EDITORIAL BOARD

Editor-in-Chief

Godefridus J. Peters

Laboratory Medical Oncology, Cancer Center, Amsterdam, The Netherlands

Associate Editors

Yehuda G. Assaraf

Department of Biology, Technion-Israel Institute of Technology, Haifa, Israel.

Wafik S. El-Deiry

Legorreta Cancer Center, Brown University, Providence, RI, USA.

Liwu Fu

State Key Laboratory of Oncology in South China, Collaborative Innovation Center of Cancer Medicine, Sun Yat-sen University Cancer Center, Guangzhou, China.

Editorial Board Members

Aamir Ahmad

Department of Medicine, University of Alabama at Birmingham, Birmingham, AL, USA.

Suresh V. Ambudkar

Laboratory of Cell Biology, Center for Cancer Research, National Cancer Institute, NIH, Bethesda, MD, USA.

Asfar Sohaail Azmi

Department of Oncology, Wayne State University School of Medicine, Detroit, MI, USA.

Maria R. Baer

University of Maryland Greenebaum Comprehensive Cancer Center, Baltimore, MD, USA.

Benjamin Bonavida

Department of Microbiology, Immunology, and Molecular Genetics, David Geffen School of Medicine, University of California, Los Angeles, CA, USA.

Stergios Boussios

Oncology Department, Medway NHS Foundation Trust, Kent, UK.

Ingolf Cascorbi

Institute of Experimental and Clinical Pharmacology, Christian Albrechts

University Kiel, Hospitalstr. 4, Kiel, Germany.

Claudio Cerchione

Hematology Unit, Istituto Scientifico Romagnolo per lo Studio e la Cura dei Tumori (IRST) IRCCS, Meldola, Italy.

Wei Chen

Department of Physics, The University of Texas at Arlington, Arlington, TX, USA.

Zhesheng Chen

Department of Pharmaceutical Sciences, College of Pharmacy and Health Sciences, St. John's University, Queens, NY, USA.

William C. Cho

Department of Clinical Oncology, Queen Elizabeth Hospital, Kowloon, Hong Kong.

Mario Ciocco

Laboratory of Molecular Medicine and Biotechnology, University Campus Bio-Medico of Rome, Rome, Italy.

Jacqueline Cloos

Department of Hematology, Amsterdam University Medical Center, VU University Medical Center, Cancer Center Amsterdam, Amsterdam, The Netherlands.

Paul Dent

Department of Biochemistry and Molecular Biology, Virginia Commonwealth University, Richmond, VA, USA.

Changming Dong

School of Chemistry & Chemical Engineering, Shanghai Jiao Tong University, Shanghai, China.

Thomas Efferth

Department of Pharmaceutical Biology, Institute of Biochemistry and Pharmacy, Johannes Gutenberg University, Staudinger Weg 5, Mainz, Germany

Marco Falasca

Curtin Medical School, Curtin Health Innovation Research Institute, Curtin University, Perth, Australia.

David Gewirtz

Department of Pharmacology and

Toxicology, Virginia Commonwealth University, Richmond, VA, USA.

Jean-Pierre Gillet

Department of Biomedical Sciences, Faculty of Medicine, University of Namur, Namur, Belgium.

Antonio Giordano

Sbarro Institute for Cancer Research and Molecular Medicine, Center for Biotechnology, Department of Biology, College of Science and Technology, Temple University, Philadelphia, PA, USA; Department of Medical Biotechnologies, University of Siena, Siena, Italy.

Elisa Giovannetti

Lab Medical Oncology, VU University Medical Center, Cancer Center Amsterdam, Amsterdam, The Netherlands; Cancer Pharmacology Lab, AIRC Start-Up Unit, University of Pisa, Pisa, Italy.

William Gmeiner

Department of Cancer Biology, Wake Forest University School of Medicine, Winston-Salem, NC, USA.

Michael M Gottesman

Laboratory of Cell Biology, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Bethesda, MD, USA.

Sanjay Gupta

Department of Urologic Oncology, Case Western Reserve University, Cleveland, Ohio, USA.

Georg Hempel

Clinical Pharmacy Group, Department of Pharmaceutical and Medical Chemistry, University of Münster, Münster, Germany.

Dominique Heymann

Institut de Cancérologie de l'Ouest, Université de Nantes, Saint-Herblain, France.

Peter J. Houghton

Department of Molecular Medicine, Greehey Children's Cancer Research Institute, UT Health San Antonio, San Antonio, USA.

Zhiqing Huang

Department of Obstetrics and Gynecology, Division of Reproductive Sciences, Duke University Medical Center, Durham, NC, USA.

Thomas Hutson

Baylor Sammons Cancer Center, Texas Oncology, Dallas, TX, USA.

Marja Jäättelä

Cell Death and Metabolism Unit, Center for Autophagy, Recycling and Disease, Danish Cancer Society Research Center, Copenhagen, Denmark.

Gerrit Jansen

Department of Rheumatology, Amsterdam Rheumatology and immunology Center (ARC), Cancer Center Amsterdam, VU University Medical Center, Amsterdam, Netherlands.

Markus Joerger

Division of Medical Oncology, University of Basel, Basel, Switzerland

Alan Prem Kumar

Department of Pharmacology, Yong Loo Lin School of Medicine, National University of Singapore, Lower Kent Ridge, Singapore.

Hang Fai Kwok

Faculty of Health Sciences, University of Macau, Macau, China.

Natasha Kyprianou

Department of Pathology and Molecular & Cell-Based Medicine, Icahn School of Medicine at Mount Sinai, New York, NY, USA.

Jonathan A. Ledermann

Cancer Institute, University College London, London, UK.

Saverio Marchi

Department of Clinical and Molecular Sciences, Marche Polytechnic University, Ancona, Italy.

Giovanni Martinelli

Istituto Scientifico Romagnolo per lo Studio e la Cura dei Tumori (IRST) Srl-IRCCS, Meldola, Italy.

Cornelis J. M. Melief

Department of Immunohematology and

Bloodtransfusion, Leiden University Medical Center, Leiden, The Netherlands.

Martin Michaelis

School of Biosciences, University of Kent, Canterbury, UK.

Enrico Mini

Department of Health Sciences, Section of Clinical Pharmacology and Oncology, University of Florence, Florence, Italy.

Priyabrata Mukherjee

Department of Pathology, Stephenson Cancer Center, University of Oklahoma Health Sciences Center, Oklahoma City, OK, USA.

Natarajan Muthusamy

Division of Hematology, Department of Internal Medicine, The Ohio State University, Columbus, Ohio, USA.

Patrycja Nowak-Sliwinska

Molecular Pharmacology, School of Pharmaceutical Sciences (EPGL), University of Geneva, Geneva, Switzerland

Gianpaolo Papaccio

Department of Experimental Medicine, University of Campania "Luigi Vanvitelli", Naples, Italy.

Paola Perego

Fondazione IRCCS, Istituto Nazionale dei Tumori, Milan, Italy.

Francesco Pezzella

Nuffield Division of Clinical Laboratory Science, Radcliffe Department of Medicine, University of Oxford, Oxford, UK.

Roger M. Phillips

School of Pharmacy, University of Huddersfield, Huddersfield, UK

Raphael E. Pollock

Department of Surgery, The Ohio State University Comprehensive Cancer Center, Columbus, OH, USA

Paolo Ettore Porporato

Department of Molecular Biotechnology and Health Science, Molecular Biotechnology Center, University of Turin, Turin, Italy.

Chiara Riganti

Department of Oncology, University of

Torino, Torino, Italy.

Robert W. Robey

Laboratory of Cell Biology, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Bethesda, MD, USA.

José Rueff

Nova Medical School (NMS), Universidade Nova de Lisboa/Faculty of Medical Sciences, New University of Lisbon, Lisbon, Portugal

Ahmad R Safa

Department of Pharmacology & Toxicology, Indiana University School of Medicine, Indianapolis, IN, USA.

John D. Schuetz

Department of Pharmacy and Pharmaceutical Science, St. Jude Children's Research Hospital, Memphis, TN, USA.

Gautam Sethi

Department of Pharmacology, Yong Loo Lin School of Medicine, National University of Singapore, Singapore

John Seymour

Department of Clinical Haematology, The Royal Melbourne Hospital and Peter MacCallum Cancer Centre, Parkville, Australia

Xiangyang Shi

State Key Laboratory for Modification of Chemical Fibers and Polymer Materials, College of Chemistry, Chemical Engineering and Biotechnology, Donghua University, Shanghai, China

Alexander Sparreboom

Division of Pharmaceutics & Pharmaceutical Chemistry College of Pharmacy, The Ohio State University, Columbus, OH, USA

Rakesh Srivastava

Scott Cancer Center, and Department of Genetics, Louisiana State University Health Sciences Center, New Orleans, LA, United States

Gary S. Stein

Department of Biochemistry, University of Vermont Larner College of Medicine, Burlington, VT, USA

Ulrike Stein

Translational Oncology of Solid Tumors, Experimental and Clinical Research Center, Charité - Universitätsmedizin und Max-Delbrück-Centrum für Molekulare Medizin, Berlin, Germany

Chunxia Su

School of Medicine, Tongji University; Deputy Director, Medical Oncology Department, Shanghai Pulmonary Hospital, Shanghai, China.

Haruhiko Sugimura

Department of Tumor Pathology, Hamamatsu University School of Medicine, Hamamatsu, Japan

Dean G Tang

Professor & Chairman, Department of Pharmacology & Therapeutics, Roswell Park Comprehensive Cancer Center, Buffalo, NY, USA.

Hailin Tang

Sun Yat-sen University Cancer Center, Guangzhou, Guangdong, China.

Kenneth Kin Wah To

School of Pharmacy, the Chinese University of Hong Kong, Hong Kong, China.

Vladimir P. Torchilin

Department of Pharmaceutical Sciences, School of Pharmacy, Bouvé College of Health Sciences, Northeastern University, Boston, MA, USA

Brian A. Van Tine

Department of Pharmacology and Toxicology, University of Alabama at Birmingham, Birmingham, AL, USA.

Robert C.A.M. van Waardenburg

Department of Pharmacology and Toxicology, University of Alabama at Birmingham, Birmingham, AL, USA

Erik A. C. Wiemer

Department of Medical Oncology, Erasmus Medical Center Cancer Institute, Rotterdam, the Netherlands.

Murali Yallapu

Department of Immunology and Microbiology, University of Texas Rio Grande Valley, McAllen, TX, USA.

Takahiro Yamauchi

Department of Hematology and Oncology, Faculty of Medical Sciences, University of Fukui, Fukui, Japan

Dong-Hua Yang

New York College of Traditional Chinese Medicine, Mineola, NY, USA.

Nadia Zaffaroni

Molecular Pharmacology Unit, Department of Experimental Oncology and Molecular Medicine, Fondazione IRCCS Istituto Nazionale Tumori, Milan, Italy.

GENERAL INFORMATION

About the Journal

Cancer Drug Resistance (CDR), ISSN 2578-532X (Online), is a peer-reviewed online journal with print on demand compilation of articles published. The journal's full text is available online at www.oaepublish.com/cdr. The journal allows free access (Open Access) to its contents and permits authors to self-archive final accepted version of the articles on any OAI-compliant institutional/subject-based repository. The journal publishes research articles, reviews, case reports, commentaries and letters on pharmacological aspects of drug resistance and its reversal, including drug design, drug delivery, drug distribution and cellular drug resistance. Molecular mechanisms of drug resistance also cover the cellular pharmacology of drug resistance such as influx and efflux pumps (including the ABC pumps), receptors and their ligands, cellular signaling pathways, drug activation and degradation (including Phase I and II metabolism), drug sequestration, target modification and DNA repair. Drug classes to be covered include DNA targeted drugs and antihormones as well as antibodies and protein kinase inhibitors. Both clinical and experimental aspects of drug resistance in cancer are included.

Cancer Drug Resistance (CDR) was founded with Professor Godefridus J. Peters as the Editor-in-Chief in March 2018. In a testament to its growing prominence and scholarly impact, **CDR** has achieved several notable milestones in recent years. The journal's recognition journey began in March 2021 with its inclusion in the esteemed **Scopus** indexing. This was followed by another significant accolade in May 2022, as **CDR** secured its place in the **PubMed Central® (PMC)** database, further amplifying its reach and accessibility to the global research community. The year 2023 marked a series of remarkable achievements for **CDR**, with Scopus bestowing a CiteScore of 5.5, which subsequently surged to an impressive 6.3 as per the latest CiteScoreTracker update as of December 5, 2023. Furthermore, June 2023 emerged as a landmark month for **CDR**, as it achieved its first **Impact Factor** of 3.7, a recognition conferred by **Clarivate Analytics** in the esteemed Journal Citation Report (JCR). These milestones not only underscore the journal's commitment to advancing the field of cancer drug resistance but also reflect its growing influence and stature in the scientific community.

Information for Authors

Manuscripts must be prepared in accordance with Author Instructions.
Please check www.cdrjournal.com/pages/view/author_instructions for details.
All manuscripts must be submitted online at www.oaemesas.com/cdr/.

Published Articles 2022

Volume 5, Issue 1

- 1-14** **Auranofin and its analogs as prospective agents for the treatment of colorectal cancer**
Lara Massai, Damiano Cirri, Tiziano Marzo, Luigi Messori
- 15-24** **Efficacy of ICIs on patients with oncogene-driven non-small cell lung cancer: a retrospective study**
Xiaojin Guo, He Du, Jiayu Li, Menghang Yang, Anweng Xiong, Haiping Zhang, Fengying Wu
- 25-35** **Epigenetic modulation in sensitizing metastatic sarcomas to therapies and overcoming resistance**
Jeff Rytlewski, Qierra R. Brockman, Rebecca D. Dodd, Mohammed Milhem, Varun Monga
- 36-63** **Emerging actionable targets to treat therapy-resistant colorectal cancers**
Emanuela Grassilli, Maria Grazia Cerrito
- 64-79** **HDAC inhibitors with potential to overcome drug resistance in castration-resistant prostate cancers**
Bernhard Biersack, Bianca Nitzsche, Michael Höpfner
- 80-89** **Approaches to identifying drug resistance mechanisms to clinically relevant treatments in childhood rhabdomyosarcom**
Samson Ghilu, Christopher L. Morton, Angelina V. Vaseva, Siyuan Zheng, Raushan T. Kurmasheva, Peter J. Houghton
- 90-92** **Understanding sarcoma drug resistance one cell at a time**
Salah-Eddine Cherradi-Lamhamedi, Danh Truong, Joseph A. Ludwig
- 93-101** **Tousled-like kinase 1: a novel factor with multifaceted role in mCRPC progression and development of therapy resistance**
Md Imtiaz Khalil, Arrigo De Benedetti
- 102-113** **Tumor-derived exosomes: immune properties and clinical application in lung cancer**
Jing Wu, Suyao Li, Pengfei Zhang
- 114-128** **Immunotherapy resistance of lung cancer**
Xin Yu, Chaonan Han, Chunxia Su
- 129-146** **Resistance to immune checkpoint inhibitors in KRAS-mutant non-small cell lung cancer**
Yunchang Li, Lanlin Hu, Xinhao Peng, Huasheng Xu, Bo Tang, Chuan Xu
- 147-164** **Mechanism underlying the immune checkpoint inhibitor-induced hyper-progressive state of cancer**
Peng Ding, Lu Wen, Fan Tong, Ruiguang Zhang, Yu Huang, Xiaorong Dong

- 165-170** **ONECUT2 as a key mediator of androgen receptor-independent cell growth and neuroendocrine differentiation in castration-resistant prostate cancer**
WonSeok William Choi, Julia L. Boland, Jianqing Lin
- 171-183** **Drug resistance and minimal residual disease in multiple myeloma**
Alessandro Gozzetti, Sara Ciofini, Anna Sicuranza, Paola Pacelli, Donatella Raspadori, Emanuele Cencini, Dania Tocci, Monica Bocchia
- 184-198** **Biological evidence of cancer stem-like cells and recurrent disease in osteosarcoma**
Camille Jubelin, Javier Muñoz-Garcia, Denis Cochonneau, Emilie Moranton, Marie-Françoise Heymann, Dominique Heymann
- 199-213** **Emerging mechanisms of immunotherapy resistance in sarcomas**
Vaia Florou, Breelyn A. Wilky
- 214-228** **Potential mechanisms of resistance to current anti-thrombotic strategies in Multiple Myeloma**
Claire Comerford, Siobhan Glavey, Jamie M. O'Sullivan, John Quinn
- 229-232** **Combating CHK1 resistance in triple negative breast cancer: EGFR inhibition as potential combinational therapy**
Casey D. Stefanski, Jenifer R. Prosperi
- 233-244** **Lysosome-mediated chemoresistance in acute myeloid leukemia**
Laia Cuesta-Casnovas, Jennifer Delgado-Martínez, Josep M. Cornet-Masana, José M. Carbó, Lise Clément-Demange, Ruth M. Risueño
- 245-260** ***In vitro* cultures of circulating tumor cells: a potential tool to unravel drug sensitivity**
Jing Wu, Suyao Li, Pengfei Zhang

Volume 5, Issue 2

- 261-270** **Circular RNA drives resistance to anti-PD-1 immunotherapy by regulating the miR-30a-5p/SOX4 axis in non-small cell lung cancer**
Jing Wu, Meng-Xuan Zhu, Ke-Sang Li, Ling Peng, Peng-Fei Zhang
- 271-276** **Cancer drug resistance in multiple myeloma**
Fatih M. Uckun
- 277-303** **The complex relationship between multiple drug resistance and the tumor pH gradient: a review**
Tomas Koltai
- 304-316** **Mechanisms of chemotherapy resistance in ovarian cancer**
Mylena Ortiz, Emma Wabel, Kerry Mitchell, Sachi Horibata
- 317-327** **Targeting the complement system in pancreatic cancer drug resistance: a novel therapeutic approach**
Naushair Hussain, Deea Das, Atreyi Pramanik, Manoj K Pandey, Vivek Joshi, Kartick C. Pramanik

- 328-338 **Immune checkpoint inhibitor resistance in soft tissue sarcoma**
Vanessa Eulo, Brian A. Van Tine
- 339-343 **Natural bioactive compounds: a potential therapeutic strategy to sensitize bladder cancer to cisplatin treatment?**
Vicenç Ruiz de Porras
- 344-367 **Characteristics of leukemic stem cells in acute leukemia and potential targeted therapies for their specific eradication**
Quinty Hansen, Costa Bachas, Linda Smit, Jacqueline Cloos
- 368-379 **DNA damage and metabolic mechanisms of cancer drug resistance**
Deanna Tiek, Shi-Yuan Cheng
- 380-400 **Venetoclax resistance: mechanistic insights and future strategies**
Faustine Ong, Kunhwa Kim, Marina Y. Konopleva
- 401-414 **RIP140 regulates *POLK* gene expression and the response to alkylating drugs in colon cancer cells**
Pascale Palassin, Marion Lapierre, Sandrine Bonnet, Marie-Jeanne Pillaire, Balázs Győrffy, Catherine Teyssier, Stéphane Jalaguier, Jean-Sébastien Hoffmann, Vincent Cavaillès, Audrey Castet-Nicolas
- 415-423 **Ovarian cancer recurrence: is the definition of platinum sensitivity modified by PARPi, bevacizumab or other intervening treatments? : a clinical perspective**
Peter G. Rose
- 424-435 **Ovarian cancer recurrence: is the definition of platinum resistance modified by PARPi and other intervening treatments? The evolving landscape in the management of platinum-resistant ovarian cancer**
Michael J. Flynn, Jonathan A. Ledermann
- 436-450 **Fusobacterium nucleatum: a new player in regulation of cancer development and therapeutic response**
Tengda Zhao, Xueping Wang, Liwu Fu, Ke Yang
- 451-458 **Ovarian cancer recurrence: “is the definition of platinum resistance modified by PARP inhibitors and other intervening treatments?”**
Tanja Pejovic, Katherine Fitch, Gordon Mills
- 459-471 **Role of prostate cancer stem-like cells in the development of antiandrogen resistance**
Prem Prakash Kushwaha, Shiv Verma, Shashank Kumar, Sanjay Gupta
- 472-486 **An overview of resistance to Human epidermal growth factor receptor 2 (Her2) targeted therapies in breast cancer**
Ahmed M. Elshazly, David A. Gewirtz
- 487-497 **Molecular vulnerabilities and therapeutic resistance in hormone receptor positive and HER2 dependent breast cancer tumours**
Ravi Velaga, Sunao Tanaka, Masakazu Toi

- 498-510 **Transcriptional coactivator MED1 in the interface of anti-estrogen and anti-HER2 therapeutic resistance**
Gregory Bick, Jasmine Zhang, Elyse E. Lower, Xiaoting Zhang
- 511-533 **Multicellular biomarkers of drug resistance as promising targets for glioma precision medicine and predictors of patient survival**
Yuting Lu, Yongzhao Shao

Volume 5, Issue 3

- 534-540 **Emerging insights to lung cancer drug resistance**
Chunxia Su
- 541-559 **Liquid biopsies in primary and secondary bone cancers**
Argia Ucci, Nadia Rucci, Marco Ponzetti
- 560-576 **Aberrant calcium signalling downstream of mutations in TP53 and the PI3K/AKT pathway genes promotes disease progression and therapy resistance in triple negative breast cancer**
Alex J. Eustace, Min Jie Lee, Grace Colley, Jack Roban, Tim Downing, Paul J. Buchanan
- 577-594 **Exosome secretion from hypoxic cancer cells reshapes the tumor microenvironment and mediates drug resistance**
Kenneth K. W. To, William C. S. Cho
- 595-611 **Electrochemotherapy using thin-needle electrode improves recovery in feline nasal planum squamous cell carcinoma - a translational model**
Matías Tellado, Sebastián Michinski, Joseph Impellizeri, Guillermo Marshall, Emanuela Signori, Felipe Maglietti
- 612-624 **Role of extracellular vesicles secretion in paclitaxel resistance of prostate cancer cells**
Ashish Kumar, Pawan Kumar, Mitu Sharma, Susy Kim, Sangeeta Singh, Steven J. Kridel, Gagan Deep
- 625-636 **AdipoRon and Pancreatic Ductal Adenocarcinoma: a future perspective in overcoming chemotherapy-induced resistance?**
Luigi Sapio, Angela Ragone, Annamaria Spina, Alessia Salzillo, Silvio Naviglio
- 637-646 **Ovarian cancer resistance to PARPi and platinum-containing chemotherapy**
Rebekah Summey, Denise Uyar
- 647-661 **Therapeutics to harness the immune microenvironment in multiple myeloma**
James J. Ignatz-Hoover, James J. Driscoll
- 662-666 **A patient with relapsed high-grade serous ovarian carcinoma with somatic *RAD51C* mutations treated with PARPi monotherapy: a case report**
Siew-Fei Ngu, Hextan Y. S. Ngan, Karen K. L. Chan

- 667-690** **Drug resistance in metastatic castration-resistant prostate cancer: an update on the status quo**
Amani Yehya, Fatima Ghamlouche, Amin Zahwe, Yousef Zeid, Kevork Wakimian, Deborah Mukherji, Wassim Abou-Kheir
- 691-702** **Persistent EGFR/K-RAS/SIAH pathway activation drives chemo-resistance and early tumor relapse in triple-negative breast cancer**
Amy H. Tang, Richard A. Hoefler, Mary L. Guye, Harry D. Bear
- 703-720** **Base excision repair accessory factors in senescence avoidance and resistance to treatments**
Elise Vickridge, Camila C. F. Faraco, Alain Nepveu
- 721-726** **GD2+ cancer stem cells in triple-negative breast cancer: mechanisms of resistance to breast cancer therapies**
Khoa Nguyen, Emily McConnell, Orielle Edwards, Bridgette M. Collins-Burow, Matthew E. Burow
- 727-748** **Liquid biopsies to predict CDK4/6 inhibitor efficacy and resistance in breast cancer**
Sasha C. Main, David W. Cescon, Scott V. Bratman
- 749-761** **Microvesicles: the functional mediators in sorafenib resistance**
Cong He, Doulathunnisa Jaffar Ali, Bo Sun, Bei-Cheng Sun, Zhong-Dang Xiao
- 762-793** **An overview of resistance to chemotherapy in osteosarcoma and future perspectives**
Dorian Yarih Garcia-Ortega, Sara Aileen Cabrera-Nieto, Haydee Sarai Caro-Sánchez, Marlid Cruz-Ramos
- 794-813** **Insight into the molecular mechanisms of gastric cancer stem cell in drug resistance of gastric cancer**
Jixian Xiong, Tiantian Zhang, Penglin Lan, Shuhong Zhang, Li Fu
- 814-828** **Butein-instigated miR-186-5p-dependent modulation of TWIST1 affects resistance to cisplatin and bioenergetics of Malignant Pleural Mesothelioma cells**
Mario Cioce, Daniela Rutigliano, Annamaria Puglielli, Vito Michele Fazio
- 829-845** **A nano-enhanced vaccine for metastatic melanoma immunotherapy**
Katelyn E. Salotto, Walter C. Olson Jr, Karlyn E. Pollack, Anuradha Illendula, Elishama Michel, Sydney Henriques, Todd Fox, Susan Walker, Marya Dunlap-Brown, Craig L. Slingluff Jr, Mark Kester, Helena W. Snyder
- 846-849** **New insights for drug resistance in metastatic castration-resistant prostate cancer**
Prem Prakash Kushwaha, Sanjay Gupta

Volume 5, Issue 4

- 850-872** **Drug and apoptosis resistance in cancer stem cells: a puzzle with many pieces**
Ahmad R. Safa
- 873-881** **Mechanisms of neratinib resistance in *HER2*-mutant metastatic breast cancer**
Lisa D. Eli, Shyam M. Kavuri

- 882-888** **Improving HER2 testing reproducibility in HER2-low breast cancer**
Elham Sajjadi, Konstantinos Venetis, Mariia Ivanova, Nicola Fusco
- 889-901** **Cancer-associated fibroblasts as accomplices to confer therapeutic resistance in cancer**
Wenyu Wang, Bing Cheng, Qiang Yu
- 902-916** **Tyrosine kinases in KMT2A/MLL-rearranged acute leukemias as potential therapeutic targets to overcome cancer drug resistance**
Fatih M. Uckun, Sanjive Qazi
- 917-925** **Tackling heterogeneity in treatment-resistant breast cancer using a broad-spectrum therapeutic approach**
Leroy Lowe, J. William LaValley, Dean W. Felsher
- 926-938** **Discovery of the inhibitor of DNA binding 1 as a novel marker for radioresistance in pancreatic cancer using genome-wide RNA-seq**
Oscar Zuniga, Stephanie Byrum, Adam R. Wolfe
- 939-953** **Aberrant Notch signaling in gliomas: a potential landscape of actionable converging targets for combination approach in therapies resistance**
Maria D'Amico, Francesca De Amicis
- 954-970** **Perspectives of metal-organic framework nanosystem to overcome tumor drug resistance**
Huafeng Wang, Shi Li, Yiting Yang, Lei Zhang, Yinghao Zhang, Tianxiang Wei
- 971-980** **Loss of HER2 in breast cancer: biological mechanisms and technical pitfalls**
Stefania Morganti, Mariia Ivanova, Emanuela Ferraro, Liliana Ascione, Grazia Vivinet, Giuseppina Bonizzi, Giuseppe Curigliano, Nicola Fusco, Carmen Criscitiello
- 981-994** **Cancer resistance to immunotherapy: What is the role of cancer stem cells?**
Gourab Gupta, George Merhej, Shakthika Saravanan, Hexin Chen
- 995-1015** **Association between genome-wide epigenetic and genetic alterations in breast cancer tissue and response to HER2-targeted therapies in HER2-positive breast cancer patients: new findings and a systematic review**
Daniela Furrer, Dzevka Dragic, Sue-Ling Chang, Frédéric Fournier, Arnaud Droit, Simon Jacob, Caroline Diorio
- 1016-1024** **The role of antiangiogenic monoclonal antibodies combined to EGFR-TKIs in the treatment of advanced non-small cell lung cancer with activating EGFR mutations: acquired resistance mechanisms and strategies to overcome them**
Danilo Rocco, Luigi Della Gravara, Giovanni Palazzolo, Cesare Gridelli

- 1-29 P-glycoprotein (ABCB1) - weak dipolar interactions provide the key to understanding allocrite recognition, binding, and transport**
Anna Seelig, Xiaochun Li-Blatter
- 30-34 Concomitant medications and circulating tumor cells: friends or foes?**
Serena Di Cosimo, Vera Cappelletti
- 35-44 New perspectives on epigenetic modifications and PARP inhibitor resistance in HR-deficient cancers**
Rachel Bayley, Ellie Sweatman, Martin R. Higgs
- 45-58 The change of paradigm in the treatment of HER2-positive breast cancer with the development of new generation antibody-drug conjugates**
Santiago Escrivá-de-Romani, Cristina Saura
- 59-77 Multimodal 4-arylchromene derivatives with microtubule-destabilizing, anti-angiogenic, and MYB-inhibitory activities**
Leonhard H. F. Köhler, Sebastian Reich, Maria Yusenko, Karl-Heinz Klempnauer, Gerrit Begemann, Rainer Schobert, Bernhard Biersack
- 78-102 Nano-TRAIL: a promising path to cancer therapy**
Siri Chandana Gampa, Sireesha V. Garimella, SanthiLatha Pandrangi
- 103-115 Targeting hormone-resistant breast cancer cells with docetaxel: a look inside the resistance**
Alexander M. Scherbakov, Anna A. Basharina, Danila V. Sorokin, Ekaterina I. Mikhaevich, Iman E. Mizaeva, Alexandra L. Mikhaylova, Tatiana A. Bogush, Mikhail A. Krasil'nikov
- 116-137 Mechanisms involved in cancer stem cell resistance in head and neck squamous cell carcinoma**
Juliana Mota Siqueira, Daniele Heguedusch, Camila Oliveira Rodini, Fabio Daumas Nunes, Maria Fernanda Setúbal Destro Rodrigues
- 138-150 Resistance to energy metabolism - targeted therapy of AML cells residual in the bone marrow microenvironment**
Yoko Tabe, Marina Konopleva
- 151-168 Targeting regulated cell death pathways in acute myeloid leukemia**
Sylvain Garciaz, Thomas Miller, Yves Collette, Norbert Vey
- 169-181 Anti-BCMA novel therapies for multiple myeloma**
Vincenzo Sammartano, Marta Franceschini, Sara Fredducci, Federico Caroni, Sara Ciofini, Paola Pacelli, Monica Bocchia, Alessandro Gozzetti
- 182-204 Heterotypic signaling of cancer-associated fibroblasts in shaping the cancer cell drug resistance**
Ramesh Butti, Ashwini Khaladkar, Priya Bhardwaj, Gopinath Prakasam

Volume 6, Issue 2

- 205-222 **Targeting MYC-driven lymphoma: lessons learned and future directions**
Sandra Martínez-Martín, Marie-Eve Beaulieu, Laura Soucek
- 223-238 **How acute myeloid leukemia (AML) escapes from FMS-related tyrosine kinase 3 (FLT3) inhibitors? Still an overrated complication?**
Salvatore Perrone, Tiziana Ottone, Nadezda Zhdanovskaya, Matteo Molica
- 239-241 **Cancer stem cells in drug resistance: an introduction to the e-book covering the special issue on the “Cancer Stem Cells and Drug Resistance”**
Balázs Sarkadi
- 242-256 **miR-16-5p enhances sensitivity to RG7388 through targeting *PPM1D* expression (WIP1) in Childhood Acute Lymphoblastic Leukemia**
Maryam Zanjirband, Soheila Rahgozar, Narges Aberuyi
- 257-272 **Review of 5-FU resistance mechanisms in colorectal cancer: clinical significance of attenuated on-target effects**
William H. Gmeiner, Charles Chidi Okechukwu
- 273-283 **Mitochondria in colorectal cancer stem cells - a target in drug resistance**

Abstract

Today colorectal cancer (CRC) is one of the leading causes of cancer death worldwide. This disease is poorly chemo-sensitive toward the existing medical treatments so that new and more effective therapeutic agents are urgently needed and intensely sought. Platinum drugs, oxaliplatin in particular, were reported to produce some significant benefit in CRC treatment, triggering the general interest of medicinal chemists and oncologists for metal-based compounds as candidate anti-CRC drugs. Within this frame, gold compounds and, specifically, the established antiarthritic drug auranofin with its analogs, form a novel group of promising anticancer agents. Owing to its innovative mechanism of action and its favorable pharmacological profile, auranofin together with its derivatives are proposed here as novel experimental agents for CRC treatment, capable of overcoming resistance to platinum drugs. Some encouraging results in this direction have already been obtained. A few recent studies demonstrate that the action of auranofin may be further potentiated through the preparation of suitable pharmaceutical formulations capable of protecting the gold pharmacophore from unselective reactivity or through the design of highly synergic drug combinations. The perspectives of the research in this field are outlined.

Keywords: Auranofin, CRC, colorectal cancer, metallodrugs, anticancer agents, gold, gold-based drugs

INTRODUCTION

Colorectal cancer (CRC) is one of the most common cancers in Western countries and is a major worldwide health problem being one of the primary causes of cancer death^[1]. Advances in the diagnosis and treatment of CRC brought a major effect in the management of this disease. Notably, in the last decades, screening programs and early diagnosis, together with new therapeutic options, allowed reducing CRC mortality considerably^[2]. Despite this progress and the remarkable increase of knowledge about CRC biology and treatment, metastatic cases are still associated with a poor prognosis. In fact, the percentage of survival drops from ~65% to ~10% in the presence of metastatic CRC disease^[3]. At least half of patients with colorectal cancer develop metastases^[4], resulting in a poor outcome. The primary site for metastasis development is liver, representing the only site of metastasis in about one third of patients. Other common organs for distant metastases are lung, peritoneum, bone, brain, and spleen^[4,5]. In CRC patients, the first therapeutic option is surgical resection, but the role of adjuvant chemotherapy (and chemoradiotherapy), in terms of disease-free survival and overall survival, is well recognized^[6,7].

CRC is reputed as poorly chemo-sensitive, and for more than 30 years fluorouracil has been the reference drug. Fluorouracil can be administered both through continuous infusion line and through bolus administration. Recent reports evidenced however no significant differences in terms of prolonged survival rate^[8,9]. Many efforts have been made to improve these results. Biochemical modulation of fluorouracil is one of the most interesting approaches to increase the therapeutic index of this compound. In metastatic disease confined to the liver, locoregional therapy through implantable pumps may be taken into account as well^[10].

Until today, the standard therapy for CRC has relied on fluorouracil plus levamisole and/or calcium folinate (folinic acid)^[6]. More recently, other treatment options have been introduced in the clinical practice. At present, there is increasing attention for the role of monoclonal antibodies (Mab) in CRC therapy. Among the various Mabs approved so far for CRC treatment, bevacizumab, panitumumab, and ramucirumab are the most commonly used^[11]. Other clinical strategies rely on portal vein infusion of fluorouracil, alone or in combination with systemic therapy^[12]. In rectal cancer, the best results are achieved by combining radiotherapy and chemotherapy. Recent reports support the use of induction or consolidation chemotherapy before surgery in locally advanced forms as well as total neoadjuvant treatment as the best therapeutic options^[13]. In advanced colorectal cancer, a standard treatment has not been established yet, and different therapeutic options can be proposed according to the tumor staging and features. Typically, the first-line chemotherapy relies on the FOLFOX (leucovorin, 5-fluorouracil, and oxaliplatin) or CAPOX (capecitabine and oxaliplatin) protocol alone or in combination with Mab. At variance, the second-line approach also relies on compounds such as irinotecan and raltitrexed now entered in the clinical practice with encouraging results. For instance, FOLFIRI-based (leucovorin, 5-fluorouracil, and irinotecan) regimens are a common clinical practice, even in combination with antiangiogenic agents^[14].

PLATINUM DRUGS IN CRC TREATMENT

Pt drugs play an important role in CRC treatment. Oxaliplatin is the only platinum anticancer drug in the clinical use for colorectal cancer, while cisplatin is not effective in the treatment of this tumor. The resistance to cisplatin in CRC is determined by several factors mostly related to the processing of cisplatin-induced DNA lesions by various biological actors. The tumor suppressor protein p53 is a key player in the cellular response to cisplatin. It is responsible for controlling the cascade of events leading to cell cycle

arrest/repair or apoptosis through transcription and activation of numerous p53-dependent DNA damage response genes. Accordingly, deactivation of p53 in CRC is involved in cisplatin chemoresistance. In this view, the DNA mismatch repair (MMR) process has a relevant role as well. Indeed, cisplatin-induced lesions are recognized by MMR. Conversely, oxaliplatin-induced lesions to DNA are not recognized. As a consequence, oxaliplatin shows cytotoxic and anticancer effects that are basically independent of the MMR process^[15,16]. However, beyond the formation of adducts with DNA, which are extensively recognized as a key step for the pharmacological activity of platinum-based anticancer drugs^[17,18], the different therapeutic indication between cisplatin and oxaliplatin was discussed by Bruno *et al.*^[19] in a seminal paper published in 2017. In this article, the authors reported on the mechanisms behind the anticancer effects of platinum-based drugs. Although it is not clear to what extent the effect of DNA-independent pathways contributes to the anticancer profile compared to the toxic effect of DNA adducts formation, the above authors pointed at the ribosome biogenesis stress induced by oxaliplatin as a likely mechanism also contributing to the overall pharmacological activity. This finding is relevant because might be involved in the distinct clinical implementation of oxaliplatin compared with cisplatin^[19].

As outlined above, Pt compounds, and oxaliplatin in particular, play a major role in the current medical treatment of CRC. Although being featured by a higher tolerability compared with cisplatin, oxaliplatin manifests a few relevant limitations such as relevant systemic toxicity and the frequent insurgence of resistance that may lead to eventual treatment failure. These limitations imply that the discovery of new drugs for colorectal cancer is absolutely mandatory and urgent. Here, we analyze specifically the chances of discovering new effective anticancer agents within the field of metal-based drugs.

METAL BASED DRUGS AS A SOURCE OF NOVEL ANTICANCER AGENTS CAPABLE OF OVERCOMING DRUG RESISTANCE: THE CASE OF GOLD COMPOUNDS

Platinum-based compounds are very effective only against a relatively limited number of tumor types and manifest at the same time some severe side effects (e.g., gastrointestinal toxicity, nervous system toxicity, and bone marrow suppression) that heavily limit their use^[20-22]. In addition, intrinsic and acquired drug resistance may greatly reduce the efficacy of platinum drugs with a consequent poor prognosis^[23]. For this reason, intense efforts are warranted to explore and identify novel anti-tumor metallodrugs that may replace platinum compounds for specific therapeutic goals and for treatment improvement. Accordingly, many new metal compounds exploiting various transition metals have been prepared and evaluated, and some of them (e.g., gold, silver, copper, ruthenium, and other active metals) turned out to manifest very encouraging antitumor effects. In particular, coinage metals (especially Au and Ag) revealed a greater application potential as they are, on average, less toxic to humans than other transition metals. From a chemical point of view, gold compounds deserve particular attention owing to the unique position of gold in the periodic table, which ultimately leads to a larger electronegativity, a higher electron affinity, and a rich and peculiar redox profile. Several gold compounds, including both gold(III) and gold(I) compounds [i.e., gold(I) carbene, gold sodium thiomalate, gold thiolates, or gold compounds with bipyridyl-type ligands], were thus considered for cancer treatment, and many of them were found to possess remarkable antiproliferative properties *in vitro* against several human cancer cell lines^[24].

Several studies have pointed out that gold compounds cause their outstanding cytotoxic effects by taking advantage of multiple molecular and cellular mechanisms. The most credited mechanisms involve inhibition of thiol-containing enzymes, especially thioredoxin reductase (TrxR)^[25-27], direct mitochondrial damage^[28-31], or alteration of DNA functions^[32,33], all of which may contribute importantly to the observed anticancer actions. Although no non-platinum metal compound has been approved so far for clinical use, some gold drug candidates are being actively investigated. A few gold compounds have shown very

promising results in preclinical research^[34], and two of them even reached clinical trials.

AURANOFIN AND ITS ANALOGS AS ANTICANCER AGENTS: CHEMICO-BIOLOGICAL ASPECTS AND MECHANISTIC INFERENCES

In the field of gold-based drugs, auranofin (AF) undoubtedly occupies a pivotal position. From the chemical point of view auranofin, i.e., [2,3,4,6-tetra-*o*-acetyl-*l*-thio- β -*d*-glyco-pyrano-sato-*S*-(triethylphosphine)-gold(I)], is a mixed ligand gold(I) complex with a linear geometry having a triethylphosphine molecule and a thioglucose derivative as gold(I) ligands [Figure 1].

Recently, various research groups have found that auranofin^[35,36], beyond its known anti-inflammatory actions, also exhibits prominent anticancer, antibacterial, and antiparasitic properties^[37-43]. Accordingly, during the past few years, auranofin has attracted a lot of attention in the medicinal chemistry scientific community as a prospective anticancer and anti-infective agent on the ground of drug repurposing strategies. As a matter of fact, AF has entered several different clinical trials as an anticancer, antiviral, or antiparasitic drug (ClinicalTrials.gov Identifier: NCT02089048, NCT01747798, NCT03456700, NCT01419691, NCT02063698, NCT02736968, NCT01737502, NCT02961829, NCT02770378, NCT03975790, and NCT01557348).

Auranofin was initially prepared in the late 1970s and found to manifest remarkable antiarthritic properties. Owing to its favorable pharmacological profile, auranofin was eventually approved for clinical use against rheumatoid arthritis in 1985, although in the absence of a precise understanding of its mode of action.

Moreover, it was found that auranofin was able to inhibit the growth of tumor cells *in vitro* and arrest the growth of an *in vivo* model tumor (leukemia P388) in mice. In fact, Mirabelli *et al.*^[44], starting from auranofin and changing systematically the phosphine ligand, the sulfur ligand, or both ligands, obtained 62 distinct Au(I) complexes. These novel complexes were tested both *in vitro*, against B16 melanoma and P388 leukemia, and *in vivo*, against mouse P388 intraperitoneal leukemia, with encouraging results. Mechanistically, it could be ascertained that auranofin behaves as a prodrug capable of releasing its two original ligands; in any case, it is well documented that the thiosugar ligand is a better leaving group than the phosphine and is the first ligand to be released. The resulting empty coordination position on the gold(I) center becomes available for coordination to biomolecules. Typically, gold compounds with the general formula Et_3PAuX manifest relevant and roughly similar anticancer profiles. This finding implies that the thiosugar ligand is not fundamental for the cytotoxic activity and that the $[\text{Et}_3\text{PAu}]^+$ moiety is likely to be the true pharmacophore. The role of the X ligand is probably related to the cellular uptake: a more lipophilic nature of the ligand might determine a more favorable pharmacokinetic and biodistribution profile.

The chemical behavior of auranofin and its reactions with biomolecules have been intensely investigated. The reaction of auranofin with biomolecules has now been studied in detail: it could be established that auranofin binds proteins tightly by forming strong coordinative bonds to free cysteine or selenocysteine residues^[45,46]. This type of reactivity may well account for its molecular mechanisms; for instance, there is now a general consensus that the tight binding of auranofin to the free selenocysteine group in the active site of TrxR is primarily responsible for its relevant actions at the cellular level, eventually leading to severe intracellular redox dysregulation and associated apoptotic cancer cell death [Figure 2].

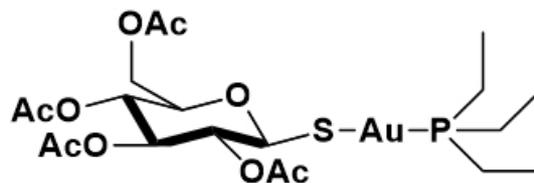

Figure 1. Chemical structure of auranofin.

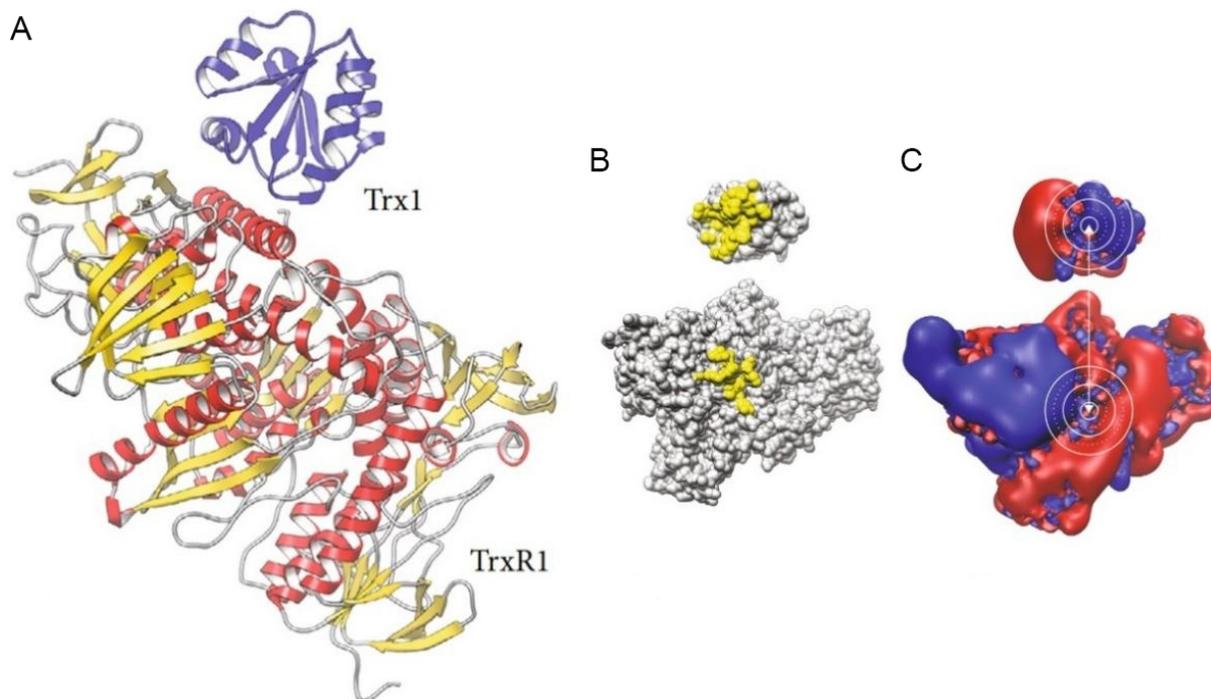

Figure 2. (A) Cartoon representation of the secondary structures of human thioredoxin-1-thioredoxin reductase 1 (Trx1-TrxR1) complex PDB: 3qfa. (B) The contact patches with direct molecular contacts are highlighted in yellow. (C) The isosurfaces of the electrostatic potential are depicted in blue (positive) and red (negative). The active site cysteinyl residues and interaction surfaces in the immediate contact area in both proteins are encircled in white lines. Reproduced and adapted from Hossain *et al.*^[47] under the Creative Commons Attribution License 4.0 International (CC BY 4.0).

However, the interpretation of the mechanism of the anticancer actions of auranofin is still controversial and not conclusive. Although thioredoxin reductase inhibition is believed to be a central trait of its mode of action, other likely targets have been proposed and partially validated. As a matter of fact, some interesting proteomics data highlight, upon auranofin treatment, a few differentially expressed proteins belonging to different cellular processes, namely cell redox homeostasis, metabolism, and cell structure. Specifically, the main altered proteins were peroxiredoxins 1 and 6, linked to cell redox balance; triosephosphate isomerase 1, which plays a key role in the glycolysis and gluconeogenesis pathways; ezrin, essential for cell structure and cell migration; and the heterogeneous nuclear ribonucleoprotein H, whose increased cleavage leads to the caspase 3 activation triggering apoptosis^[24-48].

In addition, a few recent studies suggested that AF produces important immunomodulatory effects^[49]. In particular, it was found that AF induces ICD (immunogenic cell death) in cancer cells as a consequence of endoplasmic reticulum stress and reactive oxygen species (ROS) production. Notably, Freire Boullosa *et al.*^[50] showed a significant increase in ICD-related damage-associated molecular patterns

and maturation in dendritic cells following AF treatment in mutant p53 NSCLC *in vitro*. Apparently, these effects are mediated by the immunosuppressive TGF- β cytokine. TGF- β plays a major role in immunosuppression within the tumor microenvironment through the prevention of immune infiltration into tumor tissue and promotion of tumor cell proliferation. The cooperation between AF and anti-PD-L1 therapy in triple-negative breast cancer mouse model further supports the use of AF as an immunomodulating agent^[42]. These findings are in accord with some early observations on the immunomodulatory properties of AF^[49].

Overall, these arguments demonstrate that auranofin, as already hypothesized for this compound as well as other gold(I) compounds, possesses a multi-target mode of action; indeed, auranofin interacts in cells and blood with several targets, mainly proteins with key functions, involving multiple cellular pathways and altering different biological networks.

AURANOFIN AND ITS ANALOGS SHOW PROMISE FOR COLORECTAL CANCER TREATMENT: *IN VITRO* EVIDENCE

The favorable chemical and pharmacological profile of auranofin as a prospective anticancer agent prompted researchers to synthesize and characterize some auranofin derivatives and assess their action *in vitro* against a few CRC cell lines. In particular, in recent studies, five analogs of auranofin were prepared where the thiosugar ligand was substituted by different anionic ligands (these compounds are depicted in [Figure 3](#))^[51,52]. The synthesis of these analogs is rather straightforward and starts from the commercially available Et₃PAuCl. More precisely, the iodide analog can be prepared through a simple chloride-displacing reaction carried out with an excess of potassium iodide^[51]; the cyanide derivative can be synthesized reacting the two ionic species K[Au(CN)₂] and [Au(PEt₃)₂]Cl in a biphasic reaction^[52]; and the thiocyanate and azido derivatives can be prepared by reacting the Et₃PAuCl species, respectively, with potassium thiocyanate and sodium azide after its activation with silver nitrate^[52].

Then, the antiproliferative properties of two of these analogs, i.e., Et₃PAuCl and Et₃PAuI, as well as auranofin itself were comparatively assayed *in vitro* against four representative colorectal cancer lines, i.e., HCT8, HCT116, HT29, and Caco2, and two healthy cell lines, i.e., HDF (human fibroblast, adult) and HEK293 (human embryonic kidney), by using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) test^[51]. As displayed in [Table 1](#), all tested compounds produced very notable cytotoxic effects on all the selected CRC cell lines with half-maximal inhibitory concentration (IC₅₀) values always falling in the 100-700 nM range. Et₃PAuI was slightly less cytotoxic than the other two gold complexes. In line with expectations, the presence of the thiosugar ligand turned out not to be an essential feature for the cytotoxic action. Moreover, by considering the close similarity in the measured IC₅₀ values, it can be inferred that the cellular uptake of the three compounds should not be very different. Remarkably, when measuring the cytotoxic effects on two healthy cell lines, HDF human fibroblast cells (adult) and HEK293 human embryonic kidney, no appreciable cytotoxic effects were detected for the three study complexes in the concentration range 0-5000 nM. The latter finding is a good index of selectivity for cancer cells.

Afterwards, since TrxR is reputed to be a primary target for auranofin, the inhibitory potencies of the three gold compounds against this enzyme were analyzed comparatively. The results are summarized in [Table 2](#). Interestingly, the obtained IC₅₀ values for TrxR inhibition are roughly consistent with those determined for the cytotoxic effects in CRC cell lines [[Table 1](#)]. This probably implies that the observed cytotoxic effects are somehow linked to the ability of these gold complexes to inhibit TrxR. Moreover, the present results confirm that Et₃PAuCl is not only the most potent cytotoxic agent but also the most potent TrxR inhibitor of the series; although the IC₅₀ values measured for auranofin and Et₃PAuI are only slightly higher, they still

Table 1. IC₅₀ values (nM) determined for Et₃PAuI, AF, and Et₃AuP-Cl (24 h incubation)

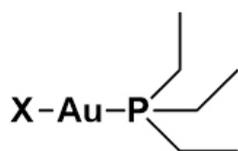

Complex	HCT8	HCT116	HT29	Caco2	HDF	HEK293
AF	132 ± 16	180 ± 17	359 ± 35	465 ± 53	> 5000	> 5000
Et ₃ PAuCl	105 ± 11	154 ± 22	122 ± 15	560 ± 93	> 5000	> 5000
Et ₃ PAuI	260 ± 28	290 ± 36	318 ± 90	706 ± 232	> 5000	> 5000

The results are reported as the average value for three independent experiments ± standard deviation. Reproduced and adapted with permission from Marzo *et al.*^[51]. IC₅₀: Half-maximal inhibitory concentration; AF: auranofin.

Table 2. Thioredoxin reductase activity assay. IC₅₀ values (nM) were determined treating 2 U/L of TrxR with aliquots of AF, Et₃AuP-Cl, and Et₃PAuI (from 1 ×M to 1 nM)

Complex	IC ₅₀ (nM)
AF	105 ± 17.3
Et ₃ AuP-Cl	51.3 ± 8.5
Et ₃ PAuI	193 ± 22.2

The results are reported as the average value for three independent experiments ± standard deviation. IC₅₀ refers to 50% enzyme inhibition. Reproduced and adapted with permission from Marzo *et al.*^[51]. IC₅₀: Half-maximal inhibitory concentration; AF: auranofin.

**Figure 3.** Chemical structures of auranofin analogs bearing different ligands in place of thiosugar moiety.

fall in the nanomolar range.

Conversely, the three auranofin analogs in which the thiosugar was replaced with stronger ligands (i.e., Et₃PAuCN, Et₃PAuSCN, and Et₃PAuN₃) turned out to be completely inactive against HCT116 cell line for concentrations ranging up to 1000 nM. This observation strongly supports the occurrence of a reaction mechanism in which the anionic groups have to be displaced from the nucleophilic active site of TrxR (the SEC-CYS motif) to observe the pharmacological activity of the [Au(PEt₃)]⁺ moiety^[52]. In conclusion, the results of this study demonstrated that auranofin and its chloride, and the iodide analogs manifest potent cytotoxic effects *in vitro* against four selected CRC lines with the measured IC₅₀ values always falling in the nanomolar range and no apparent cytotoxic effect on human fibroblast cell line and human embryonic kidney cells up to a 5 μM concentration. The TrxR activity assay revealed that both Et₃PAuCl and Et₃PAuI retain the potent inhibitory action of auranofin (nanomolar range), being consistent with their observed cytotoxic effects. Overall, these findings are consistent with the concept that TrxR remains the most probable and most relevant biomolecular target for these gold compounds. Moreover, these results, although obtained *in vitro* on cell cultures, support the idea that auranofin and its analogs are optimal drug candidates for further testing against more advanced and sophisticated CRC models. It should also be noted that the DNA-independent mode of action of AF and some of its analogs is a key aspect determining the high cytotoxicity toward *in vitro* CRC models. As an example, AF, Et₃PAuCl, and Et₃PAuI [Table 1] have been reported to exert anticancer effects significantly greater than cisplatin and even oxaliplatin on

representative colorectal cancer cell lines [Table 3]^[51,52].

Based on the above considerations, it could be inferred that the ability of auranofin and some of its analogs to exert a greater anticancer activity in CRC lines than cisplatin and oxaliplatin might depend on the different mechanisms underlying the pharmacological effects. In fact, in contrast to oxaliplatin^[55], auranofin does not efficiently bind DNA, thus being its activity substantially unaffected by MMR, p53, and nucleotide excision repair functions. In fact, gold-based drugs produce the desired anticancer effects mainly through a DNA-independent mode, i.e., targeting specific enzymes such as the Trx system^[51,52].

NEW PERSPECTIVES IN THE USE OF AURANOFIN AND ITS ANALOGS: ENCAPSULATION OF GOLD COMPOUNDS IN BIOCOMPATIBLE NANOPARTICLES

As stated above, Et₃PAuCl is an auranofin derivative exhibiting very attractive biological and pharmacological properties. Similar to auranofin, Et₃PAuCl possesses potent cytotoxic properties *in vitro* toward numerous cancer cell lines, thus being a promising anticancer drug candidate. In this frame, some investigators wondered whether Et₃PAuCl encapsulation might lead to a better pharmacological profile, considering the expected reduction of unwanted side-reactions that are mainly responsible for the adverse effects and for drug inactivation. A reasonable option to achieve this goal consists in using biocompatible nanoparticles as nanocarriers to protect the gold complex from the biological environment. To achieve this goal, Menconi *et al.*^[43] exploited organic polyethylene glycol-poly lactic acid-co-glycolic acid (PLGA-PEG)-based nanoparticles of intermediate size, which could host a certain number of metallodrug's copies into their hydrophobic core [Figure 4]. Et₃PAuCl was encapsulated in these biocompatible PLGA-PEG nanoparticles, and the new formulation was evaluated in colorectal HCT116 cancer cells in comparison to free Et₃PAuCl.

Notably, the encapsulated Et₃PAuCl mostly retains the cellular actions of the free complex and causes even larger cytotoxic effects in CRC cells, through apoptosis and autophagy. Moreover, a large inhibition of two crucial signaling pathways, namely extracellular signal-regulated kinase (ERK) and protein kinase B (AKT), by the encapsulated form of Et₃PAuCl, was clearly evidenced by the fact that this inhibition was not found in cells treated with the free drug. Overall, these results point out that encapsulation of Et₃PAuCl in PLGA-PEG nanoparticles does not significantly affect the antiproliferative properties of this gold complex. However, some changes in the biological effects of the studied gold complex could be detected, which were specifically evidenced by the differential effects produced on the ERK and AKT signaling pathways. It would be of interest to extend such experimentation to appropriate *in vivo* models of CRC.

NEW PERSPECTIVES IN THE USE OF AURANOFIN AND ITS ANALOGS: THE ROLE OF COMBINATION THERAPIES

Another valuable strategy in the use of gold compounds as anti-colorectal cancer agents is offered by the exploitation of so-called combination therapies. It is a common practice in cancer pharmacology to use anticancer drugs in association. Cocktails of drugs instead of single drugs are indeed very popular in current anticancer medical treatments for various reasons: (1) the application of lower concentrations of intrinsically toxic drugs with a narrow therapeutic index; (2) the opportunity to achieve a considerable synergism; and (3) the effective chance of reducing resistance insurgency. Combination therapy may also consist of the combination of an anticancer drug with a common non-cytotoxic drug that has nonetheless the important potential to modulate/enhance the cytotoxic effect of the first drug. This type of strategy was applied very recently by Han *et al.*^[56] to auranofin for the treatment of CRC. In detail, these authors performed a high-throughput screening of a library of 1280 FDA-approved clinical drugs in the search for compounds that might enhance the anticancer activity of auranofin *in vitro*. Surprisingly, they found that

Table 3. The IC₅₀ values (×M) determined for cisplatin and oxaliplatin (24 h incubation) against HT29 and HCT116 lines are also included as reference

Complex	HCT116	HT29
Cisplatin	21.96 ± 1.11	16.39 ± 1.10
Oxaliplatin	49.2 ± 0.9	19.7 ± 1.2

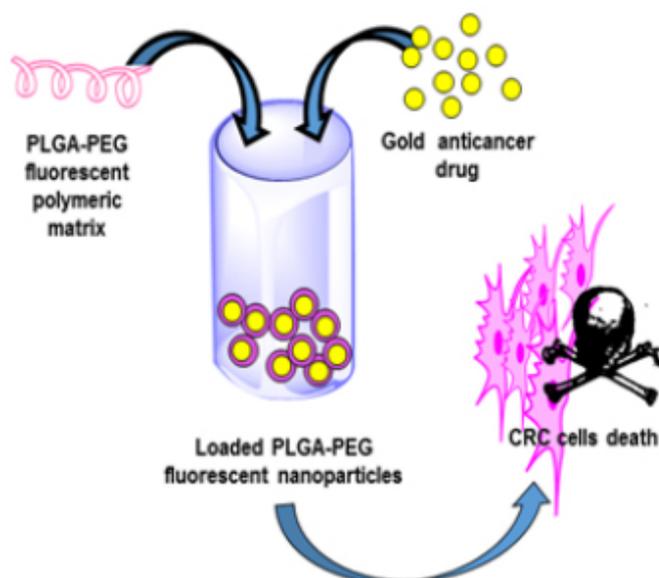

Figure 4. Schematic representation of the Et₃PAuCl-loaded NPs tested against colorectal cancer models. Reproduced and adapted from Menconi et al.^[43] under the Creative Commons Attribution License 4.0 International (CC BY 4.0).

the anti-inflammatory drug celecoxib (CE), a cyclooxygenase 2 inhibitor, strongly potentiated the anticancer activity of AF^[56].

Notably, the promising *in vitro* results obtained for the AF + CE association were later supported by very encouraging *in vivo* results, as displayed in Figure 5. Since AF and CE are FDA-approved drugs that are used in the clinic, it is quite straightforward to translate the results of this study into an immediate clinical cancer treatment.

Mechanistically, the AF/CE combination induced severe oxidative stress, resulting in ROS-mediated hexokinase inhibition and disruption of mitochondrial redox homeostasis. Overall, these effects eventually caused a significant decrease of ATP generation. The CE-induced ROS increase together with AF-mediated inhibition of thioredoxin reductase determined a large shift of Trx2 to its oxidized form, producing a degradation of MT-CO₂ (mitochondrially-encoded cytochrome C oxidase II) and a dysfunction of the electron transport chain (see Figure 6).

CONCLUSIONS

CRC is the second most deadly cancer worldwide. Medical treatments for CRC are still largely insufficient and rarely curative; it follows that the inoperable metastatic disease results in most cases in patient's death^[57]. Metal-based drugs may play a significant and growing role in the therapeutics of CRC; oxaliplatin

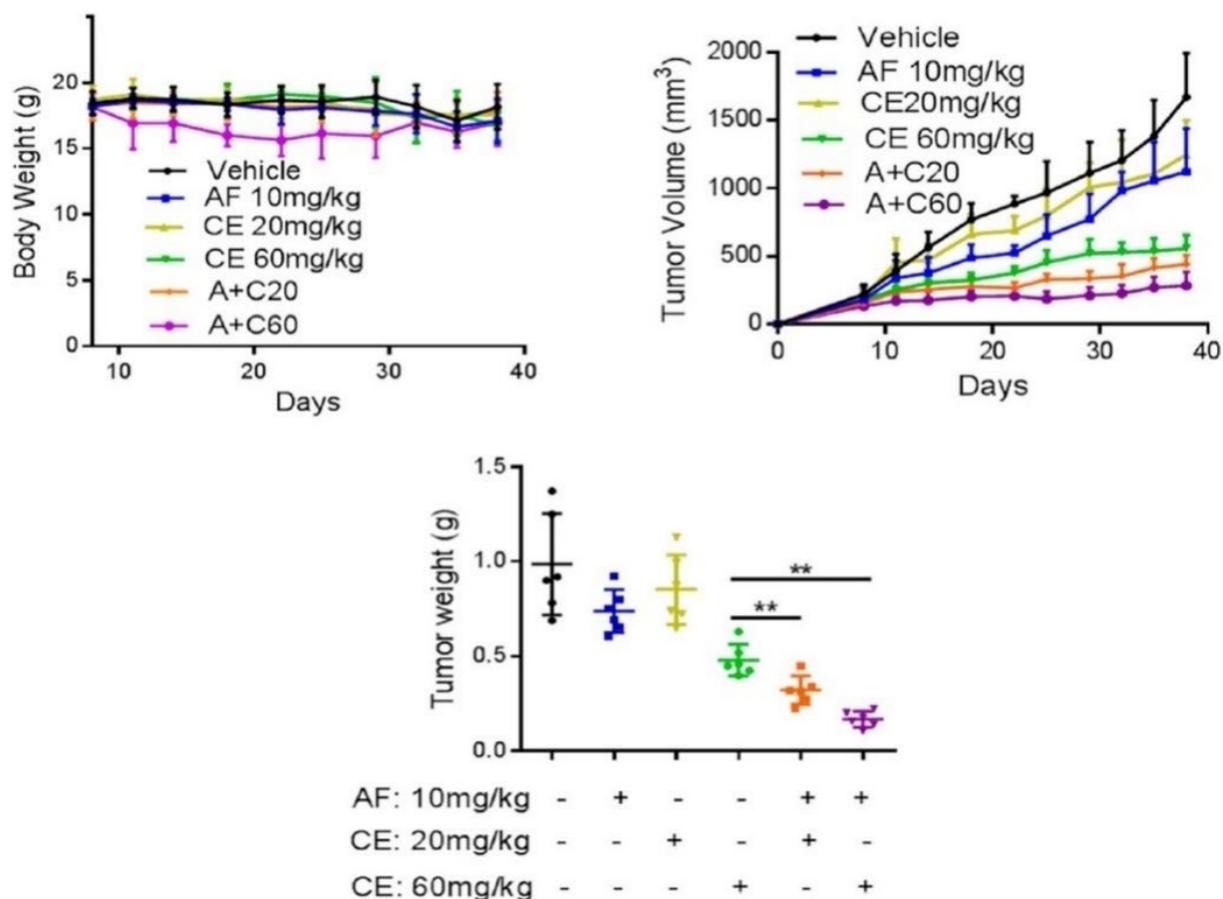

Figure 5. The effect of the combination of auranofin with celecoxib in mice. Athymic nude mice bearing DLD-1 xenografts were treated with the following drugs via oral injection (P.O.): olive oil (vehicle), AF 10 mg/kg, CE 20 mg/kg, CE 60 mg/kg, AF 10 mg/kg + CE 20 mg/kg (A + C20), and AF 10 mg/kg + CE 60 mg/kg (A + C60). Eight days after inoculation, the tumor size and body weight of mice from each group (six mice per group) were measured two times per week. The three panels show the body weight, tumor volume, and tumor weight during the treatment. Reproduced and adapted from Han et al.^[56] under the Creative Commons Attribution License 4.0 International (CC BY 4.0). AF: Auranofin; CE: celecoxib.

is already employed in the treatment of this disease, but its use is often limited by the insurgence of platinum resistance. Gold compounds are promising experimental anticancer drugs and might offer a valuable alternative to platinum drugs by overcoming resistance to Pt drugs^[58]. Among the existing medicinal gold compounds, auranofin and its analogs - given the ease of their repurposing - may be the most appropriate and obvious drug candidates for CRC^[59]. Auranofin has indeed manifested relevant anticancer actions and already entered clinical trials for other types of cancer, in particular ovarian cancer and various hematological malignancies. Surprisingly, auranofin has been scarcely tested so far for CRC treatment. However, just a few years ago, it was demonstrated that AF is very effective *in vitro* against four representative CRC lines while being far less toxic for healthy cells, thus showing some degree of selectivity. Moreover, a few studies in the recent literature suggest new valuable strategies to improve the pharmacological profiles of AF and its analogs. We refer specifically to a couple of studies that delineate feasible strategies for therapeutic intervention^[43,56]. In a first study, encapsulation of Et₃PAuCl in PLGA nanoparticles proved to bring about some favorable pharmacological effects such as retention of the cytotoxic activity, attenuation of the general reactivity of the gold center, and expected reduction of the drug's adverse effects. Alternatively, a second study showed that the anticancer action of AF in CRC may be greatly potentiated through appropriate drug combinations. In fact, a systematic screening procedure

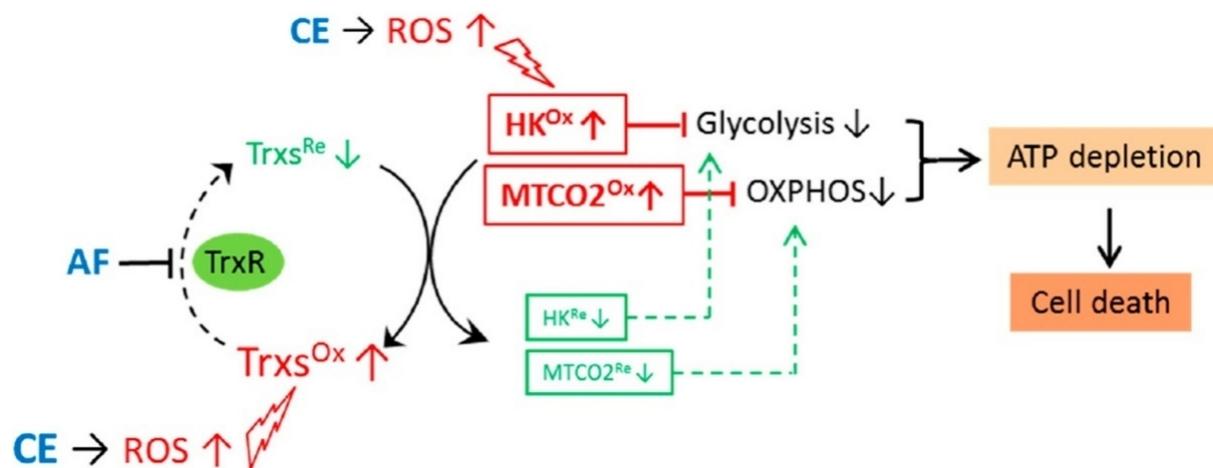

Figure 6. Synergy between auranofin and celecoxib against colon cancer *in vitro* and *in vivo* through a novel redox-mediated mechanism. CE induces ROS increase, which in turn causes oxidation of proteins (Trxs, HK, and MTCO2). AF inhibits TrxR, and thus keeps Trxs in oxidized form, which cannot reduce/repair the oxidized proteins (HK and MTCO2), leading to inhibition of both glycolysis and mitorespiration, ATP depletion, and cell death. Reproduced and adapted from Han et al.^[56] under the Creative Commons Attribution License 4.0 International (CC BY 4.0). CE: Celecoxib; ROS: reactive oxygen species; HK: hexokinase.

applied to a large library of 1280 FDA-approved drugs revealed a strong synergism between auranofin and the anti-inflammatory drug celecoxib. This synergism was well documented both *in vitro* and *in vivo*. In view of these initial yet very encouraging results, we propose that the testing of auranofin and its analogs toward suitable CRC models is further expanded and encouraged taking advantage of new pharmaceutical formulations and appropriate drug combinations. Additionally, extensive *in vivo* testing of these gold compounds against suitable animal models of CRC would be highly desirable at this stage to reinforce and validate the concepts presented here.

DECLARATIONS

Abstract

Aim: The objective of our study was to assess the efficacy of immune checkpoint inhibitors (ICIs) on patients with non-small-cell lung cancer (NSCLC) harboring oncogenic alterations.

Methods: We retrospectively enrolled patients with advanced non-squamous NSCLC who were treated with anti-PD-1-based monotherapy or combined immunotherapy. Major characteristics including PD-L1 expression, treatment, and survival were analyzed.

Results: In total, 309 non-squamous NSCLC patients with a median age of 61 years (range 20-88 years) including 70.9% male were retrospectively enrolled. The molecular alterations involved epidermal growth factor receptor (EGFR) ($n = 81$), V-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog (KRAS) ($n = 31$), anaplastic lymphoma kinase (ALK) ($n = 1$), human epidermal growth factor receptor 2 (HER2) ($n = 12$), V-raf murine sarcoma viral oncogene homolog (BRAF) ($n = 2$), rearranged during transfection ($n = 4$), and c-ros oncogene 1 (ROS1) ($n = 3$). In the EGFR subset, the ORR was 30.9% ($n = 81$) and PFS was significantly shorter than WT group (median PFS: 5.7 months vs. 7.1 months; $P = 0.0061$). In subgroup analyses, ICI combined therapy was significantly correlated with a longer PFS compared with ICI monotherapy (median PFS: 7.7 months vs. 4.7 months; $P = 0.0112$). In KRAS patients, ORR was 51.6% ($n = 31$). No significant difference was found in subgroup analyses. The ORR and PFS were 16.7%

($n = 12$) and 28.6% ($n = 7$), 7.8 months and 9.0 months for HER2 and EGFR Exon20 insertion patients, respectively. Three ROS1 patients were enrolled with a PFS of 16.0, 34.2, and 45.0 months individually, and one ALK patient with PFS of 4.4 months was identified. No response was found in two BRAF patients.

Conclusion: ICI-based combination therapy can bring benefit to patients with EGFR-mutant NSCLC. ICI-based combination therapy could be considered for patients with ROS1 rearrangement, HER2 mutation and EGFR Exon20 insertion NSCLC.

Keywords: Non-squamous NSCLC, driver mutations, immune checkpoint inhibitor

INTRODUCTION

Lung cancer is the most common cancer worldwide, in terms of both incidence and mortality^[1]. Over the past decades, great advancements have been achieved, which are attributed to the understanding of tumor biology and the molecular mechanism of tumor progression. The use of small molecule tyrosine kinase inhibitors (TKIs) has dramatically improved the prognosis of patients with specific genomic aberrations^[2-5]. However, despite the high response of TKIs, acquired resistance inevitably occurs and limits the long-term benefits^[6]. Once this happens, the subsequent anti-tumor treatment is limited.

Immune checkpoint inhibitors (ICIs), specifically those targeting PD-1 or programmed death-ligand 1 (PD-L1), have rapidly transformed the treatment paradigm for non-small cell lung cancer (NSCLC). For driver-negative NSCLC, ICIs are now the cornerstone of first-line therapy^[7]. However, whether ICIs alone or in combination with other therapies would bring benefit to those with driver mutations is still to be elucidated. Gainor *et al.*^[8] reported poor response of ICI monotherapy in patients with epidermal growth factor receptor (EGFR) mutations or anaplastic lymphoma kinase (ALK) rearrangements. In the phase II ATLANTIC study, durvalumab showed activity in driver-positive NSCLC according to final OS analysis^[9]. Therefore, continued research is required to explore the optimal use of ICI therapy in patients with driver mutations to improve outcomes of this cohort.

In our study, we retrospectively analyzed patients with locally advanced or metastatic non-squamous NSCLC that were treated with anti-PD-1 based mono- or combined-immunotherapy in Shanghai Pulmonary Hospital to assess the efficacy of ICIs on patients with driver-positive NSCLC.

METHODS

Study population

Patients with locally advanced or metastatic non-squamous non-small cell lung cancer from July 2015 to July 2020 in Shanghai Pulmonary Hospital were retrospectively enrolled. Inclusion criteria included the following: (1) a pathologic diagnosis of non-squamous non-small cell lung cancer; (2) testing data (either direct sequencing or NGS on validated platforms) for EGFR, V-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog (KRAS), ALK, human epidermal growth factor receptor 2 (HER2), V-raf murine sarcoma viral oncogene homolog (BRAF), rearranged during transfection (RET), and c-ros oncogene 1 (ROS1); and (3) anti-PD-1-based monotherapy or combined immunotherapy as first-line or posterior-line therapy. Patients treated with fewer than two circles of immunotherapies and had no available complete medical records were excluded. The patient screening process is shown in [Figure 1](#). We reviewed the medical records and abstracted the following patient characteristics: age, gender, Eastern Cooperative Oncology Group Performance Status (ECOG-PS), smoking history, histological type, clinical stage, mutation type, PD-L1 expression, details of treatment, and survival.

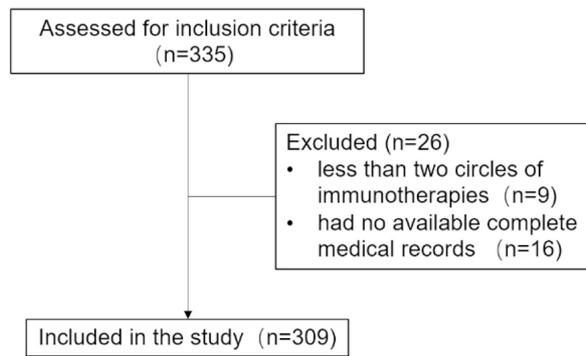

Figure 1. Flow chart of patient screening.

