analysis	A Meta-Analysis is a statistical analysis combining the results of multiple scientific studies. It is often an overview of clinical trials.	5000 max	Structured abstract including Aim, Methods, Results and Conclusion. No more than 250 words.	3-8 keywords	The main content should include four sections: Introduction, Methods, Results and Discussion.
Systematic Review	A Systematic Review collects and critically analyzes multiple research studies, using methods selected before one or more research questions are formulated, and then finding and analyzing related studies and answering those questions in a structured methodology.	3000 max	Structured abstract including Aim, Methods, Results and Conclusion. No more than 250 words.	3-8 keywords	The main content should include four sections: Introduction, Methods, Results and Discussion.
Technical Note	A Technical Note is a short article giving a brief description of a specific development, technique or procedure, or it may describe a modification of an existing technique, procedure or device applied in research.	3500 max	Unstructured abstract. No more than 250 words.	3-8 keywords	/
Commentary	A Commentary is to provide comments on a newly published article or an alternative viewpoint on a certain topic.	2500 max	Unstructured abstract. No more than 250 words.	3-8 keywords	/
Editorial	An Editorial is a short article describing news about the journal or opinions of senior editors or the publisher.	1000 max	None required	None required	/
Letter to Editor	A Letter to Editor is usually an open post-publication review of a paper from its readers, often critical of some aspect of a published paper. Controversial papers often attract numerous Letters to Editor	1000 max	Unstructured abstract (optional). No more than 250 words.	3-8 keywords (optional)	/
Opinion	An Opinion usually presents personal thoughts, beliefs, or feelings on a topic.	1200 max	Unstructured abstract (optional). No more than 250 words.	3-8 keywords	/
Perspective	A Perspective provides personal points of view on the state-of-the-art of a specific area of knowledge and its future prospects. Links to areas of intense current research focus can also be made. The emphasis should be on a personal assessment rather than a comprehensive, critical review. However, comments should be put into the context of existing literature. Perspectives are usually invited by the Editors.	2000 max	Unstructured abstract. No more than 150 words.	3-8 keywords	/

2.3 Manuscript Structure

2.3.1 Front Matter

2.3.1.1 Title

The title of the manuscript should be concise, specific and relevant, with no more than 16 words if possible. When gene or protein names are included, the abbreviated name rather than full name should be used.

2.3.1.2 Authors and Affiliations

Authors' full names should be listed. The initials of middle names can be provided. Institutional addresses and email addresses for all authors should be listed. At least one author should be designated as corresponding author. In addition, corresponding authors are suggested to provide their Open Researcher and Contributor ID upon submission. Please note that any change to authorship is not allowed after manuscript acceptance.

2.3.1.3 Abstract

Original research, systematic reviews, and meta-analyses require structured abstracts. The abstract should provide the context or background for the study and should state the study's purpose, basic procedures (selection of study participants, settings, measurements, analytical methods), main findings (giving specific effect sizes and their statistical and clinical significance, if possible), and principal conclusions. It should emphasize new and important aspects of the study or observations, note important limitations, and not overinterpret findings. Clinical trial abstracts should include items that the CONSORT group has identified as essential. It is not allowed to contain results which are not presented and substantiated in the manuscript, or exaggerate the main conclusions. Citations should not be included in the abstract.

2.3.1.4 Graphical Abstract

The graphical abstract is essential as this can catch first view of your publication by readers. We request the authors submit an eye-catching figure during the revision stage. It should summarize the content of the article in a concise graphical form. It is recommended to use it because this can make online articles get more attention. The graphic abstract should be submitted as a separate document in the online submission system along with the revised version. Please provide an image with a minimum of 730 × 1,228 pixels (h × w) or proportionally more. The image should be readable at a size of 7 × 12 cm using a regular screen resolution of 96 dpi. Preferred file types: TIFF, PSD, AI, JPG, JPEG, EPS, PNG, ZIP and PDF files.

2.3.1.5 Keywords

Three to eight keywords should be provided, which are specific to the article, yet reasonably common within the subject discipline.