PD-L1 analysis

PD-L1 immunohistochemistry was performed in Department of Pathology, Shanghai Pulmonary Hospital according to routine procedure. The antibody used was PD-L1 22C3 pharmDx (Dako, Carpinteria, CA, USA). PD-L1 positivity was defined as tumor proportion score cutoff of 1%.

Statistical analysis

Patient characteristics are expressed as median and range for continuous variables and as frequencies and percentages for categorical variables. Progression-free survival (PFS) was measured from the date of first administration of PD-1 inhibitor treatment to disease progression or death due to any cause or last follow-up. Response Evaluation Criteria in Solid Tumors guidelines 1.1 (RECIST 1.1) was used to assess tumor response. The difference of response rate among different groups was calculated using Kruskal-Wallis test. Survival data were estimated using the Kaplan-Meier method and compared using the log-rank test in the overall cohort and subgroups. The data were analyzed using GraphPad Prism 8.0 and SPSS Statistics 20. A *P* value < 0.05 was considered statistically significant.

RESULTS

Patient characteristics

In this study, 309 non-squamous non-small cell lung cancer patients treated with anti-PD-1 based monotherapy or combined immunotherapy in Shanghai Pulmonary Hospital were identified. The median age was 61 years (range 20-88 years), 70.9% were male (219/309), and 55.7% (112/309) were never smokers. The majority of the patients had adenocarcinoma histology (98.4%, 304/309) and ECOG-PS of 0-1 at the start of immunotherapy (83.5%, 258/309). Detailed characteristics are shown in [Table 1](#). In total, 182 received anti-PD-1 combined with chemotherapy (pemetrexed combined with carboplatin 85.7%, 156/182; paclitaxel-based chemotherapy 14.3%, 26/182), 42 received anti-PD-1 combined with antiangiogenic therapy (apatinib 90.5%, 38/42; bevacizumab 9.5%, 4/42). None of the enrolled patients received a combination of ICIs, chemotherapy, and antiangiogenic therapy. Among the whole cohort, 134 had genetic alteration, which involved EGFR ($n = 81$), KRAS ($n = 31$), ALK ($n = 1$), HER2 ($n = 12$), BRAF ($n = 2$), RET ($n = 4$), and ROS1 ($n = 3$). Among the 81 EGFR mutation patients, 42 had exon 19 deletions, 29 had exon20 L858R, and 10 had other mutations; 14 were harboring T790M mutation at the same time and 67 were not. The details of each subgroup are shown in [Table 1](#).

PD-L1 expression

PD-L1 expression status was available for 132 patients, of whom 54.5% (72/132) had less than 1% PD-L1 expression, 31.1% (41/72) had PD-L1 expression of 1%-49%, and 14.4% (19/132) had PD-L1 expression more than 50% [[Figure 2A](#)]. Looking into each subgroup, patients with EGFR mutation seemed to have a

ICIs: Immune checkpoint inhibitors; NOS: not otherwise specified; EGFR: epidermal growth factor receptor; KRAS: V-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog; ALK: anaplastic lymphoma kinase; HER2: human epidermal growth factor receptor 2; BRAF: V-raf murine sarcoma viral oncogene homolog; RET: rearranged during transfection; ROS1: c-ros oncogene 1; ECOG: Eastern Cooperative Oncology Group.

low PD-L1 expression (26 patients: 69.2%, 18/26 with PD-L1 < 1%, 15.4%, 4/26 with PD-L1 1%-49%, and 15.4%, 4/26 with PD-L1 ≥ 50%) [Figure 2B]. In the KRAS subgroup, the percentages of PD-L1 < 1%, 1%-49%, and ≥ 50% were all 33.3% (5/15) [Figure 2C]. Of the seven HER2 cases, 71.4% (5/7) had < 1% PD-L1 expression, while 28.6% (2/7) had a PD-L1 expression of 1%-49% [Figure 2D].

Response rate

Based on RECIST 1.1, the ORR of the patients with wild type (WT) was 34.9% and DOR was 50.3% ($n = 175$), while, in the EGFR subset, the ORR was 30.9% and DOR was 77.8% ($n = 81$). For KRAS patients, ORR was 51.6% and DOR was 83.9% ($n = 31$). The response rates in both the EGFR group and the KRAS group were statistically different from the WT group ($P = 0.029$ and $P = 0.004$, respectively) [Figure 3A]. In EGFR patients, the ICI combination therapy subset seemed to have better response rate compared to those who received ICI monotherapy ($P = 0.020$) [Figure 3B]. However, the difference was not found in KRAS patients [Figure 3C]. In 12 HER2 patients, ORR was 16.7% and DCR was 91.7%. While ORR was 28.6% and DCR was 85.7% in EGFR Exon20 insertion patients [Figure 3A].

Progression-free survival

EGFR

We investigated the outcomes of ICIs on patients with EGFR mutations. PFS of the EGFR subset was significantly shorter than that of the WT group (median PFS: 5.7 months vs. 7.1 months; $P = 0.0061$) [Figure 4A]. Regarding PD-L1 expression, PFS was not significantly different ($P = 0.3721$) [Figure 4B]. ICI combined therapy was significantly correlated with a longer PFS compared with ICI monotherapy (median PFS: 7.7 months vs. 4.7 months; $P = 0.0112$) [Figure 4C]. PFS was 5.5 months in L858R, 5.9 months in 19del, and 9.0 months in Exon20 insertion and other mutations, but the difference was not statistically significant among the three groups ($P = 0.3411$) [Figure 4D]. There was no difference in PFS between patients with or without T790M mutation (median PFS: 5.6 months vs. 5.9 months; $P = 0.8381$) [Figure 4E].

KRAS

KRAS was not associated with a benefit on PFS compared to those harboring no gene alteration (median PFS: 11.0 months vs. 7.1 months; $P = 0.5714$) [Figure 5A]. In subgroup analyses, PD-L1 positive patients seemed to have longer PFS than PD-L1 negative ones, but the difference was not statistically significant (median PFS: 15.8 months vs. 5.6 months; $P = 0.0670$) [Figure 5B]. ICI combined therapy had no advantage in PFS compared with ICI monotherapy (median PFS: 12 months vs. 7.25 months; $P = 0.5714$) [Figure 5C].

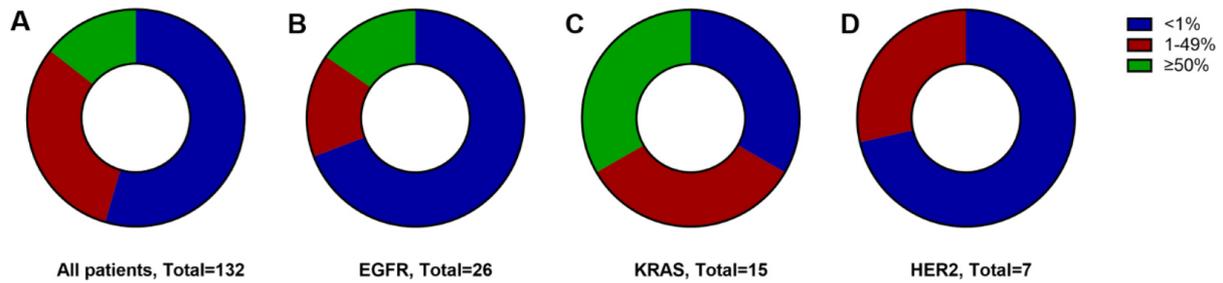

Figure 2. Categorical distribution of tumor PD-L1 expression: the whole cohort (A); EGFR-mutant NSCLC tumors (B); KRAS-mutant NSCLC tumors (C); and HER2-mutant NSCLC tumors (D). EGFR: Epidermal growth factor receptor; NSCLC: non-small-cell lung cancer; KRAS: V-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog; HER2: human epidermal growth factor receptor 2.

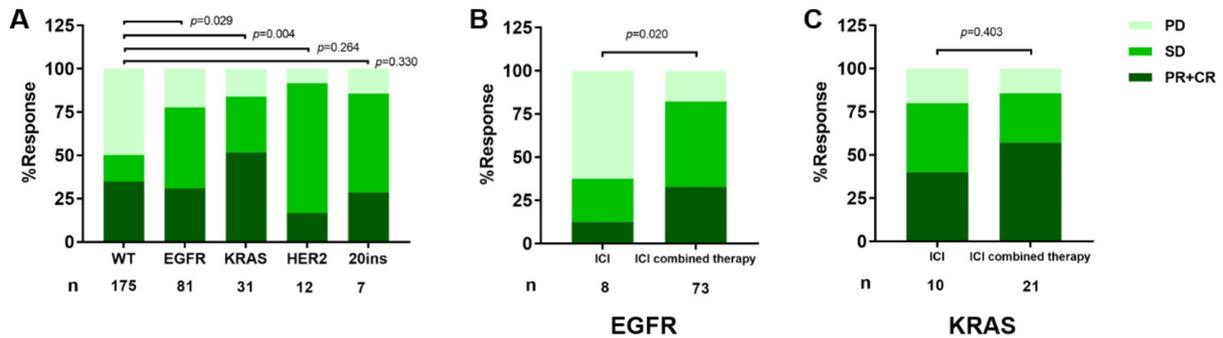

Figure 3. Response to ICIs according to Response Evaluation Criteria in Solid Tumors guidelines 1.1 (RECIST 1.1): (A) response to ICIs across molecular alterations; (B) response rate by treatment modality in EGFR patients; and (C) response rate by treatment modality in KRAS patients. ICIs: Immune checkpoint blockades; PD: progressive disease; SD: stable disease; PR: partial response; CR: complete response; WT: wild type. EGFR: epidermal growth factor receptor; KRAS: V-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog.

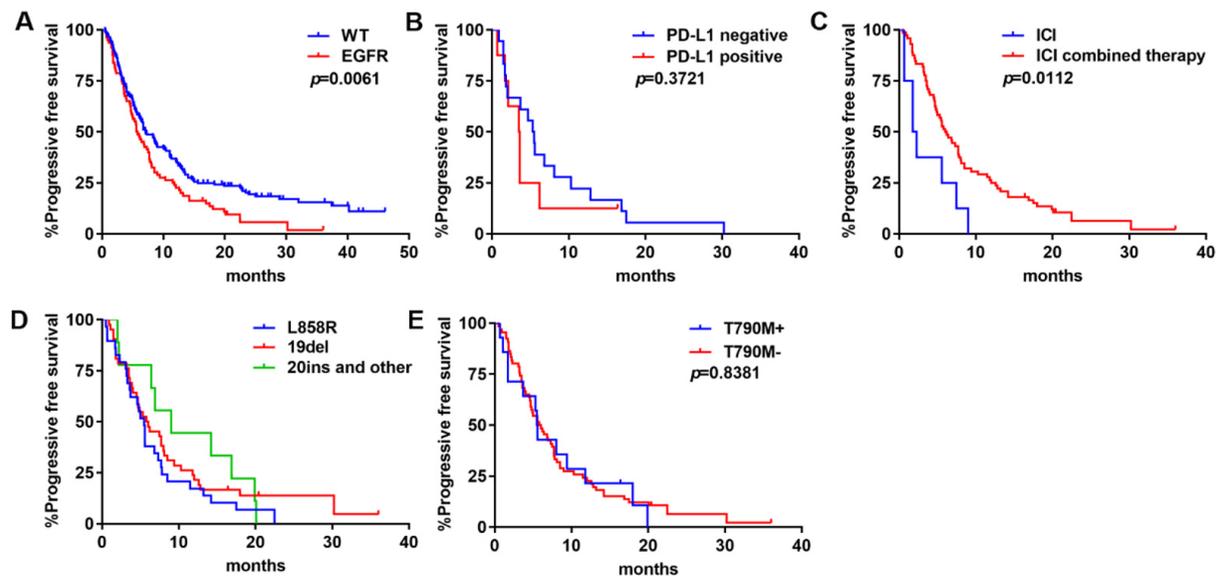

Figure 4. PFS of ICIs in EGFR-mutant NSCLC: (A) PFS in tumors with WT NSCLC or EGFR-mutant NSCLC; (B) PFS by PD-L1 expression levels; (C) PFS by treatment modality; (D) PFS by mutation type; and (E) PFS by T790M mutation status. ICIs: Immune checkpoint blockades; PFS: progression-free survival; WT: wild type; EGFR: epidermal growth factor receptor; NSCLC: non-small-cell lung cancer.

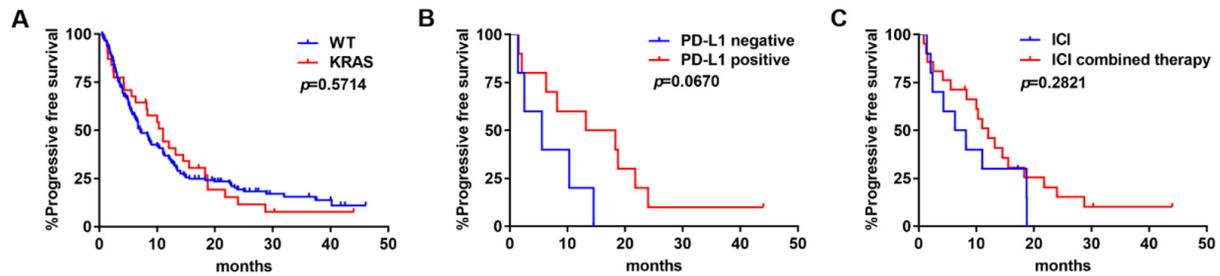

Figure 5. PFS of ICIs in KRAS-mutant NSCLC: (A) PFS in tumors with WT NSCLC or KRAS-mutant NSCLC; (B) PFS by PD-L1 expression levels; and (C) PFS by treatment modality. ICIs: Immune checkpoint blockades; PFS: progression-free survival; WT: wild type; KRAS: V-Ki-ras2 Kirsten rat sarcoma viral oncogene homolog; NSCLC: non-small-cell lung cancer.

Other molecular alterations

All three patients with ROS1 rearrangements and ECOG 1 who received ICIs combined with chemotherapy as first-line treatment had response of PR. The PFS was 16.0, 34.2, and 45.0 months, respectively. The response of the patient with the longest PFS (45 months) was ongoing [Figure 6]. Four patients with RET rearrangements had PFS of 1.5, 1.8, 4.3, and 9.8 months. Three of them had ECOG 1 and one had ECOG 2. They received first-line ($n = 2$) and second-line ($n = 2$) ICI monotherapy ($n = 1$) or ICIs combined with chemotherapy ($n = 3$). No response was found in two BRAF patients, who received after second-line ICI monotherapy. Most HER2 patients had ECOG 1 ($n = 11$). Seven of them received ICIs combined with chemotherapy, four received ICI monotherapy, and one received ICIs combined with antiangiogenic therapy. ICIs as first-line therapy were observed in six patients, as second-line in three patients, and after second-line in three patients. The median PFS was 7.8 months (range 1.0-26.9 months). ALK rearrangements was identified in only one patient, whose PFS was 4.4 months, with ECOG 3, who received ICI monotherapy as after second-line treatment. We also enrolled seven patients with EGFR Exon20 insertion. The median PFS was nine months (range 2.2-20.1 months). They received ICIs combined with chemotherapy ($n = 5$) or antiangiogenic therapy ($n = 1$) or ICI monotherapy ($n = 1$), as first-line ($n = 4$), second-line ($n = 1$), or after second-line treatment ($n = 2$), with ECOG 1 ($n = 5$), 2 ($n = 1$), or 3 ($n = 1$).

DISCUSSION

Targeted therapies against oncogene-driven NSCLC, including EGFR^[2], BRAF^[10], and HER2 mutations^[11] or ALK^[3], ROS1^[5], and RET^[12] rearrangements, have been proved to improve outcomes, and they form the standard first-line treatment in patients with advanced disease. However, progression inevitably occurs, and chemotherapy is currently the main subsequent treatment after TKI resistance. Considering the remarkable long-term benefits of ICI treatments, scientists have made lots of efforts to integrate ICIs into the treatment course of patients with oncogene-driven NSCLC. Mazieres *et al.*^[13] explored the activity of ICIs across NSCLC harboring oncogenic alterations and found driver-positive NSCLC exhibited poor response to ICI monotherapy. Hastings *et al.*^[14] reported more favorable outcomes of exon 21 mutations compared with exon 19 deletions in NSCLC treated with immunotherapy. Until now, the results on this topic are controversial.

In EGFR-driven NSCLC, initial clinical results indicate that ICIs have no clinical benefits. Meta-analysis^[15,16] of EGFR-mutated patients in Keynote 010, CheckMate 057, OAK, and POPLAR studies showed ICIs have poorer outcomes in cohorts with EGFR mutations compared to chemotherapy. We found similar findings in our research that patients with EGFR mutations had poor response to ICIs. This may be explained by the immunosuppressive and uninflamed tumor microenvironment (TME) and low tumor mutational burden (TMB), therefore being less immunogenic in the context of oncogenic addiction^[17,18]. Besides the effect of

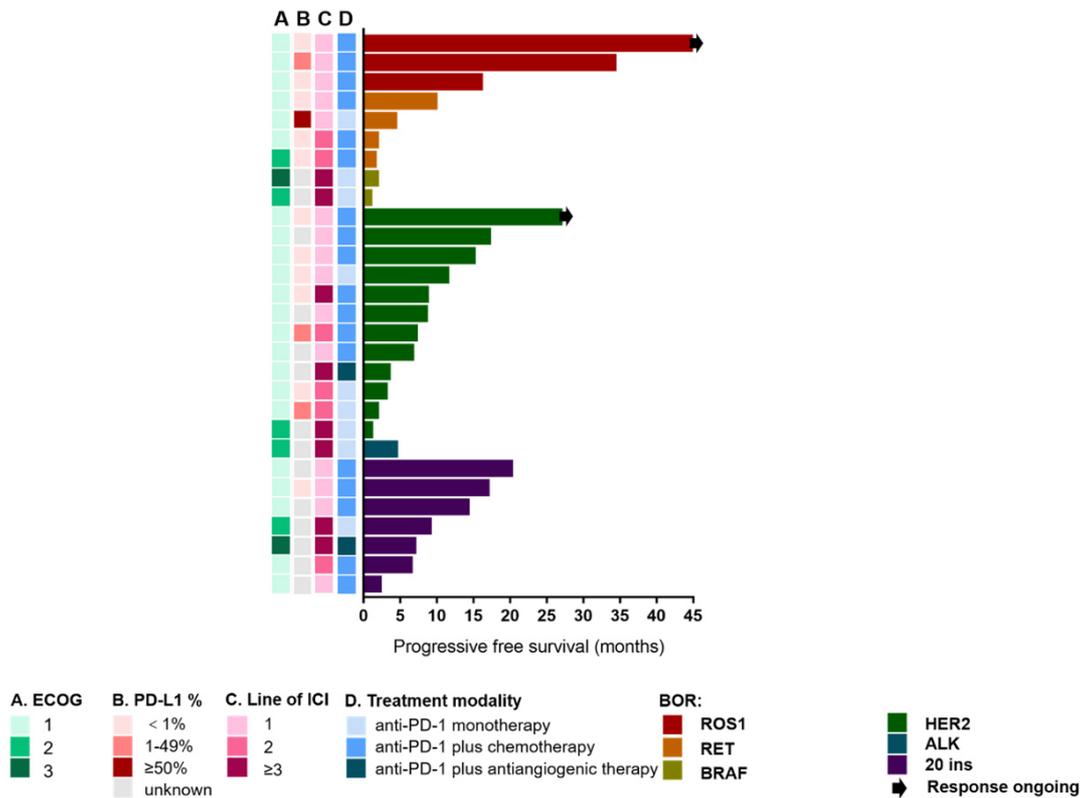

Figure 6. Swimmer's plot of PFS across molecular alterations. PFS: Progression-free survival; ALK: anaplastic lymphoma kinase; HER2: human epidermal growth factor receptor 2; BRAF: V-raf murine sarcoma viral oncogene homolog; RET: rearranged during transfection; ROS1: c-ros oncogene 1; ECOG: Eastern Cooperative Oncology Group; ICI: immune checkpoint blockade.

oncogene mutation on TME, studies have shown that EGFR TKIs, chemotherapy, and antiangiogenic therapy also influence the TME. EGFR TKIs could increase infiltration of CD8⁺ T cells, dendritic cells, and M1 TAMs and inhibit regulatory T cells infiltration^[19]. Bevacizumab, an antiangiogenic therapy, has been observed in melanoma to increase circulating CD8⁺ T cells and interleukin-6 levels so as to change the TME in combination with chemotherapy^[20]. Therefore, the use of ICI-based combined therapy as post-line treatment after TKI resistance may be more effective. In the IMpower150 study, we did see prolonged PFS and OS in the ABCP (atezolizumab, bevacizumab, carboplatin, and paclitaxel) group compared with the BCP (bevacizumab, carboplatin, and paclitaxel) group in patients with EGFR-driven NSCLC^[21]. In our study, we also found ICI combined therapy was correlated with better outcome than ICI monotherapy in EGFR-driven NSCLC patients.

In our study, we did not find any correlation between KRAS mutation and better survival, which is inconsistent with previous studies. This may be explained by the heterogeneity of KRAS-mutant NSCLC. KRAS mutation subtypes include G12C, G12D, G12V, G12A, and G13D, among others, and different KRAS mutations can activate distinct signaling pathways, leading to different downstream effects, which may result in different response to therapies^[22]. Besides, KRAS mutation is always accompanied by different patterns of co-occurring mutations, which display different immune profiles and show varying sensitivities to ICIs. In KRAS-TP53 co-mutated tumors, increased expression of PD-L1, higher TMB, and a remarkable clinical benefit of ICIs was observed^[23,24]. Conversely, KRAS-STK11 has always been associated with poor clinical response to ICIs^[24,25]. Further studies are needed to differentiate patients suitable for different treatment options.

HER2 mutations have been reported in approximately 2%-5% of lung adenocarcinomas^[26,27] and correlated with poor prognosis^[27]. The efficacy of ICIs in HER2-mutant NSCLC is ambiguous. Guisier *et al.*^[28] reported 23 patients harboring HER2 mutation treated with ICI monotherapy who had a response rate of 27%, which is close to that observed in unselected patients with NSCLC. Mazieres *et al.*^[13] reported an ORR of 7% and a median PFS of 2.5 months in 29 patients with HER2 mutation NSCLC treated with ICI monotherapy. In our study, ICI-based therapy displayed certain curative effect with 16.67% ORR, 91.7% DCR, and PFS of 7.8 months (range 1-26.9 months). For other rare driver mutations, the efficacy of ICIs on patients with ROS1 rearrangements or EGFR Exon20 insertion was rarely reported. In our study, three patients with ROS1 rearrangements had response of PR and durable PFS of 16.0, 34.2, and 45.0 months. Seven patients with EGFR Exon20 insertion had PFS of 9 months (range 2.2-20.1 months), ORR was 28.6%, and DCR was 85.7%. Therefore, ICI-based therapy may provide choices for these patients. As to BRAF, RET, and ALK, which represent a small subgroup of NSCLC, because of the limited number of patients, we could not draw a conclusion.

ICI-based combined therapy can bring benefit to patients with EGFR-mutant NSCLC. ICIs, especially ICI-based combination therapy, should not be excluded for patients with ROS1 rearrangement, HER2 mutation, and EGFR Exon20 insertion NSCLC. To achieve maximum benefit for these patients, better predictive biomarkers to select patients and combination modes of therapies should be explored.

DECLARATIONS

Authors' contributions

Made substantial contributions to conception and design of the study and performed data analysis and interpretation: Wu F, Zhang H, Guo X

Performed data acquisition, as well as provided administrative, technical, and material support: Du H, Yang M, Li J, Xiong A

Abstract

Sarcomas are a class of rare malignancies of mesenchymal origin with a heterogeneous histological spectrum. They are classically associated with poor outcomes, especially once metastasized. A path to improving clinical outcomes may be made through modifying the epigenome, where a variety of sarcomas demonstrate changes that contribute to their oncogenic phenotypes. This Perspective article identifies and describes changes in the sarcoma genome, while discussing specific epigenetic changes and their effect on clinical outcomes. Clinical attempts at modulating epigenetics in sarcoma are reviewed, as well as potential implications of these studies. Epigenetic targets to reverse and delay chemotherapy resistance are discussed. Future directions with primary next steps are proposed to invigorate the current understanding of epigenetic biomarkers to enact targeted therapies to epigenetic phenotypes of sarcoma subtypes. Modifications to prior studies, as well as proposed clinical steps, are also addressed.

Keywords: Epigenetics, sarcoma, resistance, metastasis

INTRODUCTION

Transitioning cancer from a lethal disease to a chronic one necessitates long-term limiting of cancer growth. Underpinning mechanisms of growth and proliferation are classically thought of as activation of an

oncogene or the inhibition of a former tumor suppressor^[1]. Some well-known examples of oncogenic driver mutations include EGFR-activation in non-small cell lung cancer and HER2 receptor amplification in breast cancer^[2,3]. Pharmacological advances have led to the ability to target some of these drivers of tumor growth, resulting in significant clinical benefits. The development of imatinib is perhaps one of the best examples of this effect. After targeting the pathophysiologic driver BCR-ABL in chronic myeloid leukemia, complete response improved from 14.5% to 76.2%^[4,5]. Imatinib is used in the management of gastrointestinal stromal tumors to target KIT or PDGFR α gain of function mutations which is present in the majority of tumors^[6]. Imatinib has been reported to have a transformative effect on the median overall survival in patients with metastatic disease from months to years^[7,8]. The possibility exists that some oncogene targets may be “undruggable” according to experts in the field, naturally leading to where the next best step may lie^[9]. Mechanisms of resistance often develop to druggable targets via changes in drug metabolism, cell repair, and epigenetic effects^[10]. Immunotherapy is emerging as a potential treatment option; however, response varies significantly depending on histological subtype and individual tumor pathology^[11,12].

Sarcomas are a family of malignancies mostly derived from cells of mesenchymal origin^[13]. Composed of more than 50 different subtypes, they are differentiated between soft tissue vs. bone origin, and up to 50% of patients develop metastatic disease, where median survival is 10-15 months^[14]. Treatment of sarcomas remains difficult as the variety of histological subtypes demonstrates varying sensitivities to chemotherapies^[15]. If localized, surgical resection and perioperative radiation remain the hallmark of treatment, whereas anthracycline-based chemotherapy predominates treatment of advanced soft tissue sarcoma^[15-17]. Like soft tissue sarcoma, management of localized osteosarcomas also relies heavily on wide local resection of the tumor with a preoperative and postoperative multi-drug chemotherapy regimen (high-dose methotrexate, doxorubicin, and cisplatin)^[18,19]. Treatment algorithms to both osteosarcoma and soft tissue sarcoma have remained the same over the past several years, with minimal improvements driving a desire for innovation^[20,21].

Epigenetic modulation is a process linked to disease progression and therapeutic resistance (breast cancer, multiple myeloma)^[22]. Dawson and Kouzarides^[23] describe epigenetics as “chromatin-based events that regulate DNA-templated processes”. Common mediators of epigenetics include histone de/acetylation and de/methylation, DNA de/methylation, and non-coding miRNAs that control mRNA translation without changing DNA cellular structure^[24]. Cellular disruption of epigenetic control could be detrimental to long-term or induction treatment efficacy and is a postulated mechanism of resistance for various cancers^[25,26]. One such example occurs in estrogen receptor-positive breast cancer, where the developed loss of *ARID1A* expression reduces the ability of estrogen to bind and thus decreases the therapeutic efficacy of selective estrogen receptor modulators^[27]. Similar resistance effects have been reported when hypermethylation of DNA decreased the efficacy of cisplatin therapy in non-small cell lung cancer^[28].

EPIGENETIC BACKGROUND OF SARCOMA

Soft tissue sarcomas

Epigenetic changes have been implicated in the proliferation of multiple soft tissue sarcomas (STS) subtypes through a variety of different epigenetic mechanisms^[29]. Common contributors to STS progression include TP53 (47%), CDKN2A (22%), retinoblastoma 1 (RB1; 22%), neurofibromin 1 (NF1; 11%), and ATP-dependent helicase (ATRAX; 11%)^[30-32]. While mutational profiles of these genes have been characterized, recent efforts have improved our understanding of epigenetic alterations of these genes and the correlation to STS progression and prognosis^[29-33]. For example, mechanisms of CDKN2A inactivation include histone post-translation modifications by polycomb repressive complex 2 (PRC2), hypermethylation of DNA at promoter CpG sites, and loss of function (LOF) mutations^[32,34,35]. There have been several studies, including

a phase 2 clinical trial in liposarcoma and dedifferentiated liposarcoma, investigating the efficacy of cyclin-dependent kinase 4/6 inhibitors such as palbociclib in the setting of CDKN2A loss^[36,37]. While the majority of STS with decreased CDKN2A expression exhibit LOF mutations in CDKN2A, loss of methylation in the CDKN2A promoter region has been shown to coincide with epigenetic transdifferentiation of uterine myosarcoma cells^[38]. These findings suggest that hypomethylation in the CDKN2A promoter correlates with increased heterogeneity with hypomethylated tumors containing liposarcomatous and/or rhabdomyosarcomatous components^[38]. Further investigation of DNA methylation in myosarcoma and other sarcomas could highlight novel mechanisms of tumor heterogeneity which have proven to be challenging to manage. Inhibition of other cell cycle players and their epigenetic modulators, such as the PRC2 and G2-checkpoint kinase WEE1, has also shown some preclinical efficacy in rhabdomyosarcoma (RMS)^[39-41]. A recent publication by Zoroddu *et al.*^[42] discussed the essential role of PRC2 in muscle cell differentiation, a key component of RMS progression, and a potential therapeutic avenue for RMS patients. Furthermore, targeting the catalytic subunit of PRC2, enhancer of zeste homolog 1/2 (EZH1/2), should be further explored in combination with inhibitors that target the cell cycle kinases CDK4/6 and Wee1.

Targeting epigenetic modulators at the DNA and histone levels has been reported to show efficacy in altering specific pathways implicated in STS pathogenesis as well as sensitizing sarcomas to radiation and chemotherapies. For example, synovial sarcoma (SS) is characterized by a chromosomal translocation t(X; 18)(p11.2; q11.2) that frequently results in an SS18-SSX fusion protein^[43]. This fusion includes a subunit of BRG1/BRM associated factor, ATP-dependent chromatin remodel complex, and SS-associated t(X; 18) genes, respectively. This fusion has also been reported to alter epigenetic histone modulators [SWIth/Sucrose Non-Fermentable (SWI/SNF) complex, Polycomb Repressive Complex 1 (PRC1), and Polycomb Repressive Complex 2 (PRC2) complexes], ultimately resulting in hypermethylation and subsequent gene silencing^[43]. Additionally, other sarcomas characterized by chromosomal translocations exhibit a similar effect on PRC2 and SWI/SNF, as mentioned, as well as histone deacetylases (HDAC)^[44]. HDAC activity has been implicated in sarcoma pathogenesis and is associated with advanced disease and poor clinical outcomes^[45]. For example, HDAC activity is shown to play a role in immunoreactivity (HDAC 1, 4, 6-8) in endometrial stromal sarcoma^[45]. The use of HDAC inhibitors is a promising therapeutic option. HDAC inhibition has been shown to inhibit growth while sensitizing tumors to chemotherapy^[45]. While a better understanding of chromosomal translocation-dependent epigenetic rewiring is needed, treatment of SS tumors could benefit from the use of epigenetic therapeutic agents like EZH1/2 and HDAC inhibitors.

Bone sarcomas

Investigation of epigenetics in bone sarcoma pathogenesis and potential treatment modalities has mainly focused on epigenetic mechanisms such as DNA methylation and histone modifications independently; however, mechanistic crosstalk between DNA methylation and histone modifications has been further elucidated in osteosarcomas and chondrosarcomas. A study by Li *et al.*^[46] observed that treating osteosarcoma cells with 5-aza-2'-deoxycytidine (5-Aza-CdR, decitabine) enhanced radiosensitivity by inducing a G2/M checkpoint arrest and induced apoptosis. These studies alluded to 5-Aza-CdR induction of DNA damage sensitizing the osteosarcoma cells to radiation. Furthermore, a common epigenetic marker for DNA damage is γ H2AX, a double-stranded break DNA damage-induced histone modification^[47]. Future studies characterizing γ H2AX as a biomarker for new treatment modalities such as DNA methylation inhibitors in combination with radiation therapy could be beneficial for stratifying which radiation-resistant tumors could be re-sensitized using this approach.

Chondrosarcoma (CS) is another bone sarcoma subtype for which DNA and histone methylation correlate and represent multiple angles to treating tumor resistance and recurrence. Mutations in isocitrate dehydrogenase, an enzyme involved in α -ketoglutarate (α -KG) production in the Krebs cycle, have been

documented in 52%-59% of central and 57% of dedifferentiated CS^[48,49]. These mutations result in the production of an oncometabolite, δ -2-hydroxyglutarate, which is linked to a hypermethylated profile in CS tumors at the DNA/histone level, as well as promotion of malignant transformation^[48]. Inhibiting both DNA methylation and histone methylation might be a useful approach to inhibiting the downstream function of this oncometabolite, known epigenetic compensatory mechanisms, and malignant transformation^[48]. This concept has moved forward to clinical studies, where one such trial is evaluating the combination of HDAC inhibitor (belinostat) in combination with the hypomethylating agent guadecitabine (NCT04340843).

Ewing sarcoma is associated with a fusion oncoprotein Ewing Sarcoma breakpoint region 1-Friend leukemia integration 1 transcription factor (EWS-FLI1) that has been shown to be associated with epigenetic modulation, specifically DNA methylation, as well as histone acetylation and deacetylation^[49,50]. Subsequent inhibition with sodium butyrate was also shown to be synergistic with vincristine, etoposide, and doxorubicin when grown *in vitro*^[51]. Targeted inhibition of histone deacetylase likewise leads to a decrease in *in vitro* growth, reinforcing the potential promise of epigenetics in this specific cancer subtype^[52].

DNA methylation-based classification of sarcoma

Sarcomas are a heterogeneous group stratified into many subtypes according to WHO criteria, which include distinct morphologies, immunohistochemistry, and disease-defining molecular events^[53]. However, many subtypes lack unequivocal molecular hallmarks, resulting in discrepancies between diagnosis and treatment^[53-56]. To help decrease these discrepancies, epigenetic changes such as DNA methylation could represent a resource to better distinguish sarcoma subtypes^[39,57]. One study by Koelsche *et al.*^[33] explored global DNA methylation levels using a machine learning algorithm to compare the methylome classification to initial diagnosis and using a publicly-available sarcoma classifier. Prototypical soft tissue and bone tumors were analyzed using either HumanMethylation450K BeadChip or the EPIC array. Following DNA methylome analysis of 1077 tumor cases, representing 54 histological types, 62 methylation classes were identified following unsupervised hierarchical clustering and t-Distributed Stochastic Neighbor Embedding. Identified methylation classes were defined as methylation corresponding to WHO classification (48/62), methylation corresponding with a subgroup of a WHO entity (9/62), methylation corresponding with two distinct WHO entities (3/62), or methylation representing a novel entity (2/62). The first novel classification included SARC (RMS-like), which exhibited rhabdomyoblast-like cell morphology and DICER1 mutations. The second novel classification included SARC (MPNST-like), which presents similarly to MPNST but retains H3K27me₃, an epigenetic modification that alters DNA packaging and is lost in the majority of MPNST. This study identified distinct subgroups using DNA methylation that correlates with another epigenetic mechanism, histone methylation (H3K27me₃). MPNST biology is one example in which DNA methylation and histone modifications have been correlated; however, little is known about the mechanisms of epigenetic crosstalk in sarcoma pathogenesis^[58]. Paraffin-embedded and formalin-fixed tissues can be analyzed via HumanMethylation450K BeadChip or the EPIC array. Raw data is then uploaded and analyzed using the sarcoma classifier. This publicly available resource and ongoing research in epigenetic mechanisms of STS pathogenesis could greatly benefit STS patients as new therapeutic options become available. Understanding epigenetic mutations and mechanisms as well as emerging/available clinical applications could enhance STS standard of care, including diagnosis, prognosis, and treatment efficacy.

Additional preclinical considerations

While baseline epigenetic changes of STS and bone sarcoma have been more extensively studied, few preclinical models have been assessed with respect to sarcoma cells previously treated with standard-of-care regimens. However, this approach has shown promise in preclinical models of other cancers^[59].

One study of melanoma demonstrates how combining epigenetic modulators with chemotherapy could be exploited in sarcoma with regard to acquired resistance^[60]. Zakharia *et al.*^[60] used a combination of the BRAF inhibitor vemurafenib with low-dose decitabine, a DNA methyltransferase inhibitor, in metastatic melanoma patients who had progressed on prior vemurafenib monotherapy. A fixed-dose of vemurafenib was combined with dose-escalated decitabine in a phase Ib trial design. Of the 14 patients enrolled in the trial, 3 achieved complete response, 3 achieved partial response, and 3 maintained stable disease. Clinical benefit rate was 79%, with no dose-limiting toxicities. Given the dramatic clinical responses seen in a refractory patient population, further preclinical studies were initiated to explore the effect. Decitabine was first confirmed to deplete DNA methyltransferase1 *in vitro* at concentrations below that needed to induce apoptotic effects. Separately, vemurafenib alone was able to inhibit cell growth until day 32, whereas the combined decitabine/vemurafenib regimen *in vitro* was able to maintain a cytostatic effect until day 90. Interestingly, cells in the combination treatment arm still demonstrated resistance to vemurafenib despite the prolonged stasis of cell growth in the combination treatment arm. Further analysis of patient genomics could shed light on whether non-responding patients had any shared features, though the structure of the study did not lend itself to outcome-driven analysis.

Previously performed clinical trials indicate that epigenetic modifiers within STS and bone sarcoma may demonstrate a similar effect. However, a critical area for growth is the creation of preclinical models that mimic treatment-experienced sarcoma models. Patients exposed to multiple lines of therapy in clinical settings do not have a corresponding or at least similarly derived cell line off of which treatments can be attempted. One could expect that epigenetic mechanisms similar to those seen in epithelial malignancies will have a better opportunity to be discovered and later reversed with the advent of better preclinical models^[27,28].

PREVIOUS CLINICAL ATTEMPTS AT EPIGENETIC MODULATION

Soft tissue sarcomas

Epigenetic modulators as monotherapy for sarcoma have been attempted with some success, a selected summary of which is included in [Table 1](#). Perhaps the best known is that of tazemetostat, an EZH2 inhibitor approved in unresectable epithelioid sarcoma, the first FDA-approved epigenetic therapy in a solid tumor^[61]. Chu *et al.*^[44] examined a pan-histone deacetylase inhibitor as monotherapy in 17 recurrent and metastatic soft tissue sarcoma patients. The best response in this study was stable disease in 8 patients, with no objective response seen. While limited in patient number, these two studies would suggest that unless the epigenetic target plays a role as an oncogenic driver, as in epithelioid sarcoma and EZH2 gain of function mutation, future efforts should focus on combination therapies with known cytotoxic agents as opposed to epigenetic targets as monotherapies^[62].

Dembla *et al.*^[63] enrolled 44 total patients, 26 diagnosed with STS, in a study evaluating the effect of pazopanib combined with either a histone deacetylase or inhibitors of mTOR, Her2, or MEK. The study was designed as a retrospective review of patients with metastatic sarcoma previously treated with, ideally, anthracycline-based chemotherapy analogous to the PALETTE study^[64]. Half of the patients received histone deacetylase inhibitors. Overall survival and progression-free survival of STS patients taking pazopanib with an epigenetic modifier were 38.7 weeks and 14.5 weeks, respectively. Genomic analysis via the Cancer Genome Atlas was performed as well, demonstrating mutations in 46% of the targeted epigenomic modifiers (HDAC, mTOR, Her2, MEK). Significant co-alterations were discovered between the Ras/Raf/MAPK pathway and HDAC alterations as well as between the ERBB pathway and HDAC alterations, though the specific alterations were not reported, and STS were not differentiated from bone sarcomas. Conclusions of this study are difficult to draw, in part due to incompatibility with the reference

Table 1. A summary of the selected pharmaceutical trials highlighted by the epigenetic target and most prevalent sarcoma subtypes treated in the trial

Pharmaceutical(s)	Epigenetic target(s)	Sarcoma subtype(s)
Tazemetostat	EZH2	Epithelioid sarcoma
SB939	Histone deacetylase	Synovial sarcoma Myxoid liposarcoma Endometrial stromal Ewing sarcoma
Vorinostat	Histone deacetylase	Not specified
Valproate	Histone deacetylase	Uterine leiomyosarcoma Liposarcoma Angiosarcoma Epithelioid sarcoma
Decitabine	DNA methyltransferase	Leiomyosarcoma Chondrosarcoma Adenosarcoma Carcinosarcoma
Hydralazine	DNA methyltransferase	Not specified
Valproate	Histone deacetylase	

standard overall survival of the PALETTE study, even after selecting for STS as bone sarcoma. Given that some patients in this study had undergone prior VEGF treatment, acquired resistance could explain this effect. The genomic analysis lends an opportunity to evaluate whether a synergistic effect exists between addressing multiple epigenetic pathways at once, especially the MAPK pathway and HDAC, as they were co-altered at a 97% rate. If the drop in reference to overall survival and this effect were mediated via epigenetics, it would also imply that reversing the resistance could be difficult (provided this resistance seen was due to the attempted mechanisms). As such, combining epigenetic modulators at the advent of treatment could be beneficial.

We, the authors, evaluated 46 patients diagnosed with unresectable metastatic STS with a combination regimen of gemcitabine/docetaxel, combination chemotherapy, VEGF inhibition with bevacizumab, and valproate as an HDAC inhibitor^[65]. Nearly 74% of patients had received prior chemotherapy; 30% of patients had received prior gemcitabine and docetaxel. Seventeen patients required dose reduction from the study regimen, with main adverse events being hepatotoxicity, neurotoxicity, and hypertension. The best response within the trial was a complete response in a case of epithelioid sarcoma, as well as 6 partial responses in other sarcoma subtypes. Interestingly, of patients who had previously received combination gemcitabine and docetaxel, 61% responded to the addition of valproate and bevacizumab regimen with either partial response or stable disease. Bevacizumab as monotherapy has a 13% reported response rate in STS^[66], and prior studies in treatment naïve metastatic STS patients demonstrated a 31% response rate to gemcitabine, docetaxel, and bevacizumab triple therapy^[67]. With a response rate of 15%, of which 74% had previously undergone prior therapy, the rate of response in this trial is likely attributable to prior bevacizumab monotherapy in a majority of patients, reversal of chemotherapeutic resistance with bevacizumab, valproate or both, or effective valproate monotherapy.

Another phase 1b trial conducted by our group treated metastatic soft tissue and bone sarcoma with standard gemcitabine chemotherapy and the DNA hypomethylating agent decitabine^[68]. Thirty-one patients (25 with STS) were enrolled, with 7 deemed non-evaluable; notably, 11 had received prior gemcitabine therapy with documented progression. Partial response was seen in 4 patients, with stable disease seen in 10, with a clinical benefit rate of 58%. Sarcoma subtypes with partial responses were leiomyosarcoma, adenosarcoma, and carcinosarcoma. These results combined with prior treatment with gemcitabine would imply that decitabine therapy was able to correct prior resistance to therapy.

An interesting, multifaceted approach in the setting of solid tumor treatment was performed by Bauman *et al.*^[69]. From the perspective that aberrant DNA methylation is found in prior smokers, DNA methylation was used as a target in previously treated solid tumor patients. A combination regimen of hydralazine, demonstrated to be a demethylating agent *in vitro*, as well as valproate, demonstrated to have histone deacetylation activity, was utilized prior to chemotherapy in a steady state^[70,71]. Patients were monitored for dose-limiting toxicities, and the regimen was well-tolerated, with no grade 4 side effects reported, and 5 total grade 3 side effects among 27 patients. Notable responses were seen in 2 of 3 STS patients who maintained stable disease for 3 and 4 months on second-line treatment. Further survival data of sarcoma patients was not reported. While the STS sample size was small, the data suggest a therapeutic benefit with combination epigenetic therapy that would be well-tolerated. Chavez-Blanco *et al.*^[72] discovered a similar potentiation effect with xenograft fibrosarcoma cells in a murine model, revealing a higher antineoplastic effect of chemotherapy regardless of the mechanism if co-administered with hydralazine and valproate. Further, xenograft tumors undergoing combination therapy did not regrow after the final dose of treatment, whereas tumors treated with adriamycin monotherapy did recur, reinforcing a possible increased efficacy of the coadministration regimen.

Bone sarcomas

Chu *et al.*^[44] used the same pan-histone deacetylase inhibitor monotherapy within 5 EWS-translocation sarcomas, 1 of which was diagnosed as Ewing's sarcoma, and 2 were diagnosed as chondrosarcoma. The patient in the study with Ewing's sarcoma had progression of disease whereas best response with chondrosarcoma had stable disease; EWS-translocation sarcomas had the highest percent tumor change from baseline compared to all other sarcoma subtypes in the study^[44].

Dembla *et al.*^[63] examined the effect of pazopanib combined with primarily histone de-acetylators or inhibitors of mTOR, Her2, or MEK. Overall survival and progression-free survival of osteosarcoma patients taking pazopanib with an epigenetic modifier were 35.2 weeks and 8.9 weeks, respectively. While referencing the PALETTE study in design, the PALETTE study did not include bone sarcomas in its original analysis. This cohort does not match expected pazopanib monotherapy overall survival and progression-free survival^[73]. While possibly this is due to a detrimental effect of combination therapy with epigenetic modifiers, a genomic analysis via the Cancer Genome Atlas divided by sarcoma subtype beginning with soft tissue sarcoma and bone sarcoma could demonstrate a difference between the two groups^[63].

Ongoing and recruiting clinical trials

Of the trials listed in [Table 2](#), one important step forward involves the use of epigenetic modulators and immunotherapy. This is being used with EZH2 inhibitors, PARP-inhibitors, and DNMT inhibitors, with room for expansion into other epigenetic targets, especially if the results prove to be promising.

FUTURE DIRECTIONS

While a substantive amount of information relating to the role of epigenetics in the oncogenesis of sarcoma has only recently been discovered, further exploration to best derive benefit is still needed. Specifically, determining the epigenetic profile of an individual patient specimen is needed. While this is already being pursued in part by NCT03919539 in the evaluation of osteosarcoma, we suggest similar clinical studies in STS to better correlate epigenetic profile with disease progression, treatment susceptibilities with the current standard of care, and ultimately the development of targeted epigenetic therapies. Epigenetic profiling has already been shown to lead to the improved diagnostic characterization of sarcoma^[33].

Table 2. Ongoing clinical trials evaluating epigenetics in the setting of sarcoma as documented by clinicaltrials.gov with associated clinical trial numbers

Clinical trial number	Tumor type(s)	Regimen	Epigenetic target	Study start date	Estimated end date
NCT04648826	Sarcoma, melanoma, germ cell	Aerosolized azacytidine and bintrafusp alfa	DNA methyltransferase	Oct 2021	Dec 2029
NCT04705818	Sarcoma, colorectal cancer, pancreatic cancer	Tazemetostat and durvalumab	EZH2	Jul 2021	Jul 2023
NCT03694262	Endometrial sarcoma	Bevacizumab, atezolizumab and rucaparib	PARP-inhibitor	Jul 2019	Jun 2026
NCT03919539	Osteosarcoma	Famitinib and camrelizumab	Biomarker evaluation	Dec 2019	Dec 2021
NCT04340843	Chondrosarcoma	Belinostat, guadecitabine	DNA methyltransferase, histone deacetylase	Jul 2020	Jan 2022

Some positive outcomes in prior studies suggest epigenetic therapies can delay resistance to already effective chemotherapies, as demonstrated by Zakharia *et al.*^[60] in the context of vemurafenib and melanoma, with preclinical correlates. To better elucidate these effects in sarcoma, we suggest a trial of patients with metastatic STS undergoing standard of care chemotherapy enrolled to receive concurrent epigenetic therapy to better potentially identify a prolonged duration of response. Currently, it also appears that epigenetic therapies are able to play a role in returning the effectiveness of a previously used regimen^[63,65].

None of the epigenetic therapies used are able to specifically target only epigenomic changes related to sarcoma pathogenesis, leading to a possible concern over lack of specificity. Fortunately, one consistent determination among the studies reported here is that combination epigenetic therapy inhibiting multiple targets has thus far been well-tolerated by patients. We suggest combining current standard of care regimens with multiple epigenetic therapies as opposed to the monotherapies more frequently attempted, as these will inhibit any compensatory epigenetic changes seen in monotherapies. This will likely be more beneficial in the event further identification of the epigenome is performed and concurrent mutations are identified, as shown by Dembla *et al.*^[63].

An additional approach, as seen in the NCT04648826 and NCT04705818 trials involving epigenetic targets and immunotherapy, would involve utilizing therapeutic options previously considered less effective with epigenetic targets to evaluate a change in efficacy. If effective, we hypothesize that the epigenetic target would likely unmask a therapeutic benefit similar to the re-sensitizing of chemotherapy, as shown by Monga *et al.*^[65], though if the therapeutic benefit is found, more mechanistic characterization would need to be determined. One potential modification would be to utilize combination epigenetic targets as mentioned above.

The preclinical setting, as alluded to above, also has exciting potential for growth. Arguably one of the most beneficial changes would be the development of reflective treatment-experienced preclinical cell lines for STS and bone sarcomas for both characterization of suspected epigenetic mutations seen after treatment as well as reversing acquired resistance. Finally, many targets identified in preclinical settings have yet to be truly evaluated in a clinical context to determine their efficacy, as shown by Ciarapica *et al.*^[40] who determined that inhibiting WEE1 was a promising effective therapy in high-risk RMS. This oncogenic pathway is shared by the PRC2 complex, leading to the possibility that a similar therapeutic effect may be found if the EZH2 inhibitor tazemetostat is used.

Multiple directions of study will lead to ample opportunity for growth in the study of epigenetics, as well as possibly defining the role that epigenetic modulation may play in the treatment of sarcoma.

Abstract

In the last two decades major improvements have been reached in the early diagnosis of colorectal cancer (CRC) and, besides chemotherapy, an ampler choice of therapeutic approaches is now available, including targeted and immunotherapy. Despite that, CRC remains a “big killer” mainly due to the development of resistance to therapies, especially when the disease is diagnosed after it is already metastatic. At the same time, our knowledge of the mechanisms underlying resistance has been rapidly expanding which allows the development of novel therapeutic options in order to overcome it. As far as resistance to chemotherapy is concerned, several contributors have been identified such as: intake/efflux systems upregulation; alterations in the DNA damage response, due to defect in the DNA checkpoint and repair systems; dysregulation of the expression of apoptotic/anti-apoptotic members of the BCL2 family; overexpression of oncogenic kinases; the presence of cancer stem cells; and the composition of the tumoral microenvironment and that of the gut microbiota. Interestingly, several mechanisms are also involved in the resistance to targeted and/or immunotherapy. For example, overexpression and/or hyperactivation and/or amplification of oncogenic kinases can sustain resistance to targeted therapy whereas the composition of the gut microbiota, as well as that of the tumoral niche, and defects in DNA repair systems are crucial for determining the response to immunotherapy. In this review we will make an overview of the main resistance mechanisms identified so far and of the new therapeutic approaches to overcome it.

Keywords: Colorectal cancer, resistance, chemotherapy, target therapy, EGFR, ERBB2, MET, BRAF, kinase inhibitors, immune checkpoint inhibitors, gut microbiota

INTRODUCTION

Notwithstanding widespread, effective measures of preventive screening, early detection and major advances in treatment options, colorectal cancer (CRC) is still the fourth cause of cancer-related death worldwide^[1,2]. In fact, due to the relatively asymptomatic progression of the disease in the early stages, patients are frequently diagnosed with metastatic CRC (mCRC), with a 5-year survival rate of around 14%^[3]. Neo-adjuvant or adjuvant chemotherapy, together with surgery, represent the backbone of the therapeutic approach for both early-stage and metastatic cancer patients. Depending on tumor site and progression of the disease, chemotherapy can be associated with radiotherapy^[4-6] and, in selected cases, it can be possibly integrated with targeted therapy and/or immunotherapy. However, despite a variety of therapeutic approaches, resistance - both intrinsic and acquired - to drug treatment(s) remains one of the greatest challenges in the long-term management of incurable mCRC and eventually contributes to death^[7,8]. In the last two decades, remarkable progresses have been made in the understanding of the mechanisms underlying drug resistance and in the unraveling of the feedback mechanisms fueling acquired resistance to targeted and/or immunotherapy. In addition, several phenotypes and synthetic lethality screens uncovered important liabilities that can be pharmacologically targeted in resistant tumors and in specific mutational settings^[9]. Accordingly, hundreds of clinical trials are currently undergoing to test new drugs and new combinations for the treatment of mCRC. This review will pinpoint the most promising targets emerged in the last decade.

RESISTANCE TO CHEMOTHERAPY

According to the American Society of Clinical Oncology (ASCO) guidelines (<https://www.asco.org/>), the main drugs used for chemotherapy are 5-fluorouracil (5-FU), irinotecan, and oxaliplatin, either alone or in combinations such as in the FOLFOX (5-FU + leucovorin + oxaliplatin) or FOLFIRI (5-FU + leucovorin + irinotecan) regimens. 5-FU-based chemotherapy is the main approach for advanced CRC and, when used in combination, initial responses are up to 55%-65%. When administered sequentially, median overall survival (OS) can range from 18 to 20 months^[10]. Although 5-FU initially de-bulks the tumor mass, recurrence usually occurs, thus pinpointing how acquired drug resistance, and consequent tumor re-growth, represents the main obstacle to effective clinical outcomes for CRC patients. Several different mechanisms have been identified accounting for resistance to 5-FU-based chemotherapy^[11] and increasing number of strategies are being explored to increase the responsiveness of resistant tumors to chemotherapy [Figure 1].

Dysregulated expression of drug transporters and enzymes involved in drug metabolism

Plasma membrane transporters are pivotal for the uptake into and the efflux out of the cells of endogenous and exogenous molecules. They are divided in two big families: the ATP-binding cassette (ABC) family and the solute carrier (SLC) family. Members of both families serve a range of physiological roles but some of them also are determinants of drug disposition via affecting absorption, distribution, and excretion of drugs [Table 1].

Since the mid-1980s several members of the ABC family have been deemed to be play an important role in the resistance to chemotherapy, given that their dysregulated expression may lead to a decreased uptake or an increased efflux of anticancer agents^[12-14]. Even though roughly half of the members have been shown to efflux anticancer agents in some context, the use of cell lines with high ABC transporter expression levels might have led to an overestimation of their role in cancer^[15]. In addition, transporters are usually parts of more complex networks usually under the same transcriptional regulation; therefore, their upregulation may be more of an epi-phenomenon than of a cause-related effect^[16]. A paradigmatic example of this are the data reported by Gao *et al.*^[17]. They first showed that, in colon cancer cell lines made resistant to 5-FU, drug treatment induced the expression of different ABC transporters as well as the activation of IRE1, an enzyme

Table 1. Dysregulated expression of drug transporters and enzymes involved in drug metabolism

Gene	Protein function	Correlation with drug resistance	Ref.
SLC22A3	Uptake of platinum compounds	Lower SLC22A3 expression correlates with worst PSF in patients receiving FOLFOX6 regimen Post-treatment intracellular concentration of OxPt is higher in SLC22A3-overexpressing cells; upregulation of SLC22A3 in mouse xenografts rendered tumors more responsive to OxPt treatment	[20] [21]
SLC31A1	Copper influx transporter, involved also in OxPt intake	SLC31A1 level predicts prolonged survival and enhanced response to platinum-based regimens in cancer patients with several epithelial cancers	[24]
ATP7B	Copper efflux transporter, involved also in OxPt efflux	Increased levels of ATP7B are associated with poor outcome in CRC patients receiving oxaliplatin-based chemotherapy	[23]
CYP1A2/ CYP2A6	Cytochrome P450 enzymes involved in drug metabolism	Increased expression in 5-FU-resistant HCT116 CRC cell line; addition of the CYP450 inhibitor phenylpyrrole enhanced 5-FU-induced cytotoxicity in 5-FU-resistant cells	[25]
CYP3A5		Higher intratumoral expression of CYP3A5 in patients with CRC who do not respond to irinotecan-based chemotherapy	[29]
TYMS	Enzyme that maintains the dTMP pool critical for DNA replication and repair and is inhibited by 5-FU	Increased expression of TYMS in pretreatment tumor biopsies identified tumors non-responsive to 5-FU-based therapy	[26]

PSF: Progression-free survival; OxPt: oxaliplatin; 5-FU: 5-fluorouracil; FOLFOX: 5-FU + leucovorin + oxaliplatin.

involved in the unfolded protein response ensuing from endoplasmic reticulum stress^[18]. Disabling the enzyme, by both a specific inhibitor and by RNA silencing, they observed a decrease in the expression of the transporters as well as the sensitization to 5-FU. Given that the unfolded protein response is a complex response where several genes are regulated downstream of IRE1^[19], their experiments do not rule out that the sensitization might be due to the suppression (or activation) of other components of the response. Therefore, the decrease in the expression of the transporters simply correlates with the sensitization effect without a clear cause-effect relationship having been established.

For decades now plenty of experimental data have been produced - both in *in vitro* and *in vivo* systems - showing that the increased expression of several members correlate with increased resistance to chemotherapeutic agents as well as their inhibition by specific inhibitors could restore drug sensitivity^[12,13]. Although the substrates and key roles for most of these transporters have been identified, the extent to which these transporters play an effective role in clinical multidrug resistance has not yet been clarified^[15,16], not in general nor in the specific case of CRC. In fact, *ex-vivo* data are still pretty inconclusive: for example ABCB1 expression is generally low in tumors, but for few exceptions, and specific inhibitors have clinically failed^[16].

On the other hand, some members of the SLC family 22 shown to be involved in the uptake of platinum compounds have been more directly linked to drug efficacy. For example, in a retrospective study Gu *et al.*^[20] found that high expression of SLC22A3 (OCT3) may be a protective factor for CRC patients postoperatively treated with FOLFOX6 as a first-line adjuvant chemotherapy. In line with this, the same group also demonstrated in *in vitro* and *in vivo* experimental systems that the cellular concentration of oxaliplatin and its cytotoxicity were significantly increased in response to high expression of OCT3, whereas OCT3 knockdown directly increased the invasion and migration of colon cancer cells. In addition, upregulation of OCT3 expression in colon cancer xenografts via treatment with the DNA methyltransferase inhibitor decitabine increased the cellular concentration of the drug and improved its curative effect^[21]. Key mediators for oxaliplatin accumulation inside the cells are also a series of proteins initially identified as copper transporters. It has been shown that the major copper influx transporter SLC31A1 (CTR1) regulates tumor cell uptake whereas the two copper efflux transporters ATP7A and ATP7B regulate the efflux^[22].

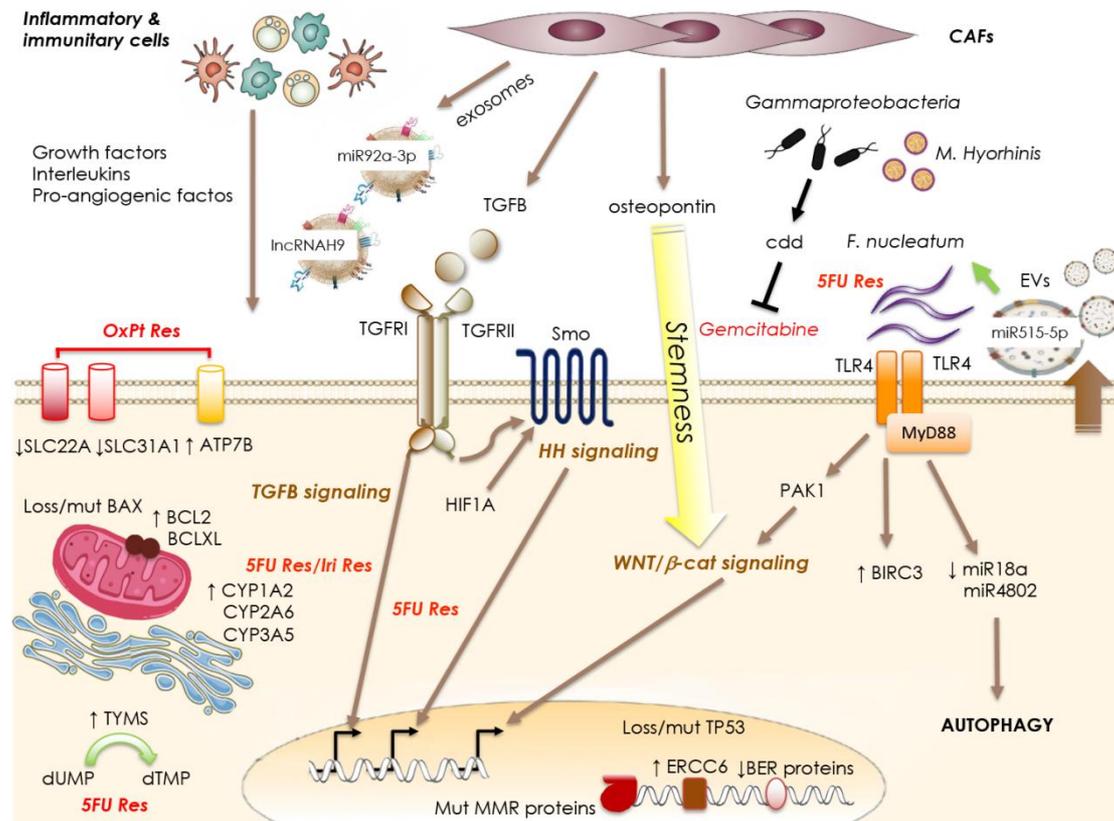

Figure 1. Mechanisms of resistance to chemotherapy. Tumor cell-intrinsic mechanisms may involve: dysregulated expression of drug transporters (SLC family members or ATP7B) and enzymes involved in drug metabolism (CYP family members), imbalanced expression of anti-/pro-apoptotic molecules (BAX mutation/loss or increased BCL2 expression), or dysregulation of DNA repair mechanisms and checkpoints (*TP53* mutation/loss, MMR proteins mutation, diminished expression of BER proteins, or increased ERCC6 expression). External signals acting on the tumor cells to trigger resistance may derive from the cells populating the tumoral niche such as the CAFs releasing TGFβ, osteopontin and exosomes containing specific lncRNAs and miRs. In addition, inflammatory and immunitary cells of the niche release a number of interleukins, growth factors, pro-angiogenic factors. Also, specific components of the microbiota can contribute to the resistance to chemotherapy by directly inactivating the drug (Gammaproteobacterial or *M. hyorhinis*) or by engaging the TLR4/MyD88 system to transduce pro-survival and autophagic signals. SLC: Solute carrier; MMR: mismatch-repair system; CAFs: cancer-associated fibroblast.

Accordingly, it has been reported that increased levels of ATP7B are associated with poor outcome in CRC patients receiving oxaliplatin-based chemotherapy^[23], whereas a large meta-analysis of literatures and datasets performed by Sun *et al.*^[24] revealed that high CTR1 level predicts prolonged survival and enhanced response to platinum-based regimens in cancer patients with a number of epithelial cancers.

A change in the expression or activation of enzymes involved in drug metabolism by cancer cells can enhance the catabolism of the drugs or result in diminished activation of prodrugs. In both cases, the result is an impairment of the pharmacological action of the chemotherapeutic agent [Table 1]. For example, Untereiner *et al.*^[25] produced a 5-FU-resistant HCT116 CRC cell line characterized by a significant increase in the expression of the drug-metabolizing cytochrome P450 enzymes CYP1A2 and CYP2A6. Accordingly, they reported that the addition of the CYP450 inhibitor phenylpyrrole enhanced 5-FU-induced cytotoxicity in 5-FU-resistant cells^[25]. Also, increased expression of thymidylate synthase (the enzyme inhibited by 5-FU) in pretreatment tumor biopsies could identify tumors that would be non-responsive to 5-FU-based therapy^[26]. At variance, downregulation of thymidine phosphorylase (which plays an essential role in activating the oral prodrug capecitabine to 5-FU) causes resistance via insufficient drug activation^[27].

Irinotecan undergoes extensive metabolism in both the liver and the intestine; it is converted to inactive metabolites by CYP3A4 and CYP3A5^[28]. Studying a CRC patient cohort, Buck *et al.*^[29] recently reported an association between the response to irinotecan and the expression CYP3A5; in fact, they found a significantly higher intratumoral expression of CYP3A5 in patients with CRC who do not respond to irinotecan-based chemotherapy and thus suggested a causal role of CYP3A5 in tumor resistance.

Dysregulation of DNA repair mechanisms and checkpoints

5-FU and all the most used drugs for treating CRC act by inducing, directly or indirectly, DNA damage and consequently activate cell's DNA damage response. Depending on the entity of the damage and on the functionality of the DNA damage response, apoptosis can be the outcome. In fact, several DNA repair mechanisms can intervene to remove or repair drug-induced damage thus avoiding cytotoxicity, and their dysregulation can contribute to the drug-resistant phenotype [Table 2]. For example, ERCC6 - a member of the excision repair cross-complementation (ERCC) family of enzymes, involved in the nucleotide excision repair pathway (NER) - is upregulated in CRC tissues compared to matched non-tumoral adjacent tissues and is also upregulated in patients resistant to 5-FU treatment. Conversely, low ERCC6 expression is associated with better response to chemotherapy and survival in CRC^[30].

Activity of the base-excision repair (BER) system is pivotal in determining 5-FU-induced cytotoxicity in cells concomitantly defective for components of the mismatch-repair system (dMMR), as shown by the fact that CRC patients expressing high levels of BER proteins have more aggressive tumors and poor outcomes after chemotherapy^[31]. Of note, zelpolib, a specific inhibitor of DNA polymerase δ an essential component of both NER and BER pathways - has been recently synthesized and shown to render cells sensitive to PARP inhibitors^[32]. Therefore, it would be of interest to assess whether PARP inhibitors are cytotoxic in ERCC6-overexpressing and MMR/BER defective 5-FU-resistant models.

MMR status is particularly important in CRC given that around 15% of patients have one or more components (*MLH1*, *MLH3*, *MSH2*, or *MSH3*) mutated or silenced, often with a microsatellite instability (MSI) phenotype. Notably, patients with stages II and III CRC are less responsive, if not at all, to 5-FU-based chemotherapy whereas a better response is achievable in patients with MMR-proficient (pMMR) tumors^[33,34]. In addition, MMR phenotype is also predictive of resistance to oxaliplatin-based chemotherapy^[35]. Notably, collections of evidence are accumulating that dMMR and MSI-high (MSI-H) heavily pre-treated patients (at least two prior lines of therapy for metastatic disease) show a durable clinical benefit when treated with programmed cell death protein 1 (PD-1) inhibitors, particularly in the metastatic setting^[36].

The response to DNA damage is tightly controlled by DNA damage checkpoints and their malfunctioning may allow the survival of damaged cells and the selection of new mutations. In this case, the resistance to chemotherapy as well as the tumor progression are favored characteristics. The best-known DNA damage checkpoint, mutated or lost in 50% to 70% of CRC cases, is *TP53* which makes it the gene with the highest mutation rate in CRC^[37,38]. Loss or impairment of *TP53* have been shown to affect the response to chemotherapy in several *in vitro* and *in vivo* systems^[37], to predict the poor response of patients with mCRC treated with chemotherapy^[38], and be associated with poor survival after FOLFOX therapy^[39,40].

Many promising synthetic lethal vulnerabilities, whose targeting kills p53-null drug resistant-resistant CRC cells, have been identified by an shRNA screen performed in our lab^[41]. Several of them have successively been validated by other labs such as PIM-1^[42], TRIB3^[43], EPHA2^[44,45], CHK1^[46], and VEGFR2^[47]. We focused our studies particularly on two targets: GSK3B and p65BTK. We showed that GSK3B is significantly more

Table 2. Dysregulation of DNA repair mechanisms and checkpoints

Gene/system	Protein function	Correlation with drug resistance	Ref.
ERCC6	Member of ERCC family of enzymes involved in the NER	Upregulated in CRC tissues compared to matched non-tumoral adjacent tissues Higher levels in patients resistant to 5-FU treatment low expression associated with better response to chemotherapy and survival	[30]
BER	Members of the BER system repairs bulky helix-distorting lesions	CRC patients with defects in components of the mismatch-repair system and expressing high levels of BER proteins have more aggressive tumors and poor outcomes after chemotherapy	[31]
MMR	Members of MMR are involved in recognizing and repairing erroneous insertion, deletion, and mis-incorporation of bases	dMMR patients with stages II and III CRC are less responsive, if not at all, to 5-FU-based chemotherapy whereas a better response is achievable in pMMR patients	[33,34]
TP53	DNA damage checkpoint	Loss or impairment of TP53 affects the response to chemotherapy in several <i>in vitro</i> and <i>in vivo</i> systems Loss or impairment of TP53 predict the poor response of patients with mCRC treated with chemotherapy Loss or impairment of TP53 associated with poor survival after FOLFOX therapy Loss or impairment of TP53 associated with poor survival after FOLFOX therapy	[37] [38] [39,40]

ERCC: Excision repair cross-complementation; NER: nucleotide excision repair pathway; BER: base-excision repair; MMR: mismatch-repair system; dMMR: defective MMR; pMMR: proficient MMR.

activated in drug-resistant vs. responsive CRC patients and is associated with cancer progression, poor response to therapy, and worse OS. Experimentally, we demonstrated that in the absence of p53, GSK3B activity allows cells to survive, despite treatment with DNA-damaging drugs, by sustaining DNA repair and that its downregulation restored sensitivity to 5-FU of p53-null colon cancer cells - both in *in vitro* and in *in vivo* models - via induction of regulated necrosis^[48]. Moreover, we also demonstrated that GSK3A is redundant with GSK3B modulating drug resistance and chemotherapy-induced regulated necrosis^[49]. A general role for GSK3B in sustaining resistance to chemotherapy has been validated also in other types of cancers and 9-ING-41, a novel GSK3B inhibitor developed by actuate therapeutics, is currently undergoing phase 1 and phase 2 trials, as a single agent and in combination with cytotoxic agents, in patients with refractory cancers, including CRCs^[9]. p65BTK is a novel isoform of the Bruton's tyrosine kinase we isolated from the screening and subsequently characterized. Compared to the known Bruton's tyrosine kinase (BTK) expressed in bone marrow-derived cell lineages, p65BTK lacks a stretch of 86 amino acids at the N-term and is translated from an mRNA containing a different first exon. Protein abundance is regulated at the post-transcriptional level and under the control of RAS/ERK pathway. Moreover, p65BTK is endowed with strong transforming activity that depends on ERK1/2 and its inhibition abolishes RAS transforming activity. Accordingly, p65BTK overexpression in CRC tissues correlates with ERK1/2 activation^[50], histotype, and cancer progression^[51]. p65BTK silencing or chemical inhibition affects the growth of CRC cells and overcomes the 5-FU resistance of p53-null CRC cells by abolishing a 5-FU-elicited TGFβ1 protective response and triggering E2F-dependent apoptosis. In addition, the combination of BTK inhibitors with 5-FU is cytotoxic for p53-null patient-derived organoids and significantly reduced the growth of xenografted tumors, thus giving the proof-of-concept for suggesting the use of BTK inhibitors in combination with 5-FU as a novel therapeutic approach in CRC patients^[51]. Further studies from our lab indicate p65BTK as an actionable target in different solid tumors other than CRC. In fact, preclinical data indicate that depending on the tumor type, BTK inhibitors used alone can induce cytotoxicity in gliomas^[52], be more effective than standard-of-care (SOC) chemotherapy in drug-resistant ovarian cancer^[53] or can kill drug-resistant tumor cells when used in combination with SOC chemotherapy or targeted therapy in non-small-cell lung cancer^[54], and melanomas (unpublished data).

Interestingly, its targeting is effective in cells with p53 loss and defects along the RAS/MAPK pathway, making it an actionable target for a broad range of solid tumors resistant to SOC chemotherapy. Notably several drugs targeting BTK are already in clinic for certain types of B-cell malignancies (e.g., ibrutinib, acalabrutinib, and zanubrutinib), whereas several others are in clinical trial for B-cell malignancies (e.g., orelabrutinib, spebrutinib, pirtobrutinib, and BGB-3111) and for different type of diseases characterized by excessive B-cell activation (e.g., remibrutinib, renebrutinib, tolebrutinib, and rilzabrunib). Thus, assessing their efficacy in drug-resistant CRCs and other solid tumors would be feasible and advantageous.

Imbalanced expression of anti-/pro-apoptotic molecules

Drug resistance has been demonstrated to be associated with low levels of the pro-apoptotic BAX protein or its loss^[55,56], which can occur in CRC patients because of inactivating mutation or somatic frameshift mutation in the dMMR setting^[57]. In a low-expressing experimental CRC model, its re-induction by using andrographolide, a natural diterpenoid, restored the apoptotic response to 5-FU of drug-resistant CRC cells^[58]. Drug resistance has also been associated with increased levels of the anti-apoptotic BCL-XL protein, which largely occurs in CRC either by amplification or by overexpression^[59]. Several molecules antagonizing BCL-XL, the so-called BH3-mimetics, are currently being tested in experimental models in combination with chemo- or targeted therapy. For example, ABT-737 has been shown to improve the response to oxaliplatin in a *TP53wt/KRASmut* background^[60]. Both ABT-737 and WEHI-539 have been shown to lower the apoptotic threshold by increasing the mitochondrial priming, thus sensitizing resistant CRC cells to chemotherapy; also, Ch282-5 potentiated the response to oxaliplatin both *in vitro* and *in vivo*^[61]. On the other hand, ABT-263 has been proven to overcome hypoxia-driven radioresistance and improve radiotherapy^[62]. Several BH-3 mimetics are currently being tested in clinical trials, even though not for CRC, but mainly for hematological malignancies and other solid tumors^[59]. Hence, it may be hypothesized that in a near future these molecules will also be tested in CRC patients.

Cancer stem cells and the tumoral niche

It has been repeatedly demonstrated that in the bulk of the tumor population, a very small fraction is represented by cancer stem cells (CSCs) that are intrinsically resistant to chemotherapy. In addition, upon exposure to anticancer agents and radiotherapy they may enter a quiescent state, resistant to anti-proliferative drugs; once the therapy is suspended, they can self-renew and differentiate into heterogeneous lineages of cancer cells, thus driving tumor recurrence^[63]. Initially, several data indicated that CSCs upregulate drug-efflux pumps, have a superior DNA-repair capacity, and have enhanced antioxidant defenses^[64]. More recently, cell plasticity and, in particular, the ability of CSCs to adopt a quiescent state have also emerged as important drivers of drug resistance. In fact, lineage-tracing approaches have revealed that the potential of committed cells to move up and down the hierarchy of differentiation (“plasticity”) is more widespread than previously thought. Interestingly, several studies have provided evidence that both CSCs and non-CSCs are plastic and capable of undergoing phenotypic transitions in response to appropriate stimuli^[64]. Therefore, under stimuli coming from the tumoral niche - composed of mesenchymal cells, tumor-infiltrating immune cells (TIIC), endothelial cells, extracellular matrix, and inflammatory mediators - the stemness phenotype can be acquired also by non-CSCs. In particular, cancer cells that can enter a reversible drug-tolerant “persister” state in response to treatment have been described^[65]; this population is made of cycling and non-cycling persisters which arise from different cell lineages with distinct transcriptional and metabolic programs. Upregulation of antioxidant gene programs and a metabolic shift to fatty acid oxidation has been associated with persister proliferative capacity across multiple cancer types, including CRC. Notably, using different inhibitors to impede oxidative stress or metabolic reprogramming led to a significant reduction in the fraction of cycling persisters^[66].