2.3.2 Main Text

Manuscripts of different types are structured with different sections of content. Please refer to Types of Manuscripts to make sure which sections should be included in the manuscripts.

2.3.2.1 Introduction

The introduction should contain background that puts the manuscript into context, allow readers to understand why the study is important, include a brief review of key literature, and conclude with a brief statement of the overall aim of the work and a comment about whether that aim was achieved. Relevant controversies or disagreements in the field should be introduced as well.

2.3.2.2 Methods

Methods should contain sufficient details to allow others to fully replicate the study. New methods and protocols should be described in detail while well-established methods can be briefly described or appropriately cited. Experimental participants selected, the drugs and chemicals used, the statistical methods taken, and the computer software used should be identified precisely. Statistical terms, abbreviations, and all symbols used should be defined clearly. Protocol documents for clinical trials, observational studies, and other non-laboratory investigations may be uploaded as supplementary materials.

2.3.2.3 Results

This section contains the findings of the study. Results of statistical analysis should also be included either as text or as tables or figures if appropriate. Authors should emphasize and summarize only the most important observations. Data on all primary and secondary outcomes identified in the section Methods should also be provided. Extra or supplementary materials and technical details can be placed in supplementary documents.

2.3.2.4 Discussion

This section should discuss the implications of the findings in context of existing research and highlight limitations of the study. Future research directions may also be mentioned.

2.3.2.5 Conclusion

It should state clearly the main conclusions and include the explanation of their relevance or importance to the field.

2.3.3 Back Matter

2.3.3.1 Acknowledgments

Anyone who contributed towards the article but does not meet the criteria for authorship, including those who provided professional writing services or materials, should be acknowledged. Authors should obtain permission to acknowledge from all those mentioned in the Acknowledgments section. This section is not added if the author does not have anyone to acknowledge.

2.3.3.2 Authors' Contributions

Each author is expected to have made substantial contributions to the conception or design of the work, or the acquisition, analysis, or interpretation of data, or the creation of new software used in the work, or have drafted the work or substantively revised it.

Please use Surname and Initial of Forename to refer to an author's contribution. For example: made substantial contributions to conception and design of the study and performed data analysis and interpretation: Salas H, Castaneda WV; performed data acquisition, as well as provided administrative, technical, and material support: Castillo N, Young V.

If an article is single-authored, please include "The author contributed solely to the article." in this section.

2.3.3.3 Availability of Data and Materials

In order to maintain the integrity, transparency and reproducibility of research records, authors should include this section in their manuscripts, detailing where the data supporting their findings can be found. Data can be deposited into data repositories or published as supplementary information in the journal. Authors who cannot share their data should state that the data will not be shared and explain it. If a manuscript does not involve such issue, please state "Not applicable." in this section.

2.3.3.4 Financial Support and Sponsorship

All sources of funding for the study reported should be declared. The role of the funding body in the experiment design, collection, analysis and interpretation of data, and writing of the manuscript should be declared. Any relevant grant numbers and the link of funder's website should be provided if any. If the study is not involved with this issue, state "None." in this section.

2.3.3.5 Conflicts of Interest

Authors must declare any potential conflicts of interest that may be perceived as inappropriately influencing the representation or interpretation of reported research results. If there are no conflicts of interest, please state "All authors declared that there are no conflicts of interest." in this section. Some authors may be bound by confidentiality agreements. In such cases, in place of itemized disclosures, we will require authors to state "All authors declare that they are bound by confidentiality agreements that prevent them from disclosing their conflicts of interest in this work." If authors are unsure whether conflicts of interest exist, please refer to the "Conflicts of Interest" of *CDR* Editorial Policies for a full explanation.

2.3.3.6 Ethical Approval and Consent to Participate

Research involving human subjects, human material or human data must be performed in accordance with the Declaration of Helsinki and approved by an appropriate ethics committee. An informed consent to participate in the study should also be obtained from participants, or their parents or legal guardians for children under 16. A statement detailing the name of the ethics committee (including the reference number where appropriate) and the informed consent obtained must appear in the manuscripts reporting such research.