In CRC it has been shown that chemotherapy enriches for cells with a CSC phenotype. However, a pivotal role for a full definition of functional stem cell is concomitantly played by tumor microenvironment (TME) properties and in particular by osteopontin - a multifunctional protein that can also act as a cytokine - produced by key cancer-associated fibroblasts (CAFs)^[67]. Recently, an escape mechanism leading to tumor re-growth after 5-FU treatment has been identified in a p53-mediated activation of the WNT/beta-catenin signaling, a pivotal pathway to sustain CRC CSCs. Accordingly, the addition of a WNT inhibitor to 5-FU effectively suppressed the CSCs and reduced tumor re-growth after discontinuing the treatment^[68]. Also, CRC CSCs can escape immune surveillance by avoiding recognition by the innate immune system and shape the TME through the release of exosomes, cytokines, and chemokines to generate an immunosuppressive niche that facilitates cancer progression^[69].

As mentioned above, TME cues from the tumoral niche can support drug resistance. Important players in this scenario are CAFs, which represent an essential component of tumoral stroma and produce several cytokines acting on tumor cells. Beyond osteopontin, another multifunctional cytokine released by CAFs is transforming growth factor beta (TGFB) that can act synergistically with hypoxia-induced tumor cell-expressed HIF1A to sustain 5-FU/oxaliplatin resistance via activation of the hedgehog pathway, as demonstrated by *in vitro* and *in vivo* experiments using patient-derived cells^[70]. Interestingly, 5-FU-induced TGFB production occurs also in CRC cells as a mechanism of resistance and targeting TGFBR1 restores the sensitivity of drug-resistant cells to 5-FU toxicity^[71]. In addition, the 5-FU-elicited TGFB1 protective action can also be abolished by the use of BTK inhibitors^[51]. Other than through cytokine release, CAFs can communicate with the cancer cell directly, by transferring exosomes. For example, it has been shown that exosomal transfer of miR-92a-3p to CRC cells activates the WNT/beta-catenin pathway and inhibits mitochondrial apoptosis, and contributes to cell stemness, epithelial-to-mesenchymal transition, metastasis, and resistance to 5-FU/oxaliplatin treatment^[72]. Also, exosomal transfer of lncRNA H19 has been found to promote the stemness and chemo-resistance of CRC via activation of the WNT/beta-catenin pathway due to its action as a competing endogenous RNA sponge for miR-141^[73]. Notably, these data further indicate WNT/beta-catenin pathway as a potentially actionable target to overcome chemotherapy resistance.

Exosomes can also be exchanged by cancer cells themselves either in normal conditions or upon chemotherapy. For example, it has been shown that miR-21 is significantly upregulated in exosomes purified from CRC cell lines and that adding them to the cells induces resistance against 5-FU through the downregulation of PDCD4^[74]. Exosomes derived from 5-FU-resistant cells instead are enriched in growth/differentiation factor 15 (GDF15) and dipeptidyl peptidase IV (DPP4), both of which proved to be potent inducers of angiogenesis^[75,76]. Accordingly, 5-FU-resistant CRC cells showed high microvascular density *in vivo*^[75]. Taken together these data indicate that GDF15 and DPP4 may be novel targets for inhibiting angiogenesis in 5-FU-resistant colon cancers.

Finally, in the tumoral niche, different types of TIICs are present that interact with cancer cells and the other components of the niche through cytokine production, eventually altering tumor growth and its response to drug therapy^[69,77]. TIICs in the TME have dual functions in cancer progression: TIIC-related inflammation facilitates tumorigenesis, but TIICs also harbor antitumor properties when appropriately activated. Cancer cell-secreted factors hijack TIIC functions to promote tumor development and metastasis and to suppress immune recognition^[69]. Accordingly, one of the most important progress in cancer treatment has been the recent addition to chemotherapy of the so-called immune checkpoint (ICIs) inhibitors that act by interrupting the immunosuppressive signals within the TME and reactivating antitumor immunity^[78].

The gut microbiota

Gut microbiota seems to be implicated in chemotherapy efficacy through numerous mechanisms [Table 3], including xenometabolism, immune interactions, and altered community structure. Evidence suggests a potential relationship between the presence of *Fusobacterium nucleatum* and resistance to 5-FU and oxaliplatin chemotherapy and no response to immunotherapy. For example, Yu et al.^[79] reported that *F. nucleatum* was abundant in CRC tissues in patients with recurrence post-chemotherapy and associated with clinicopathological characteristics. Mechanistically, *F. nucleatum* targeted TLR4 and MYD88 innate immune signaling and specific microRNAs to activate the autophagy pathway and support drug resistance^[79]. Other mechanisms by which *F. nucleatum* confers resistance to chemotherapy have been reported, such as the upregulation of BIRC3 expression (a member of the inhibitor of apoptosis family, IAPs)^[80] and the activation of the WNT/beta-catenin pathway via a TLR4/P-PAK1 cascade^[81]. In an animal model of CRC, the intratumor presence of bacteria belonging to the Gammaproteobacteria class and producing the long form of the bacterial enzyme cytidine deaminase, which mediates gemcitabine deamination, conferred resistance to gemcitabine; accordingly, the elimination of bacteria by ciprofloxacin treatment restored the response to chemotherapy. In addition, the presence of *Mycoplasma hyorhinis* determined resistance to gemcitabine^[82]. At variance, responses to oxaliplatin were reduced in efficacy in tumor-bearing mice that lacked microbiota^[83] indicating that the microbial population resident in the gut can affect both sensitivity and resistance to chemotherapy, being these effects modulated by different bacteria.

Finally, it has been recently shown that commensal bacteria can produce extracellular vesicles (EVs) able to deliver to the human cells bacterial RNA molecules with gene expression regulatory ability, thus suggesting that they might potentially regulate the expression of genes involved in drug resistance. The communication between commensal bacteria and host cells have been shown to be bi-directional suggesting a reciprocal regulation of gene expression and accordingly, biological cell function. An example of this communication having an impact in the development of drug resistance is offered by the previously mentioned study by Yu et al.^[79], where resistance to 5-FU and oxaliplatin has been shown to be mediated by *F. nucleatus*-induced autophagy through the TLR4/MYD88-mediated downregulation of miR-18a* and miR-4802. Conversely also intestinal epithelial cells exerted a reciprocal effect onto *F. nucleatus* by controlling its growth through the delivery of specific miRNAs, such as hsa-miR-515-5p. In CRC patients, altered expression of miR-515-5p might thus affect *F. nucleatus* proliferation and consequent response to chemotherapeutic drugs^[79]. EV-mediated intercellular communication between bacteria and cancer cells seems therefore to be another potential mechanism playing a role in determining the efficacy of cancer therapy and worthy of increasing attention.

RESISTANCE TO TARGETED THERAPY

According to ASCO guidelines, chemotherapy can be possibly integrated with anti-angiogenic agents such as bevacizumab or aflibercept (first-line and second-line treatment, for advanced CRC) and regorafenib (in patients with mCRC who have already received chemotherapy and other targeted therapies). In selected cases, chemotherapy may also be integrated with the addition of targeted therapy. For example, anti-EGFR (anti-epidermal growth factor receptor) monoclonal antibodies (e.g., cetuximab and panitumumab) are indicated only for *RAS*- and *BRAF*-wild type (wt) tumors since the mutation of these two genes confer resistance to the EGFR blockade. In addition, a combination using the *BRAF* inhibitor encorafenib and cetuximab may be used to treat patients with *BRAF*-mutant (mut) mCRC who have received at least one previous treatment. In the last decade, several tumor-expressed “immune checkpoints”, immunosuppressive molecules blocking antitumor immunity, have been identified and “checkpoint inhibitors” have been developed and entered the clinic. Among them are antibodies against programmed cell PD-1 or its ligand PD-L1 and cytotoxic T lymphocyte-associated protein 4 (CTLA-4). So far, immunotherapy has a limited use

Table 3. The gut microbiota and the response to chemotherapy/immunotherapy

Bacterium	Correlation with drug resistance	Mechanism	Ref.
<i>Fusobacterium nucleatum</i>	Abundant in CRC tissues of patients with recurrence post-chemotherapy and associated with clinicopathological characteristics	Targeting of TLR4 and MYD88 innate immune signaling and targeting specific microRNAs to activate the autophagy pathway	[79]
		Upregulation of BIRC3 expression	[80]
		Activation of the WNT/beta-catenin pathway via a TLR4/P-PAK1 cascade	[81]
Gammaproteobacteria <i>Mycoplasma hyorhinis</i>	Resistance to gemcitabine reverted by eliminating bacteria by ciprofloxacin treatment	Production of the long form of the bacterial enzyme cytidine deaminase which mediates gemcitabine deamination	[82]
Whole microbiota	Reduction of the response to oxaliplatin in mice lacking microbiota		[83]

SPF: Specific pathogen-free.

in CRC since PD-1 targeting monoclonal antibodies can be used only in selected cases of mCRCs bearing defects along the DNA damage response pathways. For example, pembrolizumab is used for the therapy of mCRCs that are MSI-H or dMMR. In contrast, nivolumab can be administered to patients with dMMR or MSI-H mCRC that has grown or spread after treatment with chemotherapy, either alone or in combination with ipilimumab (anti-CTLA-4 monoclonal antibody). Notably, the FDA has issued its approval for pembrolizumab as the first-line treatment of patients with dMMR/MSI-H mCRC in June 2020, even though neither the Japanese Pharmaceuticals and Medical Devices Agency nor the European Medicines Agency has yet approved pembrolizumab as the frontline regimen^[84].

To expand the range of possible combinations of precision drugs to add to chemotherapy several efforts have been made to better stratify patients and to understand the basis of resistance/insensitivity to targeted therapy.

Resistance to anti-EGFR blockade

Perhaps the best studied so far are the mechanisms and the determinants underlying the resistance to anti-EGFR drugs [Figure 2], given that they have been the first targeted drugs employed for the treatment of CRC, and are so far the most used [Tables 4 and 5]. The main genetic defects hampering the response to EGFR blockade are activating mutations leading to constitutive activation of signaling pathways downstream of EGFR such as mutations in *KRAS* (30%-40%), *NRAS* (4%), *BRAF* (7%-15%), or *PIK3CA* (17%-30%) genes and *PTEN* deletion or truncation (7%) which altogether account for unresponsiveness in around 70% of cases^[85,86]. It has been reported that in approximately 50% of *RAS*-wt patients, sensitivity to EGFR blockade is lost because of secondary occurring mutations^[87]. In a small fraction of the remaining resistant tumors two important biomarkers are emerging. Bardelli *et al.*^[88] initially reported that certain patients harboring *RAS*-wt gene and resistant to anti-EGFR therapy presented an amplification of the *MET* proto-oncogene that proved to be responsible for *de novo* and acquired resistance to anti-EGFR therapy. In fact, functional studies showed that *MET* activation conferred resistance to anti-EGFR therapy both *in vitro* and *in vivo* and could be overcome using *MET* inhibitors^[88]. Remarkably, examining circulating tumor DNA, it was possible to find *MET* amplification even before the recurrence became clinically evident. Much experimental evidence further supported the benefit of targeting *MET* in anti-EGFR-resistant CRCs and explored the mechanisms driven by *MET*. Among them, acquisition of cetuximab resistance was shown to be mediated by *TGFA* overexpression which in turn induced EGFR-*MET* interaction^[89]. Also, *SRC* activation promoted cetuximab resistance by directly interacting with *MET*; accordingly, pretreatment with

Table 4. Resistance to anti-EGFR blockade

Treatment	Mutational background	Mechanism	Ref.
Cetuximab	Activating mutations in <i>KRAS</i> , <i>NRAS</i> , <i>BRAF</i> or <i>PIK3CA</i> genes and <i>PTEN</i> deletion, truncation, or epigenetic silencing	Constitutive activation of signaling pathways downstream of EGFR	[85,86]
Cetuximab Panitumumab	<i>MET</i> amplification in wt <i>KRAS</i> setting	Activation of signaling pathways converging onto PIK3CA and MAPK; resistance bypassed using MET inhibitors	[88]
Cetuximab		TGFA overexpression which in turn induced EGFR-MET interaction	[89]
Cetuximab		Cetuximab-mediated MET activation via interaction with SRC and abolished by SRC inhibitors	[90]
Cetuximab	<i>ERBB2</i> amplification /mutations in quadruple (<i>KRAS</i> , <i>NRAS</i> , <i>BRAF</i> , and <i>PIK3CA</i>) wt setting	Constitutive activation of signaling pathways downstream of the receptor; resistance overcome by addition of anti- <i>ERBB2</i> agents	[97,98]
Cetuximab	<i>ERBB2</i> amplification and heregulin overexpression	<i>ERBB2</i> / <i>ERBB3</i> dimerization; resistance bypassed by silencing <i>ERBB2</i> and depleting heregulin	[101]
Intrinsic resistance to anti-EGFR agents	<i>ERBB2</i> activating mutations in <i>KRAS</i> -wt mCRCs	Constitutive activation of signaling pathways downstream of the receptor; resistance bypassed by dual targeting of <i>ERBB2</i> via trastuzumab and lapatinib	[103]
Cetuximab+Refametinib	<i>KRAS</i> -mut	PI3K-AKT pathway activation ensuing from autocrine loops and heterodimerization of multiple receptors (<i>ERBB2</i> , <i>ERBB3</i> , and <i>IGF1R</i>)	[112]
Cetuximab+FOLFIRI	<i>RAS</i> -wt mCRC	High levels of <i>EPHA2</i> significantly correlated with worse PSF and increased progression rate in a cohort of patients; primary and acquired resistance to cetuximab reverted in <i>in vitro</i> and <i>in vivo</i> models by adding a specific <i>EPHA2</i> inhibitor	[114]

FOLFIRI: Folinic acid + 5-fluorouracil + irinotecan; PSF: progression free survival.

SRC inhibitors abolished cetuximab-mediated MET activation and rendered CRC cells sensitive to cetuximab^[90]. Interestingly, concurrent inhibition of MET and SRC decreased viability and enhanced apoptosis in both *RAS*-wt and *RAS*-mut CRC cells. Therefore, combined inhibition of MET and SRC may be a promising strategy for treating of CRC, independent of anti-EGFR resistance^[91]. In addition, MET inhibition, by enhancing the formation of DNA double-strand breaks and possibly alleviating tumor hypoxia, has been found to sensitize CRC cells also to irradiation^[92], further expanding the actionability of MET in CRCs.

Despite experimental efficacy, the clinical trials performed so far did not confirm the expectations. In a phase 2 study the addition of the specific MET inhibitor tivantinib to cetuximab allowed only 10% of MET-high, *KRAS*-wt mCRC patients to achieve objective response, even though in a difficult-to-treat setting (tumor progression on cetuximab or panitumumab after a first-line chemotherapy)^[93].

In another phase 1/2 study addition of tivantinib to cetuximab + irinotecan was tested in *KRAS*-wt patients previously treated but who progressed or presented with mCRC. In these cases, the combination did not significantly improve progression-free survival (PFS), even though subgroup analyses trended in favor of tivantinib in patients with MET-high tumors, *PTEN*-low tumors, or those pretreated with oxaliplatin^[94]. One possible explanation for these disappointing

Table 5. Strategies to overcome resistance to EGFR inhibition

Drug(s)	Mutational background	Mechanism	Ref.
Cetuximab + Crizotinib	<i>MET</i> amplification	Double targeting of EGFR and MET	[88]
Cetuximab + PHA665752	Overexpression of TGF- α	Double targeting of EGFR and MET	[89]
Cetuximab + PHA665752	<i>RAS</i> -wt; <i>MET</i> activation	Double targeting of EGFR and MET	[90]
Cetuximab + Dasatinib		Double targeting of EGFR and SRC	
Cetuximab + Lapatinib	<i>ERBB2</i> amplification	Double targeting of EGFR and ERBB2	[97]
Cetuximab + Pertuzumab			
Trastuzumab + Neratinib	<i>ERBB2</i> amplification or mutation	Double targeting of ERBB2	[98]
Trastuzumab + Afatinib			
Trastuzumab + Lapatinib (clinical trial)	<i>ERBB2</i> overexpression; <i>RAS</i> -wt	Double targeting of ERBB2	[103]
Cetuximab + ALW-II-41-27	EPHA2 overexpression	Double targeting of EGFR and EPHA2	[114]

PHA665752: Small-molecule inhibitor of MET; ALW-II-41-27: EPH family tyrosine kinase inhibitor.

clinical results might be that clinical efficacy has been obscured by a lack of standardization in MET assessment for patient stratification. Accordingly, a very recent paper indicated that subtyping of MET expression may be required to identify MET-addicted malignancies in CRC patients who will truly benefit from MET inhibition^[95].

In 2011 *ERBB2* gene amplification was reported in 7% of patients with CRC^[96]. Subsequently, *ERBB2* amplification or somatic mutations have been described by several studies, with highly different reported rates of positivity (up to 50%) likely due to several factors such as cohort heterogeneity, a small study population, antibody clone selection, staining platform, and different scoring system. Using a molecularly annotated platform of 85 mCRC patient-derived xenografts, Bertotti *et al.*^[97] identified *ERBB2* amplification as an actionable liability in cetuximab-resistant CRCs harboring wt *KRAS/NRAS/BRAF/PIK3CA*. Moreover, they showed that the addition of anti-*ERBB2* agents to anti-EGFR monoclonal antibodies overcame resistance and inhibited tumor growth^[97]. The same group also showed that tumor growth was reduced by single targeting of *ERBB2* in cetuximab-resistant, quadruple (i.e., *KRAS, NRAS, BRAF, and PIK3CA*) wt CRC patient derived xenografts with *ERBB2* mutations. However, only double targeting of EGFR and *ERBB2* led to durable tumor regression^[98].

Later, the role of *ERBB2* amplification/mutation in predicting response to anti-EGFR treatment was confirmed by different groups. Cremolini *et al.*^[99], conducted a prospective, case-control study to demonstrate the negative predictive impact of a panel of rare genomic alteration including *ERBB2* amplification/activating mutations, *MET* amplification, *ROS1/NTRK1-3/RET* rearrangements, and *PIK3CA* exon 20, *PTEN*, and *ALK* mutations. Of the resistant cases, 51.1% were associated with one of these candidate molecular alterations, *ERBB2* amplification being the most frequent (14.9%), followed by *MET* amplification (8.5%)^[99]. A retrospective study performed in *RAS/BRAF*-wt mCRC patients reported that anti-EGFR therapy allowed a PFS significantly longer in patients without *ERBB2* amplification than in those bearing the alteration^[100]. Shorter PFS and OS were demonstrated also in cetuximab-treated CRC patients with *ERBB2*-amplified tumors and higher serum heregulin levels. In addition, *in vitro* experiments proved that silencing *ERBB2* overexpression, as well as depleting heregulin - thus disrupting of *ERBB2/ERBB3* heterodimerization - restored the response to cetuximab^[101]. Notably, *ERBB2* amplification could be identified non only in tissues but also in circulating tumor DNA of CRC patients non-responsive to anti-EGFR therapy^[102]. Sartore-Bianchi *et al.*^[103], demonstrated that *ERBB2* activating mutations in *KRAS*-wt mCRCs predicted intrinsic resistance to anti-EGFR agents that could be bypassed by combining dual targeting *ERBB2* via trastuzumab (anti-*ERBB2* monoclonal antibody) and lapatinib (dual EGFR and *ERBB2* tyrosine kinase inhibitor). A phase 2 basket trial recently obtained an overall response rate of 32% when

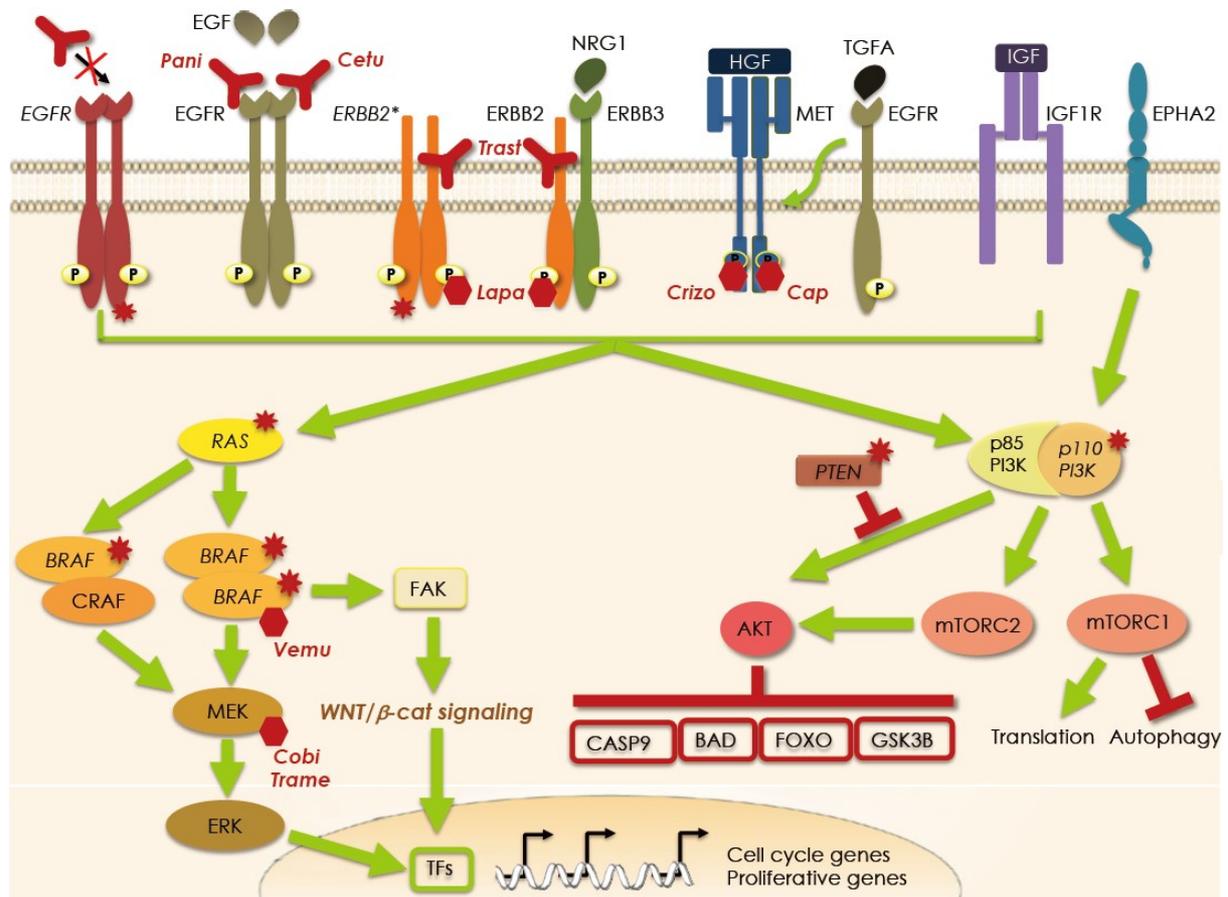

Figure 2. Mechanisms of resistance to targeted therapy against EGFR and mutated *BRAF*. Intrinsic resistance to EGFR blockade by panitumumab (Pani) and cetuximab (Cetu) occurs in case of activating mutations in the *EGFR* and its downstream effectors such as RAS, BRAF, and PIK3CA and when there is loss of *PTEN* either due to truncation or deletion. Acquired resistance stems from stimulation of collateral pathways impinging on the same downstream signaling activated by EGFR (i.e., the RAS/MAPK and the PIK3/AKT pathways). Hyperactivation of these pathways may be due to overexpression or mutation of *ERBB2*, heterodimerization of *ERBB2* and *ERBB3*, engagement of the *EGFR* by *TGFA* which in turn activates *MET*, *MET* overexpression, *EPHA2* overexpression, or *IGF1R* engagement. Strategies to overcome the insensitivity to EGFR blockade are directed at the inhibition of the collateral signaling such as using *ERBB2* blocking agents trastuzumab (Trast) and lapatinib (Lapa) and the *MET* inhibitors crizotinib (Crizo) and capmatinib (Cap). Resistance to the mutated *BRAF* inhibitor vemurafenib (Vemu) originates from the shifting in the choice of the dimerization companion. In the resistant cells instead of mutated *BRAF* homodimers, mutated *BRAF*/*CRAF* heterodimers are formed which are insensitive to the inhibitor and thus MAPK activation is refueled. To prevent heterodimerization a novel inhibitor, that specifically binds mutated *BRAF* homodimers has been developed. Another route of escape to mutant *BRAF* blockade has been described where activation of the WNT/ β -catenin signaling is triggered via FAK. Both MAPK and β -catenin signaling eventually activate a series of transcription factors (TFs) responsible for the transcription of proliferative genes. Currently, to prevent resistance to *BRAF* inhibition, a vertical blockade of the pathway is being tested in clinical trials using vemurafenib in combination with a MEK inhibitor such as cobimetinib (Cobi) or trametinib (Trame). Mutated proteins are indicated by the red stars and the italicized name.

using the dual targeting approach (pertuzumab and trastuzumab) in pretreated *ERBB2*-amplified mCRC patients^[104]. In addition, two other phase 2 clinical trials also identified *ERBB2* as a druggable target in refractory *KRAS*-wt mCRCs with *ERBB2* amplification^[105,106], and *ERBB2*-targeted combinations have been recently included in international guidelines for mCRC^[107].

Besides the above-mentioned clinical studies, several trials are currently undergoing where *ERBB2*-targeted antibody-drug conjugates (i.e., TDM-1, DS-8201, A166, ZW25, and ZW49) and novel tyrosine kinase inhibitors (i.e., tucatinib, sapitinib, neratinib, pyrotinib, poziotinib, and ceralasertib) are being tested alone

or in different combinations^[108]. A recent study pinpointed that an optimal combination may require triple targeting. Mangiapane *et al.*^[109], using 60 CRC specimens obtained a collection of CSC-derived spheres which was then used to perform preclinical experiments to validate different therapeutic options. They found that high expression levels of ERBB2 occurred in spheres showing hyperactive PI3K/AKT pathway and proved that triple targeting of ERBB2, MEK and PI3K induces CSC death and regression of anti-EGFR-resistant tumor xenografts, including those carrying *KRAS* and *PIK3CA* mutation^[109].

Even though MAPK deregulation plays a pivotal role in both intrinsic and secondary resistance to anti-EGFR agents, other mechanisms (sometimes co-occurring) contribute or can account for secondary resistance, due to CRC molecular heterogeneity^[110]. For example, stimulation of EGFR results not only in the RAS/RAF/MAPK pathway but also in the PTEN-PI3K-AKT cascade activation^[111].

Recently, Vitiello *et al.*^[112] used four different *KRAS*-mut CRC cell lines rendered resistant to a combination of cetuximab and refametinib (a selective MEK-inhibitor) and demonstrated that PI3K-AKT pathway activation acts as an escape mechanism in this setting. They showed that autocrine loops and heterodimerization of multiple receptors lead to the activation of several receptor tyrosine kinase, such as ERBB2, ERBB3 and IGF1R, whose signaling onto the PI3K/AKT pathway allows to bypass the block imposed by the double targeting of EGFR and MEK^[112]. The effect on the response to cetuximab in the setting of the three most common *AKT1* activating mutations found in CRC patients (i.e., E17K, E49K, and L52R) was recently investigated by overexpressing them in a cetuximab-sensitive *KRAS*-wt CRC cell line. Interestingly, all of them impaired the cytotoxic response not only toward cetuximab but also to chemotherapy. In addition, also the most common mutations of *CTNNB1* (i.e., T41A, S45F, and S33P) were found to sustain resistance to the same agents^[113]. These data indicate that possible therapeutic strategies to counteract the resistance to EGFR-targeted therapy would therefore be the use of inhibitors of the PI3K/AKT pathway. Notably, trials to test AKT and PI3K inhibitors for CRC are currently undergoing.

A novel predictive biomarker of resistance and a potential therapeutic target for improving the response to anti-EGFR agents has recently been identified in EPHA2. Studying a cohort of 82 *RAS*-wt mCRC patients treated with FOLFIRI + cetuximab, Martini *et al.*^[114] found that 62.6% of patients expressed the tyrosine kinase receptor and that high levels of EPHA2 significantly correlated with worse PFS and increased progression rate. In *in vitro* models a specific EPHA2 inhibitor reverted primary and acquired resistance to cetuximab causing cell growth inhibition, inducing apoptosis and cell-cycle G1-G2 arrest. In xenografts experiments the treatment with the inhibitor upon progression with cetuximab significantly inhibited tumor growth^[114].

Resistance to BRAF inhibitors

The BRAF kinase, operating downstream of RAS along the pathway leading to ERK activation, is considered an oncogenic driver in CRC and its mutation arises in 7%-15% of patients with mCRC. Over 95% of *BRAF* mutations in mCRC occur in codon 600 (V600E) whereas non-V600E *BRAF* mutations occur only in about 2% of patients and define a clinically distinct subtype with a better prognosis. In general, patients with *BRAF*-mut CRC have impaired survival not only in the metastatic setting but also in non-metastatic disease, as compared with patients with *BRAF*-wt CRC, and are resistant to chemotherapy. In fact, the median OS is 4 to 6 months after failure of initial therapy. Currently, SOC is an aggressive strategy involving triplet chemotherapy and anti-VEGF agents, but no specific tailored therapeutic approach has been standardized since no optimal combinations have been reported yet. In fact, at variance with what was observed for melanoma, vemurafenib - the first specific BRAF^{V600E} inhibitor tested - showed modest clinical activity in mCRC patients with *BRAF*-mut tumors^[115]. In addition, no responses were observed in the 10 patients with

BRAF^{V600E} mCRC enrolled in a phase 2 basket trial^[116]. Overall, only 5% of patients with *BRAF*^{V600E} CRC respond to BRAF inhibitors^[117] indicating a very high level of intrinsic resistance to its blockade [Tables 6 and 7]. The reason for the unresponsiveness to vemurafenib was uncovered in two key studies where a paradoxical effect ensuing from BRAF inhibition was shown in *BRAF*^{V600E} CRC models. *BRAF*^{V600E} can signal as RAS-independent monomers or dimers - depending on levels of RAS activation in the tumor - but predominantly exists as a drug-sensitive monomer. Vemurafenib selectively inhibits BRAF monomers. It was discovered that *BRAF*^{V600E} inhibition suppressed ERK-mediated negative feedback on EGFR activity, thus leading to EGFR-mediated reactivation of MAPK signaling, due to the formation of active RAF and CRAF protein dimers^[118,119]. Recently, PLX8394, a novel experimental BRAF inhibitor has been reported to inhibit ERK signaling by specifically disrupting BRAF-containing dimers, thus acting on tumors driven by dimeric BRAF mutants and opening a new possibility to overcome resistance to classic BRAF inhibitors^[120]. Interestingly, few possible targets for combinatorial treatment have been experimentally identified in *BRAF*^{V600E} CRCs. For example, it has been shown that in this setting anti-apoptotic MCL1 is upregulated due to ERK-mediated phosphorylation which results in stabilization of the protein. Even though MEK inhibitor cobimetinib suppressed MCL-1 phosphorylation to a greater extent than did vemurafenib, it resulted in only mildly cytotoxic effects. At variance co-targeting MEK and MCL-1 (either via silencing or via a small-molecule antagonist) significantly increased cytotoxicity *in vitro* and reduced tumor growth *in vivo*^[121]. Chen *et al.*^[122] demonstrated that in *BRAF*^{V600E} CRC cell lines BRAF inhibitors upregulated the WNT/beta-catenin pathway through activating FAK independently of EGFR and MEK signaling [Figure 2]. Accordingly, combined inhibition of BRAF/WNT pathways or BRAF/FAK pathways exerted strong synergistic antitumor both *in vitro* and *in vivo*^[122]. Recently, another mechanism of resistance to vemurafenib has been identified in the increased abundance and activity of nucleophosmin (NPM1), a protein that regulate centrosome duplication and histone assembly and that is induced by the inhibitor in resistant cells. Accordingly, pharmacological inhibition of NPM1 effectively restored the sensitivity of vemurafenib-resistant *BRAF*-mut CRC cell lines^[123].

Given the EGFR reactivation observed in BRAF inhibitor-treated CRC models, dual targeting has been tested. Adding cetuximab to vemurafenib in xenografts experiments resulted in increased antitumor activity and improved survival^[124] and combined administration of BRAF and EGFR inhibitors induces tumor regression in most patients^[116,125-127]. However, within 6 months, resistance inevitably occurs. Analyzing matched tumor tissues obtained from eight patients before treatment and at the time of disease progression after therapy, Yaeger *et al.*^[128] found that in resistant tumors new alterations occurred in genes that encode components of the RAS/RAF pathway (activating mutations of *KRAS* or *NRAS* or amplification of *NRAS*-wt, *KRAS*-wt, or *BRAF*^{V600E}). They then overexpressed *NRAS*-wt or *KRAS* wt in *BRAF*^{V600E} CRC cell lines sensitive to vemurafenib/cetuximab treatment, demonstrating that the increase in either of the two was sufficient to induce the presence of RAF and CRAF protein dimers (absent in sensitive cells) thus rendering the cells resistant to the combinatorial therapy^[128]. Therefore, it would be interesting to verify in this setting the effect of the inhibitor PLX8394 that acts by disrupting dimers^[120].

Preclinical and clinical data obtained in *BRAF*^{V600E} melanoma models and patients indicated that simultaneous and vertical targeting of more than one node along the MAPK/ERK pathway, such as BRAF and MEK, could bypass the resistance to BRAF inhibitors^[129,130] and delay the onset of relapse. However, also this combination did not live up to expectations in *BRAF*^{V600E} CRCs. In fact, combination treatment with BRAF plus MEK inhibitors, dabrafenib and trametinib, led to a median PFS of 3.5 months, with 56% of patients achieving stable disease, 9.3% partial response, and only 2.3% complete response^[131]. It has been recently shown that the combination of the BRAF inhibitor dabrafenib and the MEK inhibitor trametinib triggered a massive apoptotic response only in *BRAF*^{V600E} CRC cells harboring also *TERT* promoter

Table 6. Resistance to BRAF inhibitors

BRAFi	Mutational background	Mechanism	Ref.
Vemurafenib	BRAF ^{V600E}	Only BRAF monomers inhibited by vemurafenib; EGFR-mediated reactivation of MAPK signaling, due to the formation of active RAF and CRAF protein dimers	[118, 119]
Vemurafenib	BRAF ^{V600E}	Upregulation of Wnt/ β -catenin pathway through activation of FAK	[122]
Vemurafenib	BRAF ^{V600E}	Upregulation of NPM1	[123]

Table 7. Strategies to overcome resistance to BRAF inhibitors

Drug(s)	Mutational background	Mechanism	Ref.
PLX8394	BRAF ^{V600E}	Specific inhibition of BRAF dimers; prevent EGFR-mediated reactivation of MAPK signaling	[120]
Cobimetinib + A-1210477	BRAF ^{V600E}	Double targeting of MEK and MCL-1	[121]
Vemurafenib + PF-562271	BRAF ^{V600E}	Double targeting of BRAF ^{V600E} and FAK	[122]
Vemurafenib + ICG-001		Double targeting of BRAF ^{V600E} and β -catenin	
Vemurafenib + PF-562271 + trametinib		Triple targeting of BRAF ^{V600E} , FAK, and MEK	
Vemurafenib + ICG-001 + trametinib		Triple targeting of BRAF ^{V600E} , β -cat, and MEK	
Vemurafenib + NSC348884	BRAF ^{V600E}	Double targeting of BRAF ^{V600E} and NPM1	[123]
Encorafenib + Cetuximab (clinical trial)	BRAF ^{V600E}	Double targeting of BRAF ^{V600E} and EGFR	[136]

PLX8394: RAF inhibitor; A-1210477: elective MCL-1 inhibitor; PF-562271: FAK inhibitor; ICG-001: beta-catenin inhibitor; NSC348884: nucleophosmin (NPM1) inhibitor.

mutations but not in BRAF^{V600E} cells lacking *TERT* mutations. Accordingly, the combination of inhibitors nearly completely abolished the growth of xenografted tumors BRAF^{V600E}/*TERT*-mut but had little effect on tumors harboring only BRAF^{V600E}. Notably, after the treatment was discontinued, doubly mutated tumors remained barely measurable whereas BRAF^{V600E} tumors regrew rapidly^[132]. These findings suggest that double testing for BRAF^{V600E} and *TERT* mutations may stratify patients for combinatorial therapy with BRAF plus MEK inhibitors.

Recent clinical trials investigated the benefit of targeting different nodes along the MAPK pathway in BRAF-mut mCRC^[133-135]. BEACON III was a three-arm phase 3 study that enrolled patients with BRAF^{V600E} mCRC tumors who progressed on one or two prior regimens. In this setting the safety and efficacy of encorafenib (BRAF inhibitor) and cetuximab with or without binimetinib (MEK inhibitor) were evaluated and compared with the control arm with SOC therapy (irinotecan/cetuximab or FOLFIRI/cetuximab). Both triplet and doublet therapy induced an overall response rate that was 10 times more than in the control arm. In addition, PFS tripled and mean OS doubled for the doublet and triplet arms vs. control arm. Little difference was observed between doublet and triplet arms^[136]. Based on these results, on April 2020, the FDA approved encorafenib in combination with cetuximab for mCRCs with a BRAF^{V600E} mutation^[137].

A final note, not directly related to resistance but pointing to alternative actionable targets in BRAF^{V600E} CRCs, should be made about immunotherapy. As previously mentioned, therapy with ICIs is limited to mCRCs bearing defects along DNA damage response pathways. Notably, around 60% of BRAF-mut CRCs also are MSI-H, a condition associated with a higher proportion of tumor infiltrating lymphocytes present in the tumor^[138]. Therefore, it is reasonable to suggest that ICIs could represent the new SOC for this subgroup^[139].

Resistance to anti-angiogenic therapy

The first anti-angiogenic agent entering the clinic for the treatment of mCRC has been bevacizumab, a humanized monoclonal antibody anti-VEGF-A which binds circulating VEGF-A and blocks the interaction with its cell surface receptors (VEGFR1 and 2), thus reducing microvascular growth and inhibiting the blood supply to the tumor tissues^[140]. In recent years the development of anti-angiogenic agents has increased, leading to the addition to of aflibercept (second-line treatment for advanced CRC) and regorafenib (in patients with mCRC who have already received chemotherapy and other targeted therapies). Aflibercept is a recombinant fusion protein consisting of VEGF-binding portions from the extracellular domains of human VEGFR1 and 2, that are fused to the Fc portion of the human IgG1 immunoglobulin and acts like a “VEGF trap”. Regorafenib is multi-kinase inhibitor targeting angiogenic, stromal, and oncogenic receptor tyrosine kinase that shows strong anti-angiogenic activity due to its dual targeted VEGFR2-TIE2 tyrosine kinase inhibition. In addition, other anti-angiogenic drugs are in preclinical and clinical phase I-III studies^[141].

Despite initial promising preclinical results, anti-angiogenic monotherapies did not lead to many clinical benefits, due to primary or acquired resistance, through activation of alternative mechanisms that support vascularization and tumor growth [Figure 3]. Clinical data show that anti-angiogenesis therapies can prolong PFS but have a limited impact on OS and do not set a permanent cure in CRC^[142]. This limited clinical significance is likely due to the fact that treatment with antiangiogenic agents causes a discontinuity in the blood vessel network, which leads to a new hypoxic condition with activation of vascular mimicry, alternative pro-angiogenic pathways and recruitment of endothelial cells derived from bone marrow^[143].

So far, the mechanisms of resistance to anti-VEGF therapy have not been fully elucidated. The main factor used by cancer cells to adapt to oxygen deprivation is hypoxia-inducible factor (HIF) of which three members are known (i.e., HIF1A, HIF2A, and HIF3A). During hypoxia, HIF1A translocates into the cell nucleus to form the activated HIF1 complex along with HIF1B. Hypoxic contexts induce upregulation of VEGF expression through the upstream transcription factor HIF1A. These factors induce tumors to acquire more angiogenic and invasive potentials, promoting metastasis^[144]. Preclinical studies and clinical trials suggest that inhibition of a specific growth factor can induce the expression of others^[145]. For instance, in a phase II study in which mCRC patients were treated with a combination of 5-FU, leucovorin and irinotecan (FOLFIRI) and bevacizumab, several angiogenic factors, including the placental growth factor and hepatocyte growth factor, were found to increase before disease progression^[146]. Activin receptor-like kinase 1 (ACVRL1) is an emerging target for antiangiogenic therapy; it is a TGFB transmembrane receptor expressed preferentially from proliferating endothelial cells and is crucial to TGFB-mediated angiogenesis. Significantly, VEGF-A and ACVRL1 expression have been shown to regulate angiogenesis. Data support the hypothesis that ACVRL1 expression and function following anti-VEGF/VEGFR inhibitor treatment may contribute to vascular adaptation from the VEGF-driven neovascularization^[147]. In particular, the TGFB axis may provide an escape pathway for tumor angiogenesis^[148]. Thus, agents that inhibit TGFB signaling combined with VEGF/VEGFR- therapies may potentiate treatment response.

Moreover, alternative angiogenic pathway can contribute to the escape from anti-VEGF treatment such as the angiopoietin-TIE signaling system. TIE-1 and -2 are specific vascular receptor tyrosine kinase that control vascular permeability and the development and remodeling of blood vessels through angiopoietin-1 (ANGPT1) and angiopoietin-2 (ANGPT2). While ANGPT1 permits maturation or stabilization of blood vessels through TIE2, ANGPT2 blocks this pathway causing remodeling of vascular sprouts subsequent to exposure to VEGF^[149]. High serum levels of ANGPT2 have been related to poor response to bevacizumab treatment^[150], suggesting that ANGPT2 has a critical role in the resistance mechanism against anti-VEGF therapy^[151].

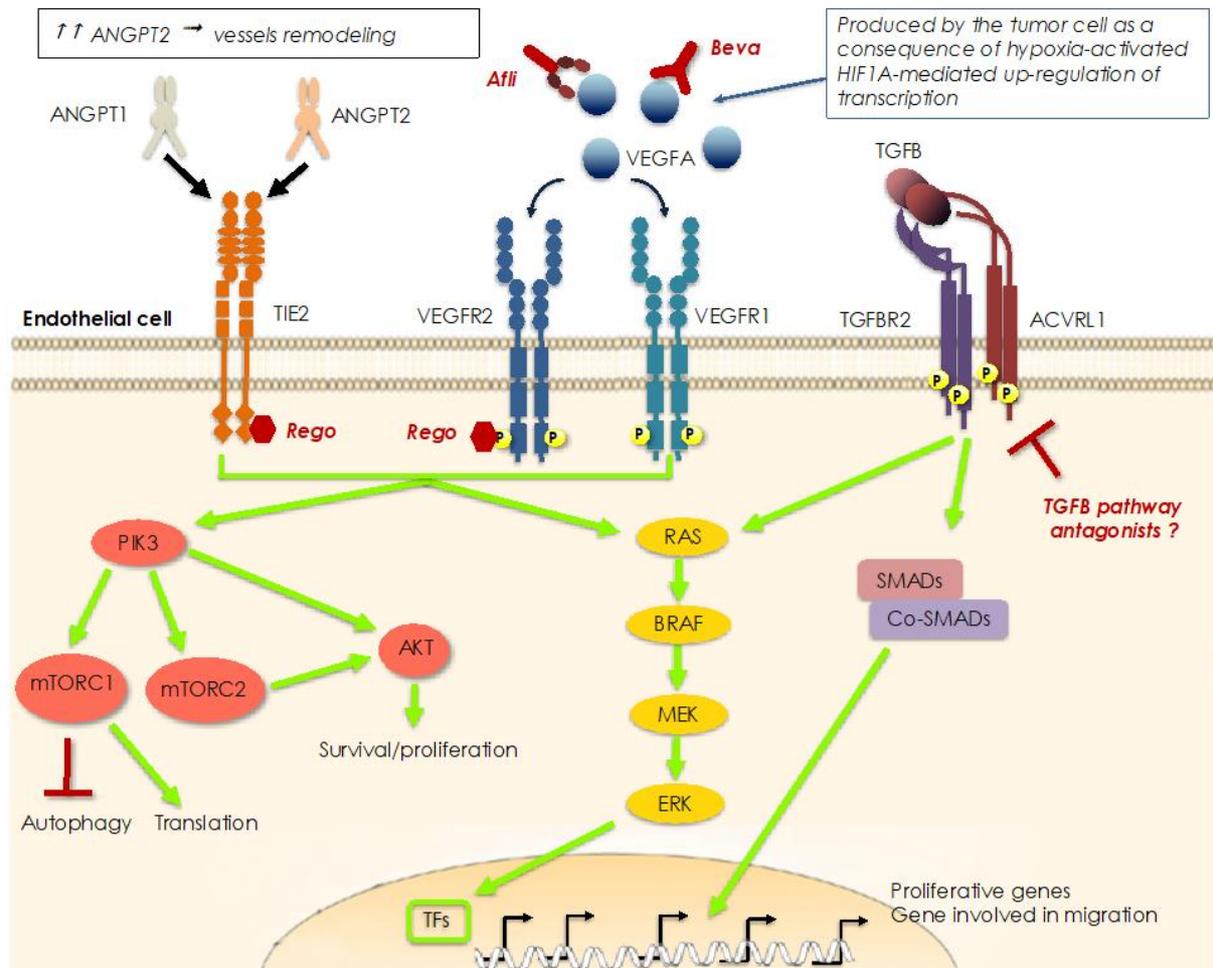

Figure 3. Mechanisms of resistance to anti-angiogenic therapy. Hyperproduction of VEGFA is a consequence of the hypoxic status in the center of the tumor which activates HIF1A, a transcription factor that regulates VEGFA transcription. Overproduction of VEGFA can be blocked by monoclonal antibodies (bevacizumab, Beva) or a VEGF-trap (aflibercept, Afli). Alternatively, the signal can be blocked downstream of the dedicated receptor by small kinase inhibitors like regorafenib (Rego), which can also inhibit the TIE2 receptor, thus imposing a double anti-angiogenic blockade. In fact, both receptors are critical in stimulating the proliferation and migration of the endothelial cells, necessary for the formation of new vessels into and around the tumor mass. In particular, TIE2 receptor is regulated by ANGPT1 and 2, the former inducing signals involved in maturation and stabilization of blood vessels, whereas the latter blocks this signaling and triggers remodeling of vascular sprouts. Overproduction of ANGPT2 can drive a parallel neo-angiogenic signaling when VEGFR-driven signaling is impeded by Beva-based therapy. In addition, another parallel neo-angiogenic pathway that can act as an escape route to VEGFA blockade is initiated by TGFβ binding to a multimeric receptor formed by a TGFβ2 dimer in complex with an activin receptor-like kinase 1 (ACVRL1) dimer.

In preclinical models, the double block of VEGF and ANGPT2 inhibited revascularization and tumor progression of tumors resistant to anti-VEGF therapy^[152,153]. Finally, cytokines have also been involved in mediating resistance to anti-angiogenic therapy. IL-17 and its downstream factor, granulocyte colony-stimulating factor (G-CSF), are the leading players of inflammation; it has been reported that a high level of IL-17 induces cells to produce a paracrine network that confers resistance to anti-VEGF therapy. Serum G-CSF levels in CRC patients are higher than those in healthy volunteers and are associated with the stage of tumor progression^[154,155].

Interestingly, a novel anti-angiogenic approach that might help in circumventing resistance to anti-angiogenic therapies could be represented by metronomic chemotherapy, a schedule where low doses of chemotherapy are administered chronically. In fact, several studies demonstrated that the administration of 5-FU under metronomic chemotherapy schedule induces an antiangiogenic effect behind the cytotoxic effect^[156]. In addition, it has been reported a reasonable disease control with minimal side effects and good quality of life in elderly or heavily pre-treated patients under metronomic chemotherapy schedule. Moreover, a phase III randomized trial has shown that maintenance therapy with metronomic capecitabine plus bevacizumab following cycles of conventional treatment with capecitabine + oxaliplatin + bevacizumab significantly improved PFS compared to the observation group with no worsening of quality of life^[157].

Resistance to immune checkpoint inhibitors

Compared to pMMR/microsatellite stable CRCs, dMMR/MSI-H CRCs - because of the defects in repairing DNA damage/insertion of microsatellites - present a high mutation burden and produce a plethora of immunogenic neoantigens on the MHC, thus recruiting more tumor infiltrating lymphocytes. However, dMMR/MSI-H CRCs also highly upregulate the expression of immune checkpoints - (i.e., PD-1 ligands, CTLA-4 ligand, LAG-3, and IDO1) that account for the suppression of an active immune response despite the high tumor infiltrating lymphocyte count [Figure 4]^[158]. Because of this scenario dMMR/MSI-H CRCs have been shown to be sensitive to treatment with ICIs in several phase 2 trials^[84,158-160]. Notably, the KEYNOTE-177 phase 3 trial compared the effect of anti-PD-1 pembrolizumab vs. SOC chemotherapy given as a first line therapy. A significant clinical benefit of pembrolizumab resulting in the doubling of PSF was evident and 83% of pembrolizumab responders were still responding after 2 years or longer, compared to the 35% of the chemotherapy responder. However, 30% of pembrolizumab-treated patients had primary resistance^[161] indicating that additional therapeutic strategies are needed in the field of immunotherapy. Interestingly, Checkmate-142 phase 2 clinical trial reported that a double targeting strategy given as a first-line therapy led to significant and clinically meaningful improvements in patients' outcomes. Specifically, anti-PD-1 nivolumab was administered together with anti-CTLA4 ipilimumab, and the PSF rate at 12-month was 77% compared to 55% reported with single PD-1 blockade in the KEYNOTE-177 study^[84]. At variance with patients with dMMR/MSI-H CRC those with microsatellite stable mCRC had very limited clinical benefit when receiving the combination with CTLA-4 and PD-L1 inhibitors^[160]. Given that about 95% of mCRC cases are pMMR/microsatellite stable tumors and resistant to ICIs, several efforts are focused on the understanding of the mechanisms of resistance to immunotherapy for the development of new therapeutic approaches. Notably, another promising inhibitor to be added to the combination of ICIs is relatlimab, a monoclonal antibody that binds to LAG-3, a checkpoint molecule that functions to negatively regulate homeostasis of T- and B-cells and NK cells^[162]. So far, it has been tested in clinical trials for treating melanomas and, interestingly, in a phase 3 trial in patients with newly diagnosed inoperable or metastatic melanomas, its combination with nivolumab doubled PSF^[162]. In addition, a newly characterized monoclonal anti-LAG-3 antibody resulted in a significant delay in tumor growth when combined with PD-1 blockade in mice transplanted with colorectal cancer cells^[163]. These results suggest that the addition of anti-LAG-3 monoclonal antibodies might improve the response to currently used ICIs also in CRC. Finally, a brief mention about IDO1 inhibitors is due, given that this enzyme is overexpressed in CRC tissues. IDO1 catalyzes the oxidative cleavage of tryptophan to kynurein, a metabolite responsible for an immunosuppressive environment via the blockade of the activation of effector cells and the stimulation of immunosuppressive cells^[164]. In particular, high levels of kynurein have been shown to predict resistance to PD-1 blockade and OS upon administration of nivolumab in advanced melanoma and renal cell carcinoma patients. Remarkably, in preclinical models IDO inhibitors had negligible effect when used alone but resulted synergic with anti-CTL-A4 and anti-PD-1 therapies in controlling cancer burden and favoring mice survival^[165]. Therefore, different inhibitors are currently being studied in several tumor types as co-administered with anti-PD-1 antibodies (i.e., nivolumab or pembrolizumab) or anti-PD-L1 antibodies (i.e.,

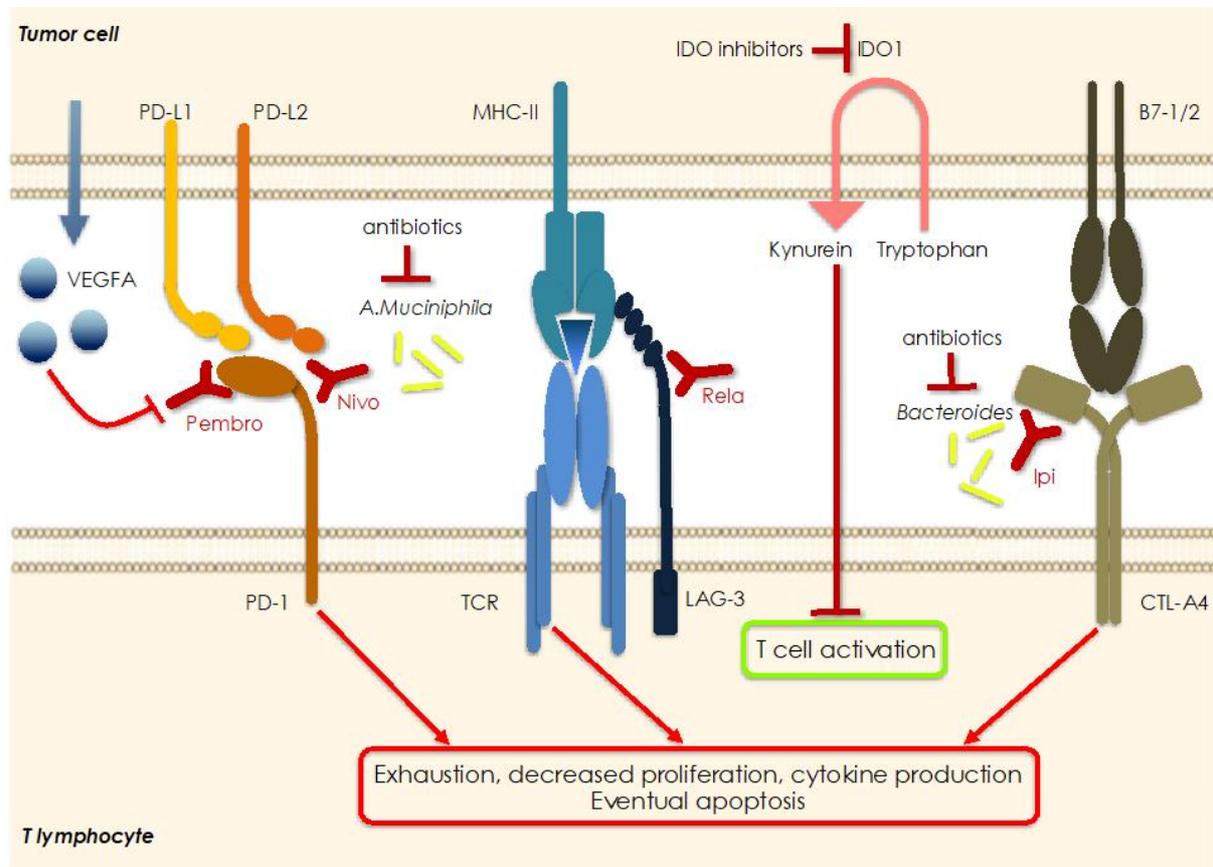

Figure 4. Mechanisms of resistance to immuno-therapy. Cancer cells can express several immunosuppressive molecules that can be blocked using specific inhibitors in order to re-activate the anti-tumor immune response. Often, they are redundant so that the re-activation of one pathway may be compensated by hyperactivation of a different immunosuppressive route so that resistance to therapy is the result. Resistance to anti-PD1 blockade may be due to overproduction and release of VEGFA, as well as by overexpression of IDO1 with consequent increased levels of kynurein in the microenvironment. Specific components of the microbiota are also necessary for the successful blockade of PD-1 and CTLA-4 indicating that antibiotics may represent a resistance factor to ICIs. Pembro: Pembrolizumab; Nivo: nivolumab; Rela: relatlimab; Ipi: ipilimumab; IDO1: indoleamine 2, 3-dioxygenase 1.

atezolizumab or durvalumab)^[166] and the same approach is to be envisaged for ICIs-resistant CRCs.

An immunosuppressive role has been reported for VEGF, which can act via different mechanisms such as by decreasing the number of TILs and activating immune checkpoint molecules^[167]. Notably, in a CRC mouse model it has been reported that addition of anti-angiogenic therapy reduced intrinsic resistance to an anti-PD-1 antibody via normalizing tumor vascularization and reducing hypoxia^[168]. Several trials are ongoing to evaluate the efficacy of combining ICIs with an anti-angiogenic strategy plus chemotherapy, being the molecules tested bevacizumab and regorafenib.

Recently, several studies have shown that the gut microbiota plays a key role in regulating the efficacy of ICIs for cancer treatment of different solid tumors [Table 3, Figure 4]^[169]. For example, the treatment with an anti-CTLA-4 monoclonal antibody controlled the growth of different tumor models (including a CRC model) in mice maintained in specific pathogen-free conditions and in the presence of specific *Bacteroides*, but not in germ-free mice and mice previously treated with antibiotics. Therefore, it appears that the gut microbiota might regulate the efficacy of immunotherapy with anti-CTLA-4. Accordingly, the introduction

of two specific *Bacteroides* species (i.e., *B. thetaiotaomicron* and *B. fragilis*) in germ-free mice and antibiotics-treated mice restored the response to anti-CTLA-4 treatment^[170]. Notably, a series of studies in melanoma mouse models and patients uncovered other microbiota components as instrumental in determining the response to ICIs. For example, in a melanoma mouse model the addition of the commensal gut *Bifidobacterium* to PD-L1 checkpoint blockade nearly abolished the growth of scarcely sensitive tumors^[171]. Comparative analysis of the oral and gut microbiome of melanoma patients undergoing anti-PD-1 immunotherapy revealed significant differences in the diversity and composition of the microbiome of responders vs. non-responders. Similarly, the analysis of patient fecal microbiome samples showed significant diversity and relative abundance of bacteria of the Ruminococcaceae family in responding patients^[172]. Analysis of baseline stool samples from metastatic melanoma patients before immunotherapy uncovered significant association between commensal microbial composition and clinical response. Bacterial species more abundant in responders included *Bifidobacterium longum*, *Collinsella aerofaciens*, and *Enterococcus faecium*. Accordingly, in a mouse model fecal microbiota transplantation from responding patients in germ-free mice improved tumor control, augmented T cell responses, and increased efficacy of anti-PD-L1 therapy^[173]. Routy et al.^[174] showed that fecal microbiota transplantation from cancer patients who responded to ICIs into germ-free or antibiotic-treated mice improved the efficacy of anti-PD-1 therapy, whereas fecal microbiota transplantation from non-responding patients was ineffective. Profiling patients' stool samples revealed low levels of the bacterium *Akkermansia muciniphila* in non-responding patients with lung and kidney cancer. Accordingly, oral supplementation of the bacteria after fecal microbiota transplantation with non-responders feces in antibiotic-treated mice restored the response to PD-1 blockade^[174]. Regulation of gut microbiota composition or addition of the "right" bacteria to therapy seems therefore a very promising approach to overcome resistance, or at least significantly improve the response to ICIs.

CONCLUSION

Intrinsic and acquired resistance to chemo-, targeted, and immune-therapy remain the core problem(s) to tackle for ameliorating the outcome of CRC patients, especially in the metastatic setting. Significant improvements and longer expectancy of life have been reached using a combination/integration of the different types of therapy, but only the identification of additional targetable liabilities to be exploited in specific settings will allow to concomitantly attack the tumor from different angles, hopefully leading to its eradication. In this sense, promising approaches are: the development of novel nanoparticles able to vehicle chemotherapy directly inside the cells avoiding the intake/efflux systems, often deregulated in resistant cells; the induction of synthetic lethality via the use of inhibitors of specific DNA damage checkpoints or DNA repair enzymes in tumors presenting defects in the DNA repair mechanisms; the use of BH-3 mimetics in tumors highly expressing anti-apoptotic members of the BCL2 family; the targeting of several kinases shown to sustain resistance to classic chemotherapy and also resistance to target therapy via activation of feed-back loops; the targeting of pathways crucial for cancer stem cells maintenance and viability; the targeting of several components of the TME, recognized to be responsible for an immune-privileged environment, among which the so-called immune checkpoints; and the modulation of the microbiota. For the most of these approaches an unavoidable task will be patient stratification according to specific biomarkers and/or genetic defects, indicating that precision medicine is the ultimate path to cover in order to identify effective therapies for each patient. In addition, given the high tumoral heterogeneity and the Darwinian pressure exerted by anti-cancer treatments, to prevent and/or overcome resistance it will be also essential to combine different types of therapies and using vertical approaches to target multiple nodes along the same pathway.

Abstract

Epigenetic mechanisms play an important role in the development and persistence of cancer, and histone deacetylase (HDAC) inhibitors are promising anticancer drugs targeting epigenetic modes. Efficient anticancer drugs for the treatment of castration-resistant prostate cancer (CRPC) are sought, and approved HDAC inhibitors have shown promising results on the one hand and severe drawbacks on the other hand. Hence, ways to break the drug resistance mechanisms of existing HDAC inhibitors as well as the design of new promising HDAC inhibitors which can overcome the disadvantages of the classic HDAC inhibitors are of great importance. In this work, HDAC inhibitors with the potential to become a mainstay for the treatment of CRPC in the future as well as suitable combination treatments of HDAC inhibitors with other anticancer drugs leading to considerable synergistic effects in treated CRPCs are discussed.

Keywords: Histone deacetylases, HDAC inhibitors, castration-resistant prostate cancer, drug resistance

INTRODUCTION

More than 1.2 million new cases of prostate cancer cases are reported per year worldwide (2018) rendering prostate cancer the second most diagnosed cancer in men along with a rising incidence over the last years^[1]. The formation of metastases dramatically reduces the survival rates in prostate cancer patients^[2]. Advanced

forms of prostate cancer are commonly treated by hormone therapy, either by surgical castration or by chemotherapy targeting hormone release^[3]. However, patients develop castration-resistant prostate cancer (CRPC) forms within a median time of two years after treatment, which pose a life-threatening danger to affected patients with distinctly poorer prognosis^[4]. CRPC can occur in metastatic (mCRPC) and non-metastatic (MoCRPC) forms. Clinical trials using anti-androgen therapies with drugs such as apalutamide, enzalutamide, or darolutamide showed promising outcomes and significantly prolonged metastasis-free survival in MoCRPC patients^[5-7]. Treatment options for mCRPC patients include taxanes such as docetaxel and cabazitaxel as well as various anti-androgens (bicalutamide and enzalutamide)^[8]. The development of the selective CYP17 inhibitor abiraterone and its prodrug abiraterone acetate, specifically blocking androgen synthesis and androgen receptors via CYP17 enzyme inhibition, has led to another valuable first-line treatment option for mCRPC patients^[9].

Chromatin remodeling is a crucial mechanism in proliferating cells and affects transcription, replication, and DNA repair processes. The nucleosome is the basic unit of chromatin and consists of the positively charged histone core octamer proteins (H2A, H2B, H3, and H4, each twice per octamer) wrapped by DNA of 147 base pairs and one attached H1 histone^[10,11]. *N*-terminal lysines of the histones are crucial for their DNA interaction, and the charge of these lysines is regulated by cellular *N*-acetylation processes. Acetylation of histones reduces their interaction with DNA leading to chromatin decondensation and gene transcription, while histone deacetylation silences gene expression in the densely packed chromatin^[12]. Histone modifying enzymes such as histone acetyl transferases (HATs), which catalyze lysine acetylation, and histone deacetylases (HDACs), which catalyze the removal of acetyl groups from target protein lysines, play an eminent role in these processes and, in particular, inhibitors of HDACs were developed as anticancer agents^[13]. The scope of HDAC inhibitors is promising since they also affect the acetylation state of non-histone proteins, such as p53, Hsp90, STAT3, and NF- κ B, and regulate the stability and/or DNA binding properties of these non-histones in this way with significant effects on, for instance, gene transcription, cell division, signal transduction, DNA repair, and apoptosis induction^[14,15]. In terms of HDACs and prostate cancers, the HDAC-based regulation of the androgen receptor (AR) via the acetylation state of Hsp90 is especially interesting and of high relevance for the design of HDAC inhibitor-based prostate cancer therapies for patients with poor prognosis (see below)^[15,16]. *N*-Methylation of lysines is another regulatory modification of histones controlled by lysine demethylases (KDMs), which can have silencing and activating effects on gene transcription in cancers^[17]. KDMA1 (LSD1) has oncogenic functions in prostate cancers by AR co-activation, suppression of p53, and activation of c-Myc expression, and the development of KDM inhibitors as anticancer agents (e.g., cyclopropylamines) paves the way to promising epigenetic treatment options. The combination of KDM1A and HDAC inhibitors showed synergistic effects on glioblastoma cells^[17]. The HDAC inhibitor vorinostat also inhibited EZ2H and H3K4 demethylases in the micromolar concentration range^[17-19].

A few HDAC inhibitors have already reached clinical application and are used for the treatment of multiple myeloma (panobinostat) and T-cell lymphoma (vorinostat, romidepsin, and belinostat); however, the performance of these first-generation HDAC inhibitors in solid tumors is rather poor^[20]. Nevertheless, HDACs can be suitable anti-prostate cancer drug targets. HDAC1, for instance, was found to be upregulated in hormone refractory prostate cancer^[21]. HDAC1, -2, and -3 expression was associated with Ki-67-positive prostate cancer cell fractions, and high HDAC2 levels were detected in patients with reduced disease-free survival^[22]. HDACs are necessary for functional AR signaling in prostate cancers, and HDAC inhibitors such as vorinostat and panobinostat blocked AR function by reducing AR expression and inhibiting coactivator/RNA polymerase II complex formation after AR binding to its DNA target element^[23]. Resistance mechanisms of prostate cancers to HDAC inhibitor treatment comprise the

upregulation of detoxifying P-glycoprotein (P-gp) transporters, increased expression of HDAC enzymes, suppression of HAT enzymes, and upregulation of tumorigenic p21 (p21 is usually a tumor suppressor, but oncogenic functions of p21 were reported upon HDAC treatment)^[24]. HDAC inhibitors also induced epithelial-to-mesenchymal transition (EMT) in prostate cancers, which might be another reason for the drawbacks of HDAC inhibitors in solid tumors^[25].

HDAC enzymes can be subdivided into four classes. Classes I (HDAC1, -2, -3, -8), IIa (HDAC4, -5, -7, and -9), IIb (HDAC6 and -10), and IV (HDAC11) are metal-dependent with a catalytic zinc ion in the active site, while Class III HDACs (sirtuins) are not dependent on metals^[26,27]. Due to the catalytic zinc ion of Class I, II, and IV HDACs, many HDAC inhibitors have a molecular zinc-binding group (ZBG) such as carboxylates, hydroxamic acids, benzamides, substituted ketones, mercaptoacetamides, or depsipeptides^[28]. The modular composition of most HDAC inhibitors comprising a ZBG and a capping group connected by a linker allows the fine-tuning of HDAC inhibitors in terms of pharmacokinetics and anticancer activity^[28]. Several dual or multimodal HDAC inhibitors have been reported, which showed improved anticancer activities especially against solid tumors^[29,30]. This development is still ongoing and offers interesting compounds for the treatment of drug-resistant CRPC where first-generation HDAC inhibitors failed to perform.

This review provides the current state of the art of HDAC inhibitors under investigation in CRPCs and the potential of HDAC inhibitors to overcome drug resistance in this severe cancer form. A focus is set on next generation HDAC inhibitors with improved biological properties.

HDAC INHIBITORS IN CRPC CLINICAL TRIALS

Several clinical trials with HDAC inhibitors were carried out to monitor advantages and problems of the usage of HDAC inhibitors in the clinics. The clinical trials of HDAC inhibitors for the treatment of castration-resistant prostate cancer diseases were recently reviewed, and only the main outcomes are summarized in [Table 1](#) and [Figure 1](#)^[24,31].

The depsipeptide romidepsin underwent a phase 2 clinical trial with 35 CRPC patients. Intravenous romidepsin treatment (13 mg/m²) led to radiological partial response in two patients and stable disease in 11 patients, while 22 patients showed progressive disease. Although no grade 4 toxicities were observed, 11 patients had to abandon the trial early, and, thus, romidepsin was not recommended for further phase 3 trials for CRPC^[32].

The hydroxamic acid vorinostat (400 mg/day, p.o.) showed drug-induced toxicities in 11 out of 27 CRPC patients during a phase 2 trial, who had to be removed from the study, while its anticancer activity was poor: only 2 patients had stable disease and 13 patients showed disease progression^[33]. It seems that high IL-6 levels contributed to the failure of vorinostat in the patients with progressive CRPC disease.

Similar to romidepsin, the hydroxamate derivative panobinostat underwent a phase 2 trial with 35 CRPC patients. Intravenous panobinostat administration (20 mg/m²) led to PSA (prostate-specific antigen) reduction in only 14% of the patients and disease progression in 29 out of 35 patients^[34]. A phase 1 study of orally administered panobinostat compared with oral panobinostat in combination with docetaxel and prednisone showed only PSA reduction effects in five out of eight CRPC patients of the combination arm of the trial^[35]. The oral panobinostat monotherapy showed no effects, and, thus, future studies should include combination therapies with suitable anticancer drugs. A combination study with oral panobinostat and bicalutamide (phase 1/2 trial) in nine CRPC patients led to stable PSA levels in three patients and to PSA

Table 1. CRPC clinical trials of HDAC inhibitors

Drug(s)	Trial	n	Dosage	Outcome
Romidepsin ^[32]	Phase 2	35	30 mg/m ² (i.v.)	PR = 2; SD = 11; PD = 22
Vorinostat ^[33]	Phase 2	27	400 mg/day (p.o.)	SD = 2; PD = 13
Panobinostat ^[34]	Phase 2	35	20 mg/m ² (i.v.)	SD = 4; PSA reduction = 5; PD = 29
Panobinostat (+ Docetaxel and Prednisone) ^[35]	Phase 1	8	15 or 20 mg 3× per week (p.o.)	PSA reduction = 5
Panobinostat (+ Bicalutamide) ^[36]	Phase 1	9	60, 90, or 120 mg/week (p.o.)	Stable PSA = 3; PSA reduction = 4
Panobinostat (+ Bicalutamide) ^[37]	Phase 2	29	40 mg triweekly for 2 weeks (p.o.)	rPF = 47.5%; median time to rP = 33.9 weeks
Pracinostat ^[38]	Phase 2	32	60 mg, 3× per week (p.o.)	SD = 7; PSA reduction = 2

PR: Partial response; SD: stable disease; PD: progressing disease; PSA: prostate-specific antigen; rP: radiographic progression; rPF: radiographic progression-free.

reduction of more than 50% in two patients^[36]. The phase 2 trial of oral panobinostat (40 mg triweekly for two weeks) with oral bicalutamide showed promising results in CRPC patients, who were resistant to second-line antiandrogen therapy (2ndLAARx)^[37]. This combination treatment was well tolerated and led to a distinct number of radiographic progression-free patients (47.5%) and prolonged median time to radiographic progression (rP) in treated CRPC patients (33.9 weeks). In addition, five patients showed PSA decline of more than 30%. The results indicate that panobinostat plus bicalutamide overcomes androgen resistance in a considerable number of CRPC patients. It is remarkable that panobinostat was less toxic to patients than other HDAC inhibitors such as romidepsin and vorinostat.

Pracinostat, which has received orphan drug status by the FDA for the treatment of AML, was also studied in a clinical phase 2 trial with 32 CRPC patients. Although only two patients displayed PSA reductions of more than 50%, the drug (60 mg, 3× per week, p.o.) was well tolerated, led to stable disease in 22% of the patients, and reduced the number of circulating tumor cells in nine patients^[38].

In brief, the cinnamoyl derivatives panobinostat and pracinostat showed improved toxicity profiles and led to certain antitumor responses in CRPC patients, in particular, when combined with other drugs such as docetaxel or bicalutamide (in the case of panobinostat). In contrast, vorinostat and romidepsin showed drug-induced toxicities in a considerable number of patients who had to stop treatment with these drugs because of them. The relatively meager responses caused by the mentioned first-generation HDAC inhibitors in CRPC patients when applied as a monotherapy is the reason why no phase 3 studies in CRPC patients have been completed for these drugs until today.

STRATEGIES TO IMPROVE HDAC INHIBITOR ACTIVITIES IN CRPC

To overcome the clinical drawbacks of the first-generation HDAC inhibitors, a thorough elucidation of HDAC inhibitor mechanisms apart from or in consequence of HDAC inhibition is necessary, in particular, in combination with other anticancer drugs. In addition, the development of new tuned HDAC inhibitors appears to be promising in terms of improved clinical outcome. The most relevant research outcomes are provided below.

HDAC inhibitor mechanisms beyond HDAC

HDAC inhibition can lead to certain downstream effects in prostate cancer cells [Figure 2, Table 2]. The chemical structures of the investigated compounds are shown in Figure 1. The endogenous HDAC1 inhibitor protein maspin (mammary serine protease inhibitor), which was induced by the HDAC inhibitor

Table 2. HDAC inhibitor effects beyond HDAC inhibition in prostate cancers

HDAC inhibitor	Effect(s)	Cell lines/tumor models
Belinostat ^[41]	Hsp90, AR, and GSK-3 β suppression	LNCaP, C4-2B, 22Rv1
Dacinostat ^[42]	AR degradation by high acetyl-Hsp90, Akt inactivation	LNCaP
Entinostat ^[39]	AR suppression, enzalutamide sensitization	LNCaP, 22Rv1
Entinostat ^[43]	IFN γ production, suppressed Foxp3, upregulated acetyl-STAT3, increased survivin vaccine activity	CR Myc-CaP
Panobinostat ^[46]	HMGA2 suppression, EMT formation, increase of acetyl-p53 and acetyl-AR	PKV, MES-like cells/tumors
Trichostatin A ^[44]	Upregulated FGF8 and NF- κ B	PC3M
Trichostatin A and sodium butyrate ^[47]	Upregulated CD133	Prostate cancer derived primary endothelial cultures

Hsp90: Heat shock protein 90; AR: androgen receptor; IFN γ : interferon- γ ; STAT3: signal transducer and activator of transcription 3; CR: castration-resistant; HMGA2: high mobility group AT-hook 2; EMT: epithelial-to-mesenchymal transition; MES: mesenchymal; PC3M: metastatic PC3 cells; PKV: *Pten*^{L/L}, *Kras*^{G12D/+}, *Vim-GFP*.