Studies involving animals and cell lines must include a statement on ethical approval. More information is available at Editorial Policies.

If the manuscript does not involve such issue, please state "Not applicable." in this section.

2.3.3.7 Consent for Publication

Manuscripts containing individual details, images or videos, must obtain consent for publication from that person, or in the case of children, their parents or legal guardians. If the person has died, consent for publication must be obtained from the next of kin of the participant. Manuscripts must include a statement that a written informed consent for publication was obtained. Authors do not have to submit such content accompanying the manuscript. However, these documents must be available if requested. If the manuscript does not involve this issue, state "Not applicable." in this section.

2.3.3.8 Copyright

Authors retain copyright of their works through a Creative Commons Attribution 4.0 International License that clearly states how readers can copy, distribute, and use their attributed research, free of charge. A declaration "© The Author(s) 2023." will be added to each article. Authors are required to sign License to Publish before formal publication.

2.3.3.9 References

Preferably original research articles that directly support the statements should be cited. Review articles could be cited

when they specifically address the statement made in the manuscript. An abstract should not be used as a reference. Non-specific citations should be avoided.

References should be numbered in order of appearance at the end of manuscripts. In the text, reference numbers should be placed in square brackets and the corresponding references are cited thereafter. If the number of authors is less than or equal to six, we require to list all authors' names. If the number of authors is more than six, only the first three authors' names are required to be listed in the references, other authors' names should be omitted and replaced with "et al.". Abbreviations of the journals should be provided on the basis of Index Medicus. Information from manuscripts accepted but not published should be cited in the text as "Unpublished material" with written permission from the source.

References should be described as follows, depending on the types of works:

Types	Examples
Journal articles by individual authors	Weaver DL, Ashikaga T, Krag DN, et al. Effect of occult metastases on survival in node-negative breast cancer. <i>N Engl J Med</i> 2011;364:412-21. [PMID: 21247310 DOI: 10.1056/NEJMoal008108]
Organization as author	Diabetes Prevention Program Research Group. Hypertension, insulin, and proinsulin in participants with impaired glucose tolerance. <i>Hypertension</i> 2002;40:679-86. [PMID: 12411462]
Both personal authors and organization as author	Vallancien G, Emberton M, Harving N, van Moorselaar RJ; Alf-One Study Group. Sexual dysfunction in 1,274 European men suffering from lower urinary tract symptoms. <i>J Urol</i> 2003;169:2257-61. [PMID: 12771764 DOI: 10.1097/01.ju.0000067940.76090.73]
Journal articles not in English	Zhang X, Xiong H, Ji TY, Zhang YH, Wang Y. Case report of anti-N-methyl-D-aspartate receptor encephalitis in child. <i>J Appl Clin Pediatr</i> 2012;27:1903-7. (in Chinese)
Journal articles ahead of print	Odibo AO. Falling stillbirth and neonatal mortality rates in twin gestation: not a reason for complacency. <i>BJOG</i> 2018; Epub ahead of print [PMID: 30461178 DOI: 10.1111/1471-0528.15541]

Unpublished material	Tian D, Araki H, Stahl E, Bergelson J, Kreitman M. Signature of balancing selection in Arabidopsis. <i>Proc Natl Acad Sci U S A</i> . Forthcoming 2002.

For other types of references, please refer to U.S. National Library of Medicine.

The journal also recommends that authors prepare references with a bibliography software package, such as EndNote to avoid typing mistakes and duplicated references.

2.3.3.10 Supplementary Materials

Additional data and information can be uploaded as Supplementary Materials to accompany the manuscripts. The supplementary materials will also be available to the referees as part of the peer-review process. Any file format is acceptable, such as data sheet (word, excel, csv, cdx, fasta, pdf or zip files), presentation (powerpoint, pdf or zip files), image (cdx, eps, jpeg, pdf, png or tiff), table (word, excel, csv or pdf), audio (mp3, wav or wma) or video (avi, divx, flv, mov, mp4, mpeg, mpg or wmv). All information should be clearly presented. Supplementary materials should be cited in the main text in numeric order (e.g., Supplementary Figure 1, Supplementary Figure 2, Supplementary Table 1, Supplementary Table 2, etc.). The style of supplementary figures or tables complies with the same requirements on figures or tables in main text. Videos and audios should be prepared in English, and limited to a size of 500 MB.