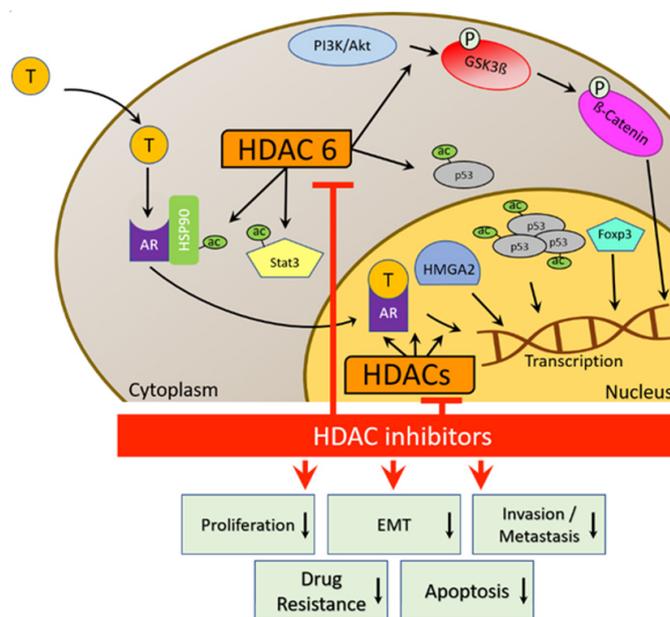

Figure 2. HDAC network and cellular effects of HDAC inhibitors in CRPC. HDAC: Histone deacetylase; HDACi: HDAC inhibitor; T: testosterone; Hsp90: heat shock protein 90; AR: androgen receptor; STAT3: signal transducer and activator of transcription 3; HMGA2: high mobility group AT-hook 2; EMT: epithelial-to-mesenchymal transition.

protein AR in LNCaP prostate cancer cells by an increase of acetylated Hsp90 levels accompanied by Hsp90-AR dissociation and AR decomposition^[42].

Dacinostat also inactivated Akt by disruption of HDAC-PP1 (protein phosphatase 1) complexes, leading to the dephosphorylation of Akt proteins in PC3 prostate cancer cells^[42]. Consequently, factors associated with Akt signaling were regulated by HDAC inhibitors. The Class I HDAC inhibitor entinostat (5 mg/kg/day, 5 days per week, p.o.) augmented distinctly the anticancer activity of the survivin peptide vaccine SurVaxM as well as IFN γ (interferon- γ) production in Myc-expressing CRPC mouse models (CR Myc-CaP). Entinostat upregulated acetyl-STAT3 accompanied by suppression of Foxp3 in cancer cells, which was suggested as its possible mode of action^[43]. As part of its hormone-independent prostate cancer promoting effect, the natural HDAC inhibitor trichostatin A (TSA) increased the transcriptional activity of NF- κ B in PC3M

prostate cancer cells associated with upregulation of fibroblast growth factor FGF8^[44]. Thus, NF- κ B suppressing agents might be promising combination partners of entinostat in terms of CRPC eradication. The PI3K/Akt signaling pathway is also involved in EMT induction^[45]. EMT processes upregulate HMGA2. HMGA2 is a protein crucial for the regulation of gene expression by binding to AT-rich regions of DNA, which is the site where a replication complex is formed and the DNA synthesis is initiated. Interestingly, panobinostat was shown to suppress HMGA2 associated with reduced EMT formation and cell stemness. In addition, panobinostat increased the acetyl-p53 and acetyl-AR levels and prevented mCRPC formation *in vivo* at a dose of 10 mg/kg for five days per week^[46]. In terms of cancer stem cell markers, the HDAC inhibitors TSA and sodium butyrate upregulated the expression of the surface stem cell marker CD133 in prostate cancer derived primary epithelial cultures, which was based on chromatin relaxation leading to gene expression^[47].

Promising combinations of HDAC inhibitors with anticancer drugs

The detailed knowledge of the mechanisms of action of HDAC inhibitors in prostate cancers can be applied for combination therapies together with other suitable drugs against prostate cancer to achieve improved anticancer responses [Table 3, Figures 1 and 3]. DNA-based mechanisms appear to be promising drug targets for combination partners of HDAC inhibitors. Inhibition of DNA methylation was positively correlated with HDAC inhibition and sodium butyrate in combination with the DNA methyltransferase inhibitor 5-aza-2'-deoxycytidine significantly enhanced histone H4 acetylation and induced AR gene re-expression in androgen-independent DU145 prostate cancer cells. Moreover, it led to G2/M cell cycle arrest and reduced toxicity to non-malignant cells^[48]. More recently, panobinostat was investigated in combination with the DNA methylation inhibitor hydralazine in various prostate cancer cells. The combination therapy was particularly active against androgen-independent DU145 prostate cancer cells, induced apoptosis, and reduced colony formation, invasion, and migration^[49]. Hence, the combination of panobinostat with hydralazine has the potential to block prostate cancer progression and might be a suitable therapy in future clinical studies.

Poly-ADP-ribosylpolymerase (PARP) is an enzyme involved in DNA repair. And the PARP inhibitor olaparib performed well in advanced clinical trials with CRPC patients who have a BRCA mutation, which led to the approval of olaparib for the treatment of BRCA-mutant prostate cancer^[50,51]. The combination of vorinostat with olaparib synergistically reduced prostate cancer cell viability, induced apoptosis in DU145 and PC3 prostate carcinoma cells, and suppressed DNA repair as well as DNA repair protein expression (BRCA1 and RAD51) in DU145 cells^[52]. The combination of vorinostat with the PARP inhibitor veliparib also revealed synergistic effects on prostate cancer cell viability (in particular, on the viability of BRCA1-mutant DU145 cells), apoptosis induction, DNA damage production, and BRCA1 suppression. The vorinostat/veliparib combination therapy suppressed BRCA1 by downregulation of the UHRF1 protein, which forms a stable DNA repair protein complex with BRCA1, and suppression of UHRF1 led to degradation of BRCA1^[53]. Thus, the combination of vorinostat with PARP inhibitors such as olaparib and veliparib appears to be a promising combination therapy for future clinical trials with CRPC patients.

Vorinostat was also studied in combination with the microtubule-stabilizing anticancer taxane drug docetaxel, and the combination showed synergistic growth inhibitory effects on 22Rv1 and VCaP CRPC cells. This combination therapy suppressed AR and Bcl-2 expression, AR translocation into the prostate cancer cell nucleus, and AR signaling. The reduced accumulation of the AR in the nucleus was based on increased acetylation and bundling of tubulin in cells treated with the HDAC inhibitor vorinostat and the microtubule stabilizer docetaxel^[54]. Another study targeting AR signaling comprised the combination treatment of androgen-acclimated DuCaP-N prostate cancer cells with the HDAC inhibitor TSA, the anti-androgen bicalutamide, and the 5 α -reductase inhibitor finasteride. The combination of TSA with

Table 3. HDAC inhibitors in combination with other drugs against CRPC

HDAC inhibitor	Combination partner (function)	Outcome
Sodium butyrate ^[48]	5-Aza-2'-deoxycytidine (DNA methyltransferase inhibitor)	Enhanced histone H4 acetylation, induced AR gene re-expression, G2/M cell cycle arrest, reduced non-malignant cell toxicity
Panobinostat ^[49]	Hydralazine (DNA methylation inhibitor)	induced apoptosis, reduced colony formation, invasion, and migration
Vorinostat ^[52]	Olaparib (PARP inhibitor)	Synergistic reduction of cell viability, induced apoptosis, suppressed DNA repair, BRCA1 and RAD51 expression downregulated
Vorinostat ^[53]	Veliparib (PARP inhibitor)	Synergistic effects on cell viability (BRCA1-mutant DU145), apoptosis induction, DNA damage production, BRCA1 suppression/degradation, suppressed UHRF1
Vorinostat ^[54]	Docetaxel (microtubules stabilizer)	Increased tubulin acetylation and bundling, suppressed AR and Bcl-2 expression, suppressed nuclear AR translocation and AR signaling
Trichostatin A ^[55]	Bicalutamide (anti-androgen) and finasteride (5 α -reductase inhibitor)	Synergistic apoptosis induction
Panobinostat ^[57]	Dovitinib (multi-RTK inhibitor)	No improved effects
Ricolinostat ^[58]	Selumetinib (MEK inhibitor) and paclitaxel (microtubules stabilizer)	Synergistic growth inhibition and apoptosis induction, suppression of KLK2 and DUSP1, increased AR accumulation in cytoplasm
Valproic acid ^[62-64]	Everolimus (mTOR inhibitor) and IFN α	Increased cell growth inhibition, suppression of EGFR (epidermal growth factor receptor), ERK1, and ERK2, increased acetyl-H3
Panobinostat ^[67]	Everolimus (mTOR inhibitor)	Myc-CaP cell growth inhibition, suppressed clonogenic survival and G0/G1 cell cycle arrest, increased p21 and p27 expression; <i>in vivo</i> suppression of tumor growth, AR, HIF-1 α , miR-20a, miR-21
Romidepsin, Entinostat ^[70]	Adenoviral TRAIL gene therapy	Restored CAR surface expression, augmented TRAIL-mediated caspase activity

PARP: Poly-ADP-ribosyl-polymerase; RTK: receptor tyrosine kinase; MEK: MAPK/ERK kinase; IFN α : interferon- α ; mTOR: mammalian target of rapamycin; EGFR: epidermal growth factor receptor; ERK: extracellular signal-regulated kinase; HIF: hypoxia inducible factor; miR: microRNA; CAR: coxsackie adenovirus receptor; TRAIL: TNF-related apoptosis-inducing ligand.

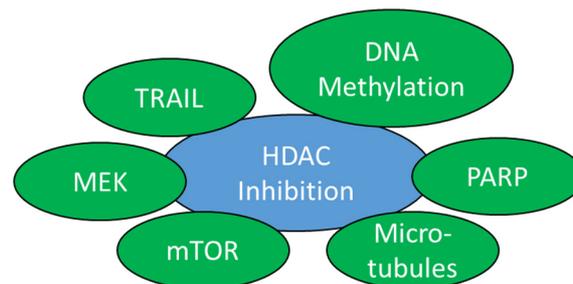

Figure 3. Suitable targets for combination therapies with HDAC inhibitors in CRPC. HDAC: Histone deacetylase; CRPC: castration-resistant prostate cancer; MEK: MAPK/ERK kinase; TRAIL: TNF-related apoptosis-inducing ligand.

bicalutamide and finasteride led to synergistic apoptosis induction in the DuCaP-N cells^[55].

Protein kinases are valuable targets for new anticancer drugs. Enhanced receptor tyrosine kinase (RTK) signaling was observed in advanced prostate cancers and appeared as a suitable drug target for targeted therapies^[56]. Thus, the combination of HDAC inhibitors with TK inhibitors seems to be reasonable. However, the combination of the multi-RTK inhibitor dovitinib (TKI258) with panobinostat did not show improved anticancer effects on prostate cancer cells since dovitinib appeared to be particularly inactive in the tested prostate cancer cells^[57]. MAPK/ERK kinase (MEK, a serine/threonine/tyrosine kinase) inhibitors suppress the Ras-MAPK signaling pathway in cancers, and a series of anticancer active MEK inhibitors was developed^[58]. The MEK inhibitor selumetinib was studied in combination with the HDAC6 inhibitor ricolinostat in various CRPC cell lines (PC3, DU145, and 22Rv1). While the combination treatment revealed

synergistic effects in all three cell lines, 22Rv1 cells were particularly sensitive in terms of growth inhibition. A suppression of the AR target genes *KLK2* and *DUSP1* was observed in treated 22Rv1 cells as well as increased AR accumulation in the cytoplasm. Addition of the taxane paclitaxel to the ricolinostat/selumetinib combination led to synergistic growth inhibition and increased apoptosis induction in all three prostate cancer cell lines, which coincides well with the aforementioned anti-prostate cancer effects of the combined vorinostat/docetaxel treatment^[59].

Akt and its downstream factor mTOR (mammalian target of rapamycin) are well established anticancer targets of the phosphatidylinositol 3-kinase (PI3K) signaling pathway^[60]. Various mTOR inhibitors such as rapamycin, everolimus, and temsirolimus were developed and approved by the FDA^[61]. The anticancer activities comprising inhibition of prostate cancer cell growth, migration, and invasion of HDAC inhibitors such as valproic acid were increased when combined with everolimus^[62,63]. Furthermore, the activity of valproic acid plus everolimus was augmented by addition of low-dose interferon- α (IFN α), and this triple-drug therapy was superior to single-drug therapy in terms of prostate tumor cell growth inhibition and dissemination. Intracellular signaling of PC3 cells was downregulated based on suppression of EGFR (epidermal growth factor receptor), ERK1, and ERK2, while acetyl-H3 levels were increased in treated cells^[64]. Panobinostat was also studied in combination with everolimus in prostate cancer. For this reason, the *c-Myc* expressing Myc-CaP prostate cancer cell line was applied because *c-Myc* expression reduced the activity of the mTOR inhibitor rapamycin in prostate cancer^[65,66]. The combination of panobinostat with everolimus exhibited significant Myc-CaP cell growth inhibition, while the combined treatment of Myc-CaP cells at non-cytotoxic doses of 10 nM for each compound suppressed clonogenic survival and induced G0/G1 cell cycle arrest associated with increased expression of the cyclin-dependent kinase inhibitors p21 and p27. In addition, combined panobinostat (10 mg/kg, i.p.) and everolimus (10 mg/kg, p.o.) treatment for 15 days (QD \times 7 schedule) showed reduction of tumor proliferation and tumor volume in mice bearing androgen-sensitive as well as castration-resistant Myc-CaP tumors. The combination treatment blocked AR and HIF-1 α transcriptional activities both *in vitro* and *in vivo* and downregulated the oncogenic microRNAs (oncomirs) miR-20a and miR-21 *in vivo*, which were associated with AR/hypoxia and *c-Myc*/hypoxia signaling pathways^[67].

Virus therapies have become interesting tools for gene therapies of tumor diseases and adenoviral TRAIL gene therapy caused signs of apoptosis in the examined prostates of prostate cancer patients^[68]. Since gene suppression in cancer cells can be reversed by HDAC inhibitors, the combination of gene therapy with HDAC inhibitors seems to be feasible. The HDAC inhibitors romidepsin and MS-275 increased the effects of adenoviral TRAIL gene therapy on castration-sensitive LNCaP prostate cancer cells without toxicity to non-malignant prostate epithelial cells^[69]. Based on this finding, the combination of TRAIL gene therapy with romidepsin or MS-275 in C4-2B CRPC cells was studied. Decreased coxsackie and adenovirus receptor (CAR) expression was correlated with increased tumorigenicity and metastasis formation in the LNCaP-derived human prostate cancer subline C4-2B, however, both aforementioned HDAC inhibitors restored CAR surface expression and augmented TRAIL-mediated caspase activity based on enhanced adenoviral transduction efficacy when combined with TRAIL gene therapy^[70].

New HDAC inhibitors

Aside from combination of approved HDAC inhibitors with other anticancer drugs, the development of new HDAC inhibitors with improved anticancer properties turned out to be a reasonable strategy to tackle CRPC [Table 4, Figure 4].

Table 4. New HDAC inhibitors with promising anti-CRPC activities

Compd.	Structural motif(s)	<i>In vitro</i> activity	<i>In vivo</i> activity
CN133 ^[71]	Hydroxamic acid, adamantyl cap	Inhibition of HDAC1-3; 100 times more active than SAHA (22Rv1 cells), inhibition of cell migration, invasion and AR signaling	Tumor growth and weight reduction by 50% (22Rv1)
2-75 ^[74,75]	Hydroxamic acid, AR-targeting enzalutamide-type cap	HDAC inhibitory activity, induced p21, higher acetyl-tubulin levels (based on stronger HDAC6 inhibition) than SAHA, suppressed Hsp90 and AR/AR-V7	Improved long-term tumor growth inhibition, enhanced apoptosis, reduced nuclear AR accumulation (LNCaP)
CUDC-101 ^[77]	Hydroxamic acid, EGFR/HER2-targeting erlotinib-type anilinoquinazoline cap	Suppressed AR, AR-V7, and HER2	Significant tumor growth inhibition without weight loss (22Rv1)
3CIQuin-SAHA, 3BrQuin-SAHA ^[84]	Hydroxamic acid, EGFR-targeting gefitinib-type anilinoquinazoline cap	Higher antiproliferative activity than gefitinib (DU145 cells), HDAC inhibition, EGFR inhibition, mTOR suppression	-
CUDC-907 (fimepino-stat) ^[86]	Hydroxamic acid, PI3K-targeting thienopyrimidine cap	High growth inhibitory activity, inhibition of HDACs and PI3K, apoptosis induction, increased Bim, suppressed Mcl-1 and Bcl-xL, suppressed DNA repair and DNA damage response proteins (Wee1, CHK1, RRM1, and RRM2), suppressed c-Myc	Tumor growth inhibition by 60% without weight loss (LuCaP 35CR patient-derived mouse xenografts)

AR: Androgen receptor; EGFR: epidermal growth factor receptor; HER2: human epidermal growth factor receptor 2; mTOR: mammalian target of rapamycin; PI3K: phosphatidylinositol 3-kinase.

The adamantyl-capped HDAC inhibitor CN133 was superior to vorinostat in terms of Class I HDAC1, -2, and -3 inhibition (IC_{50} = 0.6, 2, and 0.3 nM for CN133; 4, 11, and 3 nM for vorinostat), while vorinostat was more active against HDAC6 (IC_{50} = 2 nM) than CN133 (IC_{50} = 4.1 nM). CN133 was 100 times higher antiproliferative (IC_{50} = 10 nM) in 22Rv1 CRPC cells than vorinostat (IC_{50} = 1 μ M). CN133 inhibited CRPC cell migration and invasion and suppressed AR signaling. Mice bearing 22Rv1 CRPC were treated with CN133 (1 mg/kg), which reduced tumor volume and tumor weight by 50% in comparison with placebo group mice^[71].

Hybrid molecules targeting two or more anticancer targets can possess higher anticancer activities accompanied by reduced drug-drug interactions and less complex pharmacokinetics^[72,73]. Several chimeric HDAC inhibitors with dual or multimodal activities were reported over the last years^[29,30]. Compound 2-75 is a promising enzalutamide hybrid with HDAC inhibitory activity, which induced p21, led to higher acetyl-tubulin levels (based on stronger HDAC6 inhibition) than vorinostat, and suppressed Hsp90 and AR protein levels in C4-2 prostate cancer cells^[74]. Based on these results, deeper studies of 2-75 in CRPC were carried out. Compound 2-75 suppressed DHT-induced AR transcriptional activity and AR translocation to the nucleus stronger than enzalutamide. In addition to AR, the mutant AR-V7 was also downregulated by 2-75 in prostate cancer cells in a proteasome-dependent way, indicating enhanced AR degradation in 2-75-treated cells. *In vivo* experiments with LNCaP tumor models revealed that 2-75 treatment (10 mg/kg, intratumoral injection twice weekly) had tumor growth inhibitory activity similar to enzalutamide, but, in the long run (after Day 24), 2-75 displayed improved tumor growth inhibition when compared with enzalutamide. The *in vivo* activity of 2-75 was accompanied by increased apoptosis induction and suppressed AR nuclear accumulation in the tumor bodies of treated mice^[75].

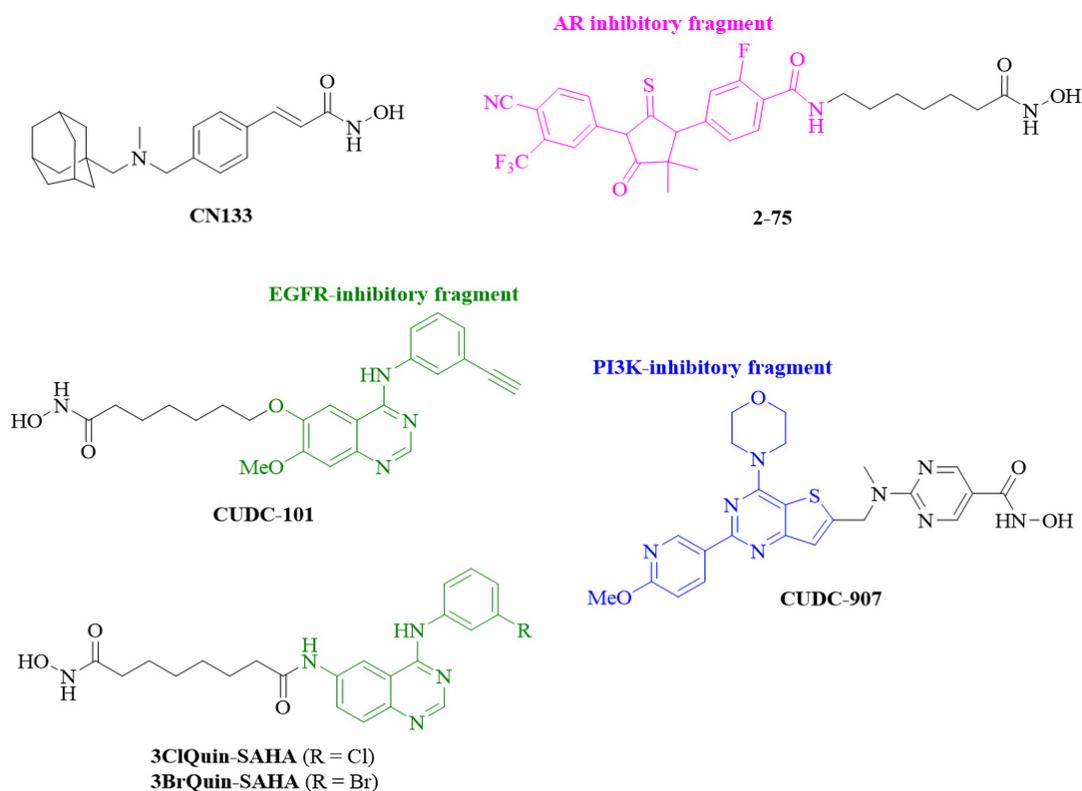

Figure 4. Structures of new HDAC inhibitors with promising activities against CRPC. HDAC: Histone deacetylase; CRPC: castration-resistant prostate cancer; AR: androgen receptor; EGFR: epidermal growth factor receptor; PI3K: phosphatidylinositol 3-kinase.

The aforementioned receptor tyrosine kinases such as EGFR are excellent targets for the design of new HDAC/EGFR inhibitors. Compound CUDC-101 combines an HDAC inhibitory fragment with an EGFR inhibitory scaffold derived from the approved anticancer active EGFR inhibitor erlotinib and inhibited HDAC, EGFR, and HER2^[76]. In CRPC cells, CUDC-101 suppressed full-length AR as well as the variant AR form AR-V7, upregulated p21, and downregulated HER2/NEU. In castrated mice bearing aggressive 22Rv1 CRPC tumors, CUDC-101 (50 µg/kg/day for 14 days) inhibited tumor growth significantly without measurable weight loss of treated mice^[77].

Erlotinib and CUDC-101 have certain drawbacks, which warranted further research efforts. The ethinylphenyl residue of erlotinib can be activated by cytochrome P450 enzymes leading to oxidized phenol and quinone compounds with certain toxicity potential^[78]. Indeed, erlotinib was reported to increase the risk of lethal gastrointestinal tract perforations in cancer patients taking corticosteroids or ciprofloxacin^[79]. A clinical phase 1 study of CUDC-101 together with chemoradiation in head and neck squamous cell carcinoma (HNSCC) patients reported that five out of twelve HNSCC patients (i.e., 41%) had to stop the therapy due to adverse events^[80]. In addition, CUDC-101 was shown to be a substrate of the cell-detoxifying ABC transporters ABCB1 (P-gp) and ABCG2 (BCRP) leading to resistance to CUDC-101 treatment, whereupon the combination with P-gp and/or BCRP inhibitors was suggested in order to avoid CUDC-101 resistance formation^[81]. In contrast to that, the approved EGFR inhibitor gefitinib reversed P-gp- and BCRP-mediated drug resistance *in vitro* and *in vivo*^[82,83]. Hence, gefitinib is a promising conjugation partner, and chimeric HDAC inhibitors with gefitinib-derived cap scaffolds based on halogen-substituted aniline rings were prepared. The chimeric compounds 3ClQuin-SAHA and 3BrQuin-SAHA showed 3-4 times higher growth inhibitory activity ($IC_{50} = 3.23 \mu\text{M}$ for 3ClQuin-SAHA and $3.53 \mu\text{M}$ for 3BrQuin-SAHA)

against DU145 CRPC cells than gefitinib ($IC_{50} = 11.9 \mu\text{M}$); however, vorinostat ($IC_{50} = 0.68 \mu\text{M}$) was still more antiproliferative in these prostate cancer cells. Nevertheless, 3ClQuin-SAHA and 3BrQuin-SAHA combined EGFR inhibitory activity with HDAC inhibition, suppressed EGFR expression comparable to vorinostat, showed only marginal unspecific toxicities, induced apoptosis in DU145 cells, and inhibited angiogenesis^[84]. Hence, these chimeric compounds can be suitable anticancer drug candidates in prostate cancer therapy in terms of reduced erlotinib (and vorinostat) toxicity and resistance formation.

CUDC-907 (fimepinostat) is another promising HDAC/kinase inhibitor, which was designed to target HDAC enzymes and the kinase PI3K^[85]. Based on previous reports describing the synergistic effects of CUDC-907 in various cancer models and since PI3K signaling also plays an eminent role for CRPC development (see the aforementioned role of mTOR inhibitors), CUDC-907 was investigated in prostate cancer models. CUDC-907 showed excellent growth inhibitory activities in a panel of eight prostate cancer cell lines with IC_{50} values between 2 and 17.4 nM, inhibited HDACs and PI3K signaling, and induced apoptosis in a dose-dependent way associated with increased pro-apoptotic Bim and suppressed anti-apoptotic Mcl-1 and Bcl-xL expression in 22Rv1 CRPC cells. In addition, CUDC-907 treatment led to enhanced DNA damage due to downregulated DNA damage response proteins (Wee1, CHK1, RRM1, and RRM2). The protein expression of the oncoprotein *c-Myc*, which regulates the mentioned apoptosis factors and DNA damage response proteins, was also suppressed by CUDC-907 and, thus, *c-Myc* suppression plays a key role in the anti-prostate cancer mode of action of CUDC-907. Finally, CUDC-907 (100 mg/kg/day, p.o.) was tested in castration-resistant LuCaP 35CR mouse xenografts and inhibited *in vivo* tumor growth by ca. 60% while no weight loss was detected^[86]. More recently, a phase 2 study of oral CUDC-907 for the treatment of relapsed/refractory diffuse large and high-grade B-cell lymphoma (DLBCL and HGBL) patients with enhanced *Myc*-expression and/or altered *MYC* gene constitutions (e.g., altered gene composition by translocation) was published revealing an overall response rate of 22% in the *MYC*-altered disease patients^[87]. Hence, patients enrolled for future prostate cancer clinical studies with oral CUDC-907 should be tested for their *MYC*-status. In contrast to CUDC-101, CUDC-907 was not a substrate of P-gp (ABCB1) transporters, and its antiproliferative activity was conserved in P-gp-expressing tumor cells. However, CUDC-907 was still efficiently inactivated by BRCP (ABCG2) transporters, similar to CUDC-101, and combinations with BCRP inhibitors were recommended to keep the high anticancer activity of CUDC-907^[88].

CONCLUSION

HDAC inhibitors exhibit reasonable *in vitro* and *in vivo* activities against CRPC. Clinical trials have shown that monotherapy with HDAC inhibitors cannot be recommended now for phase 3 studies due to low efficacy and considerable toxicity in CRPC patients. However, the combination of HDAC inhibitors with certain anticancer drugs such as taxanes and anti-androgens appeared promising based on the data from clinical studies. In preclinical studies, DNA methylation inhibitors, PARP inhibitors, various protein kinase and mTOR inhibitors, interferon, and TRAIL gene therapy appeared to be suitable combination partners for HDAC inhibitors, which should be considered for future clinical studies with CRPC patients.

Various new HDAC inhibitors have emerged over the last years, which displayed significant activity against CRPC in preclinical studies. Many of these new HDAC inhibitors were designed to target non-HDAC proteins such as protein kinases or the AR in addition to HDAC enzymes. Among them, CUDC-101 and CUDC-907, which are HDAC/kinase inhibitors, are striking examples that have already entered clinical trials. The activities of these two drug candidates were thoroughly studied in preclinical CRPC models giving hints at strengths and weaknesses of multi-targeting HDAC inhibitors. Strong CRPC growth inhibition accompanied by good drug tolerance in mice were contrasted by toxicity in patients and

resistance formation based on the expression of ABC transporters in tumor cells. Efforts to eliminate the drawbacks of CUDC-101 and CUDC-907 are already in progress and the first preclinical results of new HDAC/kinase inhibitory derivatives are available. In addition, subgroups of CRPC patients with increased Myc levels should be considered for future clinical trials with CUDC-907 since lymphoma patients with elevated Myc responded well to this sophisticated HDAC inhibitor.

The drug developments described in this work are based on the elucidation of the mechanisms of action of first-generation HDAC inhibitors, the design of new therapy regimens, and the synthesis of new HDAC inhibitors with improved anticancer properties. The close interplay of clinicians, tumor biologists, and synthetic chemists has led to promising outcomes in the field of CRPC research over the last years, and interdisciplinary work will continue to help HDAC inhibitor-based therapy to play a prominent role as efficient and well-tolerated CRPC treatment in the future.

DECLARATIONS

Authors' contributions

Abstract

Aim: Despite aggressive multiagent protocols, patients with metastatic rhabdomyosarcoma (RMS) have poor prognosis. In a recent high-risk trial (ARST0431), 25% of patients failed within the first year, while on therapy and 80% had tumor progression within 24 months. However, the mechanisms for tumor resistance are essentially unknown. Here we explore the use of preclinical models to develop resistance to complex chemotherapy regimens used in ARST0431.

Methods: A Single Mouse Testing (SMT) protocol was used to evaluate the sensitivity of 34 RMS xenograft models to one cycle of vincristine, actinomycin D, cyclophosphamide (VAC) treatment. Tumor response was determined by caliper measurement, and tumor regression and event-free survival (EFS) were used as endpoints for evaluation. Treated tumors at regrowth were transplanted into recipient mice, and the treatment was repeated until tumors progressed during the treatment period (i.e., became resistant). At transplant, tumor tissue was stored for biochemical and omics analysis.

Results: The sensitivity to VAC of 34 RMS models was determined. EFS varied from 3 weeks to > 20 weeks. Tumor models were classified as having intrinsic resistance, intermediate sensitivity, or high sensitivity to VAC therapy. Resistance to VAC was developed in multiple models after 2-5 cycles of therapy; however, there were examples where sensitivity remained unchanged after 3 cycles of treatment.

Conclusion: The SMT approach allows for *in vivo* assessment of drug sensitivity and development of drug resistance in a large number of RMS models. As such, it provides a platform for assessing *in vivo* drug resistance mechanisms at a “population” level, simulating conditions *in vivo* that lead to clinical resistance. These VAC-resistant models represent “high-risk” tumors that mimic a preclinical phase 2 population and will be valuable for identifying novel agents active against VAC-resistant disease.

Keywords: Rhabdomyosarcoma, patient-derived xenografts, combination therapy, intrinsic drug resistance, acquired drug resistance

INTRODUCTION

Advanced or metastatic rhabdomyosarcoma (RMS) has a poor prognosis. Patients with stage 4 disease, with the exception of those with embryonal RMS that are less than ten years of age, have a long-term event-free survival (EFS) of less than 20%^[1-3]. Current therapies include all the known active agents plus radiation and surgery, but neither intensification of chemotherapy by increasing the dose of cyclophosphamide and adding active agents to standard VAC therapy (Vincristine/Actinomycin-D/Cyclophosphamide), nor use of high-dose chemotherapy with stem-cell rescue has improved outcome over the last 30 years^[4]. The failure of current therapeutic approaches to effectively treat advanced or metastatic RMS despite numerous cooperative group trials, is a consequence of intrinsic or acquired resistance to the limited number of drugs that compose the armamentarium for treating this disease. Even with the use of intensive multimodality treatment, only 20% of patients will be long-term survivors. The failure of current therapies is further emphasized by the rapid progression rate of patients enrolled in a recent high-risk rhabdomyosarcoma study (ARST0431). In this trial, 25% of patients diagnosed with metastatic disease, either failed during the 52 weeks of treatment or had an event within two years (80%)^[5]. The causes of tumor resistance are poorly understood. One possible cause for resistance is tumor clonal evolution, where novel mutations acquired during therapy confer resistance^[6]; however, such studies usually rely on small cohorts as relatively few tumors are re-biopsied at relapse.

Preclinical studies aimed at understanding resistance tend to focus on individual drugs, rather than resistance to poly-chemotherapy^[7-13]. Further, often drug exposures used *in vitro* far exceed those achieved in patients, and escalating drug concentrations over time do not simulate how clinical resistance is acquired^[14]. We have previously used pediatric tumor xenografts to select for acquired resistance in mice^[7,8]. However, while this approach is perhaps more appropriate than *in vitro* selection, conventional testing is resource-intensive, and allows for only a few models to be explored^[15]. More recently, we have adopted Single Mouse Testing (SMT) to evaluate drugs in a large number of xenograft models^[16,17], an approach that significantly increases the inclusion of genetic diversity for a given cancer type^[18]. The SMT design is validated by a retrospective analysis of > 2100 tumor-drug studies undertaken by the Pediatric Preclinical Testing Program, where the response of a tumor in one mouse, selected at random from the group, was compared to the median group response. This analysis showed that the SMT accurately predicted responses in 78% of studies. Allowing for a deviation of \pm one response classification [e.g., stable disease (SD) vs. partial response (PR)], the concordance was 95%. Further, the SMT analysis was accurate in identifying the antitumor activity of 66 of 67 drugs in terms of the objective response rate determined for each drug over a range of tumor models^[18]. Prospective studies with up to 90 ALL models and up to 50 solid tumor models

show that SMT has similar concordance with conventional testing^[16]. Importantly, using SMT, one can potentially incorporate up to 20-fold the number of models for evaluation of an agent, encompassing many diseases, or encompassing the genetic diversity of a given disease. Here we have applied SMT to interrogate intrinsic resistance and to use this approach to select for acquired resistance *in vivo* to VAC therapy in 34 RMS models. Our data show that RMS models have a range of sensitivities to VAC, ranging from tumor progression through initial treatment to maintained complete response at week 20 after a single cycle of VAC treatment. Further, using the SMT design, acquired resistance can be developed over a period of 3 to 5 cycles of therapy.

METHODS

C.B.17SC *scid*^{-/-} (C.B-*Igh*-1^b/IcrTac-*Prkdc*^{scid}) female mice (Envigo, Indianapolis, IN) were maintained under barrier conditions, and experiments were conducted using protocols and conditions approved by the Institutional Animal Care and Use Committee at UTHSA as previously described^[15]. Mice were selected for VAC treatment when tumors were 200-300 mm³. Regrowth of tumors was determined following tumor regression. Endpoints were EFS, defined as tumor growing to 400% of its volume at the initiation of treatment, and percent tumor volume regression. Complete regression (CR) was defined as tumor volume < 40 mm³ (the level of detection). Limited demographic data for RMS models used in the studies are presented in [Table 1](#). Patient- and cell-derived xenograft models (PDX and CDX) have been described previously^[15,17]. Genomic data for some of the models is under <https://ocg.cancer.gov/programs/target/Pan-cancer-Model-Systems>, and in Rokita *et al.*^[19]. SJRHB011_X, SJRHB013_X, SJRHB010927_X1, SJRHB000026_X1, and SJRHB013758_X1 were obtained from The Childhood Solid Tumor Network^[20]. SMS-CTR cells were obtained from Dr. Corine Linardic, Duke University, JR1 (UK), and CCA cells were obtained from Dr. Marielle Yohe, NCI. All tumors were authenticated by short tandem repeat analysis against reference profiles.

Simulating VAC therapy in mice

All drugs were administered IP. Vincristine was administered at 0.5 mg/kg days 1,8,15, actinomycin D (0.20 mg/kg) and cyclophosphamide (120 mg/kg), both on day 1, doses considered to give clinically relevant drug exposures^[21-23]. All drugs were formulated in 0.9% w/v saline. This regimen, which simulates VAC modules used in ARST0431, was tolerated with ~10% body weight loss, and mortality < 2%.

Development of acquired resistance in mice

The schema for selecting for acquired resistance is presented in [Figure 1](#). Briefly, one mouse per tumor line received a single cycle of VAC treatment. Tumor diameters were measured weekly, and treated tumors were re-transplanted into new recipient mice when they “evented” (achieved 400% of their volume on day 1 of treatment). Treated tumors were considered resistant to VAC therapy if they progressed through treatment and had increased > 25% in volume by day 21. Tumor tissue was cryopreserved and snap frozen after each cycle of VAC therapy.

RESULTS

Intrinsic sensitivity to VAC treatment

We initially explored the sensitivity of 34 RMS xenograft models to the “gold standard” therapy for RMS, namely VAC, [Figure 2](#). The models encompass both fusion-positive (alveolar), and fusion-negative (embryonal, with and without RAS mutations). As shown in [Figure 2A](#), 18 of 34 xenograft models (53%) regressed > 50% on Cycle 1 of VAC therapy, the other models showing SD ($n = 3$) or progressive disease (PD) ($n = 13$). This experiment is ongoing, but clearly shows that SMT can be valuable for assessing drug sensitivity in a large cohort of models. Thirteen models were intrinsically resistant to VAC treatment with EFS of < 40 days, whereas others ($n = 10$) are highly sensitive (EFS > 70 days), with four models remaining

Table 1. Characteristics of RMS xenograft models and response to cycle 1 of VAC therapy

*Indicates cell line derived xenograft. ARMS: Fusion-positive; ERMS: fusion negative; RMS: rhabdomyosarcoma; VAC: vincristine/actinomycin-D/cyclophosphamide; EFS: event-free survival; PD: progressive disease; MCR: maintained complete response; CR: complete regression; PR: partial response; SD: stable disease.

in CR at 120 days, as shown in the Kaplan-Meier plot [Figure 2B]. We defined PD as tumors that increased in volume by 25% at day 21 (6 days after the last dose of vincristine). Thirteen of 34 RMS models (38%) exhibited PD to cycle 1 of VAC. An EFS of 49 days or less was also observed for 13 models, Table 1. Of these 13 intrinsically resistant models, 10 tumors were established from patients following treatment. The exceptions were Rh71, Rh85, and NCH-ERMS1, which were established as PDX models from patients prior to any treatment. Other models with short EFS (CCA, Rh36, IRS-68) each regressed > 50% (i.e., PR), but

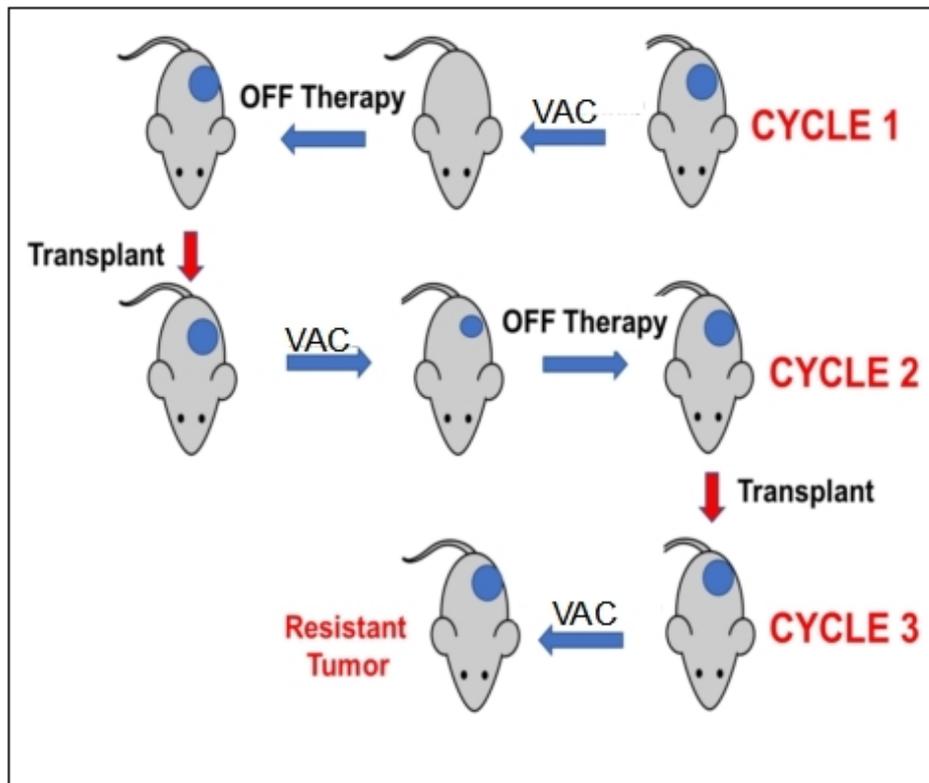

Figure 1. Schema for developing resistance to VAC therapy in mice using the single mouse study design. Mice received a single cycle of VAC (vincristine, actinomycin D, cyclophosphamide). Tumor response was determined, and tumors were transplanted in recipient mice when they achieved 400% of their volume on the first day of treatment.

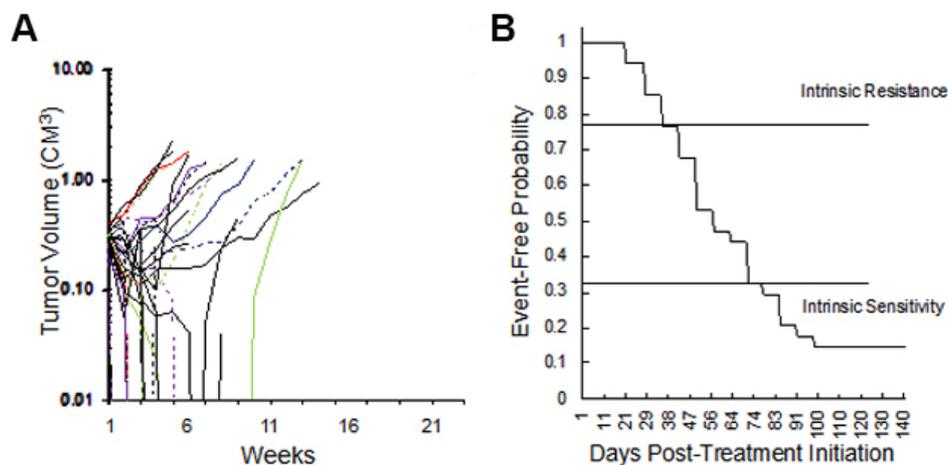

Figure 2. (A) Initial volume responses of 34 RMS models to cycle 1 of vincristine + actinomycin D + cyclophosphamide (VAC) using the SMT experimental design (ongoing expt.). (B) Kaplan-Meier plot for EFS of the same models. RMS: Rhabdomyosarcoma; VAC: vincristine/actinomycin-D/cyclophosphamide; EFS: event-free survival; SMT: single mouse testing.

rapidly regrew. Of the models having EFS of 70 days or greater ($n = 10$; 29%), 3 models had CR (Rh88, SMS-CTR, SJRHB013x, and SJRHB013758_X1), 2 had PR (SJRHB010927, Rh83), and 1 had prolonged SD (Rh84). Three models, established from tumor at diagnosis, were highly sensitive to VAC treatment with no evidence of tumor regrowth at day 120 after the start of treatment (IRS-56, Rh12, Rh28). The other 11

models had intermediate sensitivity to VAC (EFS > 40 but < 70 days).

Development of acquired resistance

The approach to selecting for acquired resistance [Figure 1], was chosen as there is an increased incidence of scid lymphoma as mice age, and also potentially altered immunity that could alter the response to chemotherapy. Consequently, we re-transplanted tumors at 400% of their volume at day 1 of treatment into new 6 to 8-week-old female C.B.17SC *scid*^{-/-} mice, and repeated this procedure until tumors became resistant. For all studies, tumors were allowed to grow to 200-300 mm³ before starting treatment. Initially, we transplanted cycle 1 tumor into two mice, in case there was toxicity, and we would lose the model if there was a death (drug related or unrelated) on cycle 2 of treatment. However, there was no mortality, so subsequently, a single mouse design was used for all subsequent cycles of VAC treatment. Where two mice were used ($n = 16$), the responses between tumors were very similar, Supplemental Figure 1. The “Swimmer plot” in Figure 3 shows examples of models exhibiting Complete Regression (Rh88) or Partial Regression (IRS-6) to VAC treatment on cycle 1 with rapid emergence of resistance, or tumor models that initially had progressive disease (i.e., intrinsically resistant), but where EFS shortened with further cycles of VAC treatment (Rh72), or a model where EFS remained constant during 3 cycles of VAC treatment (Rh73).

DISCUSSION

The outcome for patients with high-risk RMS has not improved significantly for several decades. In part, this is because new effective agents have not been identified, and agents such as irinotecan, while active against RMS^[24,25], do not increase overall survival when added to VAC therapy^[5,26]. Of the chemotherapeutic agents used in high-risk protocols such as ARST0431, all but one (vincristine), induces DNA damage. However, the mechanism(s) that confer resistance to multi-chemotherapy protocols, even protocols that combine mostly DNA damaging agents, remains unknown. A proportion of patients failing on therapies including cyclophosphamide and vincristine^[27], however, may respond to vinorelbine/cyclophosphamide^[28].

Approaches to determine mechanisms of resistance, both *in vitro* and *in vivo*, have limitations. As mentioned previously, *in vitro* studies may not accurately replicate clinical drug exposures, and continuous exposure to increasing drug levels may result in multidrug resistance mechanisms, such as overexpression of ABC transporters, that may not reflect clinical reality^[29]. *In vivo* studies in mice, using human tumor xenografts, or syngeneic tumor models, may more accurately model drug pharmacokinetics relevant to clinical exposures. However, resource constraints tend to limit their use to a few models and usually for the development of resistance to single agents. One approach to encompassing genetic diversity for a given cancer type is to use an SMT design, rather than conventional experimental designs that use 8-10 mice for control and treatment groups^[15,18]. In this pilot study, we have evaluated SMT in the context of VAC therapy in 34 RMS models, and have used this approach to develop models with acquired resistance that can be further characterized by “omics” and biochemical methods. Essentially, the approach mimics a clinical trial in that there is no “control” arm, and the response criteria are tumor volume changes and EFS. We “enrolled” RMS models when tumors were available, and the response to one cycle of VAC was assessed in a blinded manner with respect to whether the model was established from an untreated patient or from a patient following treatment. As VAC therapy has been the backbone for the treatment of RMS for over 30 years, we assume that xenografts established from treated patients received these drugs, although it is not known if additional drugs were administered to patients before their tumors were established as xenografts.

Overall the models appear to retain drug sensitivity characteristics of patient tumors. Ten of the 13 models that had PD to VAC treatment were derived from pre-treated tumors (treated, relapse, autopsy), whereas only 2 out of 11 models established from diagnosis samples progressed on cycle 1 of VAC treatment. The

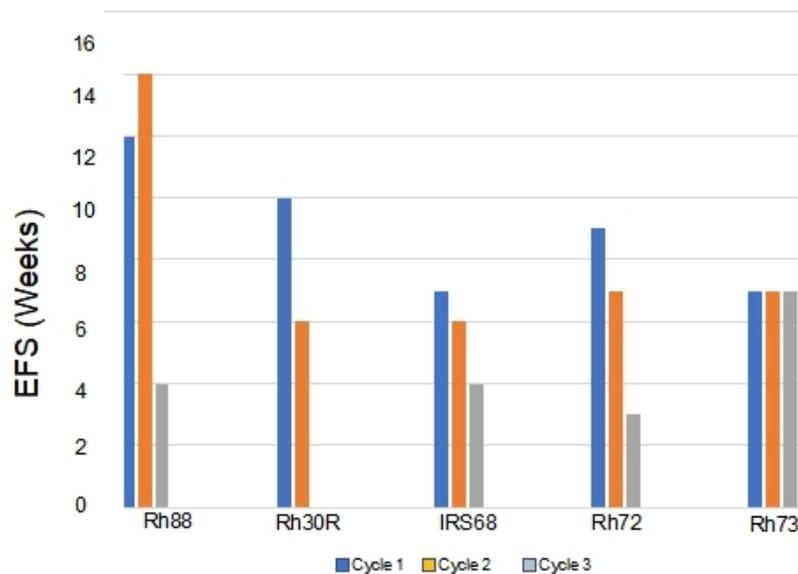

Figure 3. Development of resistance to VAC treatment (decreases in EFS) in models that were intrinsically sensitive to treatment (> PR; Rh88, Rh30R, IRS-68) or models where tumors progressed through cycle 1 of VAC treatment (Rh72, Rh73). VAC: Vincristine/actinomycin-D/cyclophosphamide; EFS: event-free survival; PR: partial response.

models established as PDX's from samples at diagnosis that were intrinsically resistant to VAC included two ERMS, one defined pathologically as a high-grade tumor (Rh71) and one with diffuse anaplasia (Rh85), which may relate to drug sensitivity^[30,31]. Tumor models having EFS of 70 days or greater included 7 established from diagnosis samples, 5 listed as “treated”, and 3 models established from tumor at relapse. Clinically, patients progressing on front-line treatment may respond to phase 2 protocols, including cyclophosphamide and *vinca* alkaloids. It is also possible that prolonged passage of tumor in untreated mice could lead to loss of resistance, or overgrowth of sensitive cells. However, the data set from 34 models serves as a reference point for understanding intrinsic resistance or sensitivity and for developing acquired resistance in those models that initially respond to VAC treatment under relevant *in vivo* conditions.

We have used two criteria for assessing tumor sensitivity to VAC: tumor regression (partial and complete response) and EFS. Tumors having PD had EFS times of 3-8 weeks; those demonstrating PR (> 50% volume regression) had EFS that ranged from 6-14 weeks, and models having CR the EFS time ranged from 7 to > 20 weeks. Thus, as in our previous study^[17], there was a relatively poor correlation between the magnitude of tumor volume regression and EFS, suggesting that EFS may be a more reliable metric of tumor response in preclinical models. Clinical data also question the value of early tumor response as a prognostic indicator, as neither computed tomography and/or magnetic resonance imaging predicted outcomes for patients with rhabdomyosarcoma^[32,33].

We have attempted to select for acquired resistance to VAC using the SMT approach. While this pilot study is far from complete, interim analysis suggests that this approach can generate a large number of VAC-resistant models that can be analyzed for genetic/epigenetic changes associated with resistance. Thirteen xenograft models showed progressive disease in response to VAC treatment, hence were classified as intrinsically resistant. However, many of these resistant tumors had reduced EFS on subsequent cycles of therapy, thus showing increased resistance. In ongoing studies, acquired resistance has been selected within 3 to 5 cycles of VAC treatment in many tumor models initially sensitive to VAC. The approach we have taken is to define intrinsic sensitivity/resistance to VAC and to select for acquired resistance in mice. An

alternative approach is to establish PDX models at diagnosis and relapse from the same patient. This is rarely possible in the context of pediatric RMS, as relapse tumor is rarely biopsied, but also engraftment into mice may select for subclones rather than represent the clonal spectrum in the patient tumor. Modeling intrinsic and acquired resistance in preclinical models has an advantage over clinical studies in that changes in gene expression can be assessed both in parental and resistant tumor, but also in response to therapy^[34].

Here we have defined the intrinsic sensitivity of 34 RMS models. Importantly, models intrinsically resistant to VAC, or those with acquired resistance to VAC treatment, may be particularly valuable for identifying novel agents that may be active in disease at relapse, and may have novel mechanisms of action independent of DNA damage.

As true for any cancer, intrinsic and acquired drug resistance represent perhaps the single biggest obstacle limiting our ability to cure patients with metastatic disease. Yet, tackling this challenge has been particularly difficult for sarcoma. First and foremost, sarcomas are rare and diverse, which splits a class of tumors representing less than 1 percent of all malignancies into more than fifty smaller molecularly and histologically distinct entities, each having its own etiology, prognosis, and clinical presentation. Even the most “common” sarcoma subtypes (e.g., liposarcoma, leiomyosarcoma, or gastrointestinal stromal tumors) have annual incidences in the thousands in the United States, whereas rarer subtypes like desmoplastic small round cell tumors number less than fifty per year. Due to their scarcity, it’s not uncommon for just a few cell lines, organoids, or patient-derived tumor explants to exist for each sarcoma subtype. This shortage limits their usefulness to model the wide variety of innate and adaptive mechanisms that exist in human tumors. Many times, no representative preclinical model exists. The scarcity of FDA-approved drugs aimed at sarcoma-specific targets, often fusion proteins and transcription factors, is also problematic.

Complicating the ability to understand tumor drug resistance, many sarcomas exhibit pronounced intra-tumoral heterogeneity, manifested by heterogeneous cell populations of varied lineages and states of differentiation. It is not unusual for osteosarcoma, for example, to harbor cells with varying degrees of

chaotic osteogenic, adipogenic, or chondrogenic cell fates. Similarly, some liposarcomas are classified into well-differentiated and dedifferentiated variants by their predominant differentiation status but usually harbor a blend of both^[1]. Even tumors like Ewing sarcoma, which appear relatively homogeneous by light microscopy, can be subcategorized by the pathognomonic genomic translocation expressed and by the presence or absence of well-described point mutations in *STAG2*, *p53*, or *CDKN2A*^[2]. Thus, while light microscopy and careful review by an experienced sarcoma pathologist remain the cornerstone of sarcoma diagnosis, a clear trend in the research setting is to deeply interrogate each tumor and precisely catalog its cellular constituencies using a wide array of genomic, proteomic, and other “-omic” technologies. As a direct result of this unparalleled opportunity to parse out distinct groups of malignant cells, a more nuanced view of sarcoma drug resistance must consider not only the global factors linked to each sarcoma subtype but also the intratumoral features such as physical and mechanical cues (e.g., extracellular matrix, stiffness or confined adhesiveness) that allow for clonal evolution in response to the selective pressures triggered by standard chemotherapy or biologically targeted therapy.

This has been achieved in other cancer types by engaging powerful single-cell technologies - before and after drug exposure - to determine a tumor’s baseline transcriptomic state and nascent cellular changes associated with drug resistance^[3-6]. Single-cell and single-nucleus RNA-sequencing (sc/snRNA-seq) are the most common methods used currently and, when paired with freely available custom-made bioinformatic tools written in R or Python, provide the revolutionary ability to deeply interrogate intra-tumoral complexity^[7-9]. Furthermore, while still in their infancy, single-cell proteomic technologies have introduced promising technologies that enable high-resolution spatial image - omic (SIO) analyses of human primary tumors, which allows one to learn not only *what* cell types exist but also *how* they interact in 2D or 3D space^[10]. Though the clinical value of checkpoint blockade and cellular immunotherapies remains to be proven across the range of sarcoma subtypes, the advent of SIO, image mass cytometry, multi-color fluorescent microscopy, and other techniques should provide a fresh opportunity to examine whether such therapies can invoke an anti-cancer response. Complementing the trained eye of an experienced sarcoma pathologist, deep-learning and artificial intelligence, while still under-utilized, are primed to aid pathologists to make sense of the torrent of data generated from each slide and may allow them to perceive subtle cell-cell interactions that contribute to drug resistance and the feedback mechanisms that sustain them^[11].

Though classic measures of drug efficacy that rely on tumor size or patient survival will persist as important clinical study endpoints, a deeper appreciation of drug sensitivity/resistance must inevitably decipher how each patient’s tumor - and the cells within them - evade therapy. Like no time in history, the tools exist today to help cure cancer one cell at a time.

Abstract

Standard treatment for advanced Prostate Cancer (PCa) consists of androgen deprivation therapy (ADT), but ultimately fails, resulting in the incurable phase of the disease: metastatic castration-resistant prostate cancer (mCRPC). Targeting PCa cells before their progression to mCRPC would greatly improve the outcome, if strategies could be devised selectively targeting androgen receptor (AR)-dependent and/or independent compensatory pathways which promote mCRPC development. Combination therapy by targeting the DNA damage response (DDR) along with ADT has been limited by general toxicity, and a goal of clinical trials is how to target the DDR more specifically. In recent years, our lab has identified a key role for the DDR kinase, TLK1, in mediating key aspects of adaptation to ADT, first by promoting a cell cycle arrest (through the TLK1>NEK1>ATR>Chk1 kinase cascade) under the unfavorable growth conditions (androgen deprivation), and then by reprogramming the PCa cells to adapt to androgen-independent growth via the NEK1>YAP/AR>CRPC conversion. In addition, TLK1 plays a key anti-apoptotic role via the NEK1>VDAC1 regulation on the intrinsic mitochondrial apoptotic pathway when the DDR is activated. Finally, TLK1 was recently identified as having an important role in motility and metastasis via regulation of the kinases MK5/PRAK and AKT (indirectly via AKTIP).

Keywords: TLK1, NEK1, YAP1, VDAC1, DNA damage response, prostate cancer, metastatic castration-resistant prostate cancer, drug resistance in mCRPC

INTRODUCTION

Prostate cancer (PCa) is one of the most common malignancies among men in the United States. Although death from PCa has been significantly reduced during the past two decades due to the advent of first (flutamide, nilutamide, cyproterone acetate, and bicalutamide) and second-generation (abiraterone acetate, enzalutamide, apalutamide, and recently approved darolutamide) anti-androgens, recent data of modeled projections suggests that the death rate is gradually increasing^[1-4]. This might partly be due to the development of increased resistance towards androgen deprivation therapy (ADT), which eventually progresses to castration-resistant phenotype during which therapeutic options become limited. PCa is mainly a disease of uncontrolled proliferation of luminal epithelial cells of the prostate gland, although in some cases, basal cells are involved. Since androgen receptor (AR) signaling regulates the growth, survival, and proliferation of prostate tumors, the majority of PCa therapies are focused on either inhibition of androgen synthesis or blockade of androgen receptor transactivation. However, the drug effect does not last long, and the tumor relapses within 18-24 months with more aggressive phenotype known as castration-resistant prostate cancer (CRPC), even in the presence of castrate level of circulatory androgen. Besides androgen ablation, radiotherapy and chemotherapy are commonly employed for the treatment of both localized PCa and CRPC. Inflicting DNA damage and enhancing apoptosis of cancer cells are the mechanistic strategy of all radiotherapeutic (e.g., external beam radiation therapy, brachytherapy, radium-223) and some chemotherapeutic (PARP inhibitors, e.g., olaparib, niraparib, talazoparib; topoisomerase inhibitors, e.g., mitoxantrone, camptothecin; platinum-based therapy, e.g., satraplatin, carboplatin, cisplatin; DNA crosslinking agent, e.g., mitomycin C) interventions (reviewed in Ref.^[5,6]). It is observed that AR signaling is still active in the majority of CRPC due to the amplification, mutation, overexpression, and alternative splicing of AR that directly regulates the expression of DNA repair genes^[5,7-10]. Therefore, a combinatorial treatment including ADT and other DNA damage-inducing agents should result in favorable clinical outcome and increase patients' survival. Despite the improvement of treatment modalities, CRPC remains incurable, and drug-refractory PCa is evident among patients. Interestingly, other compensatory oncogenic survival mechanisms might play a role in conjunction or independent of AR signaling. Several receptor tyrosine kinases and mitogen-activated protein kinases mediated signaling are found to be activated in CRPC, which can bypass AR requirement for PCa cell growth and proliferation^[11-13]. In this communication, we will focus on a less commonly reported serine/threonine kinase, TLK1 and its compensatory role in developing therapy resistance and metastatic CRPC (mCRPC) progression.

THE MAMMALIAN TOSLED LIKE KINASES AND TRANSLATIONAL UPREGULATION OF TLK1B

Mammalian homologues of plant tousled-kinase, known as tousled-like kinases (TLKs), were first cloned in 1999 and found to be implicated in DNA replication as their activities peak during the S-phase of the cell cycle^[14]. Two members of the tousled-like kinase family have been identified (TLK1 and TLK2), which were found to share similar substrates and have partly redundant functions in maintaining genomic integrity. Later on, detailed studies of these two proteins identified their individual functions in various cellular processes along with their shared ones. TLK1 is reported to directly play a role in DNA replication, transcription, cell cycle checkpoint control, DNA damage response and repair (reviewed in Ref.^[15-17]). Although multiple isoforms of TLK1 are discovered in different tissues, a translationally controlled isoform TLK1B has been thoroughly characterized by our group. TLK1B is an N-terminal truncated spliced variant of TLK1, which possesses a long, GC rich 5' UTR and two short upstream open reading frames,

characteristics of a weakly competitive mRNA. TLK1B possesses an intact C-terminal catalytic domain, and its substrates specificity is similar to TLK1. A schematic sequence alignment of TLK1 and TLK1B can be found in Ref.^[18]; while the alignment of TLK1 and its homolog TLK2 can be found in Ref.^[16,19]. Translation of TLK1B is facilitated by the overexpression of eIF4E or by the stress-related activation of the AKT-mTOR pathway, which leads to 4EBP1 hyperphosphorylation and release of eIF4E from its inhibitor^[18,20,21]. Histone H3 was one of the first identified substrates which can be phosphorylated on serine 10 residue by TLK1B. Although some other kinases (Aurora B/Ipl1 kinase) may also phosphorylate H3-S10, TLK1B phosphorylation of Histone H3-S10 promotes proper chromosomal condensation during metaphase and confers radio-resistance as observed in normal mouse breast epithelial cells (MM3MG) and yeast^[22]. Another direct substrate of TLK1/1B is Histone H3-H4 chaperone Asf1a and Asf1b, which can be phosphorylated on several residues at C-terminus and increase their affinity to bind to H3-H4 that enables nucleosomal assembly with newly synthesized DNA strand during replication and damage repair^[23,24]. TLK1B is also reported to phosphorylate Rad9 of Rad9-Rad1-Hus1 (9-1-1) heterotrimeric complex that acts as a scaffold to hold the DNA at the damaged region and recruits DNA repair factors^[25]. Following DNA repair, TLK1/1B mediated phosphorylation of Rad9 at S328 promotes its dissociation and disassembly from the 9-1-1 trimeric complex and resumes the cell cycle from DNA damaged induced checkpoint arrest^[26]. Besides these well-validated substrates of TLK1/1B, a proteomic screening from our lab identified 165 binding partners of TLK1/1B from a pool of 9000 full-length human proteins^[27]. The physiological functions of the majority of these interactions are still unknown.

TLKs play a central role in DNA damage response and repair and hence, are critical for cell survival. However, studies aimed at identifying TLKs' role in prostate cancer progression and drug resistance are very limited. Notably, the *TLK1* gene was identified by co-expression analysis using WGCNA as a key driver of PCa, highly enriched among candidate genes collected from expression Quantitative Trait Loci, somatic copy number alterations and prognostic analyses^[28]. We also recently observed from data mining that TLK1 expression at mRNA level is increased in metastatic and high grade prostatic adenocarcinoma compared to the low risk tumors^[29]. Moreover, androgen deprivation translationally increases TLK1B level in LNCaP cells and a PDX mice model through an mTORC1 dependent mechanism without increasing TLK1 mRNA expression; and mTOR inhibition by rapamycin reverses this phenomenon^[30,31]. This compensatory activation of mTOR during AR blockade might be due to the oncogenic activation of AKT. AR inhibition prevents PHLPP mediated dephosphorylation of AKT by downregulating the expression of FKBP5^[32,33]. The immunophilin *FKBP5* (FK506-binding protein 5) is an androgen-responsive gene whose scaffolding activity is required for PHLPP to dephosphorylate AKT at S473, a site on which phosphorylation is necessary for full activation of AKT^[34,35]. In addition, FKBP5 enables the pharmacologic activity of rapamycin by binding to it that allows the association of FKBP5-rapamycin complex to the FKBP5-rapamycin binding domain (FRB domain) of mTORC1. FKBP5-rapamycin binding to FRB directly inhibits mTORC1 by masking its substrates docking sites or dissociating the regulatory subunits from the mTORC1 complex (reviewed in Ref.^[36]).

ROLE OF TLK1 IN PCA PROGRESSION AND DRUG RESISTANCE

The functional implications of TLK1 overexpression and/or TLK1B translational upregulation have multifaceted role in driving drug resistance and hence, promoting PCa aggressiveness. Our group first demonstrated that TLK1/1B can mediate DNA damage response (DDR) through NIMA-related kinase 1 (NEK1). TLK1/1B tightly binds and phosphorylates NEK1 both *in vitro* and *in vivo* and this association is strengthened during DNA damage events^[27]. Several studies reported NEK1 as a crucial factor in mediating the DDR along with its functions in other cellular processes, like the regulation of mitosis. In response to genotoxic threats, NEK1 is translocated to DNA damage foci in the nucleus and triggers the cell cycle

checkpoint by activating Chk1 and/or Chk2^[37,38]. The connection between NEK1 and DDR became more convincing by the findings that NEK1 kinase activity is required for ATR-ATRIP stability and ATR activation, which, in turn, activates Chk1^[39]. Although NEK1 activity increases upon DNA damages, the upstream regulator of NEK1 was not reported before Singh *et al.*^[27] published work. Singh *et al.*^[27] reported that TLK1/1B phosphorylates NEK1 at a novel T141 residue that is adjacent to the activation loop and converts it to a hyperactive form. Since both TLK1/1B and NEK1 catalytic functions peak during the same phases of the cell cycle (S and G₂/M) and by DNA damage, it is likely that their activities are linked, i.e., TLK1/1B regulates the kinase activity of NEK1. Indeed, genetic depletion of NEK1 or overexpression of a NEK1 T141A variant or pharmacologic inhibition of TLK1/1B, all resulted in reduced activation of ATR and Chk1 and increased S phase duration, but decreased G₂/M phase cells suggesting the elimination of the cell cycle checkpoint after H₂O₂ treatment^[27].

TLK1B MEDIATED COMPLEMENTATION OF THE AR/DDR ACTIVATION LOOP

Inhibition of AR signaling by ADT leads to the downregulation of multiple key DNA repair enzymes involved in homologous recombination repair (HRR), non-homologous end joining (NHEJ), and mismatch repair (MMR) pathways, resulting in inefficient DNA repair, which leads to genomic instability^[9]. Several independent studies identified DNA-PKc, Ku70 (key players of NHEJ), BRCA1, RAD54L, RMI2 (associated with HRR), MSH2, MSH6 (key players of MMR) as direct targets of AR^[5,7-9,40]. When cells try to undergo mitotic division with excessively damaged DNA, they become vulnerable to apoptotic death. These liabilities may render prostate cancer cells particularly sensitive to inhibition of specific DDR pathways, such as PARP in homologous recombination DNA repair^[41] and Chk1 in cell cycle checkpoint and DNA repair^[42], creating opportunities for synthetic lethality^[43]. However, PCa cells may develop a compensatory mechanism by activating mTOR and translational upregulation of TLK1B to promote castration-resistant growth. Regulation via the translational increase in TLK1B isoform abrogates the need for its *de novo* gene expression, which is a faster and more energy-efficient mechanism of genome protection by activating TLK1>NEK1>ATR>Chk1 axis^[30]. Singh *et al.*^[30,31] demonstrated that combination treatment of anti-androgen (bicalutamide) and TLK1 inhibitor [Thioridazine (THD)] synergistically decreases the formation of androgen-independent (AI) colonies of LNCaP cells and LNCaP xenograft tumors and increase apoptotic rate than bicalutamide treatment alone. We have yet to test in xenografts whether combination with second-generation anti-androgens, like enzalutamide, will produce the same effects, although, from the theoretical standpoint, there is no reason to suspect it would be different. Biochemically, ADT+THD treatment reduces pNEK1 T141, pATR, and pChk1 level, which suggest the possible involvement of TLK1>NEK1>ATR>Chk1 mediated DDR pathway in the development of CRPC. Similarly, NEK1 T141A overexpressing LNCaP and xenograft tumor remain sensitive to ADT and do not transition to AI growth, which confirms the persistence of TLK1>NEK1 signaling in PCa drug resistance to ADT^[30]. Correlated increase of TLK1B and pNEK1 T141 with PCa progression was evident from a human PCa-TMA, TRAMP (a PCa mice model) and PDX tumor tissues; all suggested the universality of TLK1>NEK1 signaling in PCa models^[31]. In fact, targeting TLK1 could potentiate the activity of other DNA damaging agents as evident from our group and others' works in different cancers. For instance, TLK1 inhibition chemosensitizes PCa (PC3) and breast cancer (MDA-MB-231 and 4T1) cells to doxorubicin (Ronald *et al.*^[44], Jin *et al.*^[45]), glioblastoma cells (U87MG) to temozolomide (Ibrahim *et al.*^[46]), cholangiocarcinoma (SSP25 and HuCCT1) and ovarian cancer cells (SKOV-3) to cisplatin (Takayama *et al.*^[47]; Rho *et al.*^[48]). Since resistance to cisplatin, doxorubicin, and radiotherapies are common in CRPC, TLK1 inhibition may reverse the resistance of CRPC cells to these agents^[49,50]. Our group was first to identify a number of compounds that inhibit TLK1 and TLK2 in the class of phenothiazines antipsychotics, suggesting their repurposing as a clinical option^[44], and a newer derivative (J54) lacking appreciable anti-dopaminergic activity^[51].

ROLE OF TLK1 IN THE HIPPO/YAP PATHWAY

TLK1-NEK1 signaling has pleiotropic effects on several oncogenic processes regulating PCa progression and drug resistance. A key finding from our lab is that TLK1 dependent hyperactive NEK1 can phosphorylate YAP and promote its stability^[52]. The observation that NEK1 can interact and phosphorylate TAZ prompted us to investigate whether NEK1 can also phosphorylate YAP, a key effector of hippo pathway highly homologous to TAZ^[53]. NEK1 genetic depletion or NEK1 T141A variant overexpression or TLK1 inhibition all resulted in YAP degradation and downregulation of YAP target genes in PCa cells. In addition, we demonstrated that NEK1 can phosphorylate YAP1 in six unique residues *in vitro*, of which pYAP1 Y407 seems most interesting^[52]. YAP1 Y407 phosphorylation by NEK1 may increase the binding affinity of YAP to its transcriptional activators resulting in YAP nuclear translocation away from cytoplasmic degradation. Determining the functional relevance of these phosphorylation sites of YAP in CRPC progression and drug resistance development is currently an active pursuit of our lab. TLK1>NEK1>YAP axis may also converge with the reciprocal feedback loop of AR and DDR (AR signaling induces DNA repair genes expression and DNA damage increases AR activity), as YAP regulates AR target genes expression^[7,54,55].

ROLE OF TLK1 IN OTHER PATHWAYS

TLK1-NEK1 axis regulates other survival pathways independent of DDR and hippo/YAP regulation. We demonstrated that TLK1>NEK1 axis can promote survival of PCa cells by maintaining mitochondrial membrane integrity by phosphorylating VDAC1 leading to apoptotic suppression^[56]. VDAC1 is a pore-forming, outer mitochondrial membrane protein that regulates metabolic and ionic exchanges between the mitochondria and cell and is often overexpressed in high grade PCa (reviewed in Ref.^[57]). NEK1 can phosphorylate VDAC1 on S193 residue controlling its gatekeeping activity^[58]. We demonstrated that disruption of TLK1>NEK1 axis sensitizes the PCa cells to low doses of doxorubicin treatment by reducing VDAC1 S193 phosphorylation and its stability. Doxorubicin treatment of NEK1 T141A mutant variant overexpressing cells displayed enhanced population of sub G1 cells, reduced oxygen consumption, and increased cytochrome C (Cyt-C) release in cytoplasm resulting in the activation of intrinsic apoptotic pathway compared to the wild type NEK1 overexpressing cells^[56].

TLK1 also directly facilitates other pro-survival pathways through some substrates independent of NEK1. TLK1 mediates anti-apoptotic responses through AKT activation by interacting and phosphorylating AKT interacting protein (AKTIP). TLK1 phosphorylation of AKTIP on T22 and S237 residues increases its scaffolding activity to anchor both AKT and PDK1 to the phosphatidylinositol (3,4,5)-trisphosphate (PIP3) regions of the plasma membrane where PDK1 can phosphorylate AKT on T308 residue followed by S473 phosphorylation by mTORC2 complex for full activation of AKT^[59]. Fully activated AKT may relay pro-survival signals by inhibiting BAD, caspase 9, and FoxO3 pro-apoptotic factors through phosphorylation facilitating CRPC progression. However, the role of AKTIP phosphorylation by TLK1 in CRPC drug resistance needs to be further assessed. In a recent endeavor, we uncovered the novel interaction between TLK1 and MK5 that promotes PCa cell motility and invasion. MK5 is a known promotility kinase that can be phosphorylated by TLK1 in three unique residues that increases MK5's catalytic function. We demonstrated that one phospho-acceptor site of MK5 (S354) by TLK1 is present in all major PCa cell lines of both androgen-dependent and independent categories. Furthermore, ADT increases pMK5 S354 level in LNCaP cells, and this pMK5 protein is progressively increased in tumors of higher grades and nodal metastatic scores analyzed from TRAMP mice prostate tissue and human PCa TMA, suggesting that the TLK1>MK5 signaling may be associated with increased aggressiveness of PCa. Finally, disruption of TLK1>MK5 axis by TLK1 or MK5 inhibition drastically reduces PCa cells motility analyzed in a panel of PCa cell lines^[29]. [Figure 1](#) graphically depicts the currently known multifaceted roles of TLK1 in mCRPC progression and acquisition of drug resistance.

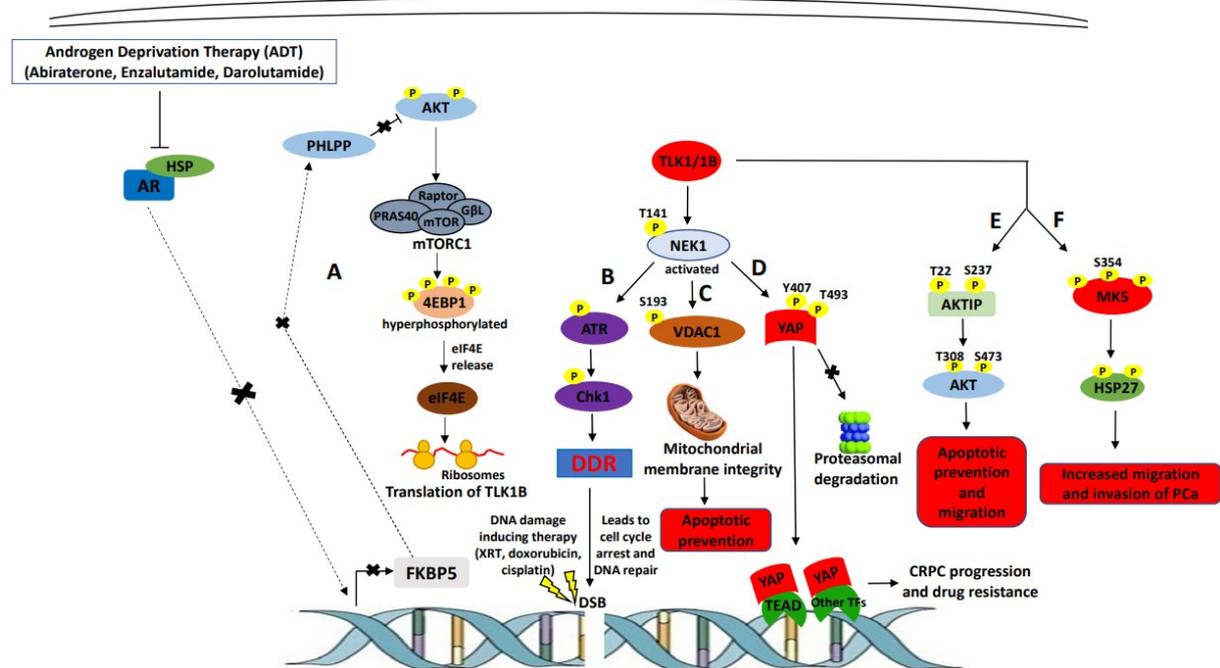

Figure 1. TLK1's role in mediating mCRPC progression and therapy resistance. (A) androgen deprivation therapy (ADT) blocks androgen receptor (AR) nuclear localization resulting in FKBP5 downregulation, which in turn, leads to AKT activation due to reduced dephosphorylation activity of PHLPP. AKT activation leads to mTORC1 activation, which activates 4EBP1 and releases eIF4E. Excess eIF4E initiates the translation of TLK1B. (B) TLK1/1B activates NEK1 by T141 phosphorylation, which in turn, activates ATR>Chk1>DNA damage response (DDR) signaling cascade. Activation of DDR promotes DNA repair inflicted by DNA damaging therapeutic agents. (C) TLK1>NEK1 axis is involved in VDAC1 S193 phosphorylation which maintains mitochondrial membrane integrity and suppresses intrinsic apoptotic signaling. (D) TLK1>NEK1 signaling phosphorylates YAP on Y407 and T493 residues and promotes the stabilization of YAP by binding to TEAD or other transcription factors (TF), leading to nuclear relocalization escaping proteasomal degradation. YAP stabilization and accumulation lead to CRPC progression and drug resistance. (E) TLK1 directly phosphorylates AKTIP on T22 and S237 residues, which stimulates AKT phosphorylation and activation, resulting in pro-survival and pro-migratory signaling. (F) TLK1 directly interacts and phosphorylates MK5, which increases its catalytic activity towards HSP27 (an MK5 substrate) and leads to increased migration and invasion, hence, metastasis of PCa cells.