2.4 Manuscript Format

2.4.1 File Format

Manuscript files can be in DOC and DOCX formats and should not be locked or protected.

2.4.2 Length

The word limit is specified in the item "Types of Manuscripts". There are no restrictions on number of figures or amount of supporting documents. Authors are encouraged to present and discuss their findings concisely.

2.4.3 Language

Manuscripts must be written in English.

2.4.4 Multimedia Files

The journal supports manuscripts with multimedia files. The requirements are listed as follows:

Video or audio files are only acceptable in English. The presentation and introduction should be easy to understand. The frames should be clear, and the speech speed should be moderate.

A brief overview of the video or audio files should be given in the manuscript text.

The video or audio files should be limited to a size of up to 500 MB.

Please use professional software to produce high-quality video files, to facilitate acceptance and publication along with the submitted article. Upload the videos in mp4, wmv, or rm format (preferably mp4) and audio files in mp3 or wav format.

2.4.5 Figures

Figures should be cited in numeric order (e.g., Figure 1, Figure 2) and placed after the paragraph where it is first cited;

Figures can be submitted in format of tiff, psd, AI or jpeg, with resolution of 300-600 dpi;

Figure caption is placed under the Figure;

Diagrams with describing words (including, flow chart, coordinate diagram, bar chart, line chart, and scatter diagram, *etc.*) should be editable in word, excel or powerpoint format. Non-English information should be avoided;

Labels, numbers, letters, arrows, and symbols in figure should be clear, of uniform size, and contrast with the background; Symbols, arrows, numbers, or letters used to identify parts of the illustrations must be identified and explained in the legend;

Internal scale (magnification) should be explained and the staining method in photomicrographs should be identified;

All non-standard abbreviations should be explained in the legend;

Permission for use of copyrighted materials from other sources, including re-published, adapted, modified, or partial figures and images from the internet, must be obtained. It is authors' responsibility to acquire the licenses, to follow any citation instruction requested by third-party rights holders, and cover any supplementary charges.

2.4.6 Tables

Tables should be cited in numeric order and placed after the paragraph where it is first cited;

The table caption should be placed above the table and labeled sequentially (e.g., Table 1, Table 2);

Tables should be provided in editable form like DOC or DOCX format (picture is not allowed);

Abbreviations and symbols used in table should be explained in footnote;

Explanatory matter should also be placed in footnotes;

Permission for use of copyrighted materials from other sources, including re-published, adapted, modified, or partial tables from the internet, must be obtained. It is authors' responsibility to acquire the licenses, to follow any citation instruction requested by third-party rights holders, and cover any supplementary charges.

2.4.7 Abbreviations

Abbreviations should be defined upon first appearance in the abstract, main text, and in figure or table captions and used consistently thereafter. Non-standard abbreviations are not allowed unless they appear at least three times in the text. Commonly-used abbreviations, such as DNA, RNA, ATP, *etc.*, can be used directly without definition. Abbreviations in titles and keywords should be avoided, except for the ones which are widely used.

2.4.8 Italics

General italic words like *vs.*, *et al.*, *etc.*, *in vivo*, *in vitro*; *t* test, *F* test, *U* test; related coefficient as *r*, sample number as *n*, and probability as *P*; names of genes; names of bacteria and biology species in Latin.

2.4.9 Units

SI Units should be used. Imperial, US customary and other units should be converted to SI units whenever possible. There is a space between the number and the unit (i.e., 23 mL). Hour, minute, second should be written as h, min, s.

2.4.10 Numbers

Numbers appearing at the beginning of sentences should be expressed in English. When there are two or more numbers in a paragraph, they should be expressed as Arabic numerals; when there is only one number in a paragraph, number < 10 should be expressed in English and number > 10 should be expressed as Arabic numerals. 12345678 should be written as 12,345,678.

2.4.11 Equations

Equations should be editable and not appear in a picture format. Authors are advised to use either the Microsoft Equation Editor or the MathType for display and inline equations.

2.5 Submission Link

Submit an article via <https://oamesas.com/login?JournalId=cdm>.

3. Research and Publication Ethics

3.1 Research Involving Human Subjects

All studies involving human subjects must be in accordance with the Helsinki Declaration and seek approval to conduct the study from an independent local, regional, or national review body (e.g., ethics committee, institutional review board, *etc.*). Such approval, including the names of the ethics committee, institutional review board, *etc.*, must be listed in a declaration statement of Ethical Approval and Consent to Participate in the manuscript. If the study is judged exempt from ethics approval, related information (e.g., name of the ethics committee granting the exemption and the reason for the exemption) must be listed. Further documentation on ethics should also be prepared, as editors may request more detailed information. Manuscripts with suspected ethical problems will be investigated according to COPE Guidelines.

3.1.1 Consent to Participate

For all studies involving human subjects, informed consent to participate in the studies must be obtained from participants, or their parents or legal guardians for children under 16. Statements regarding consent to participate should be included in a declaration statement of Ethical Approval and Consent to Participate in the manuscript. If informed consent is not required, the name of the ethics committee granting the exemption and the reason for the exemption must be listed. If any ethical violation is found at any stage of publication, the issue will be investigated seriously based on COPE Guidelines.

3.1.2 Consent for Publication

All articles published by *CDR* are freely available on the Internet. All manuscripts that include individual participants' data in any form (i.e., details, images, videos, *etc.*) will not be published without Consent for Publication obtained from that person(s), or for children, their parents or legal guardians. If the person has died, Consent for Publication must be obtained from the next of kin. Authors must add a declaration statement of Consent for Publication in the manuscript, specifying written informed consent for publication has been obtained.

3.1.3 Ethical Approval and Informed Consent for Case Report/Case Series/Clinical Dataset

A case report is considered the diagnosis, treatment and post-treatment follow-up of a single patient. A case series is considered a group of case reports involving patients who were all given similar treatments. A clinical dataset is a list of well-defined variables collected during ongoing patient care or as part of a clinical trial program. It includes electronic health records, administrative data, patient registries, and clinical trial data.

In some instances, a case report or case series containing information on less than three patients may not require ethical approval. However, this requirement is dependent on the institution, country or region implementing it and authors must ensure they have followed the correct regulatory requirements of their institution or country. A statement explaining this requirement must be included in the manuscript.

Given the specificity of details provided in a case report, case series or clinical dataset, authors are required to obtain consent for the publication of the case(s) from patients, or their guardians if they are not adults or lack capacity to provide informed consent, or next of kin if deceased. A statement confirming consent for publication has been obtained must be included in the manuscript. Authors should share this with the journal Editorial Office if requested.

3.1.4 Ethical Approval and Informed Consent for Retrospective/Database Studies

Researchers must confirm they have obtained ethical approval from ethical review boards to perform the study, as well as permission from the dataset owner to use the information in databases for the purposes of the research they are performing. If permission to use information from a database is not required (e.g., it is publicly available and unrestricted re-use is permitted under an open license), a statement explaining this must be included in the manuscript. For studies which ethics approval has been waived, authors must state clearly in the manuscript and provide brief details of the waive policy. The statement should include details of the policies under which the waive was granted.

Authors must keep data anonymized. If participants' details are not to be anonymized, authors must ensure that written informed consent, including consent for publication, was obtained from each participant, and consent statement must be included in the manuscript.

3.1.5 Ethical Approval and Informed Consent for Survey Studies

Researchers must ensure the participant's right to confidentiality has been considered, and they must inform all participants about the aims of the research and if there are any possible risks, and how the collecting data is being stored. The voluntary consent to participate of participants should be recorded and any legal requirements on data protection should be adhered to. Same with all research studies, ethics approval from IRB/local ethics committee for survey studies must be obtained before performing study. If ethics approval for certain survey study is not required, authors must include a statement to explain this clearly in the manuscript.