TARGETING TLK1 AND THE DDR TO REDUCE DRUG RESISTANCE

DNA damage response (DDR) is a vital mechanism for PCa cells' survival and propagation. In addition, intact DDR activity may give hormone-refractory PCa cells an undue advantage against DNA damage-inducing therapies by keeping their genomic instability to sub-toxic level, thus, promoting drug resistance. Targeting TLK1 might be an excellent approach to impair DDR along with other oncogenic survival pathways as mentioned earlier. TLK1 is a better druggable target than other kinases of the DDR pathway, such as ATM or Chk1, to reduce general toxicity as ADT selectively increases TLK1B level in PCa cells, which can be easily manipulated using TLK1 specific inhibitors sparing the non-cancerous cells. Further efforts need to be given to design and generate better TLK1 inhibitors with improved pharmacokinetics, safety, and tolerability for clinical application. In fact, in recent years, our lab, in collaboration with others, has designed and synthesized a phenothiazine analog named J54 with higher efficacy in TLK1 inhibition and lower non-target effects unlike THD^[51,52]. Personalized application of TLK1 inhibition as an adjuvant and neoadjuvant therapy in combination with other PCa directed treatments may overcome the drug-resistant phenotype of CRPC and bring therapeutic benefit.

DECLARATIONS

Abstract

Lung cancer is the leading cause of cancer-related death worldwide. Despite advances in diagnosis and treatment of lung cancer, the overall survival remains poor. Evidence indicates that lung cancer development is a complex and dynamic process that involves interactions between tumor cells and their microenvironments, including immune cells. Exosomes are small extracellular vesicles secreted by most cell types; they contain functional molecules that allow intercellular communication. Tumor-derived exosomes (TEXs) carry both immunosuppressive and immunostimulatory mediators and may be involved in various immunomodulatory effects. TEXs, which partially mimic profiles of the parent cells, are a potential source of cancer biomarkers for prognosis, diagnosis, and prediction of response to therapy. In addition, TEXs may interfere with immunotherapies, but they also could be used as adjuvants and antigenic components in vaccines against lung cancer. In the context of lung cancer, identifying TEXs and understanding their contribution to tumorigenesis and the response to immunotherapies represents a challenging research area.

Keywords: Lung cancer, tumor-derived exosomes, cancer biomarkers, immunotherapies

INTRODUCTION

Lung cancer is one of the most common malignant tumors with the highest morbidity and mortality worldwide^[1]. Recently, immunotherapies have shown more effectiveness than traditional chemotherapy,

and they have dramatically changed the treatment paradigm for lung cancer^[2-4]. However, only a small proportion of patients can benefit from the immunotherapies, with primary and secondary resistance complicating treatment. One potential explanation for this phenomenon is the complexity and diversity of the tumor microenvironment (TME). Interactions of lung cancer cells with the surrounding TME are critical to cancer progression and response to immunotherapy. In recent years, the communication mediated by exosomes has extensively gained attention.

Exosomes are small bilayer membrane vesicles with a size of 30-100 nm in diameter that are secreted by various cell types such as tumor cells, immune cells, and fibroblasts^[5,6]. Exosomes derived from tumor cells are referred to as tumor-derived exosomes (TEXs)^[7]. TEXs have been shown to contain a variety of biomolecules including nucleic acids, proteins, enzymes, and lipids, which are involved in cancer progression, intercellular communication, and immunological function^[8]. Studies have increasingly indicated that the number and composition of TEXs can in part reflect their cells of origin and biological state, which may serve as potential biomarkers in diagnosis and prognosis of cancer^[9-11]. TEXs may affect cancer immunotherapy either by sequestration of therapeutic antibodies or supplying self-antigen carriers to improve cancer vaccine efficacy. Their biological roles in cancer progression as well as cancer immunotherapy and biomarkers have indicated that TEXs are critical components of the TME.

In this review, we first describe how TEXs are formed and released to the extracellular matrix, and discuss the composition of TEXs. Then, we outline the immunomodulatory function of TEXs in the lung cancer microenvironment. Moreover, we focus on the utility of TEXs as diagnostic and prognostic biomarkers in lung cancer. Finally, the recent findings on TEXs in immunological changes during immunotherapy are discussed.

THE FORMATION, RELEASE, AND COMPOSITION OF TEXS

TEXs, released by tumor cells, are present ubiquitously in tumor tissues and body fluids^[12]. Exosome biogenesis initiates from the production of early endosomes via the internalization of membrane microdomains. The limiting membrane of early endosomes bud inwardly to form intraluminal vesicles, then becoming the multivesicular bodies. Finally, exosomes are released when multivesicular bodies fuse with the plasma membrane^[13]. This formation of exosomes is a tightly regulated process; it involves two pathways through an Endosomal Sorting Complex Required for Transport (ESCRT)-dependent machinery or an ESCRT-independent machinery^[14]. Once exosomes released, they are able to transfer information to their recipient cells through three main ways: endocytosis/phagocytosis, direct fusion with cellular membrane, and receptor-ligand interactions^[13] [Figure 1A].

TEXs consist of a lipid-protein bilayer membrane, including membrane transport and fusion proteins (e.g., annexins, Rab proteins, and flotillin), MHC (class I and II molecules), adhesion molecules (e.g., ICAM, EPCAM, CD44, and integrins), inhibitory ligands [e.g., FasL, TRAIL, PD-L1, and transforming growth factor (TGF)- β /LAP], tetraspanins (e.g., CD9, CD63, CD81, and CD82), tumor associated antigens, chaperones [e.g., heat-shock protein (HSP) 70 and HSP90], lipids, and glycolipids^[12,13,15-17]. In their lumen, TEXs carry a variety of multivesicular bodies biogenesis proteins [e.g., Alix and tumor susceptibility gene 101 (TSG101)], cytoskeletal proteins (e.g., actin, tubulin, and vimentin), histones, oncoproteins, soluble factors, enzymes, cytokines, signaling molecules, and nucleic acids (including DNA, mRNA, and miRNA)^[13,15] [Figure 1B]. The TEXs molecular and genetic content mimics that of parent cells, and is in part considered as surrogates of the parent tumor cells^[18]. Moreover, TEXs can transfer messages from the parent tumor to recipient cells, including immune cells, within the TME^[19].

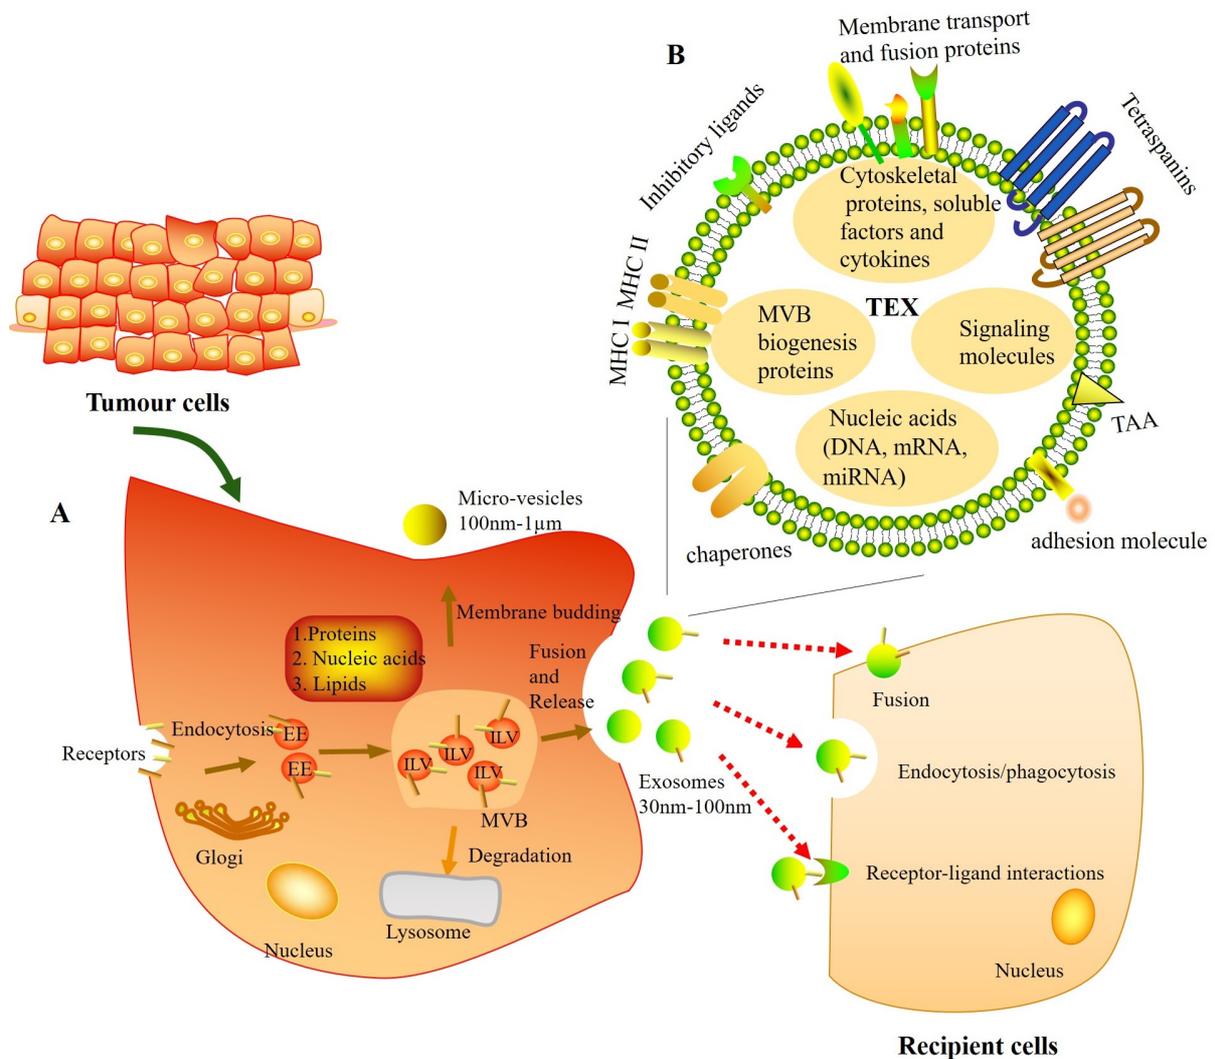

Figure 1. Molecular composition, biogenesis, release, and uptake of tumor-derived exosomes (TEXs). (A) TEXs originate from intraluminal vesicles (ILVs) in the multivesicular bodies (MVBs) (also known as late endosomes). Firstly, early endosomes (EEs) are formed when the membrane microdomains are endocytosed via inward budding of the plasma membrane. Then EEs mature into MVBs, which follow either fusion with the plasma membrane to form exosomes or degradation by lysosome. During this process, the proteins, nucleic acids, and lipids are packed into exosomes. Finally, exosomes can interact with recipient cells through the three main ways: endocytosis/phagocytosis, direct fusion with cellular membrane, and receptor-ligand interactions. (B) Schematic diagram of components of TEXs.

EFFECT OF TEXS FOR IMMUNE REGULATION IN LUNG CANCER

Recently, TEXs have been proposed to act as crucial mediators between cellular communication by transferring both immunosuppressive and immunostimulatory signals to immune cells in a lung cancer microenvironment^[20,21] [Table 1, Figure 2].

Immunosuppressive effect of TEXs

TEXs modulate the activity of T cells by promoting apoptosis and inhibiting proliferation of CD8⁺ T cells^[22]. Recent studies have indicated that TEXs contain PD-L1, which inhibits T cells activity and promotes tumor progression. Exosomes from lung cancer, melanoma, and breast cancer carry PD-L1 on their surface, which interacts with PD-1 via the extracellular domain, and thereby inactivate T cells^[23]. Poggio *et al.*^[24] discovered that the majority of PD-L1 could be presented on the surface of TEXs, and genetic blockade of exosomal

Table 1. Overview of exosomal cargo, source of exosomes, and their biological effects

Exosomal cargo	Donor	Biological effect	Ref.
PD-L1	H1299, H358, and H1264	Inactivate T cells	[23]
EGFR	NSCLC biopsies	Induce tolerogenic DCs	[28]
miR-214	Lewis lung carcinoma cells	Downregulate the PTEN-mediated signaling	[29]
miR-433	Plasma of NSCLC patients	Inactivate the WNT/ β catenin signaling	[31]
miR-21/29a	A-549 and SK-MES	Activate TLR7 and TLR8	[32]
miR-21a	Lewis lung carcinoma cells	Promote MDSCs expansion	[51]
miR-103a	CL1-5 lung cancer cells	Activate of PI3K/Akt and STAT3 signaling pathways	[52]
circFARSA	A549 and PC9 cells	Polarize macrophages to the M2 phenotype	[54]
miR-770	A549 cells	Suppress M2 macrophage polarization	[62]

NSCLC: Non small cell lung cancer; DCs: dendritic cells; MDSCs: myeloid-derived suppressor cells.

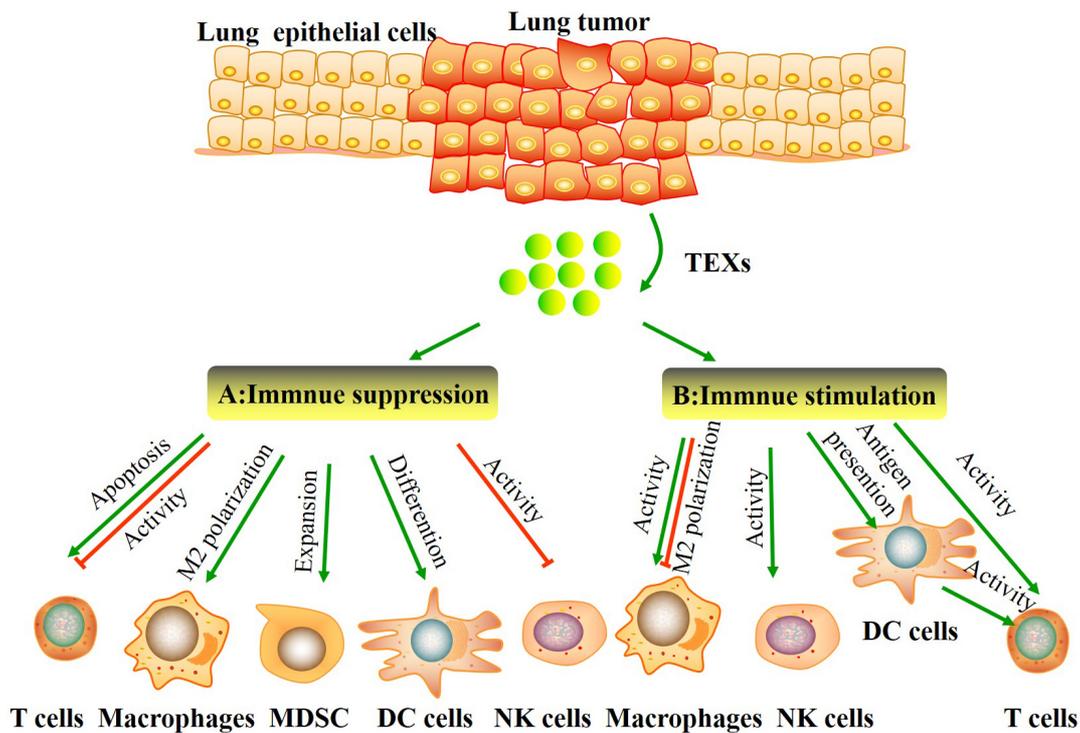

Figure 2. Tumor-derived exosomes (TEXs) carry and deliver both immunosuppressive and immunostimulatory signals to immune cells in the lung tumor microenvironment. (A) Immune suppression. TEXs contribute to establish an immunosuppressive TME by inducing apoptosis and inhibiting the activity of effector T cells, skewing M2 polarization of macrophages, expanding myeloid-derived suppressor cells (MDSCs), suppressing DCs differentiation, and impairing the function of NK cells. (B) Immune stimulation. TEXs can also stimulate immune cells to support antitumor activities, including enhancing the activity of macrophages and NK cells, suppressing M2 macrophage polarization, and increase T cells activity directly or indirectly.

PD-L1 could activate an anti-tumor immune response leading to extend survival in a subset of cancer patients. Moreover, it is suggested that TEXs with FasL expression could induce CD8⁺ T cell apoptosis^[25,26]. Czystowska *et al.*^[27] uncovered the mechanism that the PI3K/Akt pathway was a central target for TEXs in regulating CD8⁺ T cell apoptosis. Huang *et al.*^[28] indicated that about 80% of exosomes isolated from non-small cell lung cancer (NSCLC) biopsies contained EGFR. These exosomes can be captured by dendritic cells (DCs). Then tolerogenic DCs were generated and induced tumor antigen specific regulatory T cells (Tregs), which could inhibit the function of tumor specific CD8⁺ T cells. Yin *et al.*^[29] found that miR-214

was delivered into recipient CD4⁺ T cells via TEXs, so as to downregulate the PTEN-mediated signaling, thereby promoting Treg expansion and tumor growth. Interestingly, co-incubation of Treg with TEXs may enhance Treg number as well as its suppressive function with the increased production of inhibitory cytokines, TGF- β 1 and interleukin (IL)-10^[30]. Additionally, Liu *et al.*^[31] showed that exosome-derived miR-433 inactivated the WNT/ β -catenin signaling pathway via targeting transmembrane p24 trafficking protein 5, thus increasing infiltration of CD4⁺ and CD8⁺ cells in NSCLC.

Exosome-derived miR-21/29a derived from A-549 and SK-MES cells promoted lung cancer growth and metastasis through activating Toll like receptors TLR7 and TLR8 on immune cells including NK cells^[32]. NK cells express a variety of receptors that are either stimulatory or inhibitory^[33]. The downregulation of those stimulatory receptors, particularly NKG2D, may play an important role in decreasing activity of NK cells in lung cancer patients^[34]. TEXs originating from hypoxic tumor cells deliver TGF- β 1 to NK cells, and thereby reduce NKG2D expression resulting in lower activity of NK cells^[35]. TEXs can also attenuate NK cell activity via multiple mechanisms including shedding the NKG2D ligand on tumor cells, suppressing Janus kinase (Jak) 3 activation, inhibiting perforin or cyclin D3 production and down-regulation of IL-2-mediated pathways^[36-41]. Moreover, TEX-carried MICA and MICB ligands can downregulate the stimulatory receptors, especially NKG2D on NK cells^[42].

TEXs suppressed the functioning of the immune system by affecting the monocyte differentiation and maturation^[43,44]. TEXs were capable of blocking DCs migration to lymph nodes through inhibiting most C-C/C-X-C chemokine receptor expression^[45]. Co-incubation of DCs with TEXs led to the down regulation of CD80 and CD86, and subsequently inhibited DCs maturation^[46]. In addition, TEXs have been shown to induce the differentiation of myeloid precursor cells into highly suppressive myeloid-derived suppressor cells (MDSCs)^[39,47]. Heat-shock protein 72 (Hsp72) on the TEXs surface could trigger the STAT3 activation and autocrine IL-6 production in MDSCs via a TLR2/MyD88-dependent manner, leading to the increment of immunosuppressive activity of MDSCs^[48-50]. Zhang *et al.*^[51] indicated that miR-21a enriched in lung carcinoma cell-derived exosomes could promote MDSCs expansion via targeting PDCD4, thus enhancing tumor growth. Hsu *et al.*^[52] reported that miR-103a was upregulated in lung cancer derived exosomes under hypoxic conditions. Exosomal miR-103a could cause the activation of PI3K/Akt and STAT3 signaling pathways by directly targeting PTEN, thereby resulting in the enhancement of M2 polarization^[52]. Additionally, the study with A549 (wild-type p53 allele) and H358 (p53 null allele) exosomes suggested that lung cancer cell-derived exosomes mediated M2 polarization may be p53 independent^[53]. Another study showed that exosomal circFARSA was significantly upregulated in NSCLC tissues and stimulated NSCLC cell metastasis by polarizing macrophages to the M2 phenotype^[54].

Taken together, these data suggested that TEXs can modulate the immune response by transferring immunosuppressive signals to immune cells, which in turn contribute to tumor progression^[7,34,55,56].

Immunostimulatory effect of TEXs

TEXs have been reported to be involved in the suppression of the immune system in previous studies. However, since TEXs also carry stimulatory molecules that contribute to activating immune responses, recent studies also focused on anti-tumor immunity of exosomes.

TEXs can act as presenters participating in direct and indirect antigen presentation^[57]. As direct presenters, TEXs present antigen to T cells via an MHC-peptide complex on their surface. On the other hand, TEXs can also indirectly transfer tumor antigen to antigen presenting cells, like DCs, and then activate the cytotoxic activity of CD8⁺ T cells and CD4⁺ T helper cells, so as to inhibit tumor growth^[58]. Additionally, the

enrichment of HSPs on TEXs such as Hsp70, can stimulate the activity of NK cells^[59] and macrophages^[60], and induce MHC class I-restricted cytotoxic T cells activation^[61]. Tumor cell-derived exosomal miR-770 could suppress M2 macrophage polarization via targeting MAP3K1, which in turn decreased NSCLC tumor growth^[62]. Tetraspanins on the exosome surface mainly mediate cell adhesion and participate in maintaining the optimal conformation of immune proteins like MHC class II, thus playing an important role in antitumor immunity through exosomal targeting to DCs^[61,63-65].

Therefore, the effect of exosomes' immune stimulation depends mainly on their antigen presentation, while the effect of inhibiting immunity mainly depends on exosome-carried biological content consisting of ligands, miRNAs, and proteins, which may inhibit the cytotoxic activity of the NK and CD8⁺ T cells or increase suppressive immune cells such as MDSCs, Treg cells, and M2 macrophages. Understanding the effect of TEXs in immune regulation will allow for better understanding of the clinical application of TEXs in cancer diagnosis and treatment.

TEXS SERVE AS DIAGNOSTIC AND PROGNOSTIC BIOMARKERS IN LUNG CANCER

TEXs and their content in biofluids, which represent the content of parent cells, may serve as newly developed non-invasive biomarkers for diagnosis, prognosis, and monitoring the efficacy of treatment in lung cancer^[9-11].

Jakobsen *et al.*^[66] examined the potential of exosomal proteins as diagnostic markers in advanced NSCLC. The EV (extracellular vesicle) array showed that the expression levels of CD9, CD63, and CD81 were significantly high in cancerous patients. Likewise, according to the EV array, NYESO-1, EGFR, and PLAP showed a strong correlation with a poor survival in NSCLC^[11]. In addition, SRGN, TPM3, THBS1, and HUWE1 may serve as biomarkers to distinguish lung adenocarcinoma subjects from controls^[67]. Combination of carcinoembryonic antigen, exosomal alpha-2-HS-glycoprotein and extracellular matrix protein 1 (ECM1) could improve the diagnostic accuracy of NSCLC^[68]. Gao *et al.*^[69] indicated that plasma exosomal total protein, Tim-3 and Galectin-9 were significantly increased in NSCLC, and were positively associated with larger tumor size, advanced TNM stage, and distant metastases. The higher level of leucinerich a-2-glycoprotein (LRG1) was detected in urinary exosomes and may be a non-invasive diagnostic biomarker of NSCLC in urine^[70].

Several studies have shown that exosomal miRNAs may serve as potential biomarkers for the early diagnosis of lung cancer. Rabinowits *et al.*^[71] suggested that exosomal miRNAs in NSCLC patients very closely resemble those in NSCLC tissue, indicating that such a liquid biopsy may obviate the need to obtain tumor tissues. Tumor-derived exosomal miRNAs, adenocarcinoma-specific miR-181-5p, miR-361-5p, miR-30a-3p, and miR-30e-3p, and squamous cell carcinoma-specific miR-10b-5p, miR-320b, and miR-15b-5p, were isolated from the plasma of early-stage NSCLC patients, which are able to discriminate between adenocarcinoma and squamous cell carcinoma, thereby serving as noninvasive biomarkers for early diagnosis of NSCLC^[72]. Exosomal miR-1169 and miR-260 have also been identified as potential biomarkers that can distinguish between early-stage wild-type EGFR and mutant EGFR NSCLC^[73]. Exosomal miR-20b-5p and miR-3187-5p were drastically reduced in early-stage NSCLC patients than those in healthy controls, showing both exosomal miRNAs were efficient diagnostic biomarkers for early-stage NSCLC^[74]. Exosomal miR-126 has also been identified as a possible diagnostic biomarker for NSCLC progression^[75]. In fact, exosomes exist extensively in body fluids other than blood, and increasing attention has been focused on diagnostic assays in pleural fluid. Tamiya *et al.*^[76] revealed that exosomal miR-182 and miR-210 were demonstrated to have a diagnostic potential for differentiating lung adenocarcinoma pleural effusion from benign pleural effusion. Additionally, exosomal miR-200 and mRNA transcript encoding lipocalin-2 from

pleural effusions may be considered as diagnostic markers to discriminate lung adenocarcinoma patients from patients with benign inflammatory processes^[77].

Recently, exosomal RNAs have been reported to predict the prognosis of a variety of cancers including lung cancer. Dejima *et al.*^[78] showed that exosomal miR-21 and miR-4257 levels of the NSCLC patients were significantly upregulated during recurrence and can be used as recurrence-specific biomarkers. Additionally, another study reported that low exosomal let-7a-5p levels were significantly associated with a worse cancer-related survival rate in lung adenocarcinoma patients^[79]. Luo *et al.*^[80] also demonstrated that serum exosomal miR-382 was considered as an independent prognostic biomarker for NSCLC. Zhang *et al.*^[81] suggested that exosomal lncRNA MALAT-1 was highly expressed in NSCLC patients and was positively associated with lymphatic metastasis and TNM stage, thereby indicating that exosomal MALAT-1 may be a non-invasive biomarker for diagnosis and prognosis of NSCLC. Moreover, tumor-derived exosomal eIF4E has the potential for use as a biomarker for survival prediction in NSCLC^[82].

Acquired resistance to general therapies, including chemotherapy, radiotherapy, immunotherapy, and targeted therapy, is a major challenge in the treatment of lung cancer. Nowadays, the use of exosomes as biomarkers for predicting therapeutic responses has gathered much attention. Exosomal hsa_circ_0014235 isolated from plasma promoted cisplatin chemoresistance and may serve as a promising biomarker for NSCLC treatment^[83]. Exosomal miR-4443 might also promote cisplatin resistance of NSCLC by regulating FSP1-mediated ferroptosis^[84]. In addition, Li *et al.*^[85] showed that plasma exosomal miR-92b-3p was significantly increased in chemoresistant small cell lung cancer patients and might serve as a potential dynamic biomarker for monitoring the drug resistance. Exosomal miR-29a-3p and miR-150-5p were identified as circulating biomarkers during thoracic radiation therapy for NSCLC and were correlated with delivered radiation therapy dose^[86]. At present, precision medicine based on immunotherapy and targeted therapy has given new hope for lung cancer patients. The ensuing problems of drug resistance have gained much interest from the research community. For example, exosomal miR-323-3p, miR-1468-3p, miR-5189-5p, and miR-6513-5p were identified as potential biomarkers to discriminate between osimertinib-resistant and osimertinib-sensitive NSCLC patients^[87], and exosomal miR-210-3p secreted by osimertinib-resistant HCC827 and PC-9 cells was able to promote epithelial-mesenchymal transition and drug resistance in osimertinib-sensitive, EGFR mutant NSCLC cells^[88]. Moreover, exosomal circRNA_102481 enhanced EGFR-TKIs resistance through the microRNA-30a-5p/ROR1 axis in NSCLC^[89]. Peng *et al.*^[90] suggested that high exosomal miR320d, miR320c, and miR320b levels were corelated with poor response to anti-PD-1 treatment in patients with NSCLC, and exosomal miR-125b-5p was identified to be one potential target for anti-PD-1 treatment. In summary, exosomal RNAs in lung cancer could be used for monitoring therapy response/relapse to improve personalized therapy strategies.

THE ROLE OF TEXS IN IMMUNOTHERAPY OF LUNG CANCER

Effect of TEXs for resistance to immunotherapy

TEXs may suppress proliferation and differentiation of immune cells and have the ability to influence their biological function. TEXs carrying a variety of tumor associated antigens or immunoinhibitory mediators not only suppress antitumor functions of immune effector cells, but also appear to impede effective response to immunotherapy in cancer^[8]. Tumor associated antigens on TEXs could efficiently bind antibodies produced against cancer cells and block the access of therapeutic antibodies to the cancer cells, leading to a decrease in effectiveness of cancer therapy^[91]. Additionally, TEXs are able to inhibit antibody dependent cell-mediated cytotoxicity, which serves as a critical mechanism of therapeutic antitumor activity of anticancer antibodies^[91]. During therapy, immune escape in NSCLC occurs through a multistep process that facilitates tumor growth and progression. Acquired tumor resistance to immunotherapy could be

directly reflected in the production of TEXs^[92]. Most importantly, Kim *et al.*^[93] showed that lung cancer cells increased their production of immunosuppressive exosomes during acquired resistance to anti-PDL1 immunotherapy.

TEXs-based cancer vaccine and immunotherapy

TEXs are nanoscale membrane-derived vesicles that are thought to be important mediators of intercellular communication. Moreover, TEXs with distinct characteristics such as stability, permeability, biocompatibility, low immunogenicity, and low toxicity can efficiently deliver tumor antigens to DCs, thus they can be used as self-antigen carriers to stimulate immune response^[94-96]. Increasing evidences have demonstrated that the activation and maturation of DCs by TEXs could enhance anti-tumor effects and may be applied for lung cancer immunotherapy. For example, TEXs from *CD40L*-gene modified 3LL lung tumor cells have the potent ability to activate DCs, resulting in significantly increased tumor antigen-specific CD4⁺ T cell proliferation and CD8⁺ T cell responses, revealing a powerful antitumor effect^[97]. In addition, the exosomes derived from Rab27-overexpressing NSCLC cells also stimulated the proliferation and maturation of DCs effectively, promoted CD4⁺ T cell proliferation and elicited potent antitumor immune responses^[98]. Multiple studies have already proved that TEXs which were used as tumor antigens source for DC vaccines, have greater efficacy and safety than conventional tumor cell lysates^[99-103]. Wang *et al.*^[104] indicated that TEXs were more potent than tumor cell lysates to trigger DC-mediated immune responses and decrease Tregs, contributing to improving vaccine-elicited immunotherapy for lung cancer. Thus, DCs loaded with TEXs may be promising therapeutics without severe side effects and treatment resistance in clinical application^[105].

CONCLUSION

TEXs are important mediators of intercellular communication and have been proven to play a key role in the TME. The biogenesis and secretion of TEXs have been widely reported. They carry a variety of cargoes and are involved in both immunosuppressive and immunostimulatory signaling pathways by delivering molecular signals to immune cells. The small size of TEXs and their contents render them highly interesting for biomedical applications, such as biomarker molecules and anticancer vaccines. Based on the data herein, we suggest that TEXs could be manipulated to provide clinical benefits and improve the clinical management of lung cancer.

Abstract

In recent years, immunotherapy has made remarkable breakthroughs and brought long-term survival benefits to lung cancer patients. However, a high percentage of patients do not respond to immunotherapy or their responses are transient, indicating the existence of immune resistance. Current studies show that the interactions between cancer cells and immune system are continuous and dynamic. A range of cancer cell-autonomous characteristics, tumor microenvironment factors, and host-related influences account for heterogeneous responses. Furthermore, with the identification of new targets of immunotherapy and the development of immune-based combinations, we propose the response strategies to overcome resistance.

Keywords: Immunotherapy, resistance mechanisms, response strategies

INTRODUCTION

According to the latest cancer report of China, the morbidity and mortality of lung cancer are still the highest among all types of malignancies. Immune checkpoint inhibitors (ICIs) have dramatically changed the treatment landscape for advanced non-small cell lung cancer (NSCLC). In neoadjuvant therapy, ICIs combined with chemotherapy have increased the chances of cure for patients with early-stage NSCLC. In maintenance treatment, durvalumab significantly prolonged the disease-free survival time of NSCLC after concurrent radiotherapy and chemotherapy. The five-year survival rate of patients with advanced NSCLC

who received ICI monotherapy increased from 5% to 15%. At the same time, ICIs combined with chemotherapy have also brought a giant breakthrough in the treatment of advanced small cell lung cancer (SCLC). However, the majority of patients treated with ICIs are either non-responders or eventually develop progressive disease^[1,2]. Therefore, clarifying resistance mechanisms and proposing response strategies for immunotherapy are ongoing challenges that need to be coped with. The tumor is a heterogeneous and dynamic tissue, which continuously evolves in the attempt to overcome structural, metabolic, and immunologic hurdles. Thus, resistance mechanisms and pathways are intertwined. Generally, the resistance mechanism of immunotherapy can be classified into two categories: intrinsic mechanisms and extrinsic mechanisms. Intrinsic mechanisms refer to the genetic, transcriptional or functional profile of the tumor cells themselves, while the extrinsic mechanisms refer to the tumor microenvironment and factors other than the tumor itself. The changes of immunosuppressive cells, immunosuppressive cytokines, coinhibitory receptors, and costimulatory receptors in the tumor microenvironment can destroy the antitumor immune response, mediating resistance to immunotherapy. Host-related factors including physical status, previous comorbidities, distribution of intestinal flora, and use of antibiotics could also affect the efficacy of immunotherapy. This opinion article intends to discuss the currently known mechanisms of immune resistance and potential response strategies in lung cancer. The mechanisms and factors of immune resistance discussed in this opinion are summarized in [Figure 1](#).

RESISTANCE MECHANISMS OF IMMUNOTHERAPY IN LUNG CANCER

Intrinsic mechanisms and factors of resistance

The intrinsic factors and mechanisms of resistance mainly refer to the expression or inhibition of specific genes and pathways of tumor cells, such as the activation of driver genes and the inactivation of suppressor genes, low tumor mutation burden (TMB), decreased tumor antigen presentation, and changes in the expression of programmed cell death ligand 1 (PD-L1) of tumor cells.

Activation of driver genes

Genomic or epigenetic alternations in tumor cells can mediate immune escape. Several driver genes have been identified in lung cancer, such as epidermal growth factor receptor (EGFR), anaplastic lymphoma kinase (ALK), and Kirsten rat sarcoma virus oncogene homolog (KRAS). They have all been confirmed to be related to the process of immune escape.

EGFR mutation is the most common type of mutation of NSCLC in Asians, with an incidence of 40.3%-64.5%^[3]. Clinical trials showed that these patients do not respond well to immune checkpoint monotherapy^[4-6]. There are several hypotheses for the inferior response of immunotherapy in this group of people. First, the immune microenvironment of this population belongs to the immune desert or immune excluded type with poor outcomes of immunotherapy^[7,8]. After the activation of EGFR pathway, the ligand amphiregulin (AREG) could promote the production of regulatory T (Treg) cells to enhance the immunosuppressive effect through EGFR-glycogen synthase kinase-3 β (GSK-3 β)-forkhead box P3 (FOXP3) axis^[9]. Besides, the EGFR signaling pathway can also produce inhibitory cytokines, induce myeloid-derived suppressor cells (MDSC) and tumor-associated macrophages (TAM) proliferation, and inhibit CD8+ T Cell response^[10]. Second, the signal transducer and activator of the transcription 3 (STAT3) from the downstream of the signal pathway is upregulated, which in turn leads to the decreased expression of major histocompatibility complex I^[11]. STAT3 also mediates the expression of vascular endothelial growth factor (VEGF), interleukin-6 (IL-6), and interleukin-10 (IL-10) and inhibits the differentiation and maturation of dendritic cells (DC). These changes will ultimately affect the presentation of antigens and the production of new antigens. Third, although most studies have demonstrated that EGFR will upregulate PD-L1, due to the decrease of new antigens and the increase of immunosuppressive cells, patients have not received durable

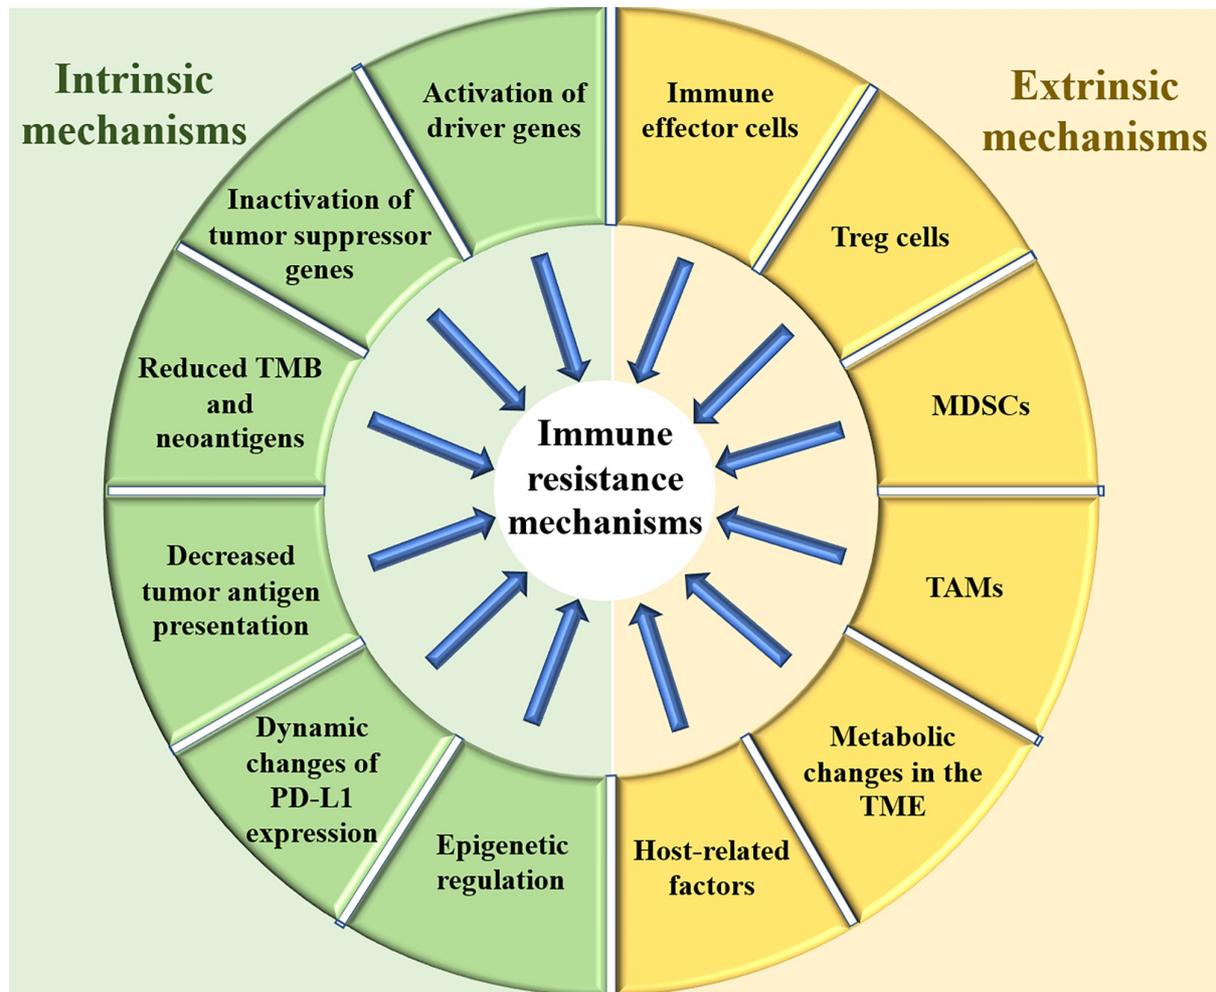

Figure 1. The intrinsic and extrinsic mechanisms and factors of immune resistance. TMB: Tumor mutation burden; PD-L1: programmed cell death ligand 1; MDSCs: myeloid-derived suppressor cells; TAMs: tumor-associated macrophages; TME: tumor microenvironment.

benefits from immune checkpoint monotherapy^[10].

Another common gene mutation in lung cancer is ALK fusion. ALK fusion can reduce the production of new antigens and increase the number of immunosuppressive cells through the PI3K-AKT and MEK-ERK pathways, resulting in poor efficacy of immune checkpoint monotherapy^[12,13]. *KRAS* is another common driver gene in lung cancer. Studies showed that *KRAS* mutation could increase the expression of PD-L1 to promote immune escape by regulating the stability of the 3'UTR region of PD-L1 mRNA^[14]. However, *KRAS* mutations are correlated with an inflammatory tumor microenvironment and tumor immunogenicity, resulting in superior patient response to PD-1/PD-L1 inhibitors. In a single-center retrospective study which included 25 cases of *KRAS* mutations and 47 wild-type cases, patients were administered with nivolumab ± anti-CTLA-4 antibody. The median overall survival (OS) of the two groups was 18.1 and 8.1 months, respectively (HR = 0.48, $P = 0.04$)^[15]. Mechanically, *KRAS* mutations induce the expression of neoantigens and change the expression a series of genes, such as cell cycle regulation, DNA replication, and DNA repair, but they have no obvious effect on activating immunosuppressive cells^[16]. Several driver mutations of NSCLC and their chances to receive ICI therapy are summarized in [Table 1](#).

Table 1. Common driver mutations of NSCLC and their chances to receive ICI therapy

EGFR mutation		ALK mutation		KRAS mutation		Other mutations	
ICI monotherapy	ICI combination therapy	ICI monotherapy	ICI combination therapy	Single mutation	KP co-mutations	KL co-mutations	MET/RET/ROS1/BRAF/HER2
×	√	×	?	√	√	×	?
Not recommended	Consider using ICIs in some cases	Not recommended	Consider using ICIs in some cases	Probably benefit from ICIs	Probably benefit from ICIs	Not recommended	No large-scale trials and need further research

NSCLC: Non-small cell lung cancer; ICIs: immune checkpoint inhibitors; EGFR: epidermal growth factor receptor; ALK: anaplastic lymphoma kinase; KRAS: Kirsten ratsarcoma viral oncogene homolog; KP: KRAS/TP53; KL: KRAS/STK11; MET: mesenchymal to epithelial transition factor; RET: ret proto-oncogene; ROS1: c-ros oncogene 1; BRAF: v-raf murine sarcoma viral oncogene homolog B; HER2: human epidermal growth factor receptor-2.

Inactivation of tumor suppressor genes

The inactivation of tumor suppressor genes, such as *PTEN* and *STK11* genes, can also lead to poor outcomes of immunotherapy for lung cancer patients. In drug-resistant populations, the occurrence of the tumor suppressor *PTEN* mutations are significantly increased^[17]. *PTEN* is a lipid phosphatase that inhibits the activity of the PI3K pathway. Current studies have shown that loss of *PTEN* expression is the most common way to activate the PI3K pathway in multiple cancers^[18]. The PI3K pathway plays an indispensable role in tumor growth by regulating tumor proliferation and survival. Another study found a decreased expression of tumor-infiltrating lymphocytes (TILs) in patients with a high deletion rate of *PTEN* gene^[19]. In addition, *PTEN* can upregulate the expression of VEGF and prevent tumor immune escape mediated by lymphocyte infiltration. *STK11/LKB1* is another tumor suppressor gene. About 8%-39% of patients with NSCLC have *STK11* gene mutation, which has the function of negatively regulating the rapamycin signal pathway. *STK11* gene mutations are often accompanied by a decreased infiltration of cytotoxic CD8+ T lymphocytes, leading to the “cold” immune microenvironment^[20]. Co-mutations of *KRAS* and *STK11* (KL) or *TP53* (KP) could also affect the efficacy of ICI therapy. Skoulidis *et al.*^[21] reported that patients with *KRAS* mutations and *STK11/LKB1* alterations had reduced efficacy to immunotherapy in a cohort of 165 patients diagnosed with *KRAS*-mutated lung adenocarcinoma who had received PD-1/PD-L1 inhibitors treatment. In a mice model of *KRAS* mutation, the deletion of *STK11* gene promotes the resistance of PD-1 inhibitors monotherapy. Thus, KL tumors show resistance to PD-1 inhibitors, while KP tumors are more sensitive. Besides, the mutation rate of *SMARCA4* gene in NSCLC is about 10%, which is responsible for encoding the catalytic unit of the SWI/SNF chromatin remodeling complex. A study included 2690 NSCLC patients, of whom 211 patients carried *SMARCA4* mutations^[22]. Further analyses revealed that *KRAS* and *SMARCA4* co-mutations are the most prevalent type. Among the NSCLC patients harboring *KRAS* mutations, patients with the co-occurrence of *SMARCA4* mutation had a reduced objective response rate (ORR) (0.0% vs. 23.5%, $P = 0.02$), progression-free survival (PFS) (1.7 months vs. 4.1 months, $P < 0.001$), and median OS (4.0 months vs. 14.9 months, $P < 0.001$). In summary, mutations of driver genes and tumor suppressor genes can lead to changes in tumor neoantigens and can also alter the composition of the immune microenvironment, which is reflected in the heterogeneous efficacy of immunotherapy. Thus, it is necessary to interpret its impact on the efficacy of immunotherapy and the predictive value of drug resistance in clinical practice.

Reduced TMB and neoantigens

TMB is the number of substitution, insertion, and deletion mutations per megabase in the exon coding region of the evaluated gene. Yarchoan *et al.*^[23] analyzed the TMB of 27 tumor types and found a superior ORR of immune checkpoint monotherapy for tumor types with high TMB. NSCLC and melanoma have relatively higher mutation loads and immunogenicity, and they are more sensitive to ICI therapy. On the contrary, pancreatic cancer, prostate cancer, and thyroid carcinoma have lower mutation loads and exhibit

lower immune responses^[23-25]. Tumor neoantigens refer to antigens that are not expressed in normal tissues but only exist in tumor tissues, which are usually highly immunogenic. Several studies have shown that increased TMB, DNA mismatch repair gene deletion, and high genomic microsatellite instability can increase tumor antigen expression and improve immune efficacy^[24,26]. Anagnostou *et al.*^[27] found that the neoantigen load of NSCLC patients treated with pembrolizumab with sustained clinical benefit was significantly higher than that of patients with non-sustained benefit. The study also found that 7-18 mutation-related neoantigens that can produce anti-cancer responses were lost and replaced by more complicated new mutations before drug resistance. The proportion of new mutations involved in encoding tumor antigens had decreased (8% *vs.* 19%) and the clonality of T cell receptors (TCR) was changed, leading to the acquired drug resistance.

Decreased tumor antigen presentation

The major histocompatibility complex (MHC) is a key molecule involved in the immune response, participating in the processing and presentation of antigens, thereby activating T cells and mediating the immune response. β 2-microglobulin (β 2-GM) is one of the important proteins that compose the heavy chain of MHC class I molecules, which is responsible for folding and transporting MHC class I molecules to the cell surface^[28]. Studies confirmed that *B2M* gene mutations can lead to the loss of MHC class I molecules on the cell surface, which in turn promotes the recognition dysfunction of CD8+ T cells and induces immune resistance in NSCLC^[29]. In addition, studies found that defective expression of MHC class II molecules in tumor cells and infiltrating lymphocytes cannot effectively activate T helper cells. The low antigen presentation reduces the immunogenicity of lung cancer, while weak immunogenic tumors can escape the surveillance of the immune system and promote immunotherapy resistance in lung cancer^[30].

Dynamic changes of PD-L1 expression

Tumor cells with high expression of PD-L1 can also mediate immune escape. PD-L1 could transmit negative signals and induce T cell apoptosis or dysfunction when combined with its receptor, thereby evading the immune system. In patients with acquired resistance, studies have found that interferon- γ (IFN- γ) secreted by both TILs and tumor antigen-specific T cells can mediate the upregulation of PD-L1 expression after tumor antigen recognition. In addition, there are many ways for tumors to upregulate the expression of PD-L1. For example, the currently known PTEN deletion^[18], PI3K, or AKT mutations^[31] can induce the expression of PD-L1 in tumor cells to escape from immune system. However, clinical trials including KEYNOTE-024 and KEYNOTE-208 have demonstrated that the high PD-L1 expression of tumor cells were more sensitive to immunotherapy^[32,33]. Chinese Society of Clinical Oncology guidelines and The National Comprehensive Cancer Network guidelines also indicate that the expression level of PD-L1 can be used as one of the predictors of the efficacy of immunotherapy. These studies suggest that the functions of PD-L1 may be diverse, rather than simply categorized as “promoting” or “inhibiting”. A recent study confirmed that deacetylation-dependent nuclear translocation of PD-L1 promotes immune escape and upregulates the immune checkpoint genes such as PD-L2 and VISTA of tumor cells, thereby mediating resistance to PD-1/PD-L1 inhibitors^[34]. In addition, nuclear PD-L1 can also induce immune response-related gene expression, including type I and type II IFN signaling pathways, nuclear factor kappa-B (NF- κ B) signaling pathways, and antigen presentation pathways. These results indicate the dual role of PD-L1, which participates in both drug resistance and immune response pathways.

Epigenetic regulation

Epigenetics is the study of heritable changes in gene expression caused by mechanisms other than changes in the nucleotide sequence of the gene, including DNA methylation, histone modification, nucleosome remodeling, and non-coding RNA expression. Epigenetic changes can affect the expression of immune

checkpoints, disrupt the process of antigen presentation, and inhibit the migration of T cells to the tumor microenvironment and the activation of T cells^[35]. In addition, miRNA is also involved in the above process. Studies have shown that miR-214, miR-126, and miR-568 could promote the development and function of Treg cells and lead to T cell exhaustion^[35].

Extrinsic mechanisms and factors of resistance

The extrinsic mechanisms and factors of resistance mainly refer to the tumor microenvironment (TME). The TME is the internal environment for the emergence and growth of tumor cells. Immunologists have tried to find ways to positively affect the immune response, such as the usage of cytokines, adoptive immunotherapy, and other treatments, but the results are not satisfactory. Recently, researchers are focusing on the balance between the “positive factors”, such as immune effector cells, and “negative factors”, such as Treg cells and MDSC in TME to enhance the efficacy of immunotherapy.

Immune effector cells

The lower infiltration and exhaustion of immune effector cells lead to immune suppression and mediate immune escape. Based on the distribution of CD8⁺ T cells, the immune phenotypes are divided into three types: immune inflamed, immune excluded, and immune desert. In a phase II clinical trial of durvalumab combined with olaparib in SCLC, 14 evaluable patients were included, of whom nine were immune excluded, three were immune-inflamed, and two were immune desert type. They study found that immunotherapy may play a role in the TME infiltrated by CD8⁺ T cells^[36]. Guo *et al.*^[37] analyzed the single-cell sequencing of 12,346 T cells in the peripheral blood, cancer tissue, and adjacent tissues from 14 patients with NSCLC, and they found that infiltrating T cells were mainly comprised of three subgroups. In addition to tumor-infiltrating CD8⁺ T cells undergoing exhaustion, two other clusters of cells exhibited states preceding exhaustion, and a high ratio of “pre-exhausted” to exhausted T cells was associated with better prognosis of lung adenocarcinoma. NK cells are not restricted by MHC or antibodies and can directly release perforin and TNF to exert their immune functions. The dysfunction of NK cells could mediate immune escape through such mechanisms as overexpression of inhibitory receptors and impaired production of cytokines. Trefny *et al.*^[38] analyzed 35 patients with NSCLC who were treated with nivolumab and found a correlation between immunoglobulin-like receptor gene *KIR3DS1* expressed by NK cells and therapeutic efficacy. Mutations of *KIR3DS1* gene could lead to resistance to immunotherapy. In addition, several studies have revealed the relationship between the immune response of B cells and tertiary lymphoid structures (TLS). Compared with non-responders, responders have significantly higher B cell-related gene expression levels before ICI treatment. The density of CD20-positive B cells and TLS in the tissues and the ratio of TLS to tumor area in patients who respond to immunotherapy were significantly higher^[39-41]. In general, these studies have shown the role of immune effector cells in regulating anti-tumor immunity and immunotherapy efficacy.

Treg cells

Treg cells are a type of T cell group with immunosuppressive function, which can inhibit the activation and proliferation of CD4⁺ and CD8⁺ T cells and the functions of naive and memory T cells. Treg cells play an indispensable role in maintaining the balance of autoimmunity and can effectively weaken the immunity of autoantigens. However, they are also “utilized” by tumors cells that could express autoantigens to avoid immune surveillance^[42]. Elevated Treg levels were found in lung, breast, and pancreatic cancers^[43], while the Treg levels were significantly reduced after surgical removal of the tumor^[44]. Animal experiments^[45] have proved that the depletion of CD25⁺ Treg cells could effectively improve the anti-tumor immune response of mice. Thus, it is believed that the elimination of Treg cells should be an essential part of the treatment. Several chemotherapeutic drugs are known to interfere with the function of Treg cells non-specifically, including cyclophosphamide, gemcitabine, methotrexate, and thalidomide^[46]. Drugs for Tregs targeting

CD25 and CTLA-4 and eliminating tumor-related Treg cells include the well-known CTLA-4 antibodies ipilimumab and tremelimumab. In addition, the anti-CD25 antibody daclizumab^[47], the anti-OX40 (CD134) monoclonal antibody^[48], and the chemokine receptor 8^[49] are in phase I clinical trials, which bring hopes for the treatment of cancer patients.

MDSCs

MDSC is a type of cell population with immunosuppressive function, which can mediate immune escape and immune tolerance through a variety of ways^[50]. In addition to secreting molecules such as TGF- β and IL-10 that directly inhibit T effector cells, MDSCs can also induce the proliferation of other immunosuppressive cells. Studies have shown that MDSCs could promote the production of FOXP3+ Treg cells by secreting IFN- γ and IL-10^[51,52]. MDSCs can also exert immunosuppressive effects by blocking lymphocyte homing and regulating enzymes required for adenosine metabolism. Kim *et al.*^[53] found that the MDSC level of tumor-bearing mice that are resistant to ICIs increased by 5-7 times compared with non-tumor-bearing mice. They also found that a high level of PI3K γ in MDSCs can promote the production of inflammatory mediators and immunosuppressive factors. When combining PI3K inhibitors with PD-1/CTLA-4 inhibitors, the MDSC level of tumor-bearing mice decreased significantly and was comparable to the control group. De Henau *et al.*^[54] verified that PI3K γ inhibitors could remodel the immune microenvironment and prevent tumor growth. High expression of indoleamine 2,3-dioxygenase (IDO) was found on MDSCs in immune-resistant lung cancers. Previous studies showed that the expression level of IDO was positively correlated with clinical stages^[55]. The application of IDO inhibitor INCB023843 downregulates the expression of IDO and increases the infiltration of CD8+ T cells, thereby reactivating the T cell anti-tumor response^[56]. These studies reveal the potential value of suppressing MDSCs and its combination with immune checkpoint inhibitors.

TAMs

Circulating monocytes and macrophages are recruited into the tumor site and change the tumor microenvironment in the process of tumor progression. The phenotypes of macrophages could be transformed with the changes of signals produced by tumor and stromal cells. Macrophages could be divided into two categories based on their functions. M1 type macrophages are related to inflammatory response, pathogen elimination, and anti-tumor immunity, while M2 type macrophages have tumor-promoting properties. TAMs are very similar to M2 type macrophages^[57]. Studies of multiple tumor types including breast cancer^[58], ovarian cancer^[59], and NSCLC^[60] have shown that the aggregation of macrophages is positively correlated with CCL2 levels. In addition to CCL2, other chemokines such as CCL3, CCL4, CCL5, and cytokines are also involved in the recruitment of macrophages^[61,62]. TAMs inhibit the function of T cells by weakening the ability of antigen presentation and releasing immunosuppressive factors such as IL-10 and TGF- β . Studies have shown that the inhibition of the recruitment of macrophages through the regulation of chemotactic agents is effective. For example, bindarit is used to inhibit CCL2^[63], and monoclonal antibodies that block VEGFR2 reduce macrophage infiltration and tumor growth^[64]. CSF-1R blockade can also reduce the number of TAMs and activate T cells in TME^[65]. These preclinical trials have provided a basis for reversing the drug resistance raised by TAMs.

Metabolic changes in the TME

Metabolic changes in the TME can reduce immune effects by producing immunosuppressive metabolites to inhibit immune cell infiltration^[66]. For example, some tumors use glutamine as an energy source, and the metabolically decomposed ammonia can activate autophagy in neighboring immune cells. Arginine metabolism plays an important role in the activation of T cells and the regulation of immune response. The immunoregulatory cells expressing arginase 1 (ARG1) in TME degrade arginine and restrict its use by T

cells. Therefore, inhibition of arginase in TME can enhance the efficacy of ICIs. A clinical trial of the combination of ARG1 inhibitor INCB001158 and nivolumab is ongoing. Besides, the rate of fatty acid synthesis is increased to produce cell membrane phospholipids and signal molecules in tumor cells, and targeting these metabolic pathways is a promising way to enhance anti-tumor immunity. In recent years, many studies have focused on the metabolic process of the TME, providing new perspectives for overcoming immune resistance.

Host-related factors

The immune system function degenerates with age, and the number and function of antigen-presenting cells and lymphocytes are also decreased^[67]. A study found that elderly patients with melanoma responded better to immunotherapy than younger people^[68]. A meta-analysis including 11,351 cases with advanced or metastatic cancer found that male patients had superior efficacy of immunotherapy^[69]. Compared with the control group, the overall survival HR of male and female patients treated with ICIs was 0.72 and 0.86, respectively ($P = 0.0019$). In addition, studies have suggested that weight can also affect the efficacy of immunotherapy. A study conducted a pooled analysis of four studies of OAK, POPLAR, BIRCH, and FIR, reporting a correlation between the overall survival of atezolizumab in patients with advanced NSCLC and body mass index^[70]. The results show that obesity was associated with a significant increase in the OS of patients receiving PD-L1 inhibitors treatment, and the risk of death in obese patients was reduced by 64% (HR = 0.36, 95%CI: 0.21-0.62). Smoking is also a crucial factor. The average frequency of gene mutations in smokers is more than 10 times higher than that of non-smokers^[71]. A recent study reported that benzopyrene in cigarettes can induce an increase in PD-L1 level, which further explains why smoking patients respond better to immunotherapy^[72]. In addition, studies have shown that gut microbiota have a significant impact on the efficacy of immunotherapy^[73]. There is evidence of the importance of the intestinal microbiota in the response to chemotherapy and immunotherapy and how their alteration and the concomitant use of antibiotics inhibit the benefit of ICIs in advanced cancer, decreasing OS and PFS in NSCLC. With respect to microbiota composition, the relative abundance of *Akkermansia muciniphila* appears to significantly affect the clinical response to anti-PD-1/PD-L1 therapy in NSCLC and renal cell carcinoma^[74]. Another study demonstrated that a greater diversity of the gut microbiome is related to favorable responses to ICI therapy in NSCLC^[75]. Among the different immune cells, the microbiota have been shown to be associated with the development of effector cells of the immune system, such as Th1, Th2, Th17, and Treg cells^[76-78]. However, in the case of SCLC, there is little evidence that supports the role of the microbiome as an immune resistance mechanism. Thus, host-related factors could also affect the efficacy of immunotherapy.

IMMUNOTHERAPY-BASED COMBINATIONS TO COPE WITH RESISTANCE

There are no standard treatments after resistance of immunotherapy. At present, the most promising and effective treatment methods are immunotherapy combinations that aim to convert “cold” tumors with lower immune response into “hot” tumors with better response. A variety of combined treatment strategies, such as immunotherapy combined with targeted therapy, chemotherapy, and radiotherapy can modulate the immune response at different stages and overcome drug resistance. Clinical trials of immunotherapy-based combinations related to lung cancer patients are summarized in [Table 2](#).

Dual immunotherapy

Anti-tumor immune response involves antigen recognition, presentation, and activation of immune cells. Currently, many studies focus on the immune checkpoint inhibitors targeting PD-1, PD-L1, lymphocyte activating gene 3 (LAG-3), T cell immunoglobulin domain and mucin domain-3 (TIM-3), and T cell immunoglobulin and ITIM domain protein (TIGIT). The combined application of these immune

Table 2. Clinical trials of immunotherapy-based combinations related to lung cancer patients

Immunotherapy-based combinations	Combination strategies	Drugs	Clinical trials
Dual immunotherapy	Anti-PD-1 + Anti-CTLA-4	Nivolumab + Ipilimumab	Checkmate 227 (NCT02477826)
	Anti-PD-1 + Anti-LAG-3	Nivolumab + MK-4280	Keynote 495 (NCT03516981)
		Nivolumab + Relatimab	NCT03607890
	Anti-PD-1/PD-L1 + Anti-TIGIT	Pembrolizumab + IMP321	NCT03625323
		Atezolizumab + Tiragolumab	CITYSCAPE (NCT03563716)
	Anti-PD-L1 + Anti-TIM-3	LY3300054 + LY3321367	NCT02964013 NCT03099109
ICIs combined with CT	Anti-PD-1/PD-L1 + CT	Pembrolizumab + Pemetrexed/Platinum	Keynote 189 (NCT02578680) Keynote 021 (NCT02039674)
		Atezolizumab + Paclitaxel/Carboplatin	IMpower 130 (NCT02367781) IMpower 131 (NCT02266949)
		Atezolizumab + Etoposide/Carboplatin	IMpower 133 (NCT02763579)
	Anti-PD-L1 + Anti-VEGF + CT	Atezolizumab + Bevacizumab + Paclitaxel/Carboplatin	IMpower 150 (NCT02366143)
	Anti-PD-L1 + Anti-RTK	Nivolumab + Sitravatinib	NCT02954991
	Anti-PD-L1 + Multitarget inhibitor	Atezolizumab + Cabozantinib	COSMIC-021 (NCT03170960)
ICIs combined with RT	Durvalumab after concurrent RT + CT		PACIFIC (NCT02125461)
	Pembrolizumab + SBRT		PEMBRO-RT (NCT02492568)
Individualized immunotherapy	Anti-PD-1 + Vaccine	Nivolumab + NEO-PV-01	NCT02897765
	Anti-PD-1 + MDM2 inhibitor	Pembrolizumab + APG-115	NCT03611868

ICIs: Immune checkpoint inhibitors; PD-1: programmed cell death 1; PD-L1: programmed cell death ligand 1; CTLA-4: cytotoxic T lymphocyte-associated antigen-4; LAG-3: lymphocyte activation gene-3; TIGIT: T cell immunoglobulin and ITIM domains; TIM-3: T cell immunoglobulin-3; CT: chemotherapy; RTK: receptor tyrosine kinases; RT: radiotherapy; SBRT: stereotactic body radiation therapy; MDM2: mouse double minute 2 homolog.

checkpoint inhibitors could exert synergistic effects. The most common strategy is PD-1 inhibitor combined with anti-CTLA-4 antibody. Both CheckMate 227 and CheckMate 032 studies have confirmed that the efficacy of dual-immunotherapy is better than that of single-agent therapy^[79,80]. LAG-3 is expressed on the activated CD4+, CD8+ T cells, NK cells, and Treg cells, which can bind to its ligand fibrinogen-like protein-1 (FGL1) to inhibit T cell function. The trial of LAG-3 antibody MK-4280 combined with pembrolizumab in advanced NSCLC (KEYNOTE-495/NCT03516981) recruited 33 patients with solid tumors who have failed previous treatments. The DCR of the monotherapy group and the combination treatment group was 17% and 40%, respectively. TIGIT is a specific negative regulator of CD226 costimulatory receptor and plays an important role in immunosuppression. The CITYSCAPE study enrolled 135 patients with PD-L1-positive treatment-naïve NSCLC who were randomly assigned to TIGIT antibody tiragolumab combined with atezolizumab (TA group) or placebo combined with atezolizumab (PA group). The results show that, in the intention-to-treat population, the ORR and PFS of the TA group was increased compared with the PA group (31.3% vs. 16.2%; 5.4 months vs. 3.6 months), and the risk of disease progression was reduced by 43%^[81]. In addition, the phase II clinical trial of relatimab combined with nivolumab in the treatment of solid tumors (NCT03607890) and the phase II clinical trial of IMP321

combined with pembrolizumab in the treatment of patients with advanced NSCLC (NCT03625323) are both underway. The phase I clinical trial of pembrolizumab combined with TIGIT antibody in the treatment of patients with metastatic solid tumors (NCT02964013) and the phase I trial of TIM-3 inhibitor combined with PD-L1 antibody in the treatment of advanced relapsed/refractory solid tumors (NCT03099109) are ongoing.

Immunotherapy combined with chemotherapy

Immunotherapy combined with chemotherapy can not only increase the cross-presentation of antigens by DCs^[82] but also eliminate the immunosuppressive components of the TME^[83], such as Treg cells, MDSCs, and immunosuppressive cytokines. The KEYNOTE-189 study showed that the efficacy of pembrolizumab combined with chemotherapy in patients with advanced NSCLC in first line is superior to chemotherapy alone^[84]. The OS of the two groups was 22.0 and 10.7 months and the PFS was 9.0 and 4.9 months, respectively. In addition, the CheckMate 012, KEYNOTE-021, IMpower130, and IMpower131 studies have shown that immunotherapy combined with chemotherapy has a greater survival benefit than chemotherapy alone despite using different checkpoint inhibitors. Based on these studies, the U.S. Food and Drug Administration has approved nivolumab and pembrolizumab combined with platinum-based chemotherapy for EGFR/ALK wild-type NSCLC. Besides, results from the double-blind, randomized phase III study IMpower133 show that, compared with chemotherapy alone, atezolizumab combined with chemotherapy in the first-line treatment of extensive-stage SCLC achieved OS benefit, which represents a breakthrough in the treatment of SCLC^[85].

Immunotherapy combined with targeted therapy

Targeted therapy can increase tumor antigens and play a synergistic effect with immunotherapy in multiple aspects. Anti-angiogenic agents can promote the normalization of blood vessels, enhance immune effector cells to infiltrate the tumor, and reduce the activity of immunosuppressive cells. The IMpower150 study evaluated atezolizumab combined with bevacizumab and chemotherapy in the first-line treatment of non-squamous NSCLC patients, including EGFR and ALK mutant populations, and the results confirm that patients in ABCP group have significant survival benefits^[86]. Cohort 7 of the COSMIC-021 study included 30 advanced NSCLC patients with negative driver genes who had previously been treated with immune checkpoint inhibitors. The results show that the ORR was 23%, DCR was 83%, and the median duration of response was 5.6 months^[87]. A phase I randomized clinical study explored the efficacy of nivolumab combined with erlotinib in the treatment of patients with EGFR-mutant advanced NSCLC. Twenty EGFR-TKI resistant cases and one EGFR-naive case were included. The results show that the median PFS was 5.1 months^[88]. In addition, the combination of novel targeted agents with immunotherapy has also shown great prospects. Nivolumab combined with the small molecule inhibitor sitravatinib in the treatment of patients with advanced non-squamous NSCLC who are resistant to immunotherapy obtained an ORR of 32.14%, a median PFS of 6.8 months, and a median OS of 15.1 months^[89]. Pembrolizumab combined with JAK1 inhibitor itacitinib in the treatment of NSCLC patients with PD-L1 expression > 50% reported an ORR of 66.7%.

Immunotherapy combined with radiotherapy

The PACIFIC study included 713 patients with locally advanced unresectable NSCLC. The results show that the median PFS of the durvalumab treatment group after concurrent radiotherapy and chemotherapy was 17.2 months, and the median OS was also significantly improved compared with control group^[90]. The PEMBRO-RT study explored the efficacy of radiotherapy and concurrent immunotherapy. Patients were treated with pembrolizumab seven days after receiving stereotactic body radiotherapy, while the control group only used immunotherapy. The ORR of the two groups was 36% and 18% and the median OS was 15.9 and 7.6 months, respectively^[91]. In addition, a retrospective study included 26 NSCLC patients with

acquired resistance of immunotherapy. In total, 15 patients were administered with local treatment without systemic treatment, and 11 of them continued to receive immunotherapy after local treatment. The two-year survival rate was 92%, and the median OS has not yet been reached^[92]. Similarly, a retrospective study including 189 patients with acquired resistance showed that local treatment can significantly improve survival benefits^[93].

Other combination strategies are also being explored in immunotherapy-resistant populations. The VARGADO study included 57 patients with advanced NSCLC after progression with second-line immunotherapy. Patients were treated with the VEGF inhibitor nintedanib combined with docetaxel. The results show that ORR and DCR are 50% and 85%, respectively. The median PFS was 6.5 months and the median OS was 12.4 months^[94]. Although the ideas for overcoming immunotherapy resistance are various, there exist some problems that cannot be ignored while conducting clinical trials. Firstly, adequate pre-clinical evaluation should be carried out when the clinical trial is designed, and the adverse effects should be monitored. For example, in the PACIFIC study, the incidence of radiation pneumonitis in the immunotherapy group was increased (33.9% vs. 24.8%), and 15.4% of patients discontinued treatment due to adverse events. In the TATTON study, the incidence of interstitial pneumonitis in NSCLC patients receiving durvalumab combined with osimertinib was significantly increased; thus, the treatment group was promptly interrupted in the corresponding phase III clinical trial (CAURAL study). Novel treatment strategies such as immunotherapy combined with molecular inhibitors need to further consider the potential safety profiles raised by the superposition of different drugs. Secondly, the rationality of the combination strategy is supposed to be evaluated. The selected treatment drugs and immune checkpoint inhibitors should have synergistic effects in the immune feedback loop.

Individualized immunotherapy

Given the characteristics of the tumor immune microenvironment, developing drugs for tumor cell neoantigen production and presentation, T cell activation, and immunosuppressive microenvironment, such as oncolytic viruses, tumor vaccines, and adoptive immune cell therapy (TIL, CAR-T, TCR-T, CAR-NK, *etc.*), which are based on the characteristics of individualized immune microenvironments represent promising directions for overcoming immunotherapy resistance. The NT-001 study is a phase Ib clinical trial that intends to explore the efficacy of PD-1 inhibitors combined with vaccines for advanced or metastatic melanoma, smoking-related NSCLC, and bladder cancer. In total, 82 patients were enrolled. ORR for metastatic NSCLC patients reached 45.5%. MDM2 (mouse double minute 2 homolog) is one of the most important inhibitors of p53; it degrades the p53 protein and weakens its tumor suppressor effect. APG-115 is a second-generation MDM2 inhibitor that can block the MDM2-p53 interaction, thereby restoring the transcriptional regulatory function of the p53 protein, promoting cell apoptosis, and restoring tumor suppressor activity. The phase Ib clinical trial results of APG-115 combined with pembrolizumab in the treatment of metastatic melanoma or advanced solid tumors confirm that the combination of the two drugs is well tolerated, with an ORR of 16.7% and a DCR of 55.5%. With the continuous in-depth study of immunotherapy mechanisms, individualized immunotherapy targets may be a new strategy with good development prospects.

CONCLUSIONS AND FUTURE DIRECTIONS

Compared with traditional chemotherapy and targeted therapy, immunotherapy has its unique advantages and brings a new light to lung cancer treatment. With the clinical application of immunotherapy, anti-PD-1/PD-L1 monotherapy resistance has become an unavoidable phenomenon. The ongoing research on the mechanisms of immune resistance provides new ideas for the selection of patient populations and response strategies for reversing immune resistance. Immunotherapy-based combinations are becoming one of the

most promising strategies that convert non-responders to responders. In the future, studies on biomarker identifications are required to predict the efficacy and prognosis of immunotherapy. Further exploration is needed to predict immune resistance and the timing of restarting immunotherapy.

Abstract

Non-small cell lung cancer (NSCLC) patients with Kirsten rat sarcoma viral oncogene homolog (KRAS) mutation are associated with significant clinical heterogeneity and a poor prognosis to standard NSCLC therapies such as surgical resection, radiotherapy, chemotherapies, and targeted medicines. However, the application of immune checkpoints inhibitors (ICIs) has dramatically altered the therapeutic pattern of NSCLC management. Clinical studies have indicated that some KRAS-mutant NSCLC patients could benefit from ICIs; however, the responses in some patients are still poor. This review intends to elucidate the mechanisms of resistance to immunotherapy in KRAS-driven NSCLC and highlight the TME functions altered by immunoinhibitors, immunostimulators, and cancer metabolism. These metabolic pathways could potentially be promising approaches to overcome immunotherapy resistance.

Keywords: Non-small cell lung cancer, KRAS mutation, immune checkpoints inhibitors, tumor microenvironments, cancer metabolism.

INTRODUCTION

Lung cancer is the most commonly diagnosed cancer and the leading cause of cancer-related deaths worldwide^[1]. According to Global Cancer Statistics 2020, lung cancer is estimated to represent 11.4% of new cancer cases and 18.0% of cancer-related deaths^[1]. There are two main histological types of lung cancer: non-small cell lung cancer (NSCLC) and small cell lung cancer (SCLC)^[2]. About 85% of lung cancer is NSCLC, which comprises lung adenocarcinoma (LUAD), lung squamous cell carcinoma, and large cell neuroendocrine carcinoma. SCLC accounts for the remaining 15%^[3]. Despite inducements such as smoking, genetic mutations are the leading causes of lung cancer. The most common driver mutations in NSCLC involve Kirsten rat sarcoma viral oncogene homolog (KRAS), epidermal growth factor receptor (EGFR), and anaplastic lymphoma kinase^[4].

KRAS, a member of the RAS family, was one of the first oncogenes identified in NSCLC^[5]. Since KRAS mutation is reported to be associated with resistance to multiple therapies and poor prognosis in NSCLC, several preclinical and clinical studies have investigated effective therapies, including immunotherapy and targeted therapy^[6,7]. In 2021, AMG510, specifically targeting KRAS^{G12C}, was approved by the FDA as the orphan drug to treat the NSCLC with KRAS^{G12C}^[8]. Other inhibitors, peptides, and tumor vaccines are under preclinical and clinical studies, including MRTX849 targeting KRAS^{G12C}, MRTX1133 targeting KRAS^{G12D}, 12VC1 targeting KRAS^{G12C/V}, mRNA-5671 targeting KRAS^{G12C/D/V}, etc.^[9]. In addition to targeted therapy, immunotherapies have also remarkably changed the management of NSCLC^[10]. The increased expression of programmed cell death protein 1 (PD-1) and programmed cell death ligand 1 (PD-L1) has also been demonstrated to be closely related to KRAS status^[11]. Controversial results have been reported in multiple clinical studies on the efficacy of immune checkpoints inhibitors (ICIs) in NSCLC with KRAS mutation^[12-15]. Jeanson *et al.*^[16] and Arbour *et al.*^[13] demonstrated no difference in response to ICIs among NSCLC patients with or without KRAS mutations. However, other studies have demonstrated more benefits from ICIs for NSCLC patients with KRAS mutation than those without^[14,15]. In this review, we summarize and analyze the possible mechanisms underlying the resistance to ICIs in NSCLC with KRAS mutation and mainly focus on the role of the tumor microenvironment (TME) and metabolism, therapeutic implications, and potential targets for overcoming the resistance to or improving the efficacy of ICIs treatments in KRAS-mutant NSCLC.

ICIS TREATMENTS IN NSCLC WITH KRAS MUTATION

Even though the status of KRAS mutation as being able to alter the responses to ICIs in NSCLC has been verified in multiple fundamental studies, solid clinical evidence is still lacking. In this section, we review the clinical trials of ICIs in KRAS-mutant NSCLC patients.

Checkmate-057 is a random and double-blind phase 3 clinical trial with a size of 582 cases, which is designed to compare the efficacy of monotherapy of nivolumab or docetaxel in advanced non-squamous NSCLC patients. Comparing to docetaxel, nivolumab significantly elongates the overall survival (OS) (medium OS = 12.2 months vs. 9.4 months; HR = 0.73; 95%CI: 0.59-0.89; $P = 0.0002$). The subgroup analysis showed that KRAS-mutant patients have better survival benefits than KRAS-wildtype patients (HR = 0.52, 95%CI: 0.29-0.95; HR = 0.98, 95%CI: 0.29-0.95)^[17]. Another phase 3 clinical trial, KEYNOTE-042, investigated the efficacy and safety of monotherapy of pembrolizumab or platinum-based chemotherapy in locally advanced or metastatic NSCLC harboring wildtype EGFR/anaplastic lymphoma kinase (ALK) and PD-L1⁺ (TPS $\geq 1\%$). The results show that the monotherapy of pembrolizumab can prolong the OS compared to platinum-based chemotherapy. Further analysis revealed that KRAS-mutant patients show higher PD-L1 expression and tumor mutational burden (TMB) and have significantly longer progression-free survival (PFS) in the pembrolizumab treatment group than those in the platinum treatment group^[14,18].

KEYNOTE-189 evaluated the efficacy and safety of pemetrexed and platinum-based therapy or combined with pembrolizumab in metastatic non-squamous NSCLC patients. The results demonstrate that a combination of pembrolizumab and chemotherapy can significantly prolong the OS than chemotherapy regardless of the PD-L1 expression level. Both KRAS-wildtype and -mutant NSCLC patients benefit from chemotherapy combined with pembrolizumab. The pooled analysis of KEYNOTE-189 and KEYNOTE-042 indicated that the non-squamous NSCLC patients with wildtype EGFR/ALK or KRAS show a better prognosis to the combination of pembrolizumab and chemotherapy (HR = 0.55) compared to pembrolizumab monotherapy (HR = 0.86). However, for KRAS-mutant non-squamous patients, the monotherapy of pembrolizumab shows a better prognosis (HR = 0.42 and HR = 0.28) than combination treatment of pembrolizumab and chemotherapy (HR = 0.79 and HR = 1.14)^[19]. Altogether, the clinical outcomes above indicate that KRAS-mutant NSCLC patients can benefit from immunotherapy or combined treatment of immunotherapy and chemotherapy, whereas the conclusion is not supported by some meta-analyses with more solid evidence. Two meta-analyses and some retrospective analyses have reported that the status of KRAS mutation has no negative association with the survival outcome of immunotherapy in advanced NSCLC patients^[7,16,20,21].

One possible illustration is that the co-mutations besides KRAS mutation might play the predictive and prognostic role in response to ICIs in KRAS-mutant NSCLC. Skoulidis *et al.*^[22] defined three distinct co-mutation subgroups of the early stage and advanced KRAS-mutant tumors: KRAS^{mut}/serine/threonine kinase 11 (STK11)^{-/-}, KRAS^{mut}/tumor protein 53 (TP53)^{-/-} (KP), and KRAS^{mut}/cyclin dependent kinase inhibitor 2A, 2B (CDKN2A, 2B)^{-/-}/thyroid transcription factor 1^{low} (KC)^[22]. The retrospective analysis revealed that the KL patients show less responses to immunotherapy and shorter PFS and OS than KP patients^[23]. Other investigations have revealed that KP patients show significant benefits from PD-1 blockade monotherapy^[24]. Collectively, PD-L1 blockade might be more beneficial to KP patients than KL patients.

Taken together, not all the KRAS-mutant NSCLC patients could benefit from ICIs. Co-mutations increase the TMB in patients and might contribute to the poor response to ICIs. The mechanisms of resistance to ICIs in NSCLC with KRAS mutation are sophisticated and not fully investigated, which we discuss in the following sections.

THE RESISTANT MECHANISMS OF ICIS TREATMENTS IN NSCLC WITH KRAS MUTATION

KRAS regulates TME through immunomodulatory molecules

Growing evidence has implicated that the intrinsic and extrinsic resistance mechanisms to ICIs might result from the immunosuppressive TME caused by alterations in disparate signaling pathways in tumor cells^[25]. Previous studies have clearly indicated that the immunosuppressive TME can be regulated by alterations of immunoinhibitors and immunostimulators in tumor and stromal cells^[26].

Immune checkpoints exert crucial roles in preventing overreaction and minimize the duration and expansion of immune responses^[27]. PD-1 (CD279), coded by *pdccl1*, is ubiquitously expressed on various immune cells, including activated T cells, B cells, monocytes, NK cells, and dendritic cells (DCs)^[28]. PD-1 can be recognized by the ligands, PD-L1 and PD-L2, on normal tissue cells and cancer cells, which maintains the immune homeostasis but might also revoke the anti-tumor immunity^[29]. After PD-1 binds to PD-L1, PD-1 undergoes a conformational change, which leads to the inactivation of phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit alpha (PI3K)-serine/threonine kinase (AKT) and extracellular signal-regulated kinase 2 (ERK) pathways and, consequently, dysfunction of T cells^[30]. In addition, studies have reported that tumor cells can secrete exosomes carrying PD-L1, which impede the function of CD8⁺ T

cells, CD4⁺ T cells, and Tregs before infiltration^[31]. It has been widely reported that oncogenic KRAS can increase PD-L1 from different aspects, including transcription, stabilization, and recycling. In LUAD cell lines, KRAS^{mut} has been found to increase the transcriptional level of PD-L1 through the mitogen-activated protein kinase kinase 1 (MEK) pathway^[32]. In human lung and colorectal cancer, Coelho *et al.*^[33] demonstrated that the adenylate-uridylylate-rich element-binding protein tristetraprolin (TTP) can bind to the 3' untranslated region of PD-L1 mRNA and consequently induce the degradation of PD-L1. The oncogenic KRAS activates MEK signaling and further phosphorylates and inhibits the TTP by MK2, which leads to the stabilization of PD-L1 mRNA^[33]. In addition, it has been reported that mutant KRAS suppresses programmed cell death 4 and then promotes the translation of ADP ribosylation factor 6 and MYCBP associated protein expression, which facilitates PD-L1 recycling driven by platelet-derived growth factor and eventually the immune evasion^[34].

As another factor, cytokine-modulated immune responses have been investigated for decades. Cytokines are a type of small proteins secreted by almost all types of cells and can be classified into seven families: interleukin (IL), colony stimulating factor (CSF), interferon (IFN), tumor necrosis factor, tumor growth factor-beta (TGF- β) family, growth factor (GF), and chemokine family^[35]. Cytokines deliver messages in a paracrine, autocrine, or endocrine manner and can coordinate the recruitment of immune cells, spatial organization, and cellular interactions^[36,37]. Plentiful cytokines and chemokines have both pro- and anti-inflammatory functions and exert different functions in particular scenarios^[36]. It has been reported that mutant KRAS can remodel the TME by regulating the production and secretion of pro- or anti-inflammatory cytokines and chemokines^[38]. The oncogenic mutant KRAS represses the expression of interferon regulatory factor 2 (IRF2) and results in increased production of C-X-C motif chemokine ligand 3 (CXCL3), which binds to C-X-C motif chemokine receptor 2 (CXCR2) on myeloid-derived suppressor cells (MDSCs) and subsequently recruits the MDSCs to impede the cytotoxic T cells^[39]. In lung cancer, the ubiquitin-specific protease 12 (USP12) induces protein phosphatase 1B, which thwarts transcription factor P65 (NF- κ B). NF- κ B can promote the production of multiple chemokines, including CXCL8, CXCL1, CCL2, *etc.*, which can result in an immunosuppressive TME through recruiting the M2 macrophages, inducing PD-L1 expression and blocking the responses to T cells. Oncogenic mutant KRAS inhibits USP12 and further promotes the production of chemokines through NF- κ B, which ultimately causes the resistance to anti-PD-1^[40]. Additionally, it has been reported that the development of resistance to anti-PD-L1 and MEK inhibition is the result of increasing IL-17 and IL-22 secreted by accumulated infiltration of Th17 in KRAS^{mut}/TP53^{-/-} co-mutant lung cancer patients^[41]. Moreover, KRAS has been reported to induce the releasing of pro-inflammatory cytokines (IL-6, IL-8, and IL-1) and anti-inflammatory cytokines (IL-10, IL-22, and TGF- β), as reviewed by Hamarsheh *et al.*^[42].

Immunomodulators are composed of all molecules that can regulate the immune response, including receptors/ligands on both tumor cells and stromal cells in TME and cytokines and chemokines secreted by cells. The studies cited above have uncovered that KRAS could mediate the rearrangement of immunomodulators through different signaling pathway in multiple cancers, which might contribute to the resistance to ICIs in NSCLC. A schematic figure of KRAS-driven signaling pathways in the regulation of immunomodulators is presented in [Figure 1](#).

KRAS regulates TME through metabolic alteration

For the past decades, many studies have revealed adjustments of energy metabolism in cancers, which are involved in almost every stage of cancer development^[43,44]. Oncogenic KRAS mutation has been reported to regulate diverse metabolic networks to fulfill the excessive requirement of distinct nutrients to support tumor growth and metastasis^[45,46]. In this section, we discuss the mechanisms underlying how KRAS orchestrates the TME through metabolic networks.

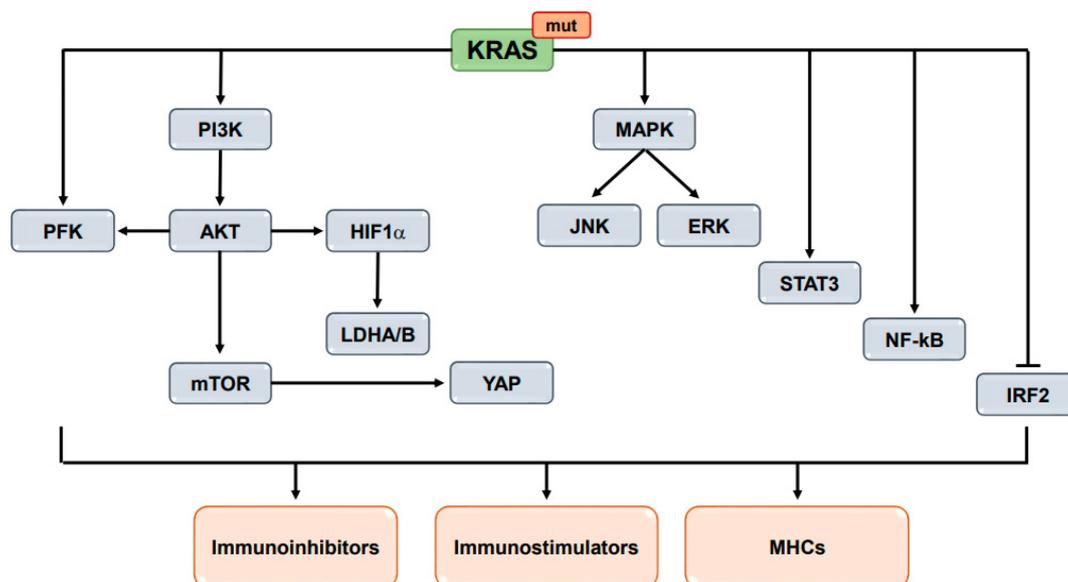

Figure 1. A schematic figure of KRAS-driven signaling pathways in the regulation of immunomodulators. PI3K: Phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit alpha; AKT: serine/threonine kinase; MAPK: mitogen-activated protein kinase 1; ERK: extracellular signal-regulated kinase 2; PFK: phosphofructokinase; HIF1 α : hypoxia inducible factor 1 subunit alpha; JNK: mitogen-activated protein kinase 8; mTOR: mechanistic target of rapamycin kinase; LDHA/B: lactate dehydrogenase A/B; YAP: yes1 associated transcriptional regulator; IRF2: interferon regulatory factor 2; STAT3: signal transducer and activator of transcription 3; NF- κ B: transcription factor P65; MHCs: major histocompatibility complex.

Glycolysis

In normal cells, glucose can be consumed either through oxidative phosphorylation (in mitochondria) or anaerobic glycolysis (in cytosol) to produce energy for cell activities. Glucose is mainly transported into cells with the help of glucose transporters (GLUTs) in an energy-consuming-free way. In cytosol, glucose is catalyzed to glucose-6-phosphate (G6P) by hexokinase (HK). G6P can enter the pentose-phosphorylation pathway with catalyzation of G6P dehydrogenase and be processed to ribulose-5-phosphate for the synthesis of purine. G6P can also be isomerized to fructose-6-phosphate (F6P) and further phosphorylated to fructose-1,6-biphosphate (FBP), which enters the glycolysis pathway. Under the aerobic condition, FBP is catalyzed to pyruvate and then converted to acetyl-CoA by pyruvate dehydrogenase (PDH), which participates in the TCA cycle. Under the anaerobic condition, pyruvate does not enter the TCA cycle but is converted to lactate by the lactate hydrogenase (LDH). Under normal condition, a small portion of F6P also enters the hexosamine pathway (HBP) with the help of glutamine--fructose-6-phosphate aminotransferase (GFPT) and provides glycans for protein glycosylation^[47,48].

Back in 1985, it was reported that rat-1 cell maintains a higher level of glycolysis in the presence of *ras* transfection^[49]. Accumulating evidence shows that oncogenic KRAS mutation modulates glycolysis through promoting the uptake of glucose and increasing glycolysis flux. In pancreatic ductal adenocarcinoma (PDAC) with KRAS^{G12D}, metabolomic and RT-qPCR analyses have revealed increasing glucose transporter solute carrier family 2-member 1 (GLUT1) expression and enhanced glycolysis flux. KRAS^{G12D} was found to upregulate the expression of several enzymes, including HK, PFK, enolase, *etc.*^[50]. Many studies have explored in more detail about how mutant KRAS interacts with the enzymes involved in the carbon metabolism pathways. In KRAS-driven PDAC, 6-phosphofructo-2-kinase/fructose-2,6-biphosphatase 3 is phosphorylated by p38 γ induced by KRAS mutation and forms a ternary complex with solute carrier family 2 member 2 (GLUT2), which promotes the uptake of glucose^[51]. In addition, GLUT1 has been found significantly upregulated in NSCLC with KRAS mutation^[52]. KRAS4A, a shorter isoform of KRAS, has been

found to bind to the N-terminal of HK1 and block the allosteric inhibition feedback, which promotes the transition of glucose to G6P and increases the glycolysis flux^[53]. Based on both an *in vivo* mice model and an *in vitro* H23 cell line study, Wang *et al.*^[54] reported that KRAS activation is required for HK2 expression. In a KRAS^{mut}/STK11^{-/-} co-mutated lung cancer model, KRAS mutation induces the expression of GLUT. Meanwhile, the loss of STK11 impedes the phosphorylation and activation of protein kinase AMP-activated catalytic subunit alpha 1 (AMPK), thereby leading to the activation of GFPT enzyme. The increasing activity of GLUT and GFPT promotes HBP^[55]. Glucose is also the primary energy source for the proliferation and differentiation of immune cells^[56,57]. As a result of increasing glycolysis in tumor cells, the access to glucose for immune cells is limited in TME. A cruel competition between tumor cells stromal cells consequently impairs the glycolytic metabolism and normal functions of immune cells^[58,59]. More specifically, the limited glycolysis causes the weakened activity of the AKT/mammalian target of rapamycin (mTOR) pathway in T cells, which impedes the production of INF- γ ^[59]. The limited availability of glucose also results in insufficient production of glycolytic metabolite phosphoenolpyruvate to maintain the anti-tumor activity through calcium and NFAT signaling pathways in infiltrated T cells^[60]. In NK cells, the aberrant expression of fructose-1,6-bisphosphatase (FBP1) in gluconeogenesis and TCA cycle leads to the halt in glycolysis and induction in cell death^[61]. It has also been found that inhibition of glycolysis impairs the oligomerization of C-C motif chemokine receptor 7 and thus hinders the migration of DCs to draining lymph nodes^[62].

One important metabolite of glycolysis is lactate. In KRAS-driven NSCLC, the high expressions of LDH-A and LDH-B are reported to be associated with tumorigenesis and disease progression^[63,64]. One study found that phosphoglycerate kinase 1 (PGK1) can be phosphorylated by ERK1/2, which is the downstream of KRAS. The phosphorylated PGK1 phosphorylates PDHK1, the latter further phosphorylating and inhibiting PDH, which blocks the conversion of pyruvate to acetyl-CoA and subsequently promotes the conversion of pyruvate to lactate^[65]. In PDAC, hypoxia and active KRAS can induce the expression of hypoxia inducible factor 1 subunit alpha (HIF1 α) and inhibit the degradation of HIF1 α , respectively. HIF1 α then transcriptionally enhances the expression of the lactate transporter, solute carrier family 16 member 4 (MCT4), which transports lactate out of cells^[66]. The accumulation of lactate from the excessive glycolysis in tumor cells is transported by MCT4 out of cells, which generates a low-pH environment that discourages the normal proliferation and function of immune cells^[67]. The accumulated lactate promotes the polarization of macrophages toward anti-inflammatory M2 phenotype and leads to a downregulation of interferon gamma (IFN- γ) secreted by the infiltration of T cells and NK cells^[68,69]. Besides, the accumulated lactate directly blocks the glycolytic flux in T cells^[70].

Taken together, the studies described above suggest that KRAS mutation can promote glycolysis by promoting various signaling pathways and molecules, such as related enzymes and transporters. The outrageous requirement of glucose and excessive excretion of lactate impair the normal proliferation and function of different immune cells, which ultimately diminishes the anti-tumor activity.

Lipid metabolism

Lipid metabolism is constantly in homeostasis due to the balance of fatty acids synthesis (FAS) and fatty acids oxidation (FAO) in normal cells. In the process of *de novo* lipogenesis, citrate is catalyzed to acetyl-CoA in assistance with ATP-citrate lyase (ACLY) and then transformed to palmitate by FA synthetase (FASN), phosphatidic acids, and finally triacylglycerol. Triacylglycerol can be stored in the lipid droplets (LDs) in the cytoplasm^[71]. Phospholipids are another source of lipogenesis and can be converted to arachidonic acid (ARA) by phospholipases (PLA2)^[72]. ARA can be catalyzed by cyclooxygenase 1 and 2 (COX-1 and COX-2) and transformed to prostaglandins 2 (PGE2), which has been shown to play a vital

role in tumorigenesis and immune response^[73]. The FAO process can be classified into harmless β -oxidation and fatal lipid peroxidation. In β -oxidation, FAs are catalyzed to produce acetyl-CoA, NADH, and FAD. Besides, lipid peroxidation is believed to start from polyunsaturated fatty acid chains, induced by reactive oxygen species (ROS), and results in ferroptosis^[74]. In the mouse model of KRAS-driven LUAD, the loss of stress-induced metabolic regulators, regulated in development and DNA damage responses 1, can induce a HIF-dependent lipid storage pathway, which induces the FA transporter CD36 and thereby uptake of exogenous fatty acid^[75]. KRAS mutation has been shown to promote FA synthesis through inducing FASN and stearoyl-CoA desaturase mediated by ERK2^[76]. Besides, the FA metabolism has been reported to be upregulated by the PI3K-mTOR pathway^[77], which has already been demonstrated to be regulated by KRAS^[78]. The active AKT can facilitate both the ACLY and mTORc1. ACLY promotes the transformation of citrate to acetyl-CoA, which subsequently boosts lipogenesis. Active mTORc1 can activate slicing factor serine/threonine-protein kinase (SRPK2) and transcriptional factor sterol regulatory element binding protein-1c in the nucleus, which ensures the expression of a series of lipogenesis enzymes, including ACLY, FASN, etc.^[79-81]. Besides promoting FAS, KRAS mutation has also been reported to suppress the oxidation of lipids. The suppression of hormone-sensitive lipase (HSL) by KRAS mutation leads to the decreased β -oxidation of FAs, which results in the accumulation of FAs^[82]. STK11 deficiency has been found to cause the downregulation of FAO upregulation of fatty acid synthesis via activation of acetyl-CoA carboxylase due to the low level of phosphorylation of AMPK^[83]. Kelch like ECH associated protein 1 (KEAP1) is another frequently observed co-mutation along with KRAS^{mut}/STK11^{-/-}. KEAP1 mutation has been reported to decrease lipid peroxides via enhancing the transcription factor nuclear factor, erythroid 2 like 2, which directly upregulates the suppressor of ROS, glutathione peroxidase 4^[74,84,85]. The accumulated FAs in the TME have been found to cause the dysfunction of immune cells in KRAS-mutant mice model^[86]. In the infiltrated cytotoxic CD8⁺ T cells, the long-chain fatty acids are unbreakable and can result in a reduction of very-long-chain acyl-CoA dehydrogenase and lipid toxicity in T cells, which cause the exhaustion of infiltrated T cells^[87]. In addition, the excess FAs caused by immunoglobulin-like transcript 4/paired immunoglobulin-like receptor B via mitogen-activated protein kinase 1/ERK1/2 signaling has been demonstrated to cause the senescence of effector T cells^[88]. Moreover, the absorption of the FA-carrying tumor-derived exosomes by DCs can generate increasing storage of FAs and the enhancement of β -oxidation. The shift of mitochondrial oxidative phosphorylation due to the fuel alteration results in the dysfunction of DCs^[89].

Previous studies have revealed that the accumulated FAs provides sufficient raw material for PGE2 production^[90,91], and KRAS mutation can also enhance the production of PGE2 via upregulation of COX-2^[92]. In NSCLC, PGE2 has been found to induce forkhead box P3 (FOXP3) expression and subsequently promotes the activity of CD4⁺ and CD25⁺ Tregs^[93]. In metastatic murine renal carcinoma, overproduced PGE2 has also been reported to suppress the anti-tumor cytotoxic T cell lymphocyte responses by preventing the production of IFN- γ ^[94]. Moreover, the excess PGE2 in TME suppresses the production of X-C motif chemokine ligand 1 and CCL5 by NK cells and further blocks the recruitment of the conventional type 1 dendritic cells (cDC1s) through downregulating the respective receptors on cDC1s^[95]. Increasing evidence indicates that the accumulated PGE2 in tumor cells exerts an immunosuppressive TME.

Cholesterol is normally synthesized from acetyl-CoA. Recent studies have found that cholesterol exerts an immunosuppressive TME by promoting the expression of immune checkpoint on CD8⁺ T cells, which induces ER stress and consequently exhaustion of those T cells^[96,97]. In KRAS-driven NSCLC, the synthesis of cholesterol has been found to be induced by Myc proto-oncogene protein (MYC) activation. The activation of MYC leads to an accumulation of cholesteryl esters (CE) stored in LDs and the increased

influx and the decreased efflux of cholesterol in tumor cells. Of note, the deactivation of MYC following activation gives rise to an additional increase of CEs^[98].

In conclusion, there is supporting evidence indicating that FA metabolism can be induced by KRAS mutation through regulating various molecules. The excessive synthesis of FA and associated metabolites impedes the normal function of immune cells.

Glutamine and tryptophan metabolism

In normal cells, amino acid metabolism facilitates cells with energy and material for the biosynthesis of macromolecules, such as proteins and nucleotides. Amino acid metabolism reprogramming is required for hyperactive tumor cells to meet the high demand of energy and proteins required for cell proliferation^[99]. Among the 21 amino acids within the human body, glutamine and tryptophan have been broadly reported to be rewired in various tumor cells and build an immune suppressive TME, which facilitates tumor cells to evade immune surveillance.

Glutamine can be successively transformed to glutamate, α -ketoglutarate, oxaloacetate, and aspartate by the catalyzation of glutaminase (GLS1), glutamate dehydrogenase 1, and glutamic-oxaloacetic transaminase 1/2, respectively^[100]. KRAS mutation in NSCLC enhances the glutamine metabolism by inducing glutamine uptake, which results in a glutamine deficiency in TME^[101]. KRAS mutation has been found to induce multiple glutamine transporters, such as solute carrier family 1 member 5 (SLC1A5) in NSCLC^[102,103], solute carrier family 7 member 5 (SLC7A5)^[104], and solute carrier family 38 member 2 (SLC38A2) via activation of hippo effector yes1 associated transcriptional regulator (YAP1)^[103]. The upregulated transporter SLC1 increases the influx of glutamine, and the increased antiporter SLC7A effluxes glutamines and intakes other essential amino acids. The essential amino acids transported by SLC7A induce mTORC1-ribosomal protein S6 kinase B1 signaling and further promote protein synthesis^[103,104]. It has also been shown that the mRNA level of GLS is higher in KRAS-mutated NSCLC, which indicates a higher consumption of glutamine in NSCLC^[102]. Additionally, the KRAS^{mut}/STK11^{-/-}/KEAP1^{-/-} co-mutant NSCLC was found dependent on glutaminolysis for fuel and was specifically sensitive to GLS inhibitors^[85]. The high uptake of glutamine in tumor cells leads to a glutamine deficiency in TME, which causes immune suppression through blocking active T cells or producing immune suppressive cells. One study illustrated that the lack of glutamine results in the increase of HIF and then the rising secretion of IL-23 by macrophages, which promotes the proliferation of Tregs through the STAT3 signaling pathway. Tregs subsequently secretes TGF- β and IL-10 and suppresses the cytotoxicity of T cells^[105]. Besides the shortage of glutamine in the TME, other conditions can also result in glutamine deprivation in tumor infiltrated immune cells. One study showed that the shortage of glucose causes defective N-linked glycosylation and endoplasmic reticulum stress and accordingly activates the endoplasmic reticulum to nucleus signaling 1 (IRE1) - X-box binding protein 1 (XBP1) axis. Activated XBP1 represses the glutamine transporters through post-translational regulation, which blocks glutamine uptake. The low level of glucose and glutamine causes the dysfunction of mitochondria, which impedes the production of IFN- γ by active T cells^[106]. Moreover, glutamine deprivation increases the secretion of G-CSF and GM-CSF through activating the IRE1 α /c-Jun N-terminal kinase pathway in cancer cells, which manipulates the formation of immunosuppressive MDSCs in TME^[107]. However, the results from one study also indicate that high glutamine in TME tends to polarize the macrophages to pro-tumorigenic M2 type and inhibit the differentiation of the M1 macrophage^[108], which is contrary to the conclusion from the above research. The contradictory conclusion of deprived glutamine indicates the complexity of glutamine in regulating TME.

Tryptophan can either be catalyzed to 5-hydroxytryptophan, serotonin, and 5-hydroxyindoleacetic acid by tryptophan hydroxylase 1 and 2 (TPH1, TPH2), dopa decarboxylase, and monoamine oxidase A and B, respectively, or be catalyzed to kynurenine, kynurenic acid by indoleamine 2,3-dioxygenase 1 and 2 (IDO1/2), and tryptophan 2,3-dioxygenase (TDO2). In NSCLC, the KRAS mutation has been shown to reprogram tryptophan metabolism through upregulating the expression of immune checkpoint markers IDO1 according to microarray data^[109]. The detailed mechanism remains to be discovered. The tryptophan metabolism has a pivotal role in promoting immune evasion. In tumor cells, tryptophan is transformed into kynurenine by IDO1. The upregulated IDO1 level induces excess kynurenine, which could be transferred to TME to promote Tregs and suppress effector T cells^[110]. It has been illustrated that the activity of IDO can reflect the advanced disease, tumor metastasis, and immunotherapy responses to PD-1 inhibitors. The high expression of IDO can recruit immunosuppressive MDSCs through Tregs, which is Foxp3 dependent^[111,112].

In summary, cancer cells can rely on glutamine as the main source of fuel and the precursor of other biomacromolecules. The deficiency of glutamine and increase of metabolite from tryptophan metabolism in TME give rise to an immunosuppressive phenotype. KRAS has been found to modulate several signaling pathways involved in glutamine metabolism, whereas further work is required to illustrate the more detailed mechanisms.

Besides the metabolism mentioned above, mutant KRAS has also been reported to regulate additional metabolic signaling pathways, including asparagine metabolism^[113], autophagy^[46,114], micropinocytosis^[115], etc. More detailed reviews of the metabolic rewiring driven by KRAS mutation can be found elsewhere^[46,116-118]. Nutrient scavenging is a practical method for both tumor cells and immune cells to grab necessities from TME. Tumor cells and immune cells often outcompete stromal cells for nutrients or metabolites in TME, which leads to a nutrient-deprived environment^[43]. However, most nutrients and some metabolites are also essential for the biosynthesis of macromolecules and production of energy craved by immunocytes^[56,57,61,119,120]. Studies have also asserted that excess metabolites, such as lactate, alter the environment and affect the functions of immune cells^[60,86,87,89,121]. A more comprehensive description of cancer metabolic reprogramming and immune response can be found in other reviews^[122-125]. Collectively, the limited nutrients and redundant metabolites arouse the dysfunction in immune cells, which is one of the leading causes of resistance to ICIs. Taken together, KRAS mutation rewires the metabolic network in TME and thereby might cause a poor response to ICIs. A schematic figure of KRAS-driven metabolic signaling pathways in cancer cells is shown in [Figure 2](#).

PROSPECTIVE STRATEGIES FOR OVERCOMING RESISTANCE TO ICIS

According to the ASCO guidelines, five main therapeutic strategies are applied in NSCLC: surgery, radiation therapy, chemotherapy, target therapy, and immunotherapy. The therapeutic schedule depends mostly on the stage and mutation type. As illustrated above, the efficacy of monotreatment of immunotherapy is controversial in NSCLC patients; thus, researchers have begun investigating the combinational strategy of immunotherapy and other therapies. In this section, we discuss the promising combined treatments of immunotherapy and other therapies in preclinical and clinical studies.

It is discussed above that PD-1/-L1 expression plays an essential role in response to ICIs. Therefore, targeting pathways modulating PD-1/-L1 expression might show potential for overcoming the resistance to ICIs, which has been demonstrated in several studies. In the KRAS-mutant lung cancer model, blockade of both PD-1 and helix-loop-helix transcription factor inhibitor of differentiation 1 knock out significantly enhances the amount of CD8⁺ T cells as well as the expression of PD-L1, which impairs the tumor growth and increases the survival^[126]. In other studies of KRAS^{mut} lung cancer, anti-PD-1 combined with inhibition

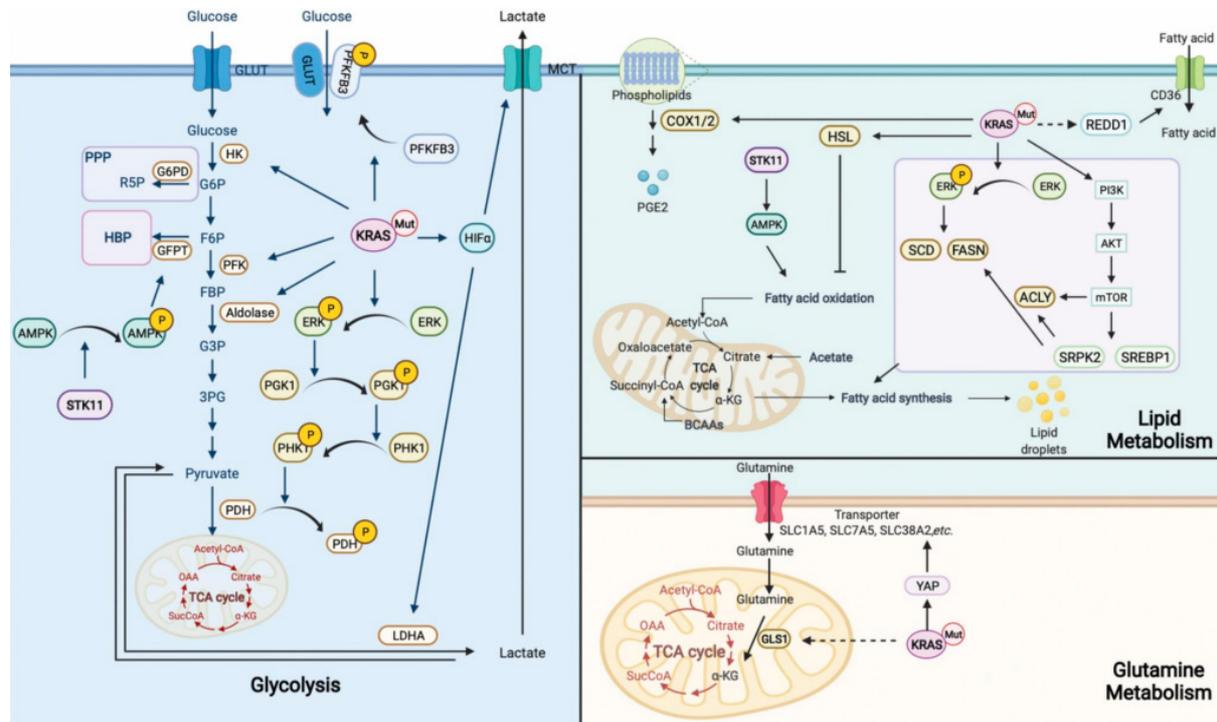

Figure 2. A schematic figure of KRAS-driven signaling pathways in the regulation of metabolic signaling pathways. GLUT: Glucose transporters; HK: hexokinase; PFK: phosphofructokinase; PI3K: phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit alpha; AKT: serine/threonine kinase; MAPK: mitogen-activated protein kinase 1; ERK: extracellular signal-regulated kinase 2; PDH: pyruvate dehydrogenase; PGK: phosphoglycerate kinase 1; HIF1 α : hypoxia inducible factor 1 subunit alpha; JNK: mitogen-activated protein kinase 8; mTOR: mechanistic target of rapamycin kinase; LDHA/B: lactate dehydrogenase A/B; YAP: yes1 associated transcriptional regulator; IRF2: interferon regulatory factor 2; STAT3: signal transducer and activator of transcription 3; NF- κ B: transcription factor P65; HSL: hormone-sensitive lipase; COX: cyclooxygenase; SCD: stearyl-CoA desaturase; FASN: FA synthetase; ACYL: ATP-citrate lyase; GLS: glutaminase.

of the AKT-mTOR pathway by mTOR inhibitor or the STAT3 pathway by natural compound luteolin can remarkably decreased the expression of PD-1 or PD-L1, respectively, which consequently surmounts the resistance to anti-PD-1^[127,128].

Other potential strategies to overcome the ICIs resistance include promoting the proliferation and activation of cytotoxic T cells and thwarting immunosuppressive immune cells, among others. The cholesterol-lowering drug statin has been reported to inhibit prenylation of KRAS and cause ER stress and immunogenic cell death, which cross-primes DCs and provokes CD8⁺ T cells. Combinational treatment of anti-PD-1, statin, and oxaliplatin has shown the potential to overcome resistance to anti-PD-1^[129]. In the KRAS^{mut}/TP53^{-/-} lung cancer mouse model, chemokine CCL7 has also been found to recruit CD11c⁺ or Zbtb46⁺ DCs and promote T cell expansion, which increases the immune responses. When combined with anti-PD-1, CCL7 profoundly increases the survival of the NSCLC mouse model^[130]. The BET bromodomain inhibitor has also been demonstrated to increase the number of infiltrated T-helper type 1 cells and reduce the population of Tregs, which augments the anti-tumor response to anti-PD-1^[131]. Utilization of antibodies or natural compounds to block immunosuppressive cytokines or chemokines has been reported to hamper the resistance to ICIs in KRAS-mutant NSCLC mouse models^[41,132].

Due to the approval of the KRAS^{G12C} inhibitor AMG 510 in KRAS^{G12C} NSCLC by the FDA, studies have been investigating the effect of the combination of KRAS inhibitors and ICIs at the bench and in clinics. In the

KRAS^{G12C} CT26 syngeneic mouse model, AMG510 treatment has been found to induce a pro-inflammatory microenvironment by enhancing the tumor infiltrated CD8⁺ T cells, DCs, NKs, *etc.*, and it exerted extended anti-tumor efficacy when combined with anti-PD-1^[133]. A phase 1 clinical study designed to evaluate the safety and efficacy of AMG 510 and immunotherapy is in process now (NCT03600883). In the KRAS^{G12C} CT26 syngeneic mouse model, KRAS inhibitor MRTX849 combined with anti-PD-1 has also been shown to increase major histocompatibility complex I expression and decrease immunosuppressive factors, which increased PFS compared to monotherapy^[134]. Phase 1/2 studies evaluating the safety, tolerability, PK, and clinical activity of MRTX849 in combination with pembrolizumab in patients with NSCLC are now recruiting (NCT04613596 and NCT03785249).

Other attempts have been made to combine ICIs with inhibitors targeting KRAS downstream. A phase 1/2 clinical trial has investigated the efficacy of the PLK inhibitor rigosertib combined with nivolumab in NSCLC patients with KRAS mutation (NCT04263090). The early results indicate that 29% (2/7) of patients achieved partial responses, most of whom harbor a KRAS^{G12C} or KRAS^{G12V} mutation; 43% (3/7) of patients had a stable disease; and 57% (4/7) of patients had progressive disease^[135]. Studies on the combinational efficacy of other KRAS^{G12C} inhibitors and ICIs, such as GDC-6036 (NCT04449874) and JDQ-443 (NCT04699188), are now recruiting. The efficacy of ICIs combined with tumor vaccine mRNA-5671, which specifically target KRAS^{G12C/D/V} and KRAS^{G13D}, is now under investigation (NCT03948763).

Combination treatments which are not specifically for KRAS-mutant NSCLC have also received positive results in the NSCLC group. Multiple ICI treatment has shown promising results in NSCLC patients. In a phase 3 trial, patients were designed to receive mono-nivolumab, nivolumab combined with ipilimumab, nivolumab combined platinum-based chemotherapy, or mono-chemotherapy. The nivolumab combined with ipilimumab treatment group (medium OS = 17.1 months; 95%CI: 15.0-20.1) has shown longer median duration of overall survival compared to the chemotherapy treatment group (medium OS = 14.9 months; 95%CI: 12.7-16.7) among patients with PD-L1 (TPS ≥ 1%). The two-year overall survival rates were 40% and 32.8% and the median duration responses were 23.2 and 6.2 months, in the nivolumab combined with ipilimumab treatment group and chemotherapy treatment group, respectively. Patients with a PD-L1 (TPS < 1%) also benefit from nivolumab combined with ipilimumab (medium OS = 17.2; 95%CI: 12.8-22.0) compared with chemotherapy treatment (medium OS = 12.2 months; 95%CI: 9.2-14.3)^[136]. In a phase 2 clinical trial, 97 patients were enrolled to study whether stereotactic body radiotherapy (SBRT) enhances the tumor responses to pembrolizumab. The results show that the ORR at 12 weeks was 36% in experimental arm (SBRT plus pembrolizumab) *vs.* 18% in control arm (pembrolizumab), the median PFS was 6.6 months (SBRT plus pembrolizumab, 95%CI: 4.0-14.6) *vs.* 1.9 months (pembrolizumab, 95%CI: 1.7-6.9), and the median OS was 15.9 months (SBRT plus pembrolizumab, 95%CI: 7.1 to not reached) *vs.* 7.6 months (pembrolizumab, 95%CI: 6.0-13.9)^[137]. A phase 2 trial enrolled 96 patients to study the efficacy of combinational anti-PD-1 (SHR-1210) and anti-VEGFR (Apatinib) in NSCLC patients with wild-type EGFR and ALK (NCT03083041). The ORR was 29.7% and DCR was 81.3%. Further analysis showed that the ORR reached 50% in the patients with high TMB, indicating that this combo-treatment is acceptable in NSCLC patients with high TMB^[138].

All the clinical trials mentioned above have illustrated good outcomes comparing with mono-immunotherapy in NSCLC, regardless of KRAS status. Further umbrella analyses are still needed to elucidate the combo-treatment efficacy on the KRAS-mutant NSCLC groups. All clinical trials are listed in [Table 1](#).

Table 1. Immune checkpoint inhibitors active in clinical trials

Immune checkpoint inhibitors	NCT identifier numbers	Combined therapy	Target	Allocation	Phase	Size	Primary ends	Status
Anti-PD-1/-L1	NCT03600883	AMG 510	KRAS ^{G12C}	Randomized	Phase 1	733	AEs, DLTs, significant clinical changes	Recruiting
Atezolizumab	NCT04449874	GDC-6036 bevacizumab, cetuximab, rrlotinib	KRAS ^{G12C} VEGFR EGFR TKI	Non-randomized	Phase 1	236	AEs, DLTs	Recruiting
Pembrolizumab	NCT04429542	BCA101	EGFR/TGF- β	Non-randomized	Phase 1	292	Safety, Cmax, PFS, AEs, ORR, OS, DLTs, MTD	Recruiting
	NCT04613596	MRTX849	KRAS ^{G12D}	N/A	Phase 2	120	Clinical activity	Recruiting
	NCT03785249	MRTX849	KRAS ^{G12D}	N/A	Phase 1	565	Safety, tolerability, drug levels, molecular effects, and clinical activity	Recruiting
	NCT03299088	Trametinib	MEK	Non-randomized	Phase 1	15	DLTs, ORR, PFS	Active, not recruiting
	NCT02779751	Abemaciclib Anastrozole	CDK Estrogen synthesis	Non-randomized	Phase 1	100	PFS, AEs, ORR, OS, DCR, PK	Active, not recruiting
	NCT03948763	mRNA-5671/V941	Vaccine	Non-randomized	Phase 1	100	DLTs, AEs, ORR	Recruiting
	NCT04340882	Docetaxel Ramucirumab	Chemotherapy VEGFR	N/A	Phase 2	41	PFS, AEs, ORR, OS	Recruiting
	NCT03225664	Trametinib	MEK	N/A	Phase 1/2	37	ORR	Active, not recruiting
	NCT02492568	Radiation		N/A	Phase 2	96	ORR, toxicity	Complete
Nivolumab	NCT04263090	Rigosertib	PLK1	N/A	Phase 1/2	30	MTD, ORR, PFS, OS	Recruiting
	NCT02852083	Pioglitazone Clarithromycin	PPAR γ Bacteria proteins	Randomized	Phase 2	86	PFS, AEs, ORR, OS	Unknown status
	NCT02492568	Ipilimumab	Anti-CTLA-4	N/A	Phase 3	1980	OS, ORR, disease related symptom	Recruiting
SHR-1210	NCT03083041	Apatinib	Anti-VEGFR	N/A	Phase 2	117	AEs, ORR	N/A

AEs: Adverse events; DLTs: dose-limiting toxicities; PFS: progression-free survival; OR: overall survival; RR: response rate; MTD: maximum tolerant doses; ORR: objective response rate; DCR: disease control rate; PK: pharmacokinetics; Cmax: plasma concentration.

The application of dietary modifications to supplement other cancer therapies is drawing more attention currently. The intake of different nutrients might alter the nutrient availability in the plasma, thus the TME^[139]. Preclinical and retrospective studies have assumed that cancer development and prognosis are negatively correlated to unhealthy diets, such as diets high in sodium and fat^[121,140]. Growing research has found that restriction or supplementation of specific metabolites might ameliorate therapeutic responses. The manipulation of nutrient accessibility remarkably reprograms the metabolic activity and therefore leads to alterations in cell activities and sensitivity to therapies, which is mainly modulated by nutrient-sensing pathways^[141-144]. The dietary modifications enhance cancer therapy through sophisticated mechanisms, which are well summarized in other reviews^[145-147]. As mentioned above, glucose is the primary source for not only energy but also metabolic intermediates for macromolecule synthesis for both tumor cells and immune cells. A diet low in glucose but normal in calories can reduce the blood glucose and decelerate tumor growth in some tumor models^[148]. However, the glucose restriction might also affect the normal

function of immune effect cells. During the process of proliferation, differentiation, and activation of immune cells, the requirement for glucose might differ. Studies have found that inhibition of glycolysis restrains the differentiation of CD4⁺ T cells to Treg cells and promotes the differentiation of activated CD8⁺ T cells to long-lived memory CD8⁺ T cells^[119,149]. Accordingly, we presume that timing and personalized diet should be taken into account when applying glucose restriction to supplement ICI treatment. Likewise, the lipid and amino acid metabolisms function differently at different stages of differentiation and activation of immune cells, thus the need for nutrients varies^[120,150-152]. Therefore, it is critical to understand the metabolic network and landscape in TME in KRAS-driven NSCLC and how they affect the behavior of tumor cells and the function of stromal cells. Moreover, the impact of dietary modification on ICI response might be influenced by patient-specific variables. Many studies are currently investigating the molecular mechanisms and evaluating the effects of dietary interventions in enhancing cancer therapies. Collectively, dietary modification is a promising strategy for overcoming resistance to or improving the efficacy of ICI treatment in KRAS-mutant NSCLC.

CONCLUSION

Further understanding of the resistance mechanisms to ICIs mediated by KRAS mutation in NSCLC could provide implications on prospective therapeutic interventions to overcome the resistance or improve the efficacy. This will need further investigations to unearth metabolic pathways regulated by specific KRAS mutations, as well the modulatory effect on shaping TME directly and indirectly. Additional attempts to identify metabolic signaling pathways that promote immunosuppressive TME and resistance to ICIs will help discover the targetable metabolic vulnerabilities to improve the efficacy or overcome the resistance to ICIs through dietary modifications.

Abstract

Immune checkpoint inhibitors (ICIs) are gradually replacing chemotherapy as the cornerstone of the treatment of advanced malignant tumors because of their long-lasting and significant effect in different tumor types and greatly prolonging the survival time of patients. However, not all patients can respond to ICIs, and even rapid tumor growth after treatment with ICI has been observed in a number of clinical studies. This rapid progression phenomenon is called hyper-progressive disease (HPD). The occurrence of HPD is not uncommon. Past statistics show that the incidence of HPD is 4%-29% in different tumor types, and the progression-free survival and overall survival of patients with HPD are significantly shorter than those of the non-HPD progressor group. With the deepening of the study of HPD, we have established a preliminary understanding of HPD, but the diagnostic criteria of HPD are still not unified, and the addition of biomarkers may break this dilemma. In addition, quite a few immune cells have been found to be involved in the occurrence and development of HPD in the tumor microenvironment, indicating that the molecular mechanism of HPD may be triggered by a variety of ongoing events at the same time. In this review, we summarize past findings, including case reports, clinical trials, and fundamental research; compare the diagnostic criteria, incidence, and clinical prognostic indicators of HPD in different studies; and explore the molecular mechanism and future research direction of HPD.

Keywords: Immune checkpoint inhibitors, hyper-progressive disease, immunotherapy, tumor microenvironment

INTRODUCTION

Immune checkpoint inhibitors (ICIs) have continuously promoted the progress of the treatment of malignant tumors since their advent. They have gradually replaced chemotherapy as the cornerstone for the treatment of malignant tumors; however, ICIs are only effective in some patients and remain ineffective in most populations. Changes in the tumor microenvironment (TME) induced by ICIs stimulate the accelerated growth of malignant tumor cells. This special tumor progression mode is called the hyper-progressive disease (HPD) state. Lahmar *et al.*^[1] reported the HPD phenomenon for the first time in a wall newspaper at the 2016 European Society of Medical Oncology Annual Meeting. Eight patients with advanced non-small cell carcinoma (NSCLC) exhibiting fast progression at the time of initial examination were identified as HPD cases. HPD gained attention in 2017 when Champiat *et al.*^[2] reported a 9% HPD incidence in 131 cancer patients in a phase I prospective study. Evidence of HPD, the phenomenon of early crossover of the survival curve, is also reported in some phase III clinical studies, including in NSCLC (CheckMate026^[3], CheckMate057^[4], and CheckMate227^[5]), HNSCC (CheckMate141^[6]), and uroepithelial carcinoma (Keynote045^[7] and IMvigor211^[8]). Patients receiving immunotherapy died at a greater rate in the first three months than those treated with chemotherapy. HPD is not unique to immunotherapy and can also be caused by chemotherapy^[9] and targeted therapy^[10]. However, the incidence of HPD after ICI treatment is significantly higher than in the chemotherapeutic regime^[11]. Since its discovery in 2016, several studies on HPD have been reported in the last five years. Nevertheless, the incidence, diagnostic criteria, and pathogenesis of HPD remain in the preliminary stages. This review summarizes the recently published cases, clinical studies, and basic studies on HPD.

DIAGNOSTIC CRITERIA FOR HPD

At present, there is no agreement on the diagnostic criteria of HPD. Although many clinical studies on HPD adopt different diagnostic criteria, the diagnostic indicators of HPD mainly focus on the following five: tumor growth rate (TGR), Δ TGR, tumor growth kinetics (TGK), Response Evaluation Criteria in Solid Tumors (RECIST), and time to failure (TTF). TGR represents the percentage of monthly tumor volume growth (excluding new and immeasurable lesions), and the difference between the two at and before treatment is defined as Δ TGR. TGK is defined similarly to TGR, but it primarily reflects tumor growth rate per unit time. TTF refers to the time of treatment failure. Champiat *et al.*^[2] earlier adopted such criteria as $TGR > 2$ and RECIST to assess the progress for the first time to define HPD. In the same year, Ferrara *et al.*^[9] used a different cut-off value of Δ TGR $> 50\%$. Kato *et al.*^[12] added TTF < 2 months on the basis of predecessors. Saâda-Bouzid *et al.*^[13] used a new index, TGK, as a measure of tumor growth rate that may be more appropriate to define HPD. Kim *et al.*^[14] reviewed the survival time of 335 patients with advanced NSCLC who received ICI monotherapy; it was proved that HPD defined by volume measurement (TTF < 2 months, TGK > 2 , and Δ TGR $> 50\%$) is more accurate than that defined based on one-dimensional analysis (RECIST 1.1). Kas *et al.*^[15] conducted a retrospective study of 406 patients with advanced NSCLC treated with ICIs. They calculated their results using the different definitions of five clinical studies. The incidence of HPD ranged from 5.4% to 18.5%, and the median survival ranged from 3.4 to 6.0 months. Δ TGR was found to be most correlated with poor prognosis, and Δ TGR $> 100\%$ was updated as the optimal threshold.

Although the volumetric method is superior to the RECIST standard, there are practical problems: first, not all patients can complete the pre-baseline computed tomography (CT) scan, especially those receiving ICI as late first-line treatment. Second, new and unmeasurable lesions cannot be measured by TGR.

Matos *et al.*^[16,17] returned to RECIST standard and proposed a new method to define HPD: (1) target lesions increased by more than 40% from baseline; and/or (2) target lesions increased by more than 20% from baseline and new lesions appeared in at least two different organs. The overall survival (OS) of the HPD group using the new standard decreased significantly, which was statistically significant, compared to the non-HPD group, whereas the OS of the HPD group using TGR decreased, but not statistically significantly. However, Gomes da Morais *et al.*^[18] reviewed the literature and compared the main criteria of HPD proposed by Ferté, Le Tourneau, Garralda, and Caramella. These criteria include Δ TGR > 100 (Caramella) and 20% target lesion progression plus the occurrence of new lesions in at least two different organs. The incidence of HPD was 23.9%, 23.9%, 32.4% and 8.4%, respectively. They believed that the Caramella standard has low sensitivity; the Garralda standard has low specificity; and the Le Tourneau and Ferté standards seem to have similar performance in detecting HPD, but, from a practical point of view, the two-dimensional evaluation of TGK (Le Tourneau) is easier than the three-dimensional evaluation of TGR (Ferté). The importance of pre-baseline CT scanning in diagnosing HPD was thus highlighted, but only 71 eligible patients were enrolled in this study. Later, Abbar *et al.*^[19] expanded the study to 169 advanced NSCLC patients treated with ICI; the incidence of HPD (11.3%, 5.7%, 17.0%, 9.6% and 31.7%) was calculated based on five indicators. In addition to the discovery of large heterogeneity, the definition of HPD based on TTF standard was correlated with OS, while the other diagnostic criteria were not correlated with OS.

Thus, combining indicators with each other may be more conducive to diagnosis. The radiological and clinical diagnostic criteria for HPD are still being explored. With the deepening of the understanding of biomarkers for HPD, biomarkers may be involved in the diagnostic criteria of HPD in the future, and the joint definition of HPD by three diagnostic methods may be more accurate and practical.

INCIDENCE AND PROGNOSTIC INDICATORS OF HPD

The incidence and clinical prognostic indicators of HPD are also different. Chen *et al.*^[20] reviewed the medical records of 377 patients with multiple malignancies and reported the incidence of HPD (10.08%). Factors associated with HPD include the presence of more than two metastatic sites, Eastern Cooperative Oncology Group score \geq 2, liver metastasis, and lactic dehydrogenase level higher than the normal upper limit. Kirsten rat sarcoma viral oncogene homolog status is significantly correlated with HPD in colon cancer patients. Two large-scale meta-analyses reported the incidence of HPD in patients with pan-cancer as 1%-30%^[21] and 5.9%-43.1%^[22]. The clinical prognostic markers used in these analyses were similar to those reported by Chen *et al.*^[20]. Ferrara *et al.*^[9], using RECIST 1.1 and TGR criteria, reported a 13.8% (56/406) HPD incidence in patients with advanced NSCLC; HPD was associated with more than two metastases before immunotherapy. Kim *et al.*^[23] first defined three criteria (TGR, TGK, and TTF) to calculate the incidence of HPD (20.9%, 20.5%, and 37.3%, respectively). In HPD patients who satisfied both TGR and TGK criteria, poorer progression-free survival (PFS) and OS were observed. Although no clinicopathological variables of HPD were reported in the study, in the exploratory biomarker analysis of peripheral blood, CD8⁺ T lymphocytes, lower effector/memory subsets (CCR7⁺CD45RA⁻ T cells in total CD8⁺ T cells), and higher populations of severely depleted cells (TIGIT⁺ T cells in PD-1⁺CD8⁺ T cells) were associated with HPD and poor survival. In two real-world studies, the incidence of HPD in advanced NSCLC was 19.2% (16/83)^[24] and 8.1% (6/74)^[25]. Among them, one study reported an increased rate of fluid accumulation (up to 90%) and decreased albumin level, while the other showed a significant increase in the number of circulating Treg cells in HPD patients. Chen *et al.*^[26] performed a meta-analysis consisting of 1389 NSCLC patients from six clinical studies and found that the incidence of HPD was 8.02%-30.43%. The incidence of HPD and clinical prognostic indicators in cancer types are shown in [Table 1](#).

Table 1. Recent retrospective studies on hyper-progression after immunotherapy

Tumor type	Agents	HPD criteria	HPD incidence	Prognostic indicators	Outcomes (HPD vs. non-HPD)	Ref.
Multiple tumor types	PD-1/PD-L1 inhibitor monotherapy	-	1%-30% (217/1519)	Serum LDH > upper normal limit; > 2 metastatic sites prior to immunotherapy; liver metastatic sites; RMH prognostic score ≥ 2 ; positive PD-L1 expression status	-	Kim et al. ^[21] (2019)
Multiple tumor types	PD-1/PD-L1 inhibitor monotherapy	RECIST criteria (1.4 \times baseline sum target lesions or 1.2 \times baseline sum target lesions + new lesions in at least 2 different organs) or TGR ≥ 2	RECIST criteria, 10.7% (29/270); TGR criteria, 6.3% (14/221)	RECIST criteria of no or TGR criteria of liver metastatic sites; > 2 metastatic sites prior to immunotherapy	OS: 5.23 months vs. 7.33 months, $P = 0.04$, by RECIST; 4.2 months vs. 6.27 months, $P = 0.346$, by TGR	Matos et al. ^[17] (2020)
Multiple tumor types	PD-1 inhibitors (nivolumab or pembrolizumab)	Δ TGR > 50%	10.08% (38/377)	> 2 metastatic sites prior to immunotherapy; ECOG ≥ 2 ; hepatic metastases; serum LDH > upper normal limit; KRAS status in colorectal cancer	OS: 3.6 months vs. 7.3 months, $P < 0.01$	Chen et al. ^[20] (2021)
Multiple tumor types	PD-1 or PD-L1 inhibitor monotherapy or combined with CTLA-4 inhibitor	4 categories (TGR, TGK, early tumor burden increase, or combinations of the above)	5.9%-43.1% (3109)	-	-	Park et al. ^[22] (2021)
NSCLC	PD-1 or PD-L1 inhibitor monotherapy or combined with CTLA-4 inhibitor	RECIST 1.1 progression and Δ TGR > 50%	14% (56/406 treated with ICI); 5% (3/59 treated with chemotherapy)	> 2 metastatic sites prior to immunotherapy	OS: HR = 2.18, 95%CI: 1.29-3.69, $P = 0.03$	Ferrara et al. ^[9] (2018)
NSCLC	PD-1 inhibitors (nivolumab)	< 3 nivolumab injections	20% (57/292)	PS > 2 at nivolumab initiation	OS: 1.4 months vs. 13.5 months, $P < 0.0001$	Costantini et al. ^[112] (2019)
NSCLC	PD-1 or PD-L1 inhibitor monotherapy	Volumetric time-dependent criteria (TGK ≥ 2) or one-dimensional criteria: RECIST 1.1 progression	14.3% (48/335 by volumetric assessment); 13.1% (44/335 by one-dimensional criteria)	High neutrophil-to-lymphocyte ratio; LKB1 mutation	OS: 4.7 months vs. 7.9 months, $P = 0.009$, by volumetric; 5.2 months vs. 7.1 months, $P = 0.288$, by RECIST	Kim et al. ^[14] (2020)
NSCLC	PD-1 or PD-L1 inhibitor monotherapy	TGK ≥ 2 , TGR ≥ 2 , or TTF < 2 months	20.9% (55/263 TGK), 20.5% (54/263 TGR), 37.3% (98/263 TTF)	≥ 2 metastatic locations; liver metastases; neutrophils; neutrophil-to-lymphocyte ratio; LDH; high CD8 ⁺ PD-1 ⁺ TIGIT ⁺ T cells; low CD8 ⁺ CCR7 ⁺ CD45RA ⁺ T cells	PFS: HR = 4.62, 95%CI: 2.87-7.44, $P < 0.05$; OS: HR = 5.71, 95%CI: 3.14-8.23, $P < 0.05$	Kim et al. ^[23] (2019)
NSCLC	PD-1 inhibitors (nivolumab)	RECIST 1.1 progression and TGR ≥ 2	19.2% (16/83)	Pleura or pericardium metastasis; low circulating albumin	PFS: 0.43 months vs. 1.35 months; OS: 2.2 months vs. 4.1 months	Kim et al. ^[24] (2020)

CASE SUMMARY

The limitations of ICIs, as they may not be appropriate for some patients, caused “disease flare” in a 54-year-old man with stage IIB lung adenocarcinoma after 10th-line treatment with nivolumab^[27]. This case opened up the HPD patient reports, and, according to incomplete statistical data, in 44 cases involving 53 patients, malignant tumor types were mainly distributed in the respiratory system, digestive system, and urinary system and were immune to single and double drugs to a significantly higher degree than due to the immune or anti-angiogenesis drugs with combination chemotherapy. Most patients with HPD after ICI treatment developed liver, lung, and brain metastases. Selected case studies are listed in Table 2. Among them, the youngest patient was a 13-year-old girl suffering from malignant melanoma, which progressed to HPD mode after two cycles of treatment with avelumab in palliative radiotherapy. The Food and Drug Administration has approved ICIs for the treatment of children with microsatellite unstable malignant tumors based on reports in adults^[28]. However, the interaction between children’s immune systems and anti-PD1 therapy remains unclear. The oldest patient was an 80-year-old patient with lung squamous carcinoma^[29]. The symptoms of HPD were pneumonia, pleural effusion, and pericardial effusion. Many patients developed the same symptoms after ICI treatment for malignant tumors of the respiratory system and digestive system and malignant melanoma. A previous study in South Korea reported a higher frequency of increased fluid accumulation in HPD patients with pleural or pericardial metastases after treatment with nivolumab as compared to the progressive disease (PD) patients without HPD [90% (9/10) vs. 28.6% (4/14); $P = 0.005$]; the circulating albumin level was significantly reduced in HPD patients ($P = 0.030$)^[24]. A considerable proportion of HPD occurred in patients after radiotherapy, which suggested that radiotherapy had a bidirectional regulatory effect on the anti-tumor immune response. If the immunosuppressive function of radiotherapy is dominant, a combination of ICIs may lead to HPD^[30]. A clinical study of head and neck squamous cell carcinoma also suggested that previous local irradiation was an important predictor of HPD^[31]. In addition to being associated with radiotherapy, AKT1 E17K mutation^[32] and PI3K/AKT pathway^[33] were also related to HPD. Interestingly, after immunohistochemical staining of the primary tumor and metastases samples with HPD, Barham *et al.*^[34] showed that the tumor infiltrating lymphocyte (TIL) number was not necessarily correlated with ICI response, as levels of granzyme B and TIA-1 of infiltrated CD8⁺ T cells were mostly negative, indicating that these were inflammatory T cells which cause tumor drug resistance and myocarditis. They cannot effectively dissolve the tumor, so additional functional markers are required to distinguish between inflammatory and cytolytic CD8⁺ TIL. For treatment, the salvage therapy in HPD has not been limited to chemotherapy. A patient with lung adenocarcinoma developed HPD with rib metastasis shortly after ICI-based combination therapy, and the lesion was significantly reduced after implantation of I¹²⁵ particles into the chest wall^[35]. Another patient with lung adenocarcinoma showed MET amplification on re-biopsy after HPD and remission occurred with a c-MET inhibitor^[36]. A patient with triple-negative breast cancer showed HPD after pembrolizumab treatment combined with chemotherapy and remission with atezolizumab administration combined with chemotherapy^[37]. A patient with cardiac cancer was in remission after salvage

Table 2. Cases summary on hyper-progression after immunotherapy

Tumor type	Gender	Age (years)	Agents	Radiotherapy before ICIs	Clinical symptoms	Progressive organ	Ref.
SCLC	Male	35	Nivolumab	No	Pleural effusion	Chest wall	Chiba et al. ^[119] (2020)

therapy with paclitaxel and ramucirumab following HPD^[38].

MOLECULAR MECHANISM UNDERLYING HPD

The mechanism of action underlying ICI is the removal of the “braking” function of immune checkpoints and reduction in the escape of tumor cells to enhance the anti-tumor immune response of effector T cells^[39]. ICIs reverse the immunosuppressive state of T cells by disrupting the programmed cell death-1/programmed cell death-ligand 1 (PD-1/PD-L1) axis^[40]. However, PD-1 receptors are present not only on the surface of T cells but also on the surface of many innate or acquired immune cells, including NK cells, monocytes, macrophages, Treg cells, and B cells^[41]. Furthermore, immune cells have varying impacts on PD-1/PD-L1 axis disruption, boosting or inhibiting immune function. In addition, tumor treatment through ICI intervention may also induce changes in the oncogenic pathways of the tumor cells and result in their rapid proliferation and spread^[42]. Therefore, HPD may not be triggered by a single factor, but by a series of events that occur simultaneously. Most of the current studies on the molecular mechanisms of HPD focus on the tumor and the tumor microenvironment. In the next sections, we discuss these in detail to facilitate the understanding of the molecular mechanisms underlying ICI-induced HPD. The molecular mechanisms underlying HPD are shown in [Table 3](#).

Alteration in the tumor cell types following ICI

HPD is a type of primary resistance to immunotherapy, and the mechanism of its occurrence involves alteration in the tumor cell types and the tumor microenvironment. These changes range from enhanced proliferative capacity, invasiveness, and drug resistance of tumor cells to a reduced immunosuppressive capacity in the tumor microenvironment. The tumor cells themselves are altered due to the following reasons: (1) loss of expression of

Table 3. Mechanisms summary on hyper-progression after immunotherapy

Tumor cells		Tumor microenvironment
1. Loss of expression of tumor-associated antigens ^[43]	Treg cells	1. Competition with conventional T cells for IL-2 via Foxp3 ^[66,136]
2. Impairment of antigen processing and delivery ^[44]		2. Secretion of the anti-inflammatory cytokines TGFβ, IL-10, and IL-35 ^[68,69]
3. Persistent upregulation of PD-L1 expression on the surface of tumor cells ^[45]		3. The dual expression of CD39 and CD73; the CTLA-4-mediated downregulation of CD80 and CD86 on the surface of APCs ^[71,73]
4. Apoptotic resistance in tumor cells ^[46,47]		4. Production of FGL2 to suppress CD8 ⁺ T cells and APCs through FcγRIIb ^[74,137]
5. Induced dormancy and senescence of tumor cells ^[48]		5. Express PD-1 receptors
6. Tumor cells undergo dedifferentiation and EMT ^[49]	T cells	6. A spatial ecological niche dedicated to immunosuppression ^[76]
7. MDM2/MDM4 amplification and EGFR mutation ^[58]		1. Release the cytokines IFNγ ^[80] , IL-17 ^[86,87] , IL-22 ^[88,89] , TNFα ^[90,91] and IL-6 ^[92]
		2. The combination of multiple cytokines, such as TGFβ and TNFα ^[80] or IFNγ and TNFα ^[93]
	B cells	3. The binding of CD27 receptor to CD70 ligand ^[94]
		IgG4 competes with IgG1 to bind to Fc receptors on the surface of immune effector cells ^[107]
	Fc receptor	The binding of the Fc region of the anti-PD-1 antibody to the macrophage FcγR ^[62]

tumor-associated antigens^[43]; (2) impairment of antigen processing and delivery, including the loss of human leukocyte antigen expression, failing to deliver tumor antigens to the cell surface^[44]; (3) persistent upregulation of PD-L1 expression on the surface of tumor cells, which competes with ICI for binding to PD-1 receptors on the surface of CD8⁺ T cells and inhibits the anti-tumor immune response^[45]; (4) apoptotic resistance in tumor cells^[46,47]; (5) induced dormancy and senescence of tumor cells^[48], whereby the tumor cells are temporally controlled and lay the groundwork for future recurrence and metastasis; and (6) tumor cells undergo dedifferentiation and epithelial to mesenchymal transition (EMT)^[49].

MDM2/MDM4 amplification and EGFR mutation

In 2017, Kato *et al.*^[12] evaluated 155 patients with advanced tumors and found a 3.9% incidence of HPD. Through Next-Generation Sequencing (NGS), murine double minute 2/4 (MDM2/MDM4) amplification was identified in six patients who had TTF < 2 months and two patients were diagnosed with HPD; in 10 other patients, epidermal growth factor receptor (EGFR) mutations were identified. By multivariate analysis, it was found that MDM2/MDM4 amplification and EGFR mutations were associated with TTF < 2 months. The presence of MDM2 amplification and EGFR mutations in patients with HPD were also found in a clinical study by Singavi *et al.*^[50] and Economopoulou *et al.*^[51]. The MDM2 protein encoded by the *MDM2* gene is a major negative regulator of the p53 protein. MDM2 can ligate to the p53 protein through the E3 ubiquitin ligase, and the ubiquitinated p53 can be transferred to the cytoplasm and targeted for degradation by the proteasome^[52]. Thus, MDM2 amplification can promote tumorigenesis directly or indirectly through the inhibition of p53. In 2018, Kato *et al.*^[53] extended the scope of NGS sequencing to include 102,878 patients with different malignancies and found MDM2 amplification in 3.5% of patients; this was present in a small proportion of patients in most tumor types, and 97.6% of these patients had potentially targetable genomic co-alterations, which suggested that appropriately targeted drugs could be designed to target MDM2 amplification-induced HPD. Fang *et al.*^[54] conducted preclinical studies using the MDM2 inhibitor, APG-115. It acts as an indirect p53 activator, suppresses M2 macrophage polarization, and slows tumor invasion and progression, improving anti-tumor immunity to anti-PD-1 treatment. APG-115-mediated p53 activation promoted anti-tumor immunity in TME regardless of the Trp53 status of the tumor itself. Sahin *et al.*^[55] also used the MDM2 inhibitor AMG-232 in combination with anti-PD-1 antibody therapy to enhance T cell-mediated killing of tumors regardless of PD-L1 expression. Another MDM2 inhibitor, idasanutlin (RG7388), in combination with cytarabine therapy, is the first to enter phase III clinical trials for AML^[56,57].

EGFR is the first identified member of the ErbB family and plays an important role in physiological processes, including cell growth, proliferation, and differentiation. EGFR is also involved in tumor development and immunotherapy-related resistance. A meta-analysis involving 21,047 patients from 35 randomized controlled trials indicated that patients with EGFR wild type had significantly prolonged PFS and OS after treatment with ICI, while those with EGFR mutations did not show any improvement^[58]. This in part reflected the fact that EGFR mutations are a cause of ICI resistance. The TME in EGFR mutated lung adenocarcinoma was non-inflammatory; interestingly, the non-inflammatory TME had a high infiltration of CD4⁺ Treg cells. EGFR signaling activates cJun/cJun N-terminal kinase and reduces the level of interferon regulatory factor-1; the former increases CCL22 and thereby recruits CD4⁺ Treg cells, while the latter reduces the levels of CXCL10 and CCL5 and, in turn, induces CD8⁺ T cell infiltration^[59]. In addition, EGFR can upregulate the number of immunosuppressive receptors and induce the secretion of cytokines with immunosuppressive functions [IL-6, IL-10, and transforming growth factor (TGFβ)] from the TME, which in turn leads to ICI treatment resistance^[60]. To some extent, this may explain the occurrence of HPD in patients with EGFR mutations after ICI treatment; however, the exact mechanism of induction needs to be further elucidated. Other somatic mutations and carcinogenic pathways exist in addition to MDM2 amplification and EGFR mutations. Xiong *et al.*^[61] evaluated the mutational and transcriptional characteristics of tumors before and after anti-PD-1 immunotherapy in two patients who acquired HPD. Somatic mutations in recognized cancer genes, including tumor suppressor genes such as *TSC2* and *VHL*, were discovered, as well as transcriptional activation of carcinogenic pathways including IGF-1, ERK/MAPK, PI3K/AKT, and TGFβ.

Treg cells

Treg cells are important for the maintenance of the body's immune tolerance. The majority of CD4⁺ Treg cells are produced by the thymus, which accounts for 10% of circulating CD4⁺ T cells. The major transcription factor is Foxp3, which determines the phenotypic and functional characteristics of Treg cells^[62]. In a normal organism, Treg cells negatively regulate immune cells such as effector T cells to prevent autoimmune overload, while, in tumors, Treg cells exhibit different biological functions^[63]. Kang *et al.*^[25] found significantly higher FoxP3⁺ Treg cells in 74 patients with advanced NSCLC who developed HPD and significantly fewer Treg cells in non-HPD patients ($P = 0.024$). Therefore, PD-1⁺ Treg cells could be an effective biomarker for the identification of HPD^[64]. Previous studies have shown that high Foxp3⁺ Treg cell infiltration in tumors is significantly associated with poorer OS^[65]. Foxp3 is a transcriptional repressor of IL-2 that also isolates transcriptional activators acute myeloid leukemia 1 and nuclear factor of activated T-cells outside the nucleus, preventing Treg cells from producing IL-2^[66]. However, Tregs and conventional CD4⁺ T cells both require IL-2 to survive. As a result, Treg cells compete with conventional T cells for IL-2 via Foxp3 by boosting the expression of CD25 (IL2α), leading to the formation of a high-affinity IL-2 receptor (heterotrimeric complex (IL2Rαβγ))^[67].

Treg cells secrete the anti-inflammatory cytokines TGFβ, IL-10, and IL-35 to deplete conventional T cells^[68,69]. TGF, as a Th1 inhibitor, stimulates the TGFβRI/II receptor on conventional T cells to block IFNγ-induced Th1 activation by inhibiting the expression of two essential Th1 transcription factors, T-bet and IFN regulatory factor 1^[70]. Indeed, IL-10⁺ and IL-35⁺ Treg cells account for a large proportion of tumors. Gene profiles of conventional T cells exposed to these Treg subtypes were analyzed, and it was discovered that T cells depletion was promoted by IL-35⁺ Treg, but antitumor effects were inhibited by IL-10⁺ Treg^[68].

Treg cells, which have the dual expression of CD39 and CD73, block T cell activation by adenosine triphosphate (ATP) and generate adenosine to inhibit T cells. CD39 and CD73, respectively, hydrolyze ATP/ADP to AMP and AMP to adenosine, leading to a large enrichment of adenosine around Treg cells. Adenosine can induce actin cytoskeleton rearrangement and hence function as a chemoattractant for

dendritic cells (DCs), causing DCs to congregate towards Treg cells^[71]. Then, with enhanced leukocyte function-associated antigen-1 stability and expression, Treg cells and DCs create a tight aggregate, decreasing the interaction of T cells to DCs^[72]. On the other hand, cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) is mediated by Treg cells, resulting in the downregulation of CD80 and CD86 on the surface of antigen-presenting cells (APCs) to restrict the activation of conventional T cells^[73]. However, it is uncertain whether the capacity of Treg cells to control CD80 and CD86 is simply dependent on CTLA-4 expression.

Treg cells produce fibrinogen-like protein 2 (FGL2) to suppress CD8⁺ T cells and APCs through Fc γ RIIb. FGL2 is considered a signaling molecule for Treg cells as Foxp3 in Treg stimulates the expression of FGL2^[74]. The major immunomodulatory effect of FGL2 is mediated via Fc γ RIIb in APCs. A study has demonstrated that mice lacking the Fc γ RIIb receptor develop autoimmune glomerulonephritis^[75].