3.1.6 Trial Registration

CDR requires all authors to register all relevant clinical trials that are reported in manuscripts submitted. *CDR* follows the World Health Organization (WHO)'s definition of clinical trials: "A clinical trial is any research study that prospectively

assigns human participants or groups of humans to one or more health-related interventions to evaluate the effects on health outcomes. Interventions include but are not restricted to drugs, cells, other biological products, surgical procedures, radiologic procedures, devices, behavioral treatments, process-of-care changes, preventive care, *etc.*”

In line with International Committee of Medical Journal Editors (ICMJE) recommendation, *CDR* requires the registration of clinical trials in a public trial registry at or before the time of first patient enrollment. *CDR* accepts publicly accessible registration in any registry that is a primary register of the WHO International Clinical Trials Registry Platform or in ClinicalTrials.gov. The trial registration number should be listed at the end of the Abstract section.

Secondary data analyses of primary (parent) clinical trials should not be registered as a new clinical trial, but rather reference the trial registration number of the primary trial.

Editors of *CDR* journals will consider carefully whether studies failed to register or had an incomplete trial registration. Because of the importance of prospective trial registration, if there is an exception to this policy, trials must be registered and the authors should indicate in the publication when registration was completed and why it was delayed. Editors will publish a statement indicating why an exception was allowed. Please note such exceptions should be rare, and authors failing to prospectively register a trial risk its inadmissibility to *CDR* journals.

Authors who are not sure whether they need trial registration may refer to ICMJE FAQs for further information.

3.2 Research Involving Animals

Experimental research on animals should be approved by an appropriate ethics committee and must comply with institutional, national, or international guidelines. *CDR* encourages authors to comply with the AALAS Guidelines, the ARRIVE Guidelines, and/or the ICLAS Guidelines, and obtain prior approval from the relevant ethics committee. Manuscripts must include a statement indicating that the study has been approved by the relevant ethical committee and the whole research process complies with ethical guidelines. If a study is granted an exemption from requiring ethics approval, the name of the ethics committee granting the exemption and the reason(s) for the exemption should be detailed. Editors will take account of animal welfare issues and reserve the right to reject a manuscript, especially if the research involves protocols that are inconsistent with commonly accepted norms of animal research.

3.3 Research Involving Cell Lines

Authors must describe what cell lines are used and their origin so that the research can be reproduced. For established cell lines, the provenance should be stated and references must also be given to either a published paper or to a commercial source. For de novo cell lines derived from human tissue, appropriate approval from an institutional review board or equivalent ethical committee, and consent from the donor or next of kin, should be obtained. Such statements should be listed on the Declaration section of Ethical Approval and Consent to Participate in the manuscript.

Further information is available from the International Cell Line Authentication Committee (ICLAC). *CDR* recommends that authors check the NCBI database for misidentification and contamination of human cell lines.

3.4 Research Involving Plants

Experimental research on plants (either cultivated or wild), including collection of plant material, must comply with institutional, national, or international guidelines. Field studies should be conducted in accordance with local legislation, and the manuscript should include a statement specifying the appropriate permissions and/or licenses. *CDR* recommends that authors comply with the IUCN Policy Statement on Research Involving Species at Risk of Extinction and the Convention on the Trade in Endangered Species of Wild Fauna and Flora.

For each submitted manuscript, supporting genetic information and origin must be provided for plants that were utilized. For research manuscripts involving rare and non-model plants (other than, e.g., *Arabidopsis thaliana*, *Nicotiana benthamiana*, *Oriza sativa*, or many other typical model plants), voucher specimens must be deposited in a public herbarium or other public collections providing access to deposited materials.

3.5 Publication Ethics Statement

CDR is a member of the Committee on Publication Ethics (COPE). We fully adhere to its Code of Conduct and to its Best Practice Guidelines.

The Editors of *CDR* enforce a rigorous peer-review process together with strict ethical policies and standards to guarantee to add high-quality scientific works to the field of scholarly publication.