Treg cells can also express PD-1 receptors on their surface, and, although blocking the PD-1/PD-L1 axis activates T cells, Treg cells are also highly active, immune function is greatly affected, and anti-tumor immune efficacy is reduced. However, highly activated Treg cells in lymphoid organs resist newly generated anti-tumor T cells, leading to a more attenuated anti-tumor immune effect. These result in uncontrolled tumors, which may lead to HPD. In addition, Murakami *et al.*^[76] reported a spatial ecological niche dedicated to immunosuppression which is formed between CD8⁺CD39⁺PD-1⁺ T cells and Foxp3⁺PD-1⁺ Treg cells due to potential interactions between these cells in close proximity following PD-1 blockade in renal cancer. The shift to an immunosuppressive environment is more pronounced in metastatic foci. Anti-CD25 and PD-1 bispecific antibodies are currently used for treatment to deplete Treg cells. Subsequent treatment with anti-PD-1 antibodies may only enhance conventional T cells and CD8⁺ T cells^[77]. Alternatively, adenosine, a product of Treg cells, could be inhibited by combining the anti-PD-1 antibody with adenosine deaminase for its degradation to inosine, thereby reducing cAMP production to weaken the inhibition of conventional T cells and enhance anti-tumor immunity^[62]. The possibility of interfering with the systemic immune system is considerably minimized by precisely destroying Treg cells around tumor cells.

T cells

The function of T cell adaptive immunity is to eliminate tumor cells that positively express antigens^[78]. However, ICI-enhanced T cell adaptive immune response cannot completely kill tumor cells, as reported in most clinical trials. Even after ICI treatment, adaptive immunity can promote tumor growth directly or indirectly. As a consequence, some researchers believe that enhanced tumor adaptive immune response may be the root cause of HPD in tumor patients after ICI treatment^[42]. T cell immune response can induce changes in gene expression of tumor cells, such as a downregulation of tumor surface antigens^[79] and upregulation of other immune checkpoint ligands^[45]. However, the underlying mechanism of T cell immune response leading to changes in tumor cells remains changes in tumor cells are still not clear.

The cytokine IFN γ released by T cells may explain a part of the problem. IFN γ , a common cytokine, is involved in several cellular changes, including EMT induction^[80]. EMT in tumor cells is related to the upregulation of inhibitory checkpoint ligands^[81], resistance to cell-mediated cytotoxicity^[82], and the production of immunosuppressive effects^[83]. Furthermore, IFN γ has the ability to upregulate immune checkpoint ligands^[84], inducing tumor cell dormancy, apoptosis^[84], and hyperplasia.

The same cytokine can play different roles in different environments, depending on the length of time it acts on tumor cells. For instance, prolonged exposure to IFN γ and low levels of the cytokine have been demonstrated to have pro-tumorigenic effects^[85]. Other cytokines, such as IL-17^[86,87], IL-22^[88,89], tumor

necrosis factor α (TNF α)^[90,91], and IL-6^[92], are involved in tumor promotion. The combination of multiple cytokines may have a greater tumor-promoting effect than a single cytokine; for example, TGF β 1 leads to demethylation of PD-L1 promoter and TNF α leads to the expression of demethylated promoter and co-induces the overexpression of PD-L1^[80]. IFN γ and TNF α can co-induce dormancy in tumor cells to promote carcinogenesis^[93]. However, there is no clear answer as to which T cell subsets are mainly responsible for the release of these cytokines.

In addition to cytokines, some studies report that the binding of CD27 receptor to CD70 ligand can directly promote proliferation and differentiation of tumor stem cells^[94] or T cell exosomes to induce EMT and lead to rapid tumor progression^[95]. Many T cell subsets are involved, including CD4⁺ T cells^[96,97], CD8⁺ T cells^[98,99], Th1 cells^[100], Th2 cells^[101], Th17 cells^[102], and Th22 cells^[89]. However, the proportion and spatial distribution of tumor cells and effective infiltration of immune cells may be the watershed response of adaptive immunity when the tumor-immunity balance is broken.

Although there are few studies on non-Treg CD4⁺ T lymphocytes, after ICI treatment, their levels may show an unexpected increase, which can contribute to the occurrence and development of HPD. A prospective study by Arasanz *et al.*^[103] included 70 patients with advanced NSCLC who underwent ICI treatment. Early detection of HPD in NSCLC by monitoring T cell dynamics showed a strong expansion of highly differentiated CD28⁺CD4⁺ T lymphocytes (CD4⁺ THD) between the first and second treatment cycles in HPD patients and a significant stratification among HPD patients, non-HPD patients, and effective patients (median 1.525, 1.000, and 0.9700, respectively, $P = 0.0007$). As a consequence, the strong expansion of CD28⁺CD4⁺ T lymphocytes in peripheral blood during the first treatment cycle could provide an early differential feature of HPD induced by ICI in the treatment of NSCLC. These studies suggest that CD8⁺ T cells and Treg cells are involved in the occurrence and development of HPD in TME. However, several innate and adaptive immune cells may be swept into this storm.

B cells

PD-1 can also be expressed on the surface of B cells. Some studies have pointed out that anti-PD-1 antibodies can increase the activation, proliferation, and production of inflammatory cytokines in B cells^[104]. However, follow-up studies show that the loss of B cells does not seem to have any effect on the efficacy of ICI treatment^[105]. The reason for these differences may be due to the existence of different subsets of B cells. The balance among different B cells (resting B cells, activated B cells, Bregs, and other differentiated B cells) determines the ultimate role of B cells in tumor immunity^[106]. Humoral immunity may play a role in carcinogenesis. Wang *et al.*^[107] studied the distribution and mechanism of IgG4 secreted by B cells in the tumor model and found that the increase in B lymphocytes containing IgG4 in cancer tissues and the increase in IgG4 concentration in serum were highly correlated with the poor prognoses of patients with esophageal cancer. Using a mouse model, it was verified that IgG4 competes with IgG1 to bind to Fc receptors on the surface of immune effector cells and suppresses classical immune responses such as antibody-dependent cytotoxicity (ADCC), antibody-dependent phagocytosis, and complement-dependent cytotoxicity. Thus, tumor cell growth was indirectly promoted. Interestingly, nivolumab is essentially IgG4 with a stable S228P mutation and significantly promotes the growth of tumors in mice. However, there are only a few studies on the mechanism of B cells participating in HPD after ICI treatment, and these need further validation.

Fc receptor

The binding of the Fc region of the anti-PD-1 antibody to the macrophage Fc γ R consumes M1 macrophages and stimulates their differentiation to M2-like form. This is another clear mechanism of HPD after ICI treatment in addition to Treg cell-mediated inhibition of anti-tumor immunity leading to HPD^[62]. The

antibody consists of F(ab')₂ segment bound to the antigen and Fc region bound to FcγR on the surface of immune cells. The binding of the Fc region of IgG antibody to macrophage FcγR triggers the ADCC effect, consumes M1 macrophages and NK cells, and reduces the anti-tumor immune effect^[107,108]. Other studies have shown that many M2-PD-L1⁺ macrophages were observed in the tumor tissues of NSCLC patients with HPD, which could deplete ICI through Fc-FcγR interaction, induce M2-like differentiation of macrophages, and secrete IL-10 to mediate the HPD occurrence^[109,110]. The removal of ICI in the Fc region or knockout of FcγR on the surface of macrophages may be a potential research direction for further improvement^[111].

CONCLUSION

HPD occurrence is currently a limitation of ICI treatment and represents the storm-like progression of tumors after ICI administration. The mechanism of HPD is similar to a “tug-of-war” between tumor and anti-tumor effects. Intervention through ICI breaks this balance. It leads to the occurrence of HPD if tumor cells are activated and the anti-tumor effect is inhibited. The side effects of chemotherapy cannot be ignored, although the present incidence of HPD in immune combined chemotherapy has been reduced. One day, we hope to usher in the era of “de-chemotherapy”. Then, it would be necessary to face the problem of HPD due to ICI. Hence, the review provides a significant understanding of the current underlying mechanisms for HPD.

DECLARATIONS

Acknowledgments

We thank the editors and the reviewers for their useful feedback that improved this paper.

Authors' contributions

Contributed to the conception of the study: Dong X

Wrote the manuscript: Ding P, Wen L

Helped perform the analysis with constructive discussions: Tong F, Zhang R, Huang Y

All authors reviewed and approved the final report.

Abstract

Despite androgen dependence in a majority of castration-resistant prostate cancers, some cancer cells are independent of androgen receptor (AR) function, a feature of heterogeneity in prostate cancer. One of the aggressive variants of prostate cancer that are AR independent is neuroendocrine prostate cancer (NEPC). This manuscript will focus on the new finding of human one cut domain family member 2 (ONECUT2) transcription factor and its role in castration resistance, especially in NEPC.

Keywords: Prostate cancers, castration resistant, ONECUT2, androgen receptor-independence, neuroendocrine differentiation

INTRODUCTION

Prostate cancer is the most common cancer diagnosed in men and the second leading cause of cancer-related deaths in the United States^[1]. Given its dependence on the AR axis, prostate adenocarcinoma can respond to androgen deprivation therapy (ADT) for a variable duration, but eventually, it progresses to

metastatic castration-resistant prostate cancer (mCRPC)^[2]. Most recently, the newer generation of androgen receptor (AR) signaling inhibitors such as enzalutamide and apalutamide has improved outcomes in patients with mCRPC, but they inevitably develop resistance to these drugs as well. There are several proposed mechanisms of resistance to androgen deprivation or AR inhibitors, many of which are thought to be AR-dependent, including AR-activating mutations and constitutively active AR splice variants^[2]. However, there are also AR-independent mechanisms, with very low or absent AR expression found in tumor cells that render ADT ineffective and are associated with neuroendocrine (NE) differentiation^[2]. NEPC is an aggressive variant of prostate cancer that exhibits not only AR independence but also neuroendocrine (NE) differentiation and even distinct histological features such as small cell carcinoma instead of adenocarcinoma^[2,3]. Though NEPC can rarely arise *de novo*, more commonly, it arises from adenocarcinoma in response to selection pressure for AR-independent cells from treatment with AR signaling inhibitors via lineage plasticity and NE differentiation^[3,4]. Recent studies spearheaded by Rotinen *et al.*^[5] and Guo *et al.*^[6] showed that ONECUT2 is an important regulator of AR-mediated growth and a driver of NE differentiation in transition from adenocarcinoma to NEPC, and is being investigated as a new drug target with potential therapeutic implications. This manuscript explains how ONECUT2 leads to AR independence and NE differentiation observed in NEPC.

ONECUT2 AND PROSTATE CANCER

ONECUT is a family of transcription factors related to hepatic nuclear factor 6, which has been shown to be involved in organogenesis, cell fate, and tumorigenesis^[7]. In particular, ONECUT1 plays an important role in hepatobiliary tract disease by regulating the development, differentiation, and function of hepatocytes and cholangiocytes^[7]. Decreased expression of ONECUT1 and its target genes is associated with malformation of the liver, bile duct, gallbladder, and pancreas, as well as diabetes. Furthermore, ONECUT1 may also play a role in the prevention of hepatocellular carcinoma and pancreatic cancer by acting as a tumor suppressor^[7]. In addition, ONECUT1 also helps regulate the development of retina and motor neuron^[7].

ONECUT2 is another transcription factor that regulates cell proliferation, migration, and differentiation, which was first discovered by Jacquemin *et al.*^[8] in 1999. ONECUT2 is found in various organs, including the liver, skin, brain, testis, and bladder^[8]. In contrast to ONECUT1, ONECUT2 expression has been shown to be elevated in multiple different cancers, including prostate cancer^[6], ovarian cancer^[9], gastric cancer^[10], colorectal cancer^[11], hepatocellular carcinoma^[12], lung adenocarcinoma^[13], and neuroendocrine tumors^[6]. Specifically in prostate cancer, increased ONECUT2 expression has been linked to the aggressiveness of the disease, disease progression, biochemical recurrence, and metastasis^[5,6]. ONECUT2 mRNA level was found to be elevated in mCRPC prior to any treatment and was higher than in non-metastatic tumors^[5]. ONECUT2 target genes are involved in the cell cycle, angiogenesis, and hypoxia, which in turn are implicated in tumor growth and metastasis in prostate cancer^[6].

Both ONECUT1 and ONECUT2 are transcriptional activators of the ONECUT family with similar but distinct functions in development and pathogenesis in various organs. Similarities and differences between ONECUT1 and ONECUT 2 are outlined in [Table 1](#).

ONECUT2 mediates AR independence in prostate cancer

Rotinen *et al.*^[5] showed that ONECUT2 expression is negatively correlated to AR activity. AR activity was significantly lower in mCRPC tumors with high ONECUT2 expression, whereas in tumors with high AR activity, the ONECUT2 expression was suppressed^[5]. ONECUT2 directly suppressed genes regulated by AR, including kallikrein-related peptidase 3 (KLK3)/prostate-specific antigen, kallikrein-related peptidase 2

Table 1. Characteristics of ONECUT1 and ONECUT2

	ONECUT1	ONECUT2
Location of gene	15q21.3	18q21.31
Target gene	<ul style="list-style-type: none"> - Liver genes, including hepatocyte nuclear factor (Hnf) - FOXA1/2 - Transthyretin gene - Glucokinase (Gck), glucose transporter 2 (Glut2) - miR-122 	<ul style="list-style-type: none"> - Liver genes, including hepatocyte nuclear factor (Hnf) - FOXA1/2 - Transthyretin gene - Genes regulated by AR
Functions in development	<ul style="list-style-type: none"> - Expressed in retinal progenitor cells - Important for the development of liver, bile duct, pancreas - Associated with malformation of the hepatobiliary tract, maturity onset diabetes of the young 	<ul style="list-style-type: none"> - Expressed in retinal progenitor cells - Melanocyte and hepatocyte differentiation
Associated cancers	<ul style="list-style-type: none"> - Pancreatic cancer - Hepatocellular carcinoma 	<ul style="list-style-type: none"> - Prostate cancer - Ovarian cancer - Gastric cancer - Colorectal cancer - Hepatocellular carcinoma - Lung adenocarcinoma - Neuroendocrine tumors
Ref.	[7]	[7-13]

(KLK2), and ETS homologous factor^[5]. Altogether, these findings show that ONECUT2 leads to AR independence in prostate cancer. Tumors with high ONECUT2 expression such as NEPC represent a variant group of mCRPC that is independent of AR function.

ONECUT2 promotes NE differentiation in prostate cancer

NE differentiation in prostate cancer is associated with a more aggressive phenotype, metastatic disease, and poor response to AR signaling inhibitors^[3]. ONECUT2 has been shown to play a role in NE differentiation in prostate cancer. A significantly higher level of ONECUT2 expression was found in NEPC compared to adenocarcinoma, and conversely, a reduction in ONECUT2 expression was shown to decrease NE marker gene expression^[5]. Deletion of TP53 and Rb1, two of the most frequently mutated genes in NEPC, was shown to increase ONECUT2 expression and promote NE plasticity in prostate adenocarcinoma^[6]. ONECUT2 upregulates genes involved in NE differentiation, such as neuron-specific enolase, synaptophysin, and chromogranin A^[2]. Furthermore, ONECUT2 has complex interactions with modulators of NE differentiation such as RE1-silencing transcription factor (REST), forkhead box A1 (FOXA1), and paternally expressed gene 10 (PEG10)^[5,14,15]. REST is an inhibitory regulator of NE differentiation that directly suppresses ONECUT2^[5]. A decrease in REST expression leads to upregulation of ONECUT2 mRNA and allows for the transition from adenocarcinoma to NEPC^[5]. FOXA1, another modulator that normally inhibits NE differentiation, is suppressed by ONECUT2 during transdifferentiation of adenocarcinoma into NEPC^[5]. PEG10 is different from REST and FOXA1 in that it promotes NE differentiation and is directly suppressed by AR^[5,15]. An increase in ONECUT2 expression corresponds to upregulation of PEG10 and transition from adenocarcinoma to NEPC^[5]. **Figure 1** demonstrates the role of ONECUT2 in AR independence and NE differentiation.

ONECUT2 REGULATES HYPOXIA SIGNALING, WHICH PROMOTES NE DIFFERENTIATION IN PROSTATE CANCER

Guo *et al.*^[6] demonstrated that hypoxia can induce NE differentiation and disease progression in prostate cancer, evidenced by an increase in NE marker gene expression in hypoxic conditions compared to normoxic ones. Knockdown of hypoxia-inducible factor 1 α (HIF1 α), a transcription factor that regulates the hypoxia signaling pathway, led to a reduction in NE marker gene expression^[6]. Guo *et al.*^[6] also showed that ONECUT2 is involved in regulating the hypoxia pathway, with ONECUT2 activity correlating with tumor

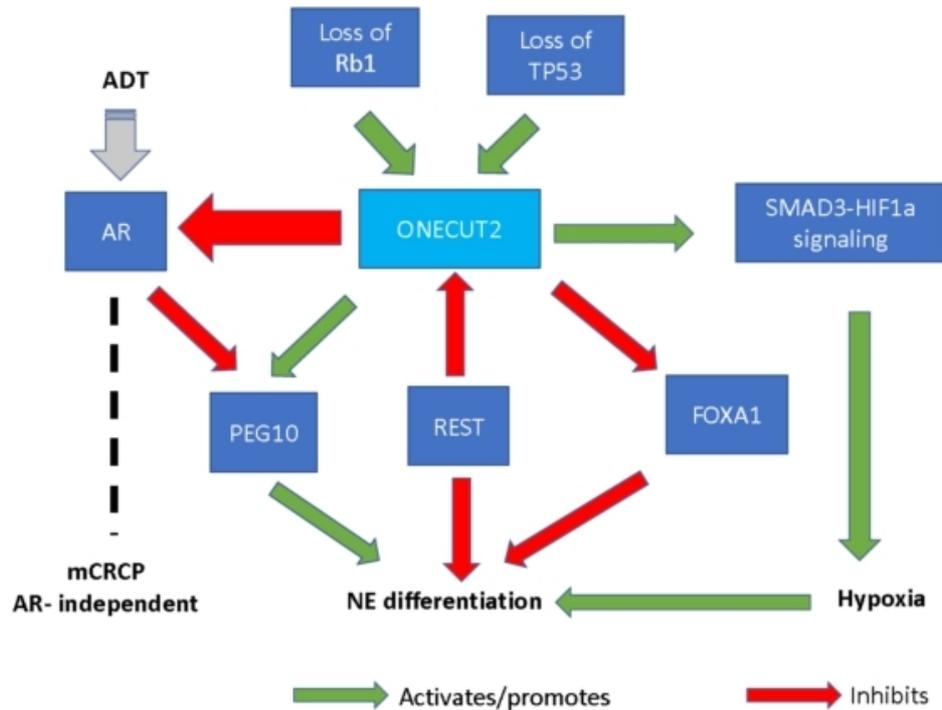

Figure 1. Role of ONECUT2 in AR independence and NE differentiation. ADT: Androgen deprivation therapy; NE: neuroendocrine; mCRPC: metastatic castration-resistant prostate cancer; ONECUT2: one cut domain family member 2; REST: RE1-silencing transcription factor; AR: androgen receptor; PEG10: paternally expressed gene 10; Rb1: retinoblastoma gene 1; FOXA1: forkhead box A1; TP53: p53-encoding gene; SMAD3: SMAD family member 3; HIF1 α : hypoxia-inducible factor 1 alpha.

hypoxia in the progression from adenocarcinoma to NEPC. ONECUT2 upregulates hypoxia-associated genes such as adrenomedullin and angiopoietin-like 4 by activating SMAD family member 3, which interacts with HIF1 α in regulating hypoxia signaling^[6] (see Figure 1). Altogether, these findings suggest that regulating the hypoxia pathway is yet another way how ONECUT2 contributes to NE differentiation.

ONECUT2 AS A DRUG TARGET IN PROSTATE CANCER

Following the discovery of ONECUT2 and its role in the transition from prostate adenocarcinoma to NEPC, new drugs targeting this pathway are being developed and studied in clinical trials. CSRM617, a small molecule inhibitor of ONECUT2 developed by Rotinen *et al.*^[5], led to cell death in prostate cancer cell lines with high ONECUT2 expression. The level of ONECUT2 expression was positively correlated with treatment response to CSRM617^[5]. *In vivo*, CSRM617 led to significant reduction in tumor size, PEG10 protein level (a marker of NE differentiation), and metastatic growth^[5].

TH-302 (evofosfamide) is a hypoxia-activated prodrug with an alkylating agent moiety that is released only in hypoxic environments, such as those found in hypoxic tumors like NEPC^[16]. TH-302 was shown to significantly inhibit tumor growth in NEPC, but less so in adenocarcinoma^[6]. There was a positive correlation between the level of ONECUT2 expression and the treatment response to TH-302^[6]. These findings show that NEPC and a higher level of ONECUT2 expression are both associated with a greater degree of hypoxia, which in turn lead to an enhanced response to TH-302. TH-302 is being studied in clinical trials, including a phase I/II clinical trial (NCT00743379) that focuses on the efficacy of TH-302 in combination with chemotherapy such as docetaxel in multiple solid tumors, including mCRPC that were not previously treated with chemotherapy. Another phase I study (NCT03098160) examines the safety and

toxicity of TH-302 in combination with ipilimumab in advanced solid malignancies, including mCRPC.

FUTURE DIRECTIONS

Given the rising use of newer generation AR signaling inhibitors, mCRPC exhibiting AR independence will likely grow in prevalence^[2]. Treatment of prostate cancer with AR inhibition may lead to selection for cancer cells with elevated ONECUT2 expression, thereby contributing to resistance to AR-targeted therapy and development of NE features that lead to more aggressive phenotypes with worse clinical outcomes^[2,3,5]. It is, therefore, crucial to continue further research on the understanding of the master regulators of AR independence such as ONECUT2 and develop safe and efficacious drugs against such targets. We believe biomarker-driven correlative studies are key for the success of future drug development targeting ONECUT2.

Abstract

Great progress has been made in improving survival in multiple myeloma (MM) patients over the last 30 years. New drugs have been introduced and complete responses are frequently seen. However, the majority of MM patients do experience a relapse at a variable time after treatment, and ultimately the disease becomes drug-resistant following therapies. Recently, minimal residual disease (MRD) detection has been introduced in clinical trials utilizing novel therapeutic agents to measure the depth of response. MRD can be considered as a surrogate for both progression-free and overall survival. In this perspective, the persistence of a residual therapy-resistant myeloma plasma cell clone can be associated with inferior survivals. The present review gives an overview of drug resistance in MM, i.e., mutation of $\beta 5$ subunit of the proteasome; upregulation of pumps of efflux; heat shock protein induction for proteasome inhibitors; downregulation of *CRBN* expression; deregulation of *IRF4* expression; mutation of *CRBN*, *IKZF1*, and *IKZF3* for immunomodulatory drugs and decreased target expression; complement protein increase; sBCMA increase; and BCMA down expression for monoclonal antibodies. Multicolor flow cytometry, or next-generation flow, and next-generation sequencing are currently the techniques available to measure MRD with sensitivity at 10^{-5} . Sustained MRD negativity is related to prolonged survival, and it is evaluated in all recent clinical trials as a surrogate of drug efficacy.

INTRODUCTION

Multiple myeloma (MM) represents the second most frequent hematological malignancy, and significant survival improvements in the years have been seen^[1-3]. Survival has ameliorated thanks to the availability of novel classes of drugs such as proteasome inhibitors (PIs: bortezomib, and carfilzomib), immunomodulatory drugs (IMiDs: thalidomide, lenalidomide, and pomalidomide), monoclonal antibodies (moAb: daratumumab, elotuzumab, isatuximab, and belantamab mafodotin). These new drugs are utilized alone or combined as triplets or quadruplets in the treatment of relapsed/refractory patients and thereafter at diagnosis with good results also in extramedullary MM^[4-17]. MM has important clinical heterogeneity and complex genetic abnormalities^[18]. Cytogenetic analysis and fluorescence *in situ* hybridization can help to distinguish different categories and risk-stratify MM patients^[19]. In particular, t(4;14), t(14;20), gain of chromosome 1q, and deletion 17p give a poorer outcome, while t(11;14) and t(14;16) seem to have an intermediate prognosis^[20-22]. In this view, relapses are seen in the majority of patients, and some of them still have a dismal prognosis. However, while cytogenetic analysis can help to stratify prognosis, it does not fully explain initial MM drug resistance (DR). Two main factors seem to emerge: (1) acquired drug resistance; and (2) sub-clonal heterogeneity^[23,24]. Mechanisms of acquired drug resistance to the main classes of new drugs available in MM have been extensively reviewed recently^[22]. A novel method to detect minimal residual disease has been developed recently^[23-35], i.e., MRD detected by next-generation flow (NGF) or next-generation sequencing (NGS), which have been reported as important tools by the International Myeloma Working Group (IMWG) in the recent response guidelines^[36]. MRD is an important surrogate for survival, as well as progression-free (PFS) and overall survival (OS)^[37]. In particular, sustained MRD negativity confirmed at one year is of great importance to predict clinical outcome of MM patients. MRD can also detect sub-clones that acquire higher genomic instability and can ultimately drive resistance^[38]. This review summarizes the main DR cell-inherent/intrinsic and extrinsic mechanisms to novel drugs in MM and will focus on recent developments regarding MRD as a tool to predict PFS and OS in clinical trials.

Drug resistance in MM

Drug resistance is the leading cause of a relapsed/refractory disease, and it can ultimately decrease survival. Many novel drugs are now available in MM with many used at diagnosis in triplet or quadruplet. MM patients can develop DR after a few cycles of therapy in a variable manner. The main mechanisms of resistance to chemotherapeutic drugs in MM can involve a drug-efflux pump, such as P-glycoprotein, or other mechanisms that inhibit the drug to enter the cell. Moreover, enzymatic inactivation of the drug or adhesion to bone marrow stromal cells, such as fibroblasts and immune cells including macrophages, in the microenvironment can be mentioned. To develop strategies for the future treatment of DR-MM patients, the main mechanisms of resistance to the different classes of drugs, namely proteasome inhibitors, immunomodulatory drugs, and monoclonal antibodies, have to be elucidated. The principal mechanisms of resistance to novel drugs and resistance escape are reported in [Table 1](#).

Drug resistance to proteasome inhibitors

The PIs used in recent years in clinical practice are bortezomib (Bor), carfilzomib (Car), and ixazomib (Ixa)^[39,40]. Bor is approved for use at diagnosis in both transplant and non-transplant eligible MM patients, while Car and Ixa are used in the relapsed and refractory treatment setting. The structure of the proteasome was first described as a hollow single-cylinder protein. The proteasome functions as an ATP-dependent organelle in which almost 90% of intracellular proteins are degraded following tagging by the polyubiquitin chain. Three subunits of the proteasome are recognized as the site of degradation in the 20S particle: β 1 (caspase), β 2 (trypsin), and β 5 (chymotrypsin). The final result of proteasome inhibition is MM plasma cell death or apoptosis via protein accumulation^[41]. Other mechanisms have been reported: p53 activation, inhibition of nuclear factor- κ B (NF- κ B) activity, activation of c-Jun N-terminal kinase, and stabilization of cell cycle inhibitors. PI can bind the β 5 subunit reversibly (Bor and Ixa) or irreversibly (Car). Resistance to

Table 1. Principal mechanisms of drug resistance and resistance escape

C	D	M of A	DR	Resistance escape	Ref.
moAb	Dara Isa Elo Bela	ADCC, CDC, macrophage-mediated phagocytosis, apoptosis via Fc-mediated crosslinking stimulatory effects on NK cells (for anti CD38 moAb), direct cytotoxicity	Decrease target expression, complement protein increase, sBCMA increase, BCMA down expression	Change drug class, upregulation of CD38 using ATRA	[61-67]
IMiDs	Tha Lena Poma	BM microenvironment targeting; degradation of <i>IKZF1</i> and <i>IKZF3</i> via <i>CRBN</i> -dependent ubiquitination; <i>IRF4</i> and <i>MYC</i> downregulation; triggering caspase 8/9-mediated apoptosis; immune modulation; anti-angiogenic activity	Downregulation of <i>CRBN</i> expression; deregulation of <i>IRF4</i> expression Mutation of <i>CRBN</i> and <i>IKZF1</i> and <i>IKZF3</i>	Change drug class, next-generation <i>CRBN</i> E3 ligase modulators (iberdomide)	[58,59]
PIs	Bort Car Ixa	Inhibition of activity of the 20S proteasome; inhibition of NF-κB activity; induction of apoptosis by activation of caspase 8/9 and p53; adhesion molecules downregulation	Mutation of β5 subunit, upregulation of pumps of efflux, HSP induction	Change drug class, pan proteasome inhibitor (marizomib), hydroxychloroquine, pan HDAC inhibitor	[46,48]

C: Class of drug; D: drug name; M of A: mechanisms of action; DR: drug resistance; moAb: monoclonal antibody; IMiDs: immunomodulatory drug; PI: proteasome inhibitors; Dara: daratumumab; Isa: isatuximab; Elo: elotuzumab; Bela: belantamab mafodotin; Tha: thalidomide; Lena: lenalidomide; Poma: pomalidomide; Bor: bortezomib; Car: carfilzomib; Ixa: ixazomib; ADCC: antibody-dependent cellular cytotoxicity; CDC: complement-dependent cytotoxicity; BCMA: b cell maturation antigen; ATRA: all trans retinoic acid; *IKZF1*: Ikaros; *IKZF3*: Aiolos; BM: bone marrow; *CRBN*: Cereblon; *IRF4*: interferon regulatory factor 4; NF-κB: nuclear factor-κB; HDAC: histone deacetylase; HSP: heat shock protein.

PIs is related to mutations in the β5 subunit gene (*PSMB5*) at both diagnosis and relapse^[42,43]. The presence of mutations at other subunits, namely *PSMA1*, *PSMB8*, and *PSMB9*, has been described, but they have not been found to be related to resistance yet and thus need to be confirmed. Another protein important for DR seems to be the X-box protein 1 that acts in the proteostasis in the MM plasma cell. Downregulation of this pathway has been reported in PI-DR cells^[44]. Decreased drug accumulation is another mechanism of DR in MM. In particular, the multidrug resistance protein P-glycoprotein (P-gp) has been well studied in the past^[45]. P-gp works by implementing drug efflux from the MM plasma cell, thus reducing drug activity. Both Car and Bor have been reported to be P-gp substrates^[46-48]. The mechanisms of resistance escape are reported in Table 1^[49,50]. The results of preclinical studies indicate that inhibition of various heat shock proteins (HSPs), e.g., HSP90, can increase the efficacy of PIs^[51]. HSPs are induced by the transcriptional blockade of protein degradation, which can contribute to drug resistance. The results from early phase I trials combining HSP90 inhibitors with PIs have identified safe doses for both drugs. In a preclinical study using bor-resistant MM cell lines, the blockade of IGF-1 downstream effectors re-sensitized cell lines to bortezomib. Furthermore, the IGF-1R inhibitor OSI-906 induced more apoptosis than Bor alone, both *in vitro* and *in vivo*^[52].

Moreover, investigators used a mouse MM model to study gene-expression signatures (GES) related to Bor resistance. GES related to resistance included nuclear factor (erythroid-derived 2)-like 2 (*NFE2L2*), highly expressed as part of an antioxidant-response pathway^[53]. Thus, MM cells with elevated antioxidant capacity before treatment might be resistant to bortezomib.

Drug resistance to immunomodulatory drugs

The IMiDs currently used in clinical practice are thalidomide, lenalidomide, and pomalidomide (Thal, Len, and Pom, respectively). All three agents were initially used in the relapsed and refractory setting, but Len and Thal are now also approved for use at diagnosis^[54]. IMiDs have antiproliferative properties and direct pro-apoptotic effects. Other mechanisms exhibited are anti-angiogenic and immunomodulatory effects, by activating NK and T cells. The E3 ligase protein Cereblon (*CRBN*) is targeted by IMiDs, in particular in complex with CRL4, ultimately leading to degradation of the Aiolos and Ikaros proteins and *IRF4* reduction^[55-57]. This mechanism of action is the principal target of DR, mainly because of occurring mutations or gene expression modifications in this complex. It has been demonstrated that *CRBN* mutations appear after a relapsed/refractory disease occurs, probably due to clonal selection after long IMiD therapy^[58]. In addition, *IRF4* has been investigated as a potential downstream target for DR in Waldenstrom macroglobulinemia after therapy with Len and Pom^[59]. Methylation of *CRBN* has also been recently reported^[60].

Drug resistance to monoclonal antibodies

Monoclonal antibodies directed at antigens present on the surface of plasma cells have recently entered the therapeutic armamentarium against MM. The approved moAb in clinical practice are daratumumab, elotuzumab, isatuximab, and belantamab mafodotin. These drugs were all tested as monotherapy first, and have since been proven to be more efficacious when combined with other agents in triplet or quadruplet^[61-65].

Even though daratumumab, an IgG 1 anti-CD38 moAb, has been found to be very efficacious, resistance can be observed during treatment. Although CD38 mutations are not described as potential mechanism of DR, it has been reported that low CD38 expression could be a cause of initial resistance to therapy. Moreover, CD38 expression reduction during treatment has been described as a major mechanism and occurs via the action of sheddases^[66]. Another occurring event observed is upregulation of CD55 and CD59 complement inhibitors^[67]. For other moAb, the DR mechanism is not currently known, although it is logical to think that, as per daratumumab, the loss of the target antigen is likely a major mechanism of resistance^[68-72].

Extrinsic mechanisms of drug resistance

The bone marrow microenvironment, including osteoblasts, osteoclasts, mesenchymal stem cells (MSC), and tumor-associated macrophages (TAM), is highly connected with MM progression and drug resistance [Figure 1]. In MM in the “osteoblastic niche”, macrophages are differentiated into osteoclasts by the release of osteoclasts activating factors (i.e., IL-6, IL-1- α , TNF- α , TNF- β , and IL-11) and promote bone resorption. Osteoprotegerin represents an antiapoptotic MM factor by binding to TNF-related apoptosis-inducing ligand. Stromal cells can give drug resistance by TGF- β inhibition of osteoblasts differentiation. Stromal cells in the microenvironment have been shown to secrete several cytokines that regulate the antiapoptotic members of the Bcl-2 family (Mcl-1, Bcl-xl, and Bcl2) via IL-6 signaling^[73]. A “vascular niche” is formed by endothelial cells (EC), MSC, and TAM and can protect MM plasma cells from cytotoxic drugs. In particular, EC can express an aberrant active phenotype (VEGFR-2 and FGFR-3) that can help to prevent MM apoptosis, favoring PC migration into the bloodstream and dissemination^[74]. MSC can contribute to bortezomib resistance in MM via Bcl2 increased expression and enhanced NF- κ B activity through cell-cell contact^[74].

TAM have a basic role in MM pathogenesis, since they promote plasma cells proliferation, homing, and angiogenesis, supporting MM immune evasion and progression^[75].

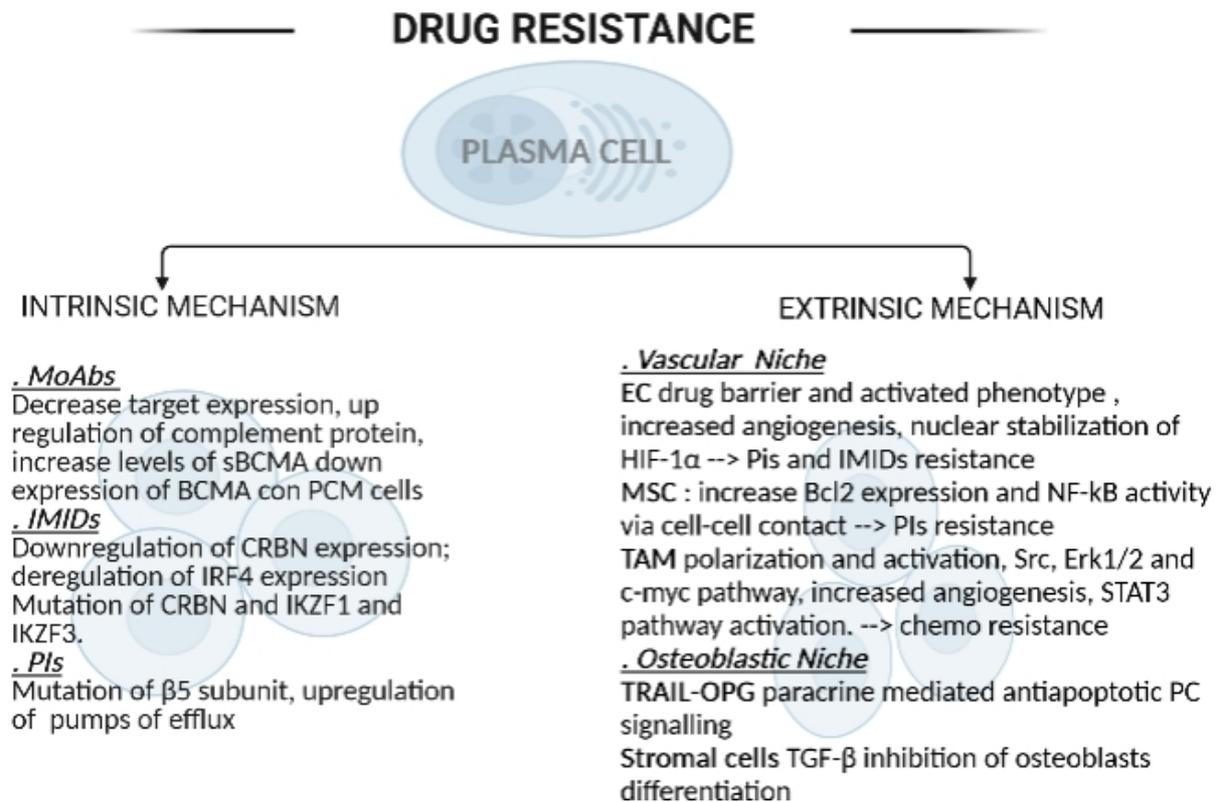

Figure 1. Drug resistance intrinsic and extrinsic mechanisms. EC: Endothelial cells; MSC: mesenchymal stem cells; TAM: tumor-associated macrophages.

MM plasma cells *in vitro* could upregulate CD206 expression and favor an M2 TAM polarization of cocultured macrophages^[76]. In a preclinical model, CD68-positive TAM were shown to inhibit drug-induced apoptosis of tumor cells by caspase 3 and poly-ADP ribose polymerase cleavage^[77,78]. Moreover, intracellular adhesion molecule-1 (ICAM-1) and P-selectin glycoprotein ligand-1 (PSGL-1) on the MM cells surface could activate TAM and favor TAM-induced chemoresistance through the *SRC*, *ERK1/2*, and *C-MYC* pathway^[79]. VEGF production by M2 TAM was demonstrated during progression from MGUS to MM, with increased angiogenic switch^[80,81].

An interesting study reported a possible correlation between the pro-tumor effect of TAM and the Stat3 pathway activation in 5T33MM cells. Interestingly, an ATP-competitive Janus kinase (*JAK*)2 inhibitor, the so-called AZD1480, could restore the sensitivity of MM cells to bortezomib^[82,83].

Clinical studies confirmed CD68/CD163 double-positive M2 TAM were associated with increased microvessel density and reduced survival, independently of the MM stage^[84-86]. In this field, high IHC CD163-positive M2 TAM expression at diagnosis was associated with lower complete response (CR) rate and reduced PFS and OS in 198 MM patients receiving bortezomib-based regimens^[84]. Interestingly, an elevated level of soluble M2 TAM markers CD163 and CD206 was associated with worse OS; conversely, higher M1 density demonstrated a correlation with OS improvement^[85].

In a retrospective study enrolling 68 MM patients, an elevated CD68-positive and CD163-positive TAM expression showed a significant reduction of six-year OS, as confirmed by multivariate analysis. As a

complementary finding, an increased CD163-positive M2 TAM number was associated with an elevated microvessel density^[86]. In another relevant study, a reduced response was observed in patients presenting with high CD68-positive and CD163-positive TAM; however, only high CD163 TAM expression was related to a reduced PFS and OS. CD163 and CD168 were combined with ISS to design a new prognostic model^[87]. M2 TAM infiltration and correlation with pro-angiogenic factor CD147 were investigated in a spectrum from MGUS to recurrence MM. CD163 was used as the M2 marker and the cutoff for M2 infiltration was 100 per core. The authors showed a significant OS reduction in relapsed MM patients with high M2 expression (32 months vs. 6 months, $P = 0.02$), suggesting a prognostic role of CD163-positive TAM in MM^[88]. Finally, Andersen *et al.*^[89] evaluated CD163 as a soluble marker in 104 blood samples and 17 BM samples in newly diagnosed MM patients. CD163 BM expression was higher compared to blood samples and was associated with a higher ISS stage. An elevated CD163 expression, with the suggested cutoff of 1.8 mg/L, was associated with poor prognosis, further suggesting M2 TAM could favor MM growth and progression^[89].

MINIMAL RESIDUAL DISEASE

New drugs in MM have revolutionized the treatment paradigm and improved both progression-free and overall survival. However, progress in the definition of response is needed, since a CR has been defined for almost 15 years simply as the absence of a monoclonal component at immunofixation and a percentage of monoclonal plasma cells < 5% in the bone marrow.

The goal is to predict patients relapsing soon after the initial therapy and distinguish them from patients who maintain a long response (sustained CR) that is a surrogate for PFS and OS. Novel drugs are combined now in triplet or quadruplet treatment schedules and can implement in a high percentage of patients CR to a virtual disease disappearance. However, most MM patients still relapse. NGF and NGS have been introduced into clinical trials, bringing more sensitivity to detect minimal residual disease after therapy^[23-34]. The detection limit of MRD is now considered 10^{-5} ; however, data suggest that a deeper limit of 10^{-6} or 10^{-7} could predict a better PFS^[90]. Although NGS has been reported initially to have a deeper limit of detection (10^{-6}) than NGF (10^{-5}), both can now reach comparable sensitivity at 10^{-6} .

NGF and NGS in MM

NGF has recently become part of the MRD evaluation, and it is based on the detection and quantification of normal PC vs. monoclonal PC using specific antibodies: PC markers such as CD38 and CD138; aberrant antigens expression such as CD45^{-low}, CD19⁻, CD27⁻, CD81⁻, and CD56; CD28; CD117; and light chains κ or λ . The Euro-Flow Consortium has introduced a more sensitive standardized technique based on two eight-color tubes that permit detecting MRD with 100% applicability^[24] with a 4 h sample processing time. Sensitivity needs to be at least 10^{-5} , but it has been reported as even better. A correct and adequate concentrate sample is needed to avoid hemodilution, and strategies to overcome CD38 monoclonal antibody interference have been described^[26].

NGS analyzes the clonal rearrangements of the immunoglobulin heavy chain (IgH) regions with parallel sequencing of reads with a sensitivity of 10^{-6} . Importantly, patient primer construction is not needed, and the depth of detection is a strength^[91]. Commercial kits are now available and FDA approved (LymphoSIGHT® and ImmunoSEQ, Adaptive Biotechnologies). Costs and a bioinformatic database for analysis as well as hemodilution are the limits^[26]. NGF and NGS are recognized as complementary techniques, and the IMWG suggests utilizing the one available at the centers in clinical trials^[36]. The Cassiopeia trial showed comparable sensitivity for NGF and NGS^[13].

Minimal residual disease sub-clone characterization

MRD can be a surrogate for PFS and OS and is becoming an important tool for risk-stratification since the depth of response is correlated with prolonged survival^[92]. In fact, a non-sustained CR can frequently be seen in MRD-positive MM patients. A goal in actual MM therapy could be to reach a sustained CR with MRD negativity lasting for at least one year. Searching for a sub-clone in MRD analysis could be an ideal way to identify drug resistance. It has been reported that MRD MM sub-clones could overexpress CD11a, CD11c, CD29, CD44, CD49d CD49e, CD54, CD138, CXCR4, and HLADR in the GEM2010MAS65 study involving 40 elderly patients^[93] treated with nine cycles of VMP (bortezomib, melphalan, and prednisone) or alternating VMP to Rd (lenalidomide and dexamethasone). In particular, integrins, chemokines, and adhesion molecules were overexpressed. These chemoresistant clones with a specific multi-flow signature also displayed genetic copy number alterations (CNA) that were present since diagnosis, and the resistant clone was selected after therapy resistance. The same group recently studied a larger number of patients ($n = 390$) in the PETHEMA/GEM2012MENOS65 protocol (six induction cycles with Bor, Lena, and dexamethasone followed by autologous stem cell transplant, two consolidation cycles with Bor, Lena, and dexamethasone, and then randomization to maintenance therapy with Lena and dexamethasone vs. Ixa, Lena, and dexamethasone)^[88]. They used NGF to identify detectable MRD and mechanisms related to resistance in 90 patients with high-risk (HR; i.e., del17p, t4;14, or t14;16) cytogenetics and 300 patients with standard-risk cytogenetics (SR; i.e., other anomalies not HR). Importantly, the results show the superiority of 90% PFS in MRD-negative patients vs. MRD-positive patients, irrespective of the cytogenetic status. Moreover, NGF studies and whole-genome sequencing showed clonal selection and higher genomic aberrations and mutations in 40 patients with multi-resistant clones^[94]. Most mutations affected *KRAS*, *BRAF*, *CCND1*, *ROS1*, *NRAS*, and *FLT3* genes. CNA and mutations present at diagnosis were more likely to disappear in SR-cytogenetics patients, while HR patients had novel mutations during treatment, suggesting more genomic instability. In addition, when evaluating transcriptional clones, patients with HR cytogenetics showed the expression of *PRDX6* and *SOD1*, which were related to a worst PFS. The authors concluded that, in HR cytogenetics MM patients, MRD resistance can arise from clones that evolve transcriptionally after therapy.

Minimal residual disease negativity after current upfront therapies for transplant and non-transplant eligible myeloma patients

With the introduction of novel drugs, responses can be seen in the majority of MM patients treated at diagnosis, both transplant and non-transplant eligible, with PFS lasting up to five years [Tables 2 and 3].

It is now evident that PFS alone cannot be the main parameter to judge new drugs in clinical trials. MRD has been proven to be a good prognosticator for PFS, OS, and drug resistance^[92]. In the GIMEMA-MMY-3006 study, VTD was compared to TD in 480 MM transplant eligible patients for induction therapy and double ASCT followed by consolidation therapy^[95]. VTD incorporated into a double ASCT strategy plus consolidation therapy proved to be superior to TD in terms of CR attained (58% vs. 41%, respectively) and PFS and OS at 10 years (34% vs. 17% and 60% vs. 46%, respectively)^[96]. Although MRD was not done at that time, one study showed that, in a subset of patients treated with VTD consolidation after ASCT, MRD negativity was achieved and relapses were delayed^[97]. In the IFM 2009, VRD was compared with VRD + ASCT, and in the latter group CR was superior (59% vs. 49%) but OS did not differ significantly^[98]. Importantly, MRD negativity was significantly correlated with improved three-year PFS (87% vs. 42%), independently of the therapy received. Car was combined with Len and dexamethasone in the KRd regimen tested as induction and consolidation + maintenance therapy for up to 10 cycles^[93,99]. Although relatively few patients were treated, MRD negativity was reached in a high percentage of patients. Recently, Dara was added to VTD and compared to VTD alone in 1085 patients in the CASSIOPEIA study^[13]: response and MRD negativity were superior in Dara-VTD vs. VTD (64% vs. 44%). Dara was added before

ASCT to VRD in the GRIFFIN study and then compared to VRD alone^[100,101]. Consolidation and maintenance therapy were also applied for up to 26 months of total therapy. MRD negativity was significantly superior in the Dara group (64% vs. 30%).

In the non-transplant eligible setting, great improvement with respect to the standard VMP or RD used until a few months ago^[102-104] was brought recently by the addition of daratumumab. The MAIA study^[12] compared Dara-Rd vs. Rd in MM patients not eligible for ASCT. At five years of follow-up, PFS has not been reached for the Dara-Rd group. CR was reached in 47% vs. 24% and MRD negativity was significantly higher (31% vs. 10%). The Alcyone trial^[11] compared VMP vs. Dara-VMP. This study confirmed the superiority of the triplet with Dara, in both PFS and MRD negativity. Lastly, VRD was superior to RD in the SWOGS0777 trial in patients not proceeding to ASCT (PFS 41 months vs. 29 months)^[105]. Daratumumab was tested as consolidation therapy in patients achieving a > VGPR after ASCT in the DART4MM study^[106,107]. An interim analysis showed MRD negativity in 45% of the patients at six months of treatment. Besides the great progress achieved with the new drugs with regard to the depth of responses, MRD status should not guide clinical decisions.

CONCLUSION

MM patients still relapse after a variable period of remission. Drug resistance is a major cause of MM relapse with both intrinsic and extrinsic mechanisms. Therapeutic targeting of the bone marrow microenvironment and its interaction with MM plasma cells seems to be an ideal approach for the future. Besides the need for novel, more efficacious drugs, better prognosticators are also needed. MRD measured by NGF or NGS has entered into the MM diagnostic armamentarium and is a great prognosticator for novel drugs in clinical trials. Sustained MRD negativity is likely to be a long-term remission pre-requisite. Research has to be done to better clarify its role in identifying minimal residual sub-clones resistant to drugs commonly utilized in MM. NGF seems promising in this biological view. The characterization of these clones should be pursued in future large MM trials.

Abstract

Sarcomas are a large family of cancers originating in the mesenchyme. Composed of more than 100 histological subtypes, soft tissue and bone sarcomas remain clinically challenging, particularly in children and adolescents in whom sarcomas are the second most common malignant entities. Osteosarcoma is the main primary bone tumor in adolescents and young adults and is characterized by a high propensity to induce distant metastatic foci and become multi-drug resistant. The innate and acquired resistance of osteosarcoma can be explained by high histological heterogeneity and genetic/molecular diversity. In the last decade, the notion of cancer stem-like cells (CSCs) has emerged. This subset of cancer cells has been linked to drug resistance properties, recurrence of the disease, and therapeutic failure. Although CSCs remain controversial, many elements are in favor of them playing a role in the development of the drug resistance profile. The present review gives a brief overview of the most recent biological evidence of the presence of CSCs in osteosarcomas and their role in the drug resistance profile of these rare oncological entities. Their use as promising therapeutic targets is discussed.

Keywords: Cancer stem cells, bone sarcoma, soft tissue sarcoma, drug resistance, tumor microenvironment, recurrent disease, residual disease

INTRODUCTION

Sarcomas are composed of highly heterogeneous soft tissue and bone oncological entities that are members of the mesenchymal tumor family^[1,2]. Osteosarcoma is the main bone sarcoma, with high prevalence in adolescents and young adults. Two peaks of incidence are described in the literature, a main peak around 18 years and a second in the sixth decade of life, more frequently diagnosed in patients following Paget's disease or radiotherapy and referred to as secondary osteosarcomas^[2-4]. The conventional therapeutic regimen for osteosarcoma is based on a sequential approach combining surgery and neoadjuvant and adjuvant polychemotherapies^[5]. Considered to be radioresistant, radiotherapy is nevertheless part of the therapeutic arsenal, proposed in osteosarcomas for which the surgical procedure is delicate, such as tumors in high-risk locations, and can be used for better local control of the tumor^[6]. Unfortunately, the therapeutic response in osteosarcoma patients has not improved in the last four decades, with an overall survival rate of around 70% after five years for localized disease. This rate drops dramatically to 30% when lung metastases can be detected^[7].

As described in other types of cancer, osteosarcoma evolves under the pressure of random mutational changes^[8,9], with preferential clonal proliferation and epigenetic modifications^[10-13] within the clonal population, leading to genetic instability, high genetic diversity, and high tumor heterogeneity^[13,14]. Therapeutic failure is frequently attributed to this intratumoral heterogeneity, and more specifically to the emergence of oligoclonal tumor cells capable of evading the therapeutic drugs. From this observation the concept of CSCs has emerged, in reference to embryonic stem (ES) cells. CSCs express transcription factors (e.g., Nanog, Oct4, and Sox2) initially detected in ES cells and exhibit pluripotent differentiation properties into various functional cells able to reconstitute the complete tumor mass. The tumor-initiating cells, the CSCs, have been described as tumor cells capable of reproducing all features of the initial tumor mass and have been associated with tumor recurrence, propagation, and drug resistance^[15-18]. Unfortunately, long-term relapse in patients considered clinically disease-free is observed in numerous cancers, including osteosarcoma^[19,20]. Minimal residual disease is defined as malignant cells that are resistant to treatment and that remain in patients after remission, leading to relapse and metastasis. Minimal residual disease is composed of drug-resistant tumor cells and is presented dynamically as persister/dormant/quiescent/cancer cells in residual tumors, such as circulating tumor cells in peripheral blood and disseminated tumor cells in bone marrow and other metastatic sites^[13-15,21]. In this context, tumor recurrence may be related to the persistence of CSCs. Increasing evidence highlights the existence of CSCs in osteosarcomas, although their real contribution to pathogenesis remains speculative. The present review aims to give a brief overview of the most recent knowledge available on CSCs in osteosarcoma and their potential clinical interest as new therapeutic targets.

PROPERTIES OF CANCER STEM-LIKE CELLS IN OSTEOSARCOMA AND BIOLOGICAL *IN VIVO* EVIDENCE

Around 5% of osteosarcoma patients develop local recurrence of their disease between 6 and 28 months after their first line of treatment and disease-free survival of up to 12 years is usually observed in 46% of patients^[22]. A large series confirmed a relatively low rate of local recurrence of high-grade osteosarcoma in contrast to the relapse disease associated with lung metastases^[23,24]. In 2010, Perrot *et al.*^[20] described local recurrence with metastatic foci in patients with telangiectatic osteosarcoma of the humerus after 13 years of complete remission. The local recurrence exhibited the same histological subtype as the initial tumor and was observed at the injection site of autologous fat grafts that had been performed 18 months before the recurrence for plastic surgery. More recently, Pennati *et al.*^[25] studied a series of autologous fat grafts in sarcomas and did not exclude an increased risk of local recurrence after the fat grafting procedure. These clinical cases raise the question of the persistence of cancer cells that remain quiescent at the primary tumor

site during the remission phase and are reactivated by alteration to their local microenvironment. Interestingly, in 2018, Le Nail *et al.*^[26] identified osteosarcoma cells with CSC properties from high-grade osteosarcoma samples. Of the isolated cells, two showed a high ability to form spheroids, and, even though they were not tumorigenic, these cells supported tumor growth when they were co-inoculated with human osteosarcoma cell lines in immunodeficient mice.

Asymmetric cell division has been described in stable cancer cell lines, leading to the development of proliferating and quiescent cells that were functionally related to sensitive and drug resistant cells, respectively^[15]. The identification of CSCs in osteosarcoma has been extensively described in the literature [Table 1]. CSCs express CD24^[27], CD177^[28-31], Stro-1^[28-31], CD133^[32-39], and ALDH1^[39,41-43] and show specific metabolic properties^[44-47]. Telomerase (hTert) controls the lengthening of chromosome telomeres by catalyzing the addition of repetitive DNA sequence to their end. CD271 and Stro-1 were enriched in hTert and showed metabolic specificities such as uncoupling Warburg under hypoxia^[31,47]. In addition, as expected, these cells, which expressed stemness markers (e.g., *Nanog*, *OCT4*, and *Sox2*), were able to form spheroids *in vitro* and exhibited the properties of tumor-initiating cells in preclinical mouse models^[47]. Among the other metabolic particularities, CSCs exhibit high aerobic glycolysis and oxidative phosphorylation^[45], a downregulation of the citrate cycle, and increased oxidative glutathione levels^[46] and show more generally an upregulation of most amino acid metabolisms^[44,46]. A drug resistant profile has been associated with the stemness properties of CSCs, which can be modulated by epigenetic mechanisms such as DNA and mRNA methylation^[48,49] and with an increase in ALDH activity and ABC transporter expression^[50,51]. Interestingly, anti-cancer therapies based on cytotoxic agents result in enrichment of CSCs in cancer cells, highlighting the potentially harmful link between CSCs and the establishment of drug resistance^[52-54]. CSCs may be a specific subset of tumor cells with high potential for tumor-initiation and self-renewal, as has been recently observed in all primary cultures from cases of patient-derived Ewing sarcoma^[55].

MOLECULAR REGULATION OF CANCER STEM-LIKE CELLS IN OSTEOSARCOMA

Osteosarcoma growth and the distant dissemination of cancer cells are controlled by a permanent dialog between cancer cells and their microenvironment^[2,56]. These soluble and membranous mediators trigger specific intracellular molecular cascades that lead to control of cellular processes, including cell death, epithelial-mesenchymal transition, or spreading, but also proliferation and quiescence. In this context, the behavior of CSCs is controlled by the tumor microenvironment. In recent decades, key signaling pathways regulating CSCs have been identified and become the source of therapeutic development [Figure 1].

The **Wnt/β-catenin** pathway contributes to the regulation of numerous cellular processes (e.g., proliferation, differentiation, and polarization) and is thus strongly associated with embryonic development. The Wnt glycoprotein family is composed of 19 secreted members that interact with cell membranes after binding to 1 of the 10 Frizzled receptors identified which are G protein-coupled receptors or to a co-receptor such as LRP-5 or -6 or tyrosine kinase receptor chains including retinoic acid-related orphan receptor and RyK. In the absence of Wnt ligand, β-catenin is degraded by the proteasome after sequestration associated GSK-3β, and the Wnt/β-catenin pathway is considered as inactive. The Wnt/β-catenin pathway is activated by the binding of one Wnt ligand to its receptor/co-receptor complex that leads to a series of phosphorylation cascades and recruitment of the receptor chains and then to the inactivation of the β-catenin degradation process. Consequently, β-catenin accumulates to the cytoplasm and is translocated into the nucleus before interacting with transcription factors, members of the TCF/LEF family, and activating target genes [Figure 1]. Any disturbance (e.g., mutations or activation) in this molecular pathway leads to pathological situations^[57]. Recently, Deng *et al.*^[58] studied the involvement of Indian

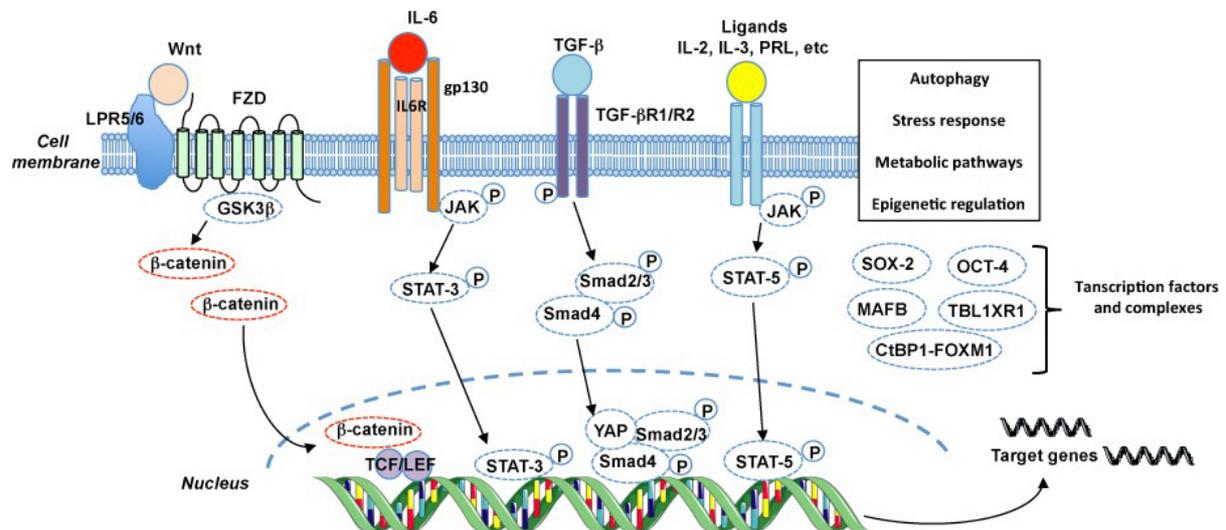

Figure 1. Main signaling pathways and mechanisms regulating the maintenance of cancer stem-like cells in osteosarcoma. LPR: Lipoprotein receptor-related protein; FZD: frizzled receptor; PRL: prolactin receptor.

hedgehog (IHH) signaling in cartilage and bone tumors by deleting *Ptch1* encoding an inhibitor of IHH receptor. They demonstrated that deleting *Ptch1* in mice was associated with an increase in Wnt member expression and the development of skeletal diseases, including osteosarcoma. Interestingly, inhibiting the Wnt/ β -catenin pathway abolished the development of osteosarcoma, highlighting the key role played by this molecular pathway in the pathogenesis of bone sarcomas^[58]. The Wnt/ β -catenin pathway might be the link among tumor development, drug resistance, and CSCs in osteosarcoma. Whether or not the Wnt/ β -catenin cascade was related to chemoresistance, it appeared to be a driver of cancer by acting directly on tumor cells, but also by modulating the immune microenvironment^[59]. This cancer driver is persistently activated in the CSCs of osteosarcoma, and the stemness properties induced by chemotherapies are related to activation of the Wnt/ β -catenin cascade^[43,60,61]. In this context, most molecular machineries that modulate the expression level of Wnt/ β -catenin may affect cancer cell behavior. Thus, epigenetic regulation of Wnt/ β -catenin using the lncRNA DLX6-AS1/miR-129-5p/DLK1 axis or histone methyltransferase SETD2 results in increased stemness properties for osteosarcoma cells, tumor growth, and drug resistance^[62,63]. The key contribution of Wnt/ β -catenin in the maintenance of CSCs may lead to the development of new targeted therapies in osteosarcoma, as described below.

IL-6/STAT3 signaling has also been identified as a crucial regulator of bone remodeling and primary bone tumors^[64]. The IL-6 family of cytokines, composed of 10 members including IL-11, OSM, and LIF, induces redundant and pleiotropic activities such as embryogenesis, differentiation, or inflammation. Most of the members of this family share the transducing receptor β -subunit gp130 as part of a multimeric receptor complex that includes a specific receptor α -subunit (e.g., IL-6R). The oligomerization of receptor subunits induced by each ligand results in various transductions of signaling pathways dominated by JAK/STAT3 activation and others such as MAPKs, p38, and JNK [Figure 1]. In addition to its functions on the tumor microenvironment (e.g., bone and immune cells), the IL-6 signaling pathway controls the maintenance of CSCs in osteosarcoma^[65]. IL-6 released by activated mesenchymal stem cells (MSCs) in the tumor microenvironment promoted osteosarcoma stemness and the spreading properties of cancer cells^[65]. In addition, MSCs supported drug resistance through STAT-3 signaling in cancer cells activated by IL-6^[66]. MSCs and osteosarcoma cells then established a reciprocal dialog initiated by TGF- β containing extracellular vesicles secreted by cancer cells that induced the production of IL-6 by MSCs, which in turn

supported stemness, drug resistance, and tumor progression^[67]. The use of active drugs confirmed the contribution of the IL-6/STAT3 axis in osteosarcoma stemness^[68,69].

The TGF- β /Smad axis regulates the self-renewal of osteosarcoma cells. TGF- β belongs to a large family of at least 30 secreted proteins sharing structural similarities. TGF- β growth factors are secreted as latent precursors which can bind to specific receptor chains after activation in mature form. TGF- β induces the assembly of type I and II TGF- β receptors, leading to the formation of heteromeric receptors and the initiation of the signal transduction. The type I TGF- β receptor shows intrinsic tyrosine kinase activity, phosphorylates the type II chain, and initiates the downstream signaling, which includes Smads phosphorylation. Phospho-Smads complexes are translocated into the nucleus where they cooperate with YAP/TAZ transcription regulators and modulate the transcription of target genes [Figure 1]. Zhang *et al.*^[70] studied the functional impact of TGF- β 1 on osteosarcoma stemness in a hypoxic environment. They demonstrated the crucial role played by TGF- β 1 on the proliferative state of cancer cells, which acquired the stem cell phenotype for self-renewal, drug resistance, neoangiogenesis, and tumorigenicity; on the contrary, blocking the TGF- β 1 signaling pathway reduced the dedifferentiation program of osteosarcoma cells. Similarly, by using gamabufotalin, a bufadienolide extracted from toad venom, it has recently been demonstrated that blockading the TGF- β /periostin/PI3K/AKT axis resulted in suppression of CSCs in osteosarcoma^[71]. CSCs associated with TGF- β activity were also linked to drug resistance, as shown for EGFR inhibitors, highlighting once again the role played by CSCs in the drug resistance process^[72].

Recently, a **series of transcription factors** were identified as regulators of cancer stemness in osteosarcoma. The transcription factor Sox determining the region Y-box 2 (Sox2) plays a key role in developing and controlling the embryonic stem cell state and was identified as a biomarker for CSCs in osteosarcoma [Table 1]. In addition, the proliferation of osteosarcoma cells and tumor development requires Sox2^[73]. Maurizi *et al.*^[73] compared tumor growth in Cre-bearing mice with identical Rb and p53 genotypes in a background of Sox2-deficient or wild-type mice. Tumor development was significantly slowed down in the Sox2-deficient mice compared to the other groups, and the survival rate was also higher in the Sox2 knockout mice. Sox2 appeared essential for the survival and proliferation of all osteosarcoma cells, including CSCs. The Hippo pathway, which is under the transcriptional control of Sox2, was directly related to the same activities, and deactivating Sox2 effectors (e.g., YAP) resulted similarly in a reduction in tumor growth^[73]. Chen *et al.*^[74] demonstrated that musculoaponeurotic fibrosarcoma oncogene homolog B (MAFB) is highly expressed in osteosarcoma and more specifically in CSCs, and this transcription factor, similar to Sox2, is required for the proliferation and tumorigenicity of osteosarcoma cells. Interestingly, they observed that maintaining the self-renewal potential of CSCs was under the transcriptional control of Sox-9, a stem cell regulator^[74]. More recently, STAT-5 associated signaling was identified as a key regulator^[75]. The knockdown of STAT-5 (A and B isoforms) using an siRNA approach reduced pimezone-induced tumor growth in mice, in addition to suppressing *in vitro* sphere formation. Inhibiting STAT-5 signaling thus impaired osteosarcoma self-renewal and development^[75]. JAK/STAT-5 activation belongs to the downstream signaling associated with various cytokine/hormone-induced signaling pathways, including prolactin, IL-2, IL-3, *etc.* Oct4 promoted osteosarcoma development by supporting the maintenance of CSCs through the increase in AK055347, a long-noncoding (lnc) RNA. Oct4 knockdown with siRNA induced a significant decrease in cell proliferation, invasion, and apoptosis^[76]. TBL1XR1 is a transcriptional co-factor which is overexpressed in osteosarcoma patients^[77]. Its overexpression in MG63 and U2-OS cell lines induced a CSC phenotype in contrast to its repression. TBL1XR1 thus provides osteosarcoma cells with tumorigenic properties and promotes the recurrence of osteosarcoma in a STAT-3 signaling dependent manner^[77]. Transcriptional complexes can also modulate osteosarcoma drug resistance. Thus, the CtBP1-FOXO1 transcriptional complex increased *MDR1* expression in osteosarcoma CSCs, which is associated

with drug resistance^[78]. Interestingly, small molecules targeting this complex reversed the MDR1-mediated resistance both *in vitro* and in murine preclinical models.

Regulating osteosarcoma growth through the oct4/lncRNA axis highlights the epigenetic regulation of osteosarcoma CSCs^[79]. This observation is supported by the rich literature emerging in the last 10 years^[76] [Table 1]. In this context, chromodomain helicase DNA binding protein 1-like significantly reduced osteosarcoma proliferation and drug resistance through its binding to DNA. It also controls chromosomal integrity maintenance, DNA repair, and transcriptional regulation^[79]. Ubiquitin-specific peptidase 39 is a crucial factor for assembling mature spliceosome complex, and its knockdown leads to the inhibition of osteosarcoma cell proliferation combined with an increase in apoptosis^[80]. Human antigen R is involved in stabilizing mRNA, and its repression in osteosarcoma cells reduced their stemness properties and increased the drug response^[81]. These activities were related to YAP activation. Several recent publications showed the role played by specific miRNA in controlling stemness in osteosarcoma, including miR29b and its target Spin1^[82], miR34a^[83] and the DNMT1/miR34a/Bcl2 axis^[84,85], TNF- α -miR155 signaling^[86], miR335 and its target POU5^[87], miR429 and its target Sox2^[88], and the TGF- β /miR499a/SHKBP1 89 axis^[89,90]. Very recently, leukemia inhibitory factor (LIF) was shown to belong to the IL-6 family of cytokines, similarly activating STAT-3, and was recently revealed as a super-enhancer-controlled regulator of CSC properties, confirming the role of STAT-3 transcription factor in the functional regulation of CSCs in osteosarcoma^[91]. TSSC3 tumor-suppressing STF cDNA 3 (TSSC3), the first apoptosis-related gene reported to be imprinted, repressed the self-renewal of osteosarcoma CSCs^[92]. Finally, lncRNAs also play a part in the biological regulation of CSCs in osteosarcoma^[76,92,93].

Autophagy^[94,95], **stress response**^[96-98], and **numerous enzymatic pathways**^[99-104] complete the landscape of the osteosarcoma CSC regulation mode. Autophagy was shown as a critical biological process for maintaining CSCs in OS^[94], and defective autophagy was directly associated with the decrease in CSCs^[95]. Similarly, the knockdown of stress-induced phosphoprotein 1 resulted in the inhibition of CSC invasiveness and migration^[96]. STIP-1 is a co-chaperone that binds to HSP70 and -90 and consequently inhibits Hsp90 by 17-AAG-reduced stem cell-like properties and decreased drug resistance in OS^[97].

THERAPEUTIC TARGETING OF CANCER STEM-LIKE CELLS IN OSTEOSARCOMA

The recent evidence of CSCs in osteosarcoma and better understanding of the molecular pathways required for their maintenance, led to the identification of new therapeutic targets, as summarized in Table 2.

Repressing the signaling pathways related to the maintenance of CSCs (see Table 1) resulted in the slowdown of tumor growth and inhibition of the metastatic process^[105-116]. As previously mentioned, Wnt/ β -catenin appeared crucial for the maintenance of CSCs and its attenuation by using tankyrase inhibitor, or tegavivint was associated with a decrease in both CSC numbers and tumor progression^[105,106]. GSK3 appeared highly expressed in osteosarcoma and targeting Akt/GSK3/ β -catenin or Akt/GSK3-/Notch-1, respectively, with dioscein or tideglusib repressed CSC and tumor growth^[107,108]. Gamabufotalin-induced similar activities by targeting TGF- β /periostin/PI3K/Akt signaling as it has been shown for hepatocarcinoma^[71,109]. Similar results were obtained by targeting BMP2R^[110]. Drugs targeting transcription factors (e.g., STAT-3 and STAT5) controlling the development of CSCs may also be used to improve the therapeutic approaches to osteosarcoma^[75,111,112]. Activation of hormone signaling can reduce stemness in osteosarcoma, as shown by the activation of estrogen receptor alpha by decitabine^[113]. Most cytokine-induced signaling pathways result in the translocation of transcription factors which modulate the transcription of target genes. Targeting of such transcription factors (e.g., KLF4 and Sox9) may be used for reducing CSCs in osteosarcoma^[114-116]. Similarly, ROCK inhibition by fasudil suppressed *in vitro* cell

Table 2. Potential therapeutic approach to CSCs in osteosarcoma

Drug	Molecular pathway involved or therapeutic approaches	Ref.
Wnt/β-catenin targeting		
Tankyrase inhibitor (IWR-1)	Attenuation of Wnt/ β -catenin signaling	[105]
Tegavivint	β -catenin/transducing β -like protein 1 (TBL1) inhibition	[106]
Dioscein	Akt/GSK3/ β -catenin	[107]
Tideglusib	GSK-3 β /NOTCH1	[108]
TGF-β/BMP2 targeting		
Gamabufotalin	TGF- β /periostin/PI3K/AKT	[109]
BMP2	BMP2 receptor signaling	[110]
Other receptor signaling targeting (STAT-3, STAT-5, ER-α, TRAF-2, etc.) and transcription factors		
Bruceine D	STAT-3 inhibition	[111]
Pimozide	STAT-5 signaling	[75,112]
Decitabine	Activation of estrogen receptor alpha (ER- α)	[113]
NCB-0846	TRAF2- and NCK-interacting protein kinase	[114]
Melatonin	Suppression of SOX9 mediated signaling	[115]
Statins	KLF4	[116]
Targeting of kinase activities		
Fasudil	Rho-associated coiled-coil containing kinase (ROCK) inhibition	[100]
Autophagy and metabolic targeting		
Thioridazine	Autophagy	[94]
Metformin	- Inhibition of mitochondrial functions (decrease in oxygen assumption, decreased mitochondrial membrane potential, decreased ATP production) - Pyruvate kinase isoenzyme M2 (PKM2) - ROS-mediated apoptosis and autophagy - Activation and phosphorylation of the energetic sensor AMPK	[117] [118] [119] [120]
Wogonin	ROS regulation	[121]
DMAMCL	Cell cycle	[122]
DAPT	γ -secretase inhibition	[123]
Combinations with chemotherapy and sensitization to chemotherapy		
Ascorbate	Sensitization to cisplatin	[124]
Ouabain	Sensitization to cisplatin: Na ⁺ /K ⁺ ATPase inhibition	[125]
Tangeretin-assisted platinum nanoparticles	Combination with doxorubicin	[126]
Senolytic drug (Fisetin)	Combination with etoposide	[127]
Immunotherapy		
Immunotherapy based on cytokine induced killer cells	CSCs spared after chemotherapy or other targeted therapies	[128,129]
Modulation of epigenetic events		
Epigenetic targeting	- USP39 silencing - HuR knockdown - Disruption of the DNMT1/miR34a/Bcl-2 axis by isovitexin - lncRNA HOXD-AS1 knockdown - RAB39A silencing - Targeting of lncRNA SOX2OT variant 7 by EGCG (polyphenol isolated from green tea)	[80] [81] [85] [92] [99] [130]
Photo therapy		
- Graphene oxide nanoparticle-loaded ginsenoside Rg3	Photodynamic therapy	[131]
- CD271 antibody-functionalized HGNs	Photothermal therapy	[132]
Drug delivery systems		

- Salinomycin-loaded PLA nanoparticles	Delivery of solinomycin	[133]
- Lipid-polymer nanoparticles with CD133 aptamers	Delivery of all-trans retinoic acid	[134]
- Lipid-polymer nanoparticles with EGFR and CD133 aptamers	Delivery of salinomycin	[135]

proliferation and reduced their tumorigenicity *in vivo*^[100]. Cell metabolism is significantly modulated in CSCs (e.g., autophagy and cell cycle), and these specificities can be used for targeting CSCs in osteosarcoma. For instance, thioridazin and metformin target autophagy and metformin and wogomin modulated ROS-mediated apoptosis in CSCs and resensitize CSCs to cell death^[114-116]. Similarly, regulation of cell cycle by DMAMCL or inhibition of γ -secretase by DAPT affects the behavior of CSCs and their function in tumor growth^[122,123].

Drugs/effective agents can be used as sensitization agents to chemotherapy^[124,125] or in combination with chemotherapeutic drugs^[126,127]. Numerous cytokines are involved in the control of local immunity of cancer cells^[128] and immunotherapies have been proposed for targeting CTCs^[129]. Specific silencing of the epigenetic partners of CSCs can induce similar regression in tumor growth and metastatic development by altering CSC maintenance^[80,81,92,95,99,129]. Nanoparticles can be used for developing phototherapies and drug delivery systems. In this context, nanoparticles have been functionalized and adapted for phototherapy with a specific aim to improve the targeting of CSCs using^[131,132]. Finally, drug delivery systems have also been proposed^[133-135]. For all these therapeutic approaches, the question of the general toxicity in healthy tissue stem cells and the specificity of the targeting remains unanswered.