Unfortunately, cases of plagiarism, data falsification, image manipulation, inappropriate authorship credit, and the like, do arise. The Editors of *CDR* take such publishing ethics issues very seriously and are trained to proceed in such cases with zero tolerance policy.

Authors wishing to publish their papers in *CDR* must abide to the following:

The author(s) must disclose any possibility of a conflict of interest in the paper prior to submission.

The authors should declare that there is no academic misconduct in their manuscript in the cover letter.

Authors should accurately present their research findings and include an objective discussion of the significance of their findings.

Data and methods used in the research need to be presented in sufficient detail in the manuscript so that other researchers

can replicate the work.

Authors should provide raw data if referees and the Editors of *CDR* request.

Simultaneous submission of manuscripts to more than one journal is not tolerated.

Republishing content that is not novel is not tolerated (for example, an English translation of a paper that is already published in another language will not be accepted).

The manuscript should not contain any information that has already been published. If you include already published figures or images, please get the necessary permission from the copyright holder to publish under the CC-BY license.

Plagiarism, data fabrication and image manipulation are not tolerated.

Plagiarism is not acceptable in *CDR*.

Plagiarism involves the inclusion of large sections of unaltered or minimally altered text from an existing source without appropriate and unambiguous attribution, and/or an attempt to misattribute original authorship regarding ideas or results, and copying text, images, or data from another source, even from your own publications, without giving credit to the source.

As to reusing the text that is copied from another source, it must be between quotation marks and the source must be cited. If a study's design or the manuscript's structure or language has been inspired by previous studies, these studies must be cited explicitly.

If plagiarism is detected during the peer-review process, the manuscript will be rejected. If plagiarism is detected after publication, we will publish a retraction and retract the paper.

If plagiarism is detected during the peer-review process, the manuscript may be rejected. If plagiarism is detected after publication, we may publish a Correction or retract the paper.

Falsification is manipulating research materials, equipment, or processes, or changing or omitting data or results so that the findings are not accurately represented in the research record.

Image files must not be manipulated or adjusted in any way that could lead to misinterpretation of the information provided by the original image.

Irregular manipulation includes: introduction, enhancement, moving, or removing features from the original image; grouping of images that should be presented separately, or modifying the contrast, brightness, or color balance to obscure, eliminate, or enhance some information.

If irregular image manipulation is identified and confirmed during the peer-review process, we will reject the manuscript.

If irregular image manipulation is identified and confirmed after publication, we may publish a Retraction or retract the paper.

CDR reserves the right to contact the authors' institution(s) to investigate possible publication misconduct if the Editors find conclusive evidence of misconduct before or after publication. OAE has a partnership with iThenticate, which is the most trusted similarity checker. It is used to analyze received manuscripts to avoid plagiarism to the greatest extent possible. When plagiarism becomes evident after publication, we will retract the original publication or require modifications, depending on the degree of plagiarism, context within the published article, and its impact on the overall integrity of the published study. Journal Editors will act under the relevant COPE Guidelines.

4. Authorship

Authorship credit of *CDR* journals should be solely based on substantial contributions to a published study, as specified in the following four criteria:

1. Substantial contributions to the conception or design of the work, or the acquisition, analysis, or interpretation of data for the work;
2. Drafting the work or revising it critically for important intellectual content;
3. Final approval of the version to be published;
4. Agreement to be accountable for all aspects of the work in ensuring that questions related to the accuracy or integrity of any part of the work are appropriately investigated and resolved.

All those who meet these criteria should be identified as authors. Authors must specify their contributions in the section Authors' Contributions of their manuscripts. Contributors who do not meet all the four criteria (like only involved in acquisition of funding, general supervision of a research group, general administrative support, writing assistance, technical editing, language editing, proofreading, *etc.*) should be acknowledged in the section of Acknowledgement in the manuscript rather than being listed as authors.

If a large multiple-author group has conducted the work, the group ideally should decide who will be authors before the work starts and confirm authors before submission. All authors of the group named as authors must meet all the four criteria for authorship.

5. Reviewers Exclusions

You are welcome to exclude a limited number of researchers as potential editors or reviewers of your manuscript. To ensure a fair and rigorous peer review process, we ask that you keep your exclusions to a maximum of three people. If you wish to exclude additional referees, please explain or justify your concerns—this information will be helpful for editors when deciding whether to honor your request.

6. Editors and Journal Staff as Authors

Editorial independence is extremely important and Editorial office staff do not interfere with editorial decisions. Editorial staff or Editors shall not be involved in the processing their own academic work. Submissions authored by editorial staff/Editors will be assigned to at least two independent outside reviewers. Decisions will be made by other Editorial Board members who do not have conflict of interests with the author. Journal staff are not involved in the processing of their own work submitted to any OAE journals.

7. Policy of the Use of AI and AI-assisted Technologies in Scientific Writing

Generative AI and AI-assisted technologies (e.g., large language models) are expected to be increasingly used to create content. In the writing process of manuscripts, using AI and AI-assisted technologies to complete key researcher work, such as producing scientific insights, analyzing and interpreting data or drawing scientific conclusions, is not allowed, and they should only be used to improve the readability and language of manuscripts.

AI and AI-assisted technologies should be used under human control and supervision as they may generate incorrect or prejudiced output, and they should not be listed as an author or co-author, nor cited as an author.

The use of AI and AI-assisted technologies should be disclosed by authors in their manuscripts, and a statement will be required in the final publication.

OAE will keep monitoring the development and adjust the policy when necessary.

8. Conflict of Interests

CDR require authors to declare any possible financial and/or non-financial conflicts of interest at the end of their manuscript and in the cover letter, as well as confirm this point when submitting their manuscript in the submission system. If no conflicts of interest exist, authors need to state “The authors declare no conflicts of interest”. We also recognize that some authors may be bound by confidentiality agreements, in which cases authors need to state “The authors declare that they are bound by confidentiality agreements that prevent them from disclosing their competing interests in this work”.

9. Editorial Process

9.1 Initial check

9.1.1 Initial manuscript check

New submissions are initially checked by the Managing Editor from the perspectives of originality, suitability, structure and formatting, conflicts of interest, background of authors, *etc.* Poorly-prepared manuscripts may be rejected at this stage. If your manuscript does not meet one or more of these requirements, we will return it for further revisions.

9.1.2 Publishing ethics

All manuscripts submitted to *CDR* are screened using iThenticate powered by CrossCheck to identify any plagiarized content. Your study must also meet all ethical requirements as outlined in our Editorial Policies. If the manuscript does not pass any of these checks, we may return it to you for further revisions or decline to consider your study for publication.

9.2 Editorial assessment

Once your manuscript has passed the initial manuscript check, it will be assigned to an Assistant Editor, and then the Editor-in-Chief, or an Editorial Board member in the case of a conflict of interest, will be notified of the submission and invited to review. Regarding Special Issue paper, after passing the initial check, the manuscript will be successively assigned to an Assistant Editor, Guest Editor, and then to the Editor-in-Chief, or an Editorial Board member in the case of conflict of interest for the Editor-in-Chief to review. The Editor-in-Chief, or the Editorial Board member may reject manuscripts that they deem highly unlikely to pass peer review without further consultation. Once your manuscript has passed the editorial assessment, the Assistant Editor will start to organize peer-review.

9.3 Process

CDR operates a single-blind review process. The technical quality of the research described in the manuscript is assessed by a minimum of two independent expert reviewers. The Editor-in-Chief is responsible for the final decision regarding acceptance or rejection of the manuscript. For controversial manuscripts, the Editor-in-Chief is responsible for making the final decision.

9.4 Decisions

Your research will be judged on scientific soundness only, not on its perceived impact as judged by Editors or referees. There are three possible decisions: Accept (your study satisfies all publication criteria), Invitation to Revise (more work is required to satisfy all criteria), and Reject (your study fails to satisfy key criteria and it is highly unlikely that further work can address its shortcomings).