CONCLUSION

Long considered as controversial, today CSCs are a realistic therapeutic target in osteosarcoma^[1,2]. Osteosarcoma remains a highly heterogeneous oncological entity in perpetual evolution due to a strong clonal dynamic^[136], leading to very efficient adaptation to drugs and the establishment of drug resistance^[15]. The dynamic properties of tumor evolution have led to numerous questions about CSCs and their functional impact: (1) Can we detect CSCs in the bloodstream and can we use circulating tumor cells to follow the minimal residual disease and identify personalized therapeutic options^[137]? (2) Are CSCs capable of migrating to distant organs to establish metastatic foci? (3) Is the dynamic evolution of osteosarcoma similar in the primary site and in the metastatic foci? (4) What is the functional regulation of CSCs and are they under the control of proliferating osteosarcoma cells? (5) Are CSCs regulated by the tumor microenvironment and by which molecular pathways? (6) Can we use immune therapies in combination with other drugs (e.g., chemotherapy) to target CSCs and improve overall survival in osteosarcoma? (7) How can we specifically control CSC metabolism and consequently can we set up specific therapeutic options to control CSC wake-up? (8) As osteosarcoma is a form of cancer that originates in the mesenchyme, can we use the fibrogenic reprogramming of CSCs as a therapeutic option^[138]? Even whether sarcomas being considered as an immune desert explaining the current poor clinical efficacy of immune therapies needs more research^[1,128], macrophage and stromal cells contribute to the establishment of drug resistance and may be identified as therapeutic target in osteosarcoma^[139]. For instance, M2 macrophage may be associated with tumor angiogenesis. Tumor cells release a high number of protons that induce local acidosis, favoring the release of inflammatory mediators by local stromal cells, which in turn facilitates tumor invasiveness and metastasis in osteosarcoma^[140]. Overall, it has been demonstrated that stromal cells significantly contribute to increase the stemness properties of osteosarcoma cells by inducing metabolic reprogramming of cancer cells^[141,142]. Consequently, stromal cells constitute an interesting reservoir of stemness targeting to reduce osteosarcoma progression, as has been shown recently^[143]. A better

understanding of the role of stromal cells in the control of stemness would help to identify new mediators associated with stemness, drug resistance, and tumor progression. Overall, CSCs are promising targets in osteosarcoma, as demonstrated by the most recent data described in this review, paving the way for a new therapeutic era focused on better-controlled residual disease in osteosarcoma through targeting CSCs.

DECLARATIONS

Authors' contributions

Supervised the work proposed and took the lead in writing the manuscript: Heymann D

Contributed to the preparation of the manuscript: Jubelin C, Muñoz-Garcia J, Cochonneau D, Moranton E, Heymann MF

All authors approved the final version submitted.

Availability of data and materials

Not applicable.

Financial support and sponsorship

This work was supported by an internal ICO grant 2018 (ref# "DorSarc-2018-ICO-DH").

Conflicts of interest

Jubelin C is an employee of Atlantic Bone Screen and prepared her PhD at the Université de Nantes (FR). Heymann D is a member of the Editorial board of Cancer Drug Resistance.

Abstract

Sarcomas are a heterogeneous group of over 150 mesenchymal neoplasms of bone and soft tissue. Clinical prognosis remains poor in the metastatic and refractory setting, despite treatment with traditional chemotherapies. A subset of sarcoma patients can exhibit remarkable responses to novel immune therapies; however, most patients will not respond. Emerging data from genetic and transcriptomic datasets suggests that patients who are resistant to checkpoint inhibitor monotherapy may have low expression of immune-related genes, suggesting that the sarcoma was not sufficiently immunogenic to trigger or maintain an immune response to generate tumor-specific immune effector cells. In this review, we discuss the emerging data surrounding potential mechanisms of resistance, including various biomarkers explored in clinical trials of immune therapy for sarcomas. We also review future directions in clinical trials that are focused on boosting tumor immunogenicity to improve the activity of checkpoint inhibitors, as well as adoptive cellular therapy approaches to bypass deficiencies in neoantigens or antigen presentation.

Keywords: Sarcoma, immune therapy, immune resistance, immunogenicity, chemotherapy, clinical trials

INTRODUCTION

Sarcomas consist of a rare and heterogeneous group of bone and soft tissue malignancies with more than

150 different histologic subtypes by the latest World Health Organization classification^[1]. While localized sarcomas can be cured with aggressive surgery and radiation treatments, in general, metastatic and refractory sarcomas are incurable with cytotoxic chemotherapies with a median overall survival of 12-18 months^[2]. Sarcomas have long been theorized to be recognizable by the immune system (tumor immunogenicity), dating back to early observations by Dr. William Coley^[3] in the 1890s, who noted that some patients with sarcoma had tumor regressions following bacterial infections. With the modern revolution in cancer immunotherapy, interest in exploring novel treatment approaches such as immune checkpoint inhibitors and adoptive cellular therapies has rebounded for sarcomas, with numerous clinical trials being conducted in a wide variety of sarcoma subtypes (See [Table 1](#) for representative trials). While there have been a few promising signals of activity, such as engineered T cell therapy targeting cancer/testis antigens in synovial sarcomas, and remarkable responses to checkpoint inhibitors in alveolar soft part sarcoma (ASPS) and cutaneous angiosarcomas, responses to immunotherapy for most sarcoma subtypes have remained modest^[4-10]. To further improve the activity of immune-modulating therapies in sarcomas, it is critical that we learn from the extensive work in other cancers aimed to explore mechanisms of response and resistance, and better understand the barriers existing in the sarcoma tumor and immune microenvironment. In this review, we will explore the emerging mechanisms of immune evasion in sarcoma and highlight ongoing studies in immunotherapeutics aimed to reverse this resistance.

Overview of immune response and evasion

To mount an effective immune response against cancer cells, a sequence of multiple events is required [[Figure 1](#)], with aberrations along any of the steps potentially leading to immune evasion and resistance^[11]. First, the cancer cell must have immunogenic tumor-specific antigens largely resulting from genetic mutations that are processed and presented in conjunction with major histocompatibility complex class I (MHC-I). At these early phases, cancers that lack mutations (such as those driven by translocations), or present weakly immunogenic antigens, or have faulty antigen-processing machinery may fail to elicit an immune response^[11]. Mutations in antigen presentation machinery components such as deletions in the beta-2 microglobulin subunit of MHC-I, deletions in the primary antigen processing enzymes such as transporter associated with antigen processing, or epigenetic silencing of MHC-I can all stall antigen presentation within the cancer cell^[11]. Once antigens have been processed and peptides expressed on the surface of the cell, antigen-presenting cells (APCs) such as dendritic cells (DCs) and macrophages must then respond to immunogenic cytokines from the cancer cells to be drawn into the tumor microenvironment (TME) and recognize the antigens^[11]. Insults that trigger immunogenic cell death of the cancer cells, such as certain types of chemotherapy and radiation, can lead to the production of type I interferons and release of other damage and pattern-associated receptors (DAMPs and PAMPs) that improve APC migration and activation^[12]. Effective APC surveillance and uptake of antigens can then lead to the priming of tumor-specific T cells in tumor-draining lymph nodes that then expand, traffic, and infiltrate into the tumor beds^[11]. Alternatively, cytotoxic T cells may directly surveil MHC-I bound antigen on the surface of the cell to trigger activation and T cell-mediated killing. Regardless, at the final stages of the cytotoxic response, the cancer cell: T cell synapse is again modulated by the expression of immune checkpoint proteins such as the programmed cell death protein 1/programmed cell death protein ligand 1 (PD-1/PD-L1) axis, which can abort T cell-mediated killing even in the setting of a robust prior immune response^[11].

A major obstacle for both APC and T cell trafficking and function is navigating the suppressive TME and retaining cytotoxic and anti-tumor potential under stress from faulty metabolism, aberrant angiogenesis, and stromal factors that slow or inhibit the infiltration of immune cells into the tumor bed. Both DCs and macrophages are versatile innate immune cells with functional plasticity that is influenced by the TME. Activated and suppressive phenotypes exist in a delicate balance, and with prolonged exposure to the TME,

there is a preponderance of suppressive immature DCs and tumor-associated macrophages (TAMs). TAMs have a complex nomenclature, with numerous functionally distinct phenotypes. A common terminology used includes M0, newly recruited monocytes to the TME prior to differentiating to M1/M2; M1, classically activated macrophages, which have anti-tumor properties; and M2, alternatively activated macrophages which have immunosuppressive activity^[13,14]. Finally, T cells progressing through various activation stages will eventually become exhausted, losing their cytotoxic potential, or skew towards suppressive phenotypes such as T regulatory cells^[15].

The landscape of immunotherapies being studied in sarcoma aims to reverse immune evasion by the cancer cells at each of these steps. However, the immune evasion and kill balance is a highly dynamic process that is dependent on numerous factors, including tumor heterogeneity within individual tumors even within individual patients, as well as extensive host factors^[16]. A variety of modalities ranging from checkpoint inhibitors, adoptive T cell transfer, oncolytic viruses, cancer vaccines, and cytokine modulation have been tested. However, one of the biggest challenges in immunotherapy in general and particularly in sarcomas is understanding the mechanisms of resistance to these therapies at any particular time, to tailor and develop therapies that can overcome the chief resistance mechanisms sequentially, or multifaceted approaches that target multiple steps in the cascade simultaneously. We will now review the emerging data in sarcomas for resistance and how this is impacting the development and efficacy of immunotherapeutic strategies.

EMERGING MECHANISMS OF RESISTANCE

Preclinical investigations in murine models

In-depth exploration of the sarcoma immune microenvironment has been limited due to the few numbers of syngeneic murine models with a competent immune system. Additionally, those models that do exist fail to capture the heterogeneity within a large number of sarcoma subtypes, genetic and immune heterogeneity within sarcomas even of the same subtype, and inter- and intratumoral heterogeneity within the same patient. Wisdom *et al.*^[17] recently reported immune profiling in a high mutational load murine model of undifferentiated pleomorphic sarcoma (UPS), generated by inducing conditional *Trp53*^{fl/fl} deletions with subsequent injection of the carcinogen 3-methylcholanthrene in the same site. The authors demonstrated resistance to radiation and PD-1 blockade in primary tumors that evolved under immune pressure, compared to transplanted tumors in different mice, which were more readily rejected. As expected, transplanted tumors showed a more inflamed microenvironment with increased activity of suppressive M2 macrophages and activated CD8+ T cells. Treatment with PD-1 blockade further increased CD8+ T cell activity with a decrease in M2 macrophages, which was not recapitulated in the primary tumors^[17]. However, another study performed similar experiments in the KP model, with conditional *Kras*^{G12D} mutation plus *Tp53* deletion, comparing the immune infiltrates and response to checkpoint blockade in primary tumors to those transplanted into naïve C57Bl/6 mice. Interestingly, in the setting of a low mutational burden tumor, there was no improvement in immunogenicity despite the transplantation, and despite an increase in immune cell infiltration, there was no improvement in response to checkpoint blockade^[18]. Finally, a third paper summarized divergent immune landscapes with transplantation of primary KP UPS and rhabdomyosarcoma models into syngeneic recipient mice. Again, a more robust immune infiltration was seen in the recipients, which was associated with higher levels of MHC-I expression^[19]. Taken together, these papers illustrate that for “cold”, antigen-poor primary sarcomas, recognition of the cells as foreign is critical to mounting an effective immune response. The lack of immunogenic neoantigens or failure of the initial recognition by APCs is likely one of the central mechanisms of resistance to immunotherapy for the majority of sarcomas.

Global assessment of immunogenicity using immune-related gene expression analysis

With the increase in available transcriptomic data, multiple studies have recently investigated immune-related gene expression signatures in human sarcomas. In an analysis of 213 sarcoma tissue samples from The Cancer Genome Atlas (TCGA), including leiomyosarcoma (LMS), UPS, and dedifferentiated liposarcomas (dLPS), deconvolution analysis showed that the majority of sarcomas lacked high expression of immune-related pathway signatures. However, 20% exhibited an immune-high expression signature which correlated with responses to pembrolizumab monotherapy and was characterized by the presence of tertiary lymphoid structures (TLSs), comprised of CD8+ T cells, B cells, and follicular dendritic cells^[20]. Additionally, these sarcomas showed high expression of early immune response signatures, including MHC-I. Close to 80% of the sarcomas had a low or heterogeneous immune signature expression, supporting clinical observations of checkpoint inhibitors inducing a response in only about 20% of patients^[4-10]. A subsequent paper utilized the CIBERSORT algorithm to query microarray expression data in 253 soft tissue sarcomas [synovial sarcoma, myxoid liposarcoma, non-translocation sarcomas with more complex genomic profiles, and gastrointestinal stromal tumor (GIST)] and identified immune signatures that were largely clustered within the histologic subtype. Several potential targets of interest were identified for the various histologies, such as CD40 in GIST and synovial sarcomas, and M0 macrophages were enriched for all subtypes. These signatures had some prognostic implications but were not correlated with any prior immunotherapy exposure^[13]. A third paper from Hu *et al.*^[21] similarly reviewed immune-related expression signatures in 259 patients with soft tissue sarcomas and again demonstrated four unique clusters of immune-related genetic expression and demonstrated associations with prognosis, including overall survival and progression-free survival. The worst prognosis cluster had the lowest immune score, lowest stromal score, and lower expression of a variety of checkpoint proteins. These collective investigations again support that failure to generate an immune response, evidenced by a lack of downstream immune activity, may be central to the resistance of most sarcomas to immune targeting therapies.

Neoantigens and tumor mutational burden

It has been widely recognized that a high tumor mutational burden (TMB), which can be detected by whole-genome sequencing (WGS), can lead to increased neoantigen expression and can correlate with immunotherapy responses^[22,23]. Although TMB is not a perfect biomarker, most sarcomas do have a lower TMB than the currently approved tissue agnostic threshold (10 mutations/Mb) that has been shown to predict responses to checkpoint inhibitors^[24]. However, 13.7% of angiosarcomas, 8.1% of UPS, and 8.2% of malignant peripheral nerve sheath tumors (MPNSTs) were found to have more than 20 mutations/Mb in an analysis of 100,000 different cancers^[24], potentially explaining the differential activity of immune checkpoint inhibitors (ICIs) in these subtypes. In contrast, in subtypes where responses to ICIs are poor, like synovial sarcoma and osteosarcoma, only 1% and 0.4% respectively had high TMB greater than 20 mutations/Mb^[24]. However, TMB does not fully explain the immunogenicity of individual sarcomas with low TMB or for remarkable responses seen in translocation-associated sarcomas such as ASPS^[25]. Some evidence exists that perhaps genetic abnormalities not picked up with standard WGS, such as fusions without an RNA product, or indels, may help to drive responses. We previously reported whole-exome and RNA sequencing results for a patient with cutaneous angiosarcoma who had a complete response to very low dose cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) inhibition on a phase 1 clinical trial^[5]. While many cutaneous angiosarcomas have been shown to have high TMB with an ultraviolet radiation damage signature resembling melanoma^[26], our patient had a very low TMB at 0.09 mutations/Mb. However, numerous putative fusion transcriptions were identified, including 31 fusions predicted to generate novel protein sequences. Increasingly, epitopes resulting from non-traditional genetic alterations, such as indels, copy number alterations, or single nucleotide variants, have been recognized to be potent antigens, potentially driving responses to immunotherapy^[27-29]. As shown in other cancers, the quality of an antigen may dominate over the number of predicted antigens, which may not be conserved from patient to patient, and

is dependent on the unique characteristics of the individual patient's MHC alleles.

Finally, there is emerging evidence that particular genetic alterations may profoundly impact oncologic signaling pathways and the development of resistance to immunotherapy. One powerful example is a patient with metastatic leiomyosarcoma who achieved a durable response to checkpoint blockade for more than two years, but then developed oligoprogression in a single metastatic site. Genetic profiling revealed loss of *PTEN* in the progressing lesion, which reduced neoantigen expression and resulting immunogenicity^[30]. Another well-reported biomarker of immunotherapy resistance is *MDM2* amplification which has been linked with hyperprogressive disease with ICIs^[31]. However, liposarcomas that are defined by *MDM2* amplification can respond to ICIs alone or in combination with chemotherapy^[9,32]. Further analysis of genetic mutations in correlation with TME features, such as PD-L1 expression and phenotyping of infiltrating lymphocytes, will be critical to better understand the impact of these genetic aberrations on the sarcoma immune microenvironment.

Tumor microenvironment

Another leading hypothesis for resistance to immune therapies for sarcomas lies in the hostile TME. Sarcomas tend to be large with aberrant angiogenesis, with frequent overexpression of major suppressive cytokines such as vascular endothelial growth factor (VEGF)^[33] or transforming growth factor beta 1 (TGFB1)^[34]. Since sarcomas are, by definition, stromal/mesenchymal neoplasms, many have theorized that suppressive forces from the stroma itself may drive resistance to immune therapy.

VEGF has been implicated in numerous complex mechanisms of resistance, including the promotion of immature and suppressive phenotypes of DCs, TAMs, and T regulatory cells, impairment of T cell trafficking and migration via faulty angiogenesis, and altering of various physiologic processes via maintenance of hypoxia^[35]. The activity of various tyrosine kinase inhibitors (TKIs) with anti-VEGF activity has led to multiple combination studies with checkpoint blockade in both bone and soft tissue sarcomas^[4,36,37]. While the mechanisms through which angiogenesis growth factors enhance immunotolerance could be related to increased vascular permeability^[33], correlative investigations to identify biomarkers of response and to elucidate resistance to combination anti-VEGF TKI therapy are still under investigation and will be discussed later in this review.

TGFB has also been implicated as a global mediator of resistance to cancer treatment, including immunotherapy^[38]. TGFB has been shown to directly inhibit T cell function by promoting FOXP3 expression on T cells, impairing natural killer cell function, decreasing MHC class II expression, and promoting suppressive phenotypes of TAMs and neutrophils^[38]. While the role of TGFB is underexplored in sarcomas, several studies have shown that TGFB-mediated expression of epithelial-mesenchymal transition (EMT)-type transcription factors, including Snails and Twist, promotes invasion and metastasis of osteosarcoma cells^[39]. Clinical investigations of TGFB inhibition in sarcoma are very limited, with the inclusion of only a few patients in all-comer Phase 1 studies^[40]. However, Vigil is an autologous tumor cell product where cells are transfected with a plasmid containing the stimulatory cytokine granulocyte-macrophage colony-stimulating factor (GM-CSF), and a short hairpin RNA to knock down furin, an enzyme required for the production of TGFB1 and TGFB2. Initial results of Vigil in patients with Ewing's sarcoma showed promising results, with a 73% 1-year survival for Vigil-treated patients compared to 23% in a contemporaneous cohort of patients who did not receive Vigil^[41]. An ongoing Phase 3 clinical trial of Vigil with irinotecan/temozolomide (NCT03495921) aims to confirm the benefit of targeting TGFB in this population, and may support further investigation of targeting this mediator.

An emerging suppressive factor of interest is sialoglycans, which are sialic acid sugar-carrying glycans, and are suggested to mediate regulatory pro-tumor growth functions of the TME and to induce angiogenesis regulated by macrophages^[42,43]. Sialoglycans are recognized by sialic acid-binding immunoglobulin-like lectins (Siglecs), a family of immunomodulatory receptors that are expressed predominantly on immune cells. Tumor sialoglycans can interact with the Siglecs and may modulate the immune TME and stimulate further Siglec expression on the infiltrating immune cells^[44]. Each Siglec preferentially recognizes a different type of sialic acid. Siglec-15, in particular, is selectively expressed in myeloid cells and osteoclasts^[45]. While studies in other types of sarcoma are lacking, preclinical studies on osteosarcoma cell lines and xenograft mouse models discovered that downregulation of Siglec-15 led to decreased tumor proliferation by inducing EMT and promotion of DUSP1^[46]. Following that finding, an analysis of 36 human osteosarcoma samples also showed that higher expression of Siglec-15 by immunohistochemistry was associated with worse overall survival compared with tumors with low Siglec-15 expression^[46]. A pan-cancer analysis utilizing the TCGA database, which included sarcoma, showed that upregulation of Siglec-15 correlated with shorter overall survival and progression-free survival (PFS) in the sarcoma cohort^[47]. Siglec-15 also positively correlated with T-regulatory cells and macrophages in most cancers^[47]. Thus, it is intriguing to speculate that the negative impact on survival from Siglec-15 expression could result from its immunosuppressive activity in sarcomas.

Biomarkers of resistance identified in clinical explorations of immunotherapy vaccines

With a central mechanism of resistance in sarcomas appearing to revolve around a lack of neoantigens that can trigger antigen presentation, immune recognition, and adaptive immune responses, it is not surprising that much hope has previously been placed in the use of therapeutic vaccines. Despite extensive efforts, the development of therapeutic vaccines in sarcomas has shown limited efficacy thus far. For example, many pediatric sarcomas express the gangliosides GM2, GD2, and GD3^[48], leading to a study of a peptide vaccine targeting these markers in 136 patients with a variety of sarcomas. Despite high expression, the vaccine did not show any benefits in survival despite eliciting a sustained serologic response^[49]. In other attempts, dendritic cell vaccines were developed using patient-derived dendritic cells loaded with tumor antigens *ex vivo*. Despite the notable serologic response, this strategy has also been unsuccessful; only 1 out of 35 evaluable patients had a partial response^[50]. The lack of response to vaccines has been attributed to downstream mechanisms of immune suppression, possibly secondary to increased tumor burden^[50]. Vaccines using peptide-pulse dendritic cells with a tumor antigen have also been used in an attempt to avoid surgical resection of tumors required to isolate tumor lysates. This strategy was also disappointing^[51] with no long-lasting responses secondary to the short lifespan of the cells in the circulation. Overall, vaccines are likely to require combination approaches, potentially agents targeting the microenvironment and/or checkpoint blockade to further improve efficacy.

Immune checkpoint inhibitors

Immune checkpoint inhibitors have transformed the treatment of multiple solid and hematologic malignancies since their initial success in melanoma and non-small cell lung adenocarcinoma. The antibodies currently approved target the inhibitory proteins PD-1, PD-L1, and CTLA-4, and block the suppressive signals towards T cells in the TME. In sarcomas, the success of checkpoint inhibitors alone is limited for most subtypes, with responses ranging consistently less than 20%^[9,52]. Exceptions to those responses have been observed in a few histologies such as UPS, dLPS, ASPS, and cutaneous angiosarcoma^[4,5,9,52]. Since ICIs are now the most commonly tested immunotherapy strategy for sarcoma patients, the majority of our knowledge on immunotherapy resistance mechanisms stems from these trial results.

The expression of PD-L1 by cancer cells is an important predictive factor of response to ICIs in many cancer types and is used as a biomarker of favorable results^[53]. However, in sarcomas, the predictive value of PD-L1 expression for responses to ICIs as well as outcomes has been inconsistent. Overall though, most subtypes show consistently low expression of PD-L1 in the range of 10%-22%^[54-57] and higher in certain subtypes such as UPS and ASPS^[4].

There is some evidence that the presence of tumor-infiltrating lymphocytes (TILs) and other immune cells within the sarcoma TME may be more predictive of ICI responses compared to PD-L1 expression on cancer cells. The prevalence of TILs in most common sarcoma subtypes has been reported to be as high as 98%^[58,59]; however, some of these studies are limited in phenotyping to determine the function of visualized cells. It has been observed that tumors that lack TILs are unlikely to respond to ICIs, regardless of PD-L1 expression^[60]. In the SARC028 trial of pembrolizumab in patients with advanced sarcoma, the objective response rate was only 17.5%^[9]. Patients who responded to ICIs, albeit few, had significantly higher infiltration of T cells (CD8+, CD3+, PD-1+) and TAMs that were PD-L1 positive at baseline compared to nonresponders^[61]. Across a variety of numerous soft tissue sarcoma subtypes, UPS was found to have a higher density of TILs with more oligoclonality compared to other subtypes, further highlighting the role of TILs in ICIs responses^[57]. However, ASPS patients treated with axitinib/pembrolizumab did not show higher TIL infiltration by immunohistochemistry compared to non-ASPS patients, but had universally positive PD-L1 expression, despite the higher response rate^[4].

Taking T cell infiltration one step further, TLSs are organized lymphoid aggregates containing CD8+ T cells, B cells, and follicular dendritic cells^[20], that influence anti-tumor immunity in cancers, well-described in melanoma and renal cell carcinoma^[62]. TLSs have been identified in various sarcoma subtypes, including UPS, dLPS, LMS, and rhabdomyosarcomas^[20,63], and their presence correlated with response to pembrolizumab monotherapy^[20]. As such, TLSs may offer a surrogate of an organized and robust anti-tumor immune response and may be used as a biomarker of response to immunotherapy, as explored in a dedicated arm in a larger phase II clinical trial of pembrolizumab and cyclophosphamide in soft tissue sarcomas^[64]. Out of 240 sarcoma patients screened for the TLS-containing cohort, 35 evaluable TLS-positive sarcoma patients achieved a 30% objective response rate, with 33.3% achieving stable disease. The overall response rate for the unselected patient population in this trial was only 2%^[65].

In addition, many soft tissue sarcomas and GIST tumors have a predominant expression of M2 macrophages, the immune-suppressive phenotype^[65]. Additionally, myeloid-derived suppressor cells (MDSCs), which are regulatory cells promoting tumor growth and immune evasion in the TME, have been shown to correlate with resistance to ICI in patients with melanoma^[66]. In sarcoma, MDSCs have been reported to correlate with higher stage and metastatic tumor burden, possibly supporting their immunosuppressive role in the sarcoma TME^[67]. Further evidence to support that was the findings of enhanced responses with ICI treatment in a murine model of rhabdomyosarcoma upon inhibition of the MDSCs trafficking to the TME^[68].

Adoptive cellular therapy

Adoptive cellular therapy aims to bypass the priming and activation of the T cells by providing *ex vivo* activated T cells against previously-identified tumor antigens directly to the patient. Three adoptive cellular therapies under study currently in sarcomas include engineered T cell receptors (TCR), which recognize MHC-I-restricted antigens, Chimeric Antigen Receptor (CAR) T cells which can recognize cell surface antigens, and adoptive transfer of TIL^[69]. Cellular therapies harnessing engineered TCRs or CARs require antigen recognition in the tumor, preferentially expressed by tumor cells and not by normal cells. New

York-esophageal squamous cell carcinoma-1 (NY-ESO-1) and melanoma-associated antigen-A4 (MAGE-A4) are two unique cancer/testis antigens expressed in selected sarcoma subtypes. NY-ESO-1 expression has been observed more frequently in synovial sarcomas (> 60%) and in myxoid liposarcomas (88.2%) and less frequently in pleiomorphic liposarcoma (21.4%), chondrosarcomas (14.3%), osteosarcomas (31.3%), and desmoplastic small round cell tumors (16.7%)^[70,71]. Similarly, MAGE-A4 has been detected more commonly in synovial sarcomas (82.2%), myxoid liposarcomas (67.7%), osteosarcomas (43.8%), angiosarcomas (41.4%), MPNSTs (24.6%) and chondrosarcomas (21.4%)^[70,71].

The responses to engineered T cells specific to NY-ESO-1 in synovial sarcomas are definitely encouraging, with a 50% objective response rate in the first cohort of treated patients^[8]. A major challenge for TCR-directed therapies, though, is the required human-leukocyte antigen (HLA) compatibility, with currently studied agents restricted to HLA-A*02 subtypes. In the first cohort of patients treated with NY-ESO-1 T cells, 120 patients were screened for HLA subtype and antigen expression to enroll 15 patients^[8]. An important insight from this study was that contrary to other cancers, loss of antigen expression and loss or mutations of genes mediating antigen presentation, including MHC-I, were not associated with acquired resistance in patients with synovial sarcoma treated with SPEAR T cells targeting NY-ESO-1^[72]. However, the lymphodepleting chemotherapy regimen is important for the effectiveness of the TCR therapies in sarcomas; it favors the combination of fludarabine and cyclophosphamide and maximizes the engraftment of adoptively transferred T cells via IL-7 and IL-15^[72].

CAR T cells provide an alternative to the HLA compatibility challenge that limits TCR therapy. However, they require antigens expressed on the surface of the tumor cells rather than peptide-MHC complexes (intracellular antigens). Extracellular antigens are limited in sarcomas overall, with a few exceptions of GD2 in osteosarcoma, rhabdomyosarcoma, and Ewing's sarcoma; platelet-derived growth factor receptor α in rhabdomyosarcoma and HER-2 in osteosarcoma^[48,73,74]. Studies are currently underway to assess the safety and efficacy of these and other therapies, including CAR T cells directed at B7-H3 (NCT04897321), EGFR (NCT03618381), and GD2 (NCT02107963, NCT04539366, NCT03721068, NCT03635632).

Finally, TIL therapy is under early investigation in sarcomas; in this modality, autologous TILs are collected from an individual patient's tumor and then expanded, and then returned to the patient with lymphodepleting chemotherapy and interleukin-2 (IL-2) therapy. An ongoing clinical trial is exploring the safety and efficacy of this approach (NCT04052334).

Overcoming resistance: future directions

While immune therapies, including checkpoint inhibitors and adoptive cellular therapies, have had promising activity in a subset of sarcoma patients, it is clear that other strategies will be needed to overcome innate resistance to immune-mediated recognition and kill the majority of sarcomas. Over the past several years, various trials have tested combination therapies aimed at reversing resistance mechanisms at various steps in the cascade, including targeting the suppressive immune microenvironment with metronomic cyclophosphamide^[65], or with VEGF blockade^[4,36,37]. Selected trials representing the scope of previous and ongoing strategies to overcome key potential mechanisms of resistance discussed in this review are listed in [Table 1](#).

While combination VEGF blockade and checkpoint inhibitors have shown activity in ASPS^[4] and osteosarcoma^[37], outcomes in other soft tissue sarcomas have not been convincingly different from what could be expected from checkpoint inhibitor therapy alone. Ongoing trials are assessing the activity of broader-spectrum anti-VEGF TKIs, such as cabozantinib (NCT04339738, NCT04551430, NCT05019703),

which could improve outcomes. Additionally, transcriptomic analysis suggested a subset of sarcomas with an angiogenic signature^[20], thus upcoming correlative analysis from previously conducted trials^[4,36] may help to identify a subset of sarcomas benefitting from this approach. Despite this, we still must identify novel strategies to address the majority of sarcomas which lack tumor immunogenicity, the ability of the sarcoma cells to induce and maintain an early immune response.

The main combination strategies aimed at inducing tumor immunogenicity include cytokines, radiation, and cytotoxic chemotherapy together with ICIs. A recent trial combined an IL-2 pathway agonist, NKTR-214, with nivolumab in a large phase I/II study for bone and soft tissue sarcomas (NCT03282344). While early results showed modest responses^[75], correlative studies presented in the abstract suggested candidate biomarkers, including changes in PD1/PD-L1 expression in tumor and immune cells with treatment, as well as genetic variations apart from TMB that may impact outcomes^[75]. The full publication is anxiously awaited as this large study may further help elucidate mechanisms of response and resistance. Additionally, Zhang *et al.*^[76] showed in a phase 0 trial that systemic use of interferon-gamma could increase MHC-I expression and T-cell infiltration in patients with synovial sarcoma and myxoid round cell liposarcomas, leading to a phase II trial of interferon-gamma with pembrolizumab (NCT03063632). While no results are yet published for this study, this is another unique strategy to target early immune responses and restore immunogenicity in cold sarcomas. Another mechanism to boost tumor necrosis and early immune responses is radiation therapy, and the final results of an ongoing study of preoperative radiation therapy for stage III UPS and dLPS with or without concurrent/adjuvant pembrolizumab (NCT02301039) are likely to contribute greatly to our understanding of the immune impact of this critical component of therapy for newly diagnosed sarcomas.

Finally, we will now discuss the emerging strategy of combining checkpoint blockade with cytotoxic chemotherapy, to induce tumor immunogenicity, neoantigen production, and trigger an early immune response, in hopes of potentiating the downstream activity of ICIs.

Chemotherapy combinations

One of the most potential inducers of tumor immunogenicity is traditional chemotherapy, with various agents inducing immunogenic cell stress, production of innate immunity attractants including type 1 interferons, and inflammasome induction^[77]. In particular, doxorubicin has been shown in a variety of preclinical tumor models to potently induce the production of DAMPs and type 1 interferons promoting downstream transcription of interferon-stimulated genes, and ultimately increased DC and T cell infiltration in tumor deposits^[78-83]. Other commonly used cytotoxic therapies in sarcomas, including gemcitabine, trabectedin, and eribulin, also have pro-immunogenic effects. Gemcitabine suppresses MDSCs within other cancer subtypes^[84], trabectedin has been shown to diminish the production of immunosuppressive cytokines in myxoid liposarcomas^[85], and eribulin helps to remodel aberrant tumor blood vessels in murine mouse models^[86]. In hopes of providing a source of immunogenic neoantigens and pro-inflammatory mediators for poorly immunogenic sarcomas, multiple studies exploring chemotherapy with checkpoint inhibitors have been recently reported or are ongoing.

Two studies have recently been published reporting very promising activity of combination doxorubicin with pembrolizumab. Pollack *et al.*^[32] reported a median PFS of 8.1 months in 37 patients with bone and soft tissue sarcomas, with a 73% progression-free rate at 24 weeks, despite an objective response rate of only 19%. Limited correlative data were reported with this study, but suggested that the presence of TILs was associated with inferior PFS. No additional phenotyping was reported to explain this surprising finding. More recently, Livingston *et al.*^[87] reported an overall response rate of 36.7%, median PFS of 5.7 months,

and a 6 month PFS rate of 44%, in 30 patients with advanced soft tissue sarcomas. Interestingly, analysis of PD-L1 expression in 29 of the 30 patients revealed an association of high PD-L1 expression with objective response rate, however, did not correlate with PFS or overall survival. The presence of TILs was not associated with any clinical outcomes, however, no phenotyping was reported with this finding. Ongoing clinical trials are exploring additional doxorubicin combinations, including doxorubicin with ifosfamide and sintilimab (anti-PD-1, NCT04356872), liposomal doxorubicin with ifosfamide and camrelizumab (anti-PD-1, NCT04606108), and doxorubicin with balstilimab (anti-PD-1) and zalifrelimab (anti-CTLA4, NCT04028063).

Regarding other cytotoxics, multiple studies are evaluating gemcitabine with checkpoint inhibitors for sarcomas (NCT04577014, NCT03123276), as well as a study combining metronomic gemcitabine with doxorubicin, docetaxel, and nivolumab (NCT04535713). Results of a study combining first-line trabectedin, ipilimumab, and nivolumab have been reported, with a best overall response rate of 22%, and median PFS had not been reached at the time of the presentation (NCT 03138161)^[88]. Finally, an ongoing study of eribulin plus pembrolizumab has shown modest responses in leiomyosarcoma^[89], with the full study still pending results (NCT03899805).

Overall, the combination of chemotherapy with checkpoint inhibitors appears the most promising strategy to date to reverse innate immune resistance of most adult sarcomas. However, correlative analysis of these studies to further confirm underlying biomarkers of response and resistance is still in infancy, with many unanswered questions.

CONCLUSION

In summary, there is still a tremendous amount to learn about resistance to immune therapy in sarcomas, but early studies have shown conclusively that for a subset of patients, immune therapy, including checkpoint inhibitors or adoptive cellular therapies, can be highly effective. Emerging research in looking at the underlying genetic and immune environments of sarcomas suggests that the pivotal mechanism of resistance is a lack of underlying tumor immunogenicity. Based on our prior experience, it appears unlikely that a single agent in combination with immune agents will be sufficient to reverse these hurdles for all sarcomas, but the promising activity of cytotoxic chemotherapy and potentially radiation combinations may eventually emerge as a crucial part of our therapeutic armamentarium. It remains critical that all early phase clinical trials of immune therapy include correlative studies, to ensure that we are learning the most from every patient, and to pool these data to understand mechanisms of response and resistance, to inform the next generation of clinical trials.

DECLARATIONS

Authors' contributions

Abstract

Multiple Myeloma (MM) is a common haematological malignancy that is associated with a high rate of venous thromboembolism (VTE) with almost 10% of patients suffering thrombosis during their disease course. Recent studies have shown that, despite current thromboprophylaxis strategies, VTE rates in MM remain disappointingly high. The pathophysiology behind this consistently high rate of VTE is likely multifactorial. A number of factors such as anti-thrombin deficiency or raised coagulation Factor VIII levels may confer resistance to heparin in these patients, however, the optimal method of clinically evaluating this is unclear at present, though some groups have attempted its characterisation with thrombin generation testing (TGT). In addition to testing for heparin resistance, TGT in patients with MM has shown markedly varied abnormalities in both endogenous thrombin potential and serum thrombomodulin levels. Apart from these thrombin-mediated processes, other mechanisms potentially contributing to thromboprophylaxis failure include activated protein C resistance, endothelial toxicity secondary to chemotherapy agents, tissue factor abnormalities and the effect of immunoglobulins/"M-proteins" on both the endothelium and on fibrin fibre polymerisation. It thus appears clear that there are a multitude of factors contributing to the prothrombotic milieu seen in MM and further work is necessitated to elucidate which factors may directly affect and inhibit response to anticoagulation and which factors are contributing in a broader fashion to the hypercoagulability phenotype observed in these patients so that effective thromboprophylaxis strategies can be employed.

INTRODUCTION

Background

Multiple Myeloma (MM) is a common haematological malignancy that remains a significant therapeutic challenge despite major advances in both treatments and biological understanding of the disease. Almost all patients will suffer relapse and in conjunction with this, MM is associated with a high rate of venous thromboembolism (VTE). It has long been acknowledged that there is a strong association between cancer and thrombosis but the risk of these events varies widely across the spectrum of cancer subgroups. VTE rates remain high in patients with MM with almost 10% of patients suffering from thrombosis during their disease course^[1,2].

The occurrence of a thrombotic event in patients with MM can be associated with significant morbidity and can lead to interruption of treatment, requirement for anticoagulation use and indeed may preclude the use of certain agents in future treatment regimens. Certain studies have also suggested that patients with MM who suffer a thrombotic event are also more likely to have poorer overall survival though further confirmatory data is awaited in this area^[3,4]. In light of these issues, optimisation of thromboprophylaxis and further understanding of the mechanisms conferring resistance to and failure of current anti-thrombotic strategies is an ongoing critical area of research [Figure 1].

Treatment of MM

The treatment of MM has rapidly evolved over the past number of years with many therapeutic options now available. Triplet/three drug combinations are the initial standard of care for induction therapy though choice of treatment will depend on factors such as patient fitness, local treatment guidelines and availability/funding of therapy^[5,6]. Generally, in younger, fitter patients who may be eligible for autologous transplantation (ASCT), initial therapy will comprise of a proteasome inhibitor such as bortezomib and either an immunomodulatory (IMiD) agent such as lenalidomide or an alkylating agent such as cyclophosphamide. These drugs are usually combined with dexamethasone, a corticosteroid, for maximum efficacy^[5]. There are also very efficacious treatments available for older patients or those who may not be fit for ASCT including a combination of lenalidomide and dexamethasone or VMP therapy (bortezomib, melphalan and prednisolone)^[5,7]. Upon relapse of disease, treatment options include carfilzomib (a second generation PI), alternative IMiDs such as pomalidomide and anti-CD38 monoclonal antibodies including daratumumab and isatuximab^[5,7]. It is well recognised that IMiD therapy confers a high thrombotic risk to the patient, particularly when combined with high doses of steroids, but the exact thrombotic risks of many other agents have been less well characterised^[8,9].

Risk assessment of venous thromboembolism

Patients with MM have a multitude of risk factors for development of thrombosis. These can generally be categorised into patient related factors such as prior VTE and increased body mass index (BMI), MM related factors (e.g., renal impairment, hyperviscosity, disease activity, reduced mobility) and therapy-related risk factors. There are a number of models and predictive scores that have attempted to stratify individual risk for VTE. The Khorana score is widely used to identify risk for cancer-associated VTE in patients with malignancy who are initiating systemic therapy. It is comprised of five clinical and laboratory indices, including type of cancer, platelet count, haemoglobin level and white cell count (WCC) as well as BMI^[10]. However, given that it is largely based on solid organ tumour data, it has been recognised that this score likely has limitations in the MM population with several studies observing that it does not accurately

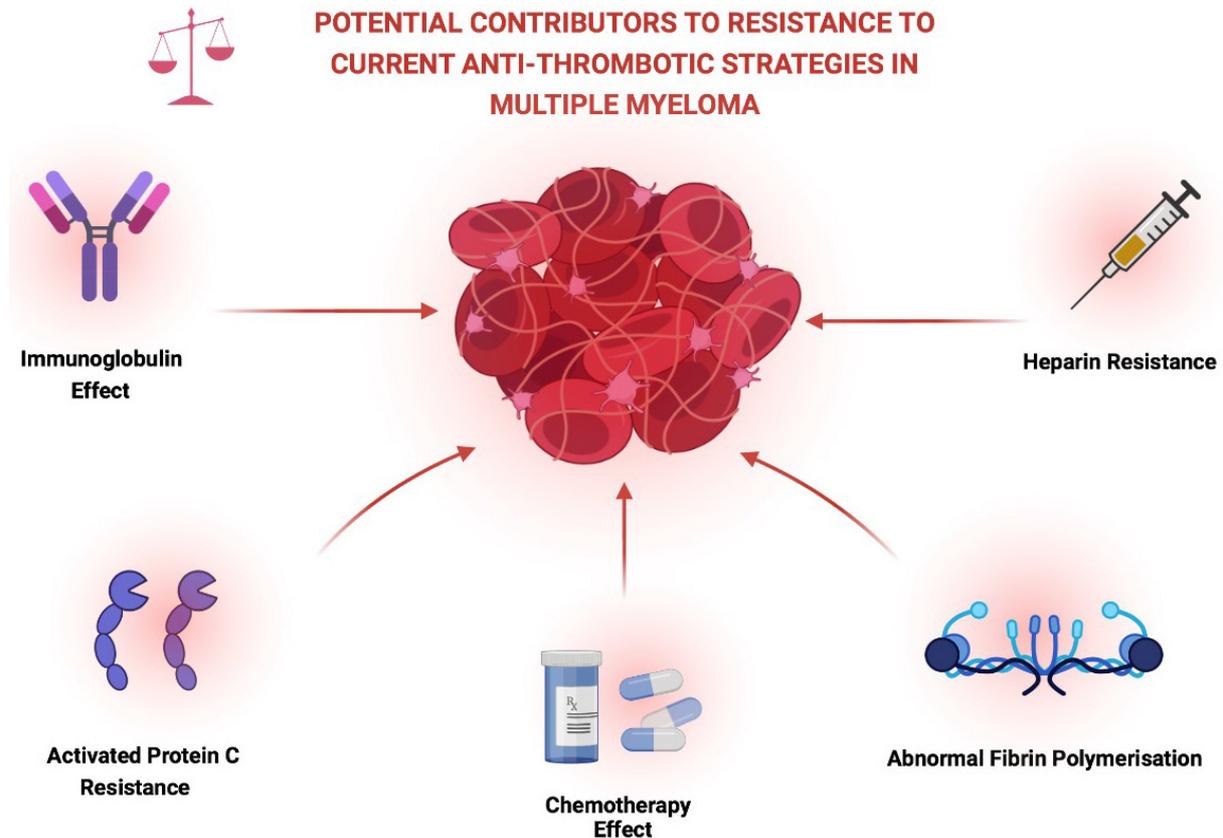

Figure 1. Description of some of the possible contributory factors to the persistently elevated VTE rates seen in multiple myeloma. Created with BioRender.com.

predict VTE risk within this cohort^[2,11,12]. In fact, in a study of over 300 patients with MM, Barrett *et al.*^[2] noted that WCC was the only single variable from the Khorana score that retained predictive significance for VTE in their cohort.

The current International Myeloma Working Group (IMWG) has provided guidance, based on stratification by Palumbo *et al.*^[13], on thromboprophylaxis in MM by compiling a VTE risk assessment incorporating individual, therapy- and myeloma-related factors. This guidance has also been incorporated into the National Comprehensive Cancer Network (NCCN) guidelines but several groups have observed that these guidelines do not fully capture VTE risk and thus have sought to develop novel and more rigorous VTE risk assessment tools [Table 1]. Sanfilippo *et al.*^[12] explored individual risk factors for VTE and combined the relevant factors to develop a risk prediction model called the “IMPEDE VTE” score which attributes scores to each contributory risk factor. Similarly, Li *et al.*^[14] evaluated the performance of the current NCCN guidelines in a large population based cohort while simultaneously developing their own VTE risk-assessment model specifically for patients undergoing therapy with IMiDs. They concluded that their own model, the SAVED score, which incorporated recent surgery, Asian ethnicity, prior history of VTE, age > 80 and dexamethasone dose had a greater discriminative power than the current consensus recommended by the NCCN guidelines^[14]. While these scoring algorithms have advanced VTE-risk discrimination in MM, some concerns have been raised that these scores were designed using retrospective data which was based upon therapies that are now less commonly used^[15]. Incorporation of additional biomarkers may further improve the accurate risk prediction of VTE for this vulnerable cohort.

Table 1. Recently developed risk stratification tools for VTE in multiple myeloma

IMPEDE VTE score Variable	Score	SAVED score Variable	Score
IMiD (immunomodulatory agent)	4	Recent surgery (within last 90 days)	2
Body mass index (>/ 25 kg/m ²)	1	Ethnicity: Asian race	-3
Fracture (pelvic, hip or femur)	4	Prior history of VTE	3
Use of erythropoietin-stimulating agent	1	Age "eight" > 80	1
Use of doxorubicin chemotherapy	3	Dexamethasone use (standard or high)	1 or 2
Use of dexamethasone (high-dose/low-dose)	4/2	Low risk: </ 1 High risk: >/ 2	
Ethnicity = Pacific Islander/Asian	-3		
Prior VTE (preceding MM)	5		
Presence of tunneled line	2		
Current/existing use of therapeutic LMWH/warfarin	-4		
Current/existing use of prophylactic LMWH/aspirin	-3		
Low risk: </ 3			
High risk: 4-7			
Very high risk: >/ 8

Current anti-thrombotic regimens in MM

It is well recognised that due to the unacceptably high thrombosis rates in MM, pharmacological thromboprophylaxis is often necessitated to try mitigate this risk. The IMWG recommend the use of aspirin in lower risk patients and either prophylactic-dose low molecular weight heparin or treatment-dose warfarin in patients at higher risk^[13]. In more recent times, focus has switched to evaluating the effectiveness of the direct oral anticoagulant medications (DOACs) including the factor Xa inhibitors (apixaban, rivaroxaban) and factor II inhibitors (dabigatran) in prevention of VTE in MM. While DOACs have been shown in several large trials to be effective and safe in both treating and preventing VTE in patients with malignancy, very few studies have sought to confirm this effect specifically in cohorts of MM patients^[16-18]. Despite this, a number of small scale studies have cautiously reported their experiences of the safe and effective use of DOACs in MM.

Storrar *et al.*^[19] have described their experience of apixaban thromboprophylaxis in 70 patients with MM, all receiving IMiDs as part of induction therapy. These patients were treated with apixaban 2.5 mg twice daily and there were no reports of VTE during the first six months of therapy with low rates of major bleeding also observed. They concluded that apixaban appeared to be a safe and attractive option for this cohort of patients. Similarly, Cornell *et al.*^[20] reported their experiences of apixaban thromboprophylaxis in a more heterogenous group of 50 patients with MM undergoing IMiD-based therapy at various timepoints of the disease course. Again, no instances of VTE were observed in the first six months of observation and, reassuringly there were also no instances of major haemorrhage during this time period. They too concluded that low-dose apixaban was safe and well-tolerated as primary prevention of VTE in patients receiving IMiD therapy. These are, however, small-scale studies and larger, prospective studies will be required to provide conclusive evidence for the long term use of DOACs in MM.

VTE rates despite thromboprophylaxis: immunomodulatory agents

The rate of VTE occurrence remains unacceptably high in MM patients with approximately 10% of patients developing a thrombosis during the course of their disease^[21,22]. It has been demonstrated that thrombosis

rates in patients with malignancy are highest in the first year following diagnosis and in particular, in MM, thrombosis rates appear to be highest in the first 3 months following diagnosis^[1,13,22,23]. It is hypothesised that these initial high rates are due to both accelerated neoplastic activity, increased tumour burden and, with treatment initiation, there may be overwhelming release of procoagulant factors and cytokines once apoptosis ensues. Given the particularly high risk of VTE associated with IMiDs, adjuvant pharmacological thromboprophylaxis is now widely in use. However, despite this, many groups have reported that VTE rates remain persistently elevated. Leclerc *et al.*^[22] reported their observations from a cohort of 213 patients who had received IMiD therapy where thrombotic events were reported in 18.3% of patients with more than half of these events occurring during the first three months of therapy, during which time the vast majority of patients were receiving thromboprophylaxis. VTE occurred more often with anti-platelet use rather than with anticoagulation, an observation that was also seen in the MELISSE study^[22,24].

Bradbury *et al.*^[25] also recently described the thrombosis rates during the Myeloma IX and Myeloma XI trials. Both trials are phase 3 trials incorporating the upfront use of an IMiD and corticosteroid-containing regimens as induction therapy with the Myeloma IX study containing data from 1936 patients and the Myeloma XI study containing data from 4358 patients. Due to the interim development of the aforementioned IMWG risk assessment guidelines, there were higher rates of thromboprophylaxis (80.5% vs. 22.3%) in the later Myeloma XI study but despite this, there was only a modest reduction in thrombosis rates in the latter trial. In the Myeloma IX trial, the 6 months cumulative thrombosis incidence rate was 20.7% in the CVAD (cyclophosphamide, vincristine, adriamycin, dexamethasone) group (non IMiD based) and 15.0% in the CTD (cyclophosphamide, thalidomide, dexamethasone) group (IMiD containing) while in the Myeloma XI trial, 6 months cumulative incidence of VTE was 10.7% in the CRD (cyclophosphamide, lenalidomide, dexamethasone) group and 11.7% in the CTD group, thus showing that despite adherence to current thromboprophylaxis guidelines, VTE rates remain disappointingly high^[25].

High VTE rates with other anti-myeloma therapies

Despite IMiDs often being regarded as the culpable prothrombotic agent, consideration has to be given to the thrombotic risk posed by other classes of drugs used to treat MM and worryingly, some of the more novel agents appear to be increasingly linked with thrombosis. Carfilzomib is a second generation proteasome inhibitor with reported VTE rates of 5%-14% in clinical trials and although thromboprophylaxis is recommended for MM patients receiving carfilzomib-containing regimens, the most effective thromboprophylaxis strategy remains to be determined, nor has the mechanism underlying carfilzomib-associated thrombosis been adequately studied^[26-29]. The findings of Piedra *et al.*^[29] suggest that these patients might benefit from a more enhanced thromboprophylaxis regimen. They recently reported their observations from a retrospective study of VTE incidence across different induction regimens used in newly diagnosed MM (NDMM). They compared rates between KRD (carfilzomib, lenalidomide, dexamethasone) + aspirin, RVD (lenalidomide, bortezomib, dexamethasone) + aspirin and KRD + rivaroxaban and found significantly differing rates of VTE depending on thromboprophylaxis agent used with rates of 16.1%, 4.8% and 4.8% observed in the groups respectively. This suggests that carfilzomib may be more thrombogenic than bortezomib (when combined with lenalidomide), a first generation proteasome inhibitor, though this risk appeared to be somewhat mitigated by using a DOAC rather than an anti-platelet agent^[29]. In addition to this, recent advances in cellular therapy have led to the availability of anti-BCMA chimeric antigen receptor T (CAR-T) cell therapy in MM. CAR T-cell therapy is associated with high rates of VTE with Parks *et al.*^[30] reporting almost 1 in 10 patients with either non-Hodgkin's lymphoma or MM reportedly developing VTE in the first 60 days post CAR-T cell infusion. There is currently a poor understanding of the pathogenesis of same or indeed on the optimal preventative and therapeutic strategies^[30].

POSSIBLE MECHANISMS OF RESISTANCE: THROMBIN-MEDIATED

Heparin resistance

Potential mechanisms contributing to heparin resistance

As discussed above, many patients with MM who are deemed at high risk of VTE are administered thromboprophylaxis with LMWH and it is also commonly utilised at therapeutic doses for treatment of thrombotic episodes in MM. Heparin binds to antithrombin and accelerates the interaction between antithrombin and thrombin or antithrombin and factor Xa, both of which should result in inhibition of prothrombotic activity. Heparin resistance is often defined as the need for higher heparin doses to achieve a targeted level of anticoagulation but it may be multifactorial and its identification is complicated by the lack of consensus on the appropriate target levels in conjunction with the optimal method for measuring heparin effect^[31].

One of the important mechanisms responsible for heparin resistance is deficiency of antithrombin (formerly known as antithrombin III). Many disease states such as liver failure, sepsis and treatments, such as asparaginase use in acute leukaemia, are associated with reductions in antithrombin levels but the prevalence of antithrombin deficiency in MM is far less well known and has not been evaluated on a large scale basis^[31,32]. It is however, well described that significant proteinuria can contribute to thrombotic potential and that reduced serum albumin levels are associated with increased urinary protein loss, including that of antithrombin^[33]. This may be of particular significance both in patients with MM and amyloidosis given the high rates of kidney impairment seen in these conditions. Thus, certain groups have highlighted the need for consideration for testing for antithrombin deficiency in patients with MM in the context of thrombosis and significant proteinuria^[21].

Aside from antithrombin deficiency, an additional factor that may contribute to heparin resistance is presence of high levels of coagulation Factor VII (FVIII). Increased doses of heparin have been necessitated for effective thromboprophylaxis in patients who exhibit high levels of FVIII such as patients suffering with acute infective/inflammatory conditions such as Covid-19^[31]. Increased FVIII levels in MM have been reported by several groups with particular elevations seen in those undergoing IMiD therapy^[34-36]. This raises the question that perhaps higher doses of heparin are necessitated in such patients to achieve adequate protective anticoagulation levels and thus reduce the high rates of VTE seen with current standard dosage.

Evaluating heparin resistance with thrombin generation testing

Thrombin generation assays (TGAs) are global haemostasis assays that seek to assess the entire coagulation process and are thought to be more sensitive than a standard coagulation profile given that the endpoint is conversion of fibrinogen to fibrin. They are *in vitro* assays that utilise tissue factor (TF) and phospholipids to activate the coagulation cascade. The concentration of thrombin is thus measured over a defined time period and a curve is generated to illustrate this production. Various measurements can then be extrapolated from the curve to describe thrombin activity such as lag time (time until thrombin initiation), peak thrombin generation and endogenous thrombin potential (ETP) which reflects the thrombin formation capacity of the plasma^[37]. Several groups have postulated that patients with MM may be “resistant” to treatment with heparin and have sought to evaluate this resistance using TGAs.

Chalayer *et al.*^[38] describe their observations where they sought to characterise the effect of heparin thromboprophylaxis on thrombin generation in a cohort of patient with MM with a view to exploring potential mechanisms of heparin resistance. They compared a group of patients with MM with intermediate/high VTE risk factors with a group of patients hospitalised with respiratory illness who were deemed to have a low thrombotic risk. They observed similar ETP levels in both of the groups and concluded that there was no *in vitro* evidence of specific resistance to LMWH in this particular cohort of

MM patients^[38]. Gracheva *et al.*^[39] also assessed a variety of global haemostasis assays (including TGAs, thromboelastography and thrombodynamics) in a cohort of 59 patients, 25 with NDMM and 34 patients undergoing stem cell mobilisation. They compared their results with a cohort of healthy individuals and found that both thrombodynamics and thromboelastography showed hypercoagulability in both sets of MM patients when compared with the healthy cohort. They then assessed TGAs in the patients undergoing stem cell mobilisation who were receiving heparin therapy and found widely varied results for each individual with no demonstration of hypocoagulability in some patients and more worryingly, a shift towards hypercoagulability in over 20% of patients. The authors concluded that the use of heparin therapy, at its current dose, was ineffective in these patients and that it may either indicate inadequate dosage or heparin resistance in this cohort^[39]. Given the stark discrepancy between these studies, further research in larger, more heterogenous groups of MM patients would be necessitated to evaluate if heparin resistance is prevalent and clinically relevant in MM.

Predicting VTE risk with thrombin generation assay testing

Thrombin generation has been studied extensively in malignancy and a large prospective observational study, the Vienna Cancer and Thrombosis Study, assessed the predictive value of thrombin generation for VTE in over 1000 patients with a variety of malignancies. They concluded that patients with an elevated peak thrombin ($>/ 611$ nM) had an increased risk for development of VTE with a hazard ratio of 2.1^[37]. However, the numbers of MM patients included in this study were small thus several groups have sought to establish the predictive value of TGAs specifically in MM.

Leiba *et al.*^[40] tested thrombin generation in a cohort of 36 patients with MM at various timepoints over a 2.5-year period with the main objective of determining if thrombin generation has a predictive value for VTE. They observed significantly higher ETPs and peak height values in those who developed thrombotic events compared with those who did not. Interestingly, they also noted a gradual increase in thrombin generation parameters in the time period preceding the thrombotic event. Unlike the findings seen by Gracheva *et al.*^[39] they noted that anticoagulation therapy was associated with a significant decrease in ETP and peak height values. As previously discussed, there is an excess incidence of VTE in MM in the first year following diagnosis and the authors observed a moderate increase in TG parameters concomitant with commencement of MM treatment suggesting that this may partially explain the timing of this excess incidence^[40]. Overall, they concluded that thrombin generation testing, both at baseline and during therapy, could serve as a predictive tool for thromboembolic events and perhaps may also have a role in monitoring individual response to heparin^[40].

Fotiou *et al.*^[41] subsequently carried out a larger prospective study of patients with NDMM and sought to explore the hypercoagulability characteristics in the period of treatment naivety pre-induction therapy. They recruited 144 patients with NDMM and compared their results to a group of healthy individuals. One of their outcomes was measurement of thrombin generation and, in direct contrast to the above findings, they found that, overall, thrombin generation was attenuated in the MM patients compared to the healthy individuals with longer lag-times and lower peak values observed. They also found significantly reduced ETPs in the MM cohort indicating an overall reduced enzymatic activity of thrombin. Interestingly, certain lower ETPs appeared to correlate with a higher risk of VTE and the authors concluded that they had identified clinically relevant biomarkers for VTE risk stratification with their hypothesis being that attenuation of thrombin generation should be interpreted as a reflection of endothelial cell activation i.e., “exhausted thrombin generation”^[41]. Legendre *et al.*^[42] also showed a potentially hypocoagulable state, with reduced peak thrombin and ETP values in a small group of 14 patients who were both chemotherapy and anticoagulant naïve.

Thus, there appears to be a marked discrepancy in the evaluation of thrombin generation in MM with both hyper- and hypo-coagulable states being observed by different groups, depending on timing of the testing and exposure of the patient to chemotherapy agents. Thrombin generation also increases with age and thus matching against younger, healthy control subjects may confound results^[42]. Further evaluation in larger studies with stringent age-matching is necessary to determine both the possible predictive value of thrombin generation for VTE and the clinical utility of such testing in monitoring response and resistance to anticoagulant use (see [Table 2](#) for result of thrombin generation testing).

The potential role of thrombomodulin in pathogenesis of thrombosis

Thrombomodulin is a transmembrane glycoprotein which is located on the luminal surface of endothelial cells. It has roles in both regulation of coagulation and inflammation with its main function being to bind to thrombin. Binding of thrombin to thrombomodulin results in loss of thrombin's procoagulant and profibrogenic properties and acquisition of the ability to activate protein C. It has thus been hypothesised that a reduction in thrombomodulin levels in MM may confer a hypercoagulable profile in patients.

Corso *et al.*^[43] sought to serially evaluate the changes in coagulation profiles in patients with RRMM both before and during/after treatment with thalidomide. While many markers were not found to significantly vary, they did observe significant variations in thrombomodulin levels. Thrombomodulin levels appeared to be slightly reduced in most patients at baseline but underwent further reductions during initial treatment with thalidomide therapy with the authors thus concluding that reductions in thrombomodulin levels may have a pathogenic role in thalidomide-related thrombosis. Fotiou *et al.*^[41] also noted a reduction in thrombomodulin levels in their cohort of 144 patients with NDMM. Zappasodi *et al.*^[44] subsequently sought to confirm the effect of thalidomide on thrombomodulin levels and evaluated the serial behaviour of thrombomodulin in 26 patients with RRMM who commenced thalidomide and dexamethasone therapy. Unlike their initial study where serum thrombomodulin levels fell during the first month of thalidomide therapy, they did not observe any significant modifications of thrombomodulin levels from baseline during the early stages of therapy. They did however note that the cohort of patients had low median basal values of thrombomodulin and thus concluded that this could perhaps suggest a thrombophilic state intrinsic to the MM disease process rather than then anti-myeloma therapy^[44]. Again, these observations are limited not only by low patient numbers but also by lack of evaluation in patients being treated with the newer therapeutic agents that are currently in widespread use.

OTHER POSSIBLE MECHANISMS OF RESISTANCE

APC resistance

Many groups have sought to unravel the prothrombotic phenotype in patients with MM with common observations including significant elevations in von Willebrand Factor (VWF) antigen, Factor VIII, D-dimer and fibrinogen levels in patients with active disease. However, the contributory effect of these abnormalities towards VTE occurrence has not been fully disentangled thus far^[15,36,45-49]. Interestingly, abnormalities of activated protein C (APC) appear to be a relatively common phenomenon exhibited in patients with MM and, unlike the above, do appear to significantly contribute to VTE occurrence. The normal biological role of APC is to inactivate Factor Va and Factor VIIIa with APC resistance (APCR) leading to non-cleavage of these factors and resultant increased thrombin generation which can potentially lead to a hypercoagulable state. In the Caucasian population, resistance to APC is one of the most common coagulation abnormalities associated with VTE and generally correlates with the presence of the Factor V Leiden R506Q mutation^[50]. However, acquired APCR has been described in association with certain malignancies including MM^[51,52].

Table 2. Results of thrombin generation evaluation in patients with MM

Author(s)	Multiple Myeloma patient cohort evaluated	Evaluated heparin resistance	Evaluated predictive potential for VTE	Findings
Chalayer <i>et al.</i> ^[38] 2019	Patients on first line therapy with high VTE risk (<i>n</i> = 6)	Yes	No	No evidence for an in vitro LMWH resistance in those with MM compared to patients without MM
Gracheva <i>et al.</i> ^[39] 2015	Patients with primary MM (<i>n</i> = 25) and patients with MM in remission (<i>n</i> = 34) undergoing blood stem cell mobilization	Yes	No	Possible "heparin resistance" with no heparin effect seen in 22% of patients and hypercoagulability seen in certain patients
Leiba <i>et al.</i> ^[40] 2017	Patients with newly diagnosed disease (<i>n</i> = 13) and patients receiving therapy upon relapse (<i>n</i> = 23)	No	Yes	Patients who had a thrombotic event exhibited significantly higher ETP and peak height values than those who did not have a thrombotic event
Fotiou <i>et al.</i> ^[41] 2018	Patients with newly diagnosed disease (<i>n</i> = 144)	No	Yes	Lower ETP values were associated with VTE occurrence
Legendre <i>et al.</i> ^[42] 2017	Patients with newly diagnosed disease (before treatment, including anti-coagulation) (<i>n</i> = 14)	No	Yes	Hypocoagulable profiles including decreased ETP values

VTE: Venous thromboembolism; MM: Multiple Myeloma; ETP: endogenous thrombin potential.

Given this association, Elice *et al.*^[53] sought to fully characterise the incidence of acquired APCR and its correlation with VTE in a large cohort of patients with MM (*n* = 1178). They recorded APCR in 109 patients (9%) but interestingly, this did not necessarily translate into the presence of factor V Leiden mutations with over half of these patients testing negatively for this mutation. Those with an abnormal APCR ratio but negative DNA testing for the factor V Leiden mutation were considered to have acquired APCR. Within this cohort of patients with acquired APCR, a higher incidence of VTE was observed when compared with controls (31% *vs.* 12%) and furthermore, they also exhibited a lower thrombosis-free survival. The authors thus concluded that the presence of acquired APCR was statistically associated with an increased VTE risk^[51,53].

Following on from this, other groups have sought to further unravel the mechanisms behind APCR and isolate the exact causative single nucleotide polymorphism (SNPs) in the endothelial protein C receptor (EPCR). EPCR has a key regulatory role in protein C activity via binding and facilitating the interaction with the thrombin-thrombomodulin complex. Several polymorphisms have been reported in EPCR with the 4678G/C SNP thought to be associated with high levels of circulating APC and reduced risk of thrombosis. Dri *et al.*^[54] sought to evaluate the presence of this polymorphism in a cohort of patients with MM who had developed thrombosis and found a significantly lower frequency of the 4678C allele of the EPCR gene in MM patients compared with the known frequency in a healthy adult population. The authors concluded that the reduced frequency of this protective allele could be contributing to overall disease hypercoagulability and that it may be useful to test for same to risk stratify MM patients. However, this was a small study and thus further evaluation of larger series of patients would be necessitated to determine that there is in fact an increased prevalence of this SNP in the MM population and if it indeed has a contributory effect to overall rates of VTE^[54].

Endothelial dysfunction and toxicity related to the effect of chemotherapy

With the widespread introduction of several novel therapies for MM, there has been a focus on emergent cardiovascular complications in conjunction with the persistence of high rates of VTE in the MM population^[26,55]. Many of the hypotheses surrounding this VTE risk centre on the toxicity that may be caused to the endothelium by certain anti-myeloma agents. Dexamethasone is a corticosteroid that is used in many of the treatment regimens for MM. Studies have shown that combining dexamethasone with other agents increases a patient's risk of VTE^[8,9]. The reasons behind this are not well understood but there is some *in vitro* evidence that dexamethasone can stimulate the endothelium to increase expression of both VWF and TF^[56]. Similarly, IMiD agents and carfilzomib are both thought to activate and cause direct toxicity to the endothelium with a downstream pro-thrombotic effect occurring following release of coagulation factors and cytokines^[57,58].

A small number of studies have been carried out specifically evaluating the toxic effects of anti-myeloma chemotherapy agents on endothelial cells (ECs). Early *in vitro* studies of IMiD agents noted that in a previously compromised/injured endothelium, as which would be seen with prior chemotherapy use, thalidomide could alter the expression of thrombin receptor PAR-1 and thus induce endothelial dysfunction and potentially a hypercoagulable state^[59]. In a more recent study, Sanchez *et al.*^[60] have reported their observations on exposure of ECs to some of the newer MM induction chemotherapy agents and they have shown that these agents can in fact lead to increased VWF and ICAM-1 expression and also an increase in cell permeability, exhibited by reduced VE-cadherin expression and cell monolayer integrity. Interestingly, this effect appeared to be somewhat counteracted by addition of the endothelial protectant agent defibrotide^[60], thus raising the hypothesis that perhaps endothelial protection agents could have some anti-thrombotic utility in MM.

The direct effects of M-protein/immunoglobulin on the prothrombotic environment and fibrin clot formation

MM is characterised by high levels of circulating clonal immunoglobulins or “M-proteins” and these immunoglobulins are hypothesised to have the ability to contribute directly to thrombotic risk, not only by direct vascular wall injury but also by interference with fibrinolysis^[61]. Fibrinolysis is the breakdown of fibrin within blood clots and is a highly regulated enzymatic process that, if functioning correctly, prevents unnecessary accumulation of intravascular fibrin. Clot stability is dependent upon many factors including local factors such as calcium concentration, thrombin concentration, pH and platelets numbers^[62]. It is also influenced by the geometric compilation of the fibrin network and the composition and diameter of the fibrin fibres from which it is constructed^[62]. Abnormal fibrin clot structure can lead to prolonged resolution/retraction of a clot^[63].

Carr *et al.*^[64] originally sought to evaluate the influence of high levels of immunoglobulin on fibrin polymerisation and clot structure *in vitro*, noting that in congenital dysfibrinogenemia, recurrent thrombosis were associated with the presence of abnormally thin fibres of fibrin. They hypothesised that, given that fibrin structures are sensitive to the environment in which they are formed, that high levels of immunoglobulin would interfere with fibrin monomer polymerisation. They characterised the clot formation in MM and, as seen in congenital dysfibrinogenemia, they noted that the clots were associated with the presence of abnormally thin fibrin fibres^[64]. They subsequently sought to evaluate the resistance of such clots to fibrinolysis and observed that these clots dissolved at a slower rate and they thus concluded that they were associated with inhibition of fibrinolysis^[65].

Undas *et al.*^[66] subsequently sought to evaluate fibrin clot properties and their determinants *ex vivo* in a cohort of 106 MM patients. Following collection of peripheral blood from these patients, they performed fibrin clot analysis, measuring variables such as clot permeation, clot compaction, turbidity measurements and also the efficiency of fibrinolysis using plasma clot lysis assays. They observed that plasmin clot variables differed significantly between the MM patients and a cohort of healthy control subjects with changes including higher fibrin fibre densities and reduced tPA-mediated lysability. They hypothesised that higher thrombin generation potentials were likely a major mechanism in these alterations in clot properties and that this abnormal fibrin clot structure likely exhibited a prothrombotic phenotype^[66].

The concept that local thrombin concentrations can impact upon the structure of clots with higher thrombin concentrations generating more stable clots which are more resistant to fibrinolysis and may promote thrombosis has been well described^[62,63,67,68]. It thus appears possible that in MM, given the dual pathology of both high circulating immunoglobulin levels and potentially high thrombin generation, clots produced could be less susceptible to fibrinolysis and thus perhaps more resistant to the current anticoagulant strategies that are employed.

Tissue factor

TF is an essential glycoprotein that serves as principal initiator of coagulation. TF-mediated conversion of Factor IX to its activated form is pivotal for effective haemostasis while disruption of the endothelium causes exposure of TF-expressing endothelial cells and thus facilitates binding of factor VII^[69]. Apart from its roles in coagulation, TF has also been implicated in both tumour spread and angiogenesis and in conjunction with this, high levels of TF have also been described in several solid organ malignancies with conflicting reports on its potential utility as a biomarker for VTE occurrence^[70]. TF can also be demonstrated on circulating microparticles (MPs) which are small, procoagulant membrane vesicles that are released from cells during activation or during apoptosis. These MPs are found in low steady state concentrations in healthy individuals and increase during times of inflammation. MPs carrying TF express platelet selectin glycoprotein ligand-1 which binds p-selectin on the surface of activated endothelial cells^[70].

In light of the above, several groups have sought to establish the role of TF in MM disease. Papageorgiou *et al.*^[71] investigated the role of TF and MP-TF *in vivo* in human myeloma cell lines. They determined that the expression of the TF gene, the presence of the TF protein on cell membrane and the procoagulant activity of TF were all detectable. They also observed that these cells could release MPs into their microenvironment and that these MPs conferred markedly increased procoagulant activity, expressing twofold higher levels of TF as compared to the original cells. The authors thus concluded that the hypercoagulability observed in MM may be enhanced by myeloma cell derived MPs released into the microenvironment^[71].

Other groups sought to evaluate the TF activity in patients with MM with Auwerda *et al.*^[72] evaluating this in a cohort of 122 patients with MM. They found that MP-TF activity levels were increased in the MM cohort in comparison to healthy volunteers. They performed serial evaluation of these activity levels and found that MP-TF activity levels showed a reduction post-induction therapy in many of the patients, but interestingly, levels remained elevated in those who had suffered a thrombotic episode^[72]. Nielsen *et al.*^[73] also sought to explore the role of TF in MM by isolating extracellular vesicles (EVs) from the peripheral blood of 20 patients with MM and subsequently demonstrating substantially higher thrombin generation and TF activity when compared with healthy control subjects. Similar to the above, they also performed serial activity levels and noted that the procoagulant activity of the EVs diminished after treatment, though of note, neither of the treatment groups that they evaluated contained the more thrombogenic IMiD agents

(treatment groups = bortezomib, cyclophosphamide and dexamethasone and melphalan, prednisolone and bortezomib)^[73].

All groups concluded that their findings may, at least in part, explain why there is an increased risk of VTE in MM but the prothrombotic contribution of TF in MM would need to be confirmed in larger cohorts of patients. In addition to this, TF activity is not routinely measured in clinical practice and a standardised assay would have to be developed and validated before it could be considered for widespread use as a biomarker.

CONCLUSION

It is clear that rates of thrombosis remain high in MM and, unfortunately, current thromboprophylaxis regimens do not entirely abrogate this risk of VTE. Thus the gap in knowledge between the persistently high levels of VTE and the inadequacies in current preventative measures needs to be bridged.

It is also increasingly evident that there are a multitude of factors contributing to the prothrombotic milieu seen in MM, many of which cannot be evaluated in a clinical setting. Further work is necessitated to elucidate specific pathways and factors contributing to the hypercoagulable phenotype observed in these patients. Additional clinical studies should focus on identifying novel biomarkers of VTE risk in MM and developing effective screening methods for anticoagulant resistance. Taken together, these approaches may help inform therapeutic strategies to overcome these mechanisms of resistance and provide effective thromboprophylaxis for patients with MM.

Abstract

Triple negative breast cancer (TNBC) is marked by a lack of expression of the Estrogen Receptor, Progesterone Receptor, and human epidermal growth factor receptor 2. Therefore, targeted therapies are being investigated based on the expression profiles of tumors. Due to the potential for acquired and intrinsic resistance, there is a need for combination therapy to overcome resistance. In the article by Lee *et al.*, the authors identify that, while prexasertib (a CHK1 inhibitor) lacks efficacy alone, combination with an EGFR inhibitor provides synergistic anti-tumor effects. Advances in targeted therapy for TNBC will benefit the clinical landscape for this disease, with this study initiating a new avenue of investigation.

Keywords: CHK1, TNBC, EGFR, chemoresistance

In the recent article by Lee *et al.*^[1], the primary goal of the authors was to identify a novel targeted therapy for triple negative breast cancer (TNBC). They are focused on the interaction and cooperation between epidermal growth factor receptor (EGFR) and CHK1. Prior to this study, it was well established that CHK1 inhibition (using prexasertib) increased cell death by blocking the cell cycle checkpoints. In addition,

© The Author(s) 2022. **Open Access** This article is licensed under a Creative Commons Attribution 4.0 International License (<https://creativecommons.org/licenses/by/4.0/>), which permits unrestricted use, sharing, adaptation, distribution and reproduction in any medium or format, for any purpose, even commercially, as long as you give appropriate credit to the original author(s) and the source, provide a link to the Creative Commons license, and indicate if changes were made.

previous studies showed that signaling through the PI3K and MAPK pathways are involved in resistance to prexasertib in sarcomas. Furthermore, prexasertib has been used in combination with PI3K inhibitors to cause changes in survival and apoptosis in TNBC^[2]. The authors mention that while prexasertib is effective as a combination therapy, its use as monotherapy has been less successful in part due to drug resistance. It's unclear, however, whether the resistance is related to CHK1 expression, as the CHK1 expression in [Supplementary Figure 1](#) does not appear to correlate to the efficacy of prexasertib.

In this paper, the authors test a panel of TNBC cell lines, and show that the MDA-MB-468 cells are highly resistant to prexasertib, whereas the MX-1 cells are sensitive^[1]. Two cell lines used in this panel, MDA-MB-468 and HCC1937, are both Rb-deficient. This deficiency could impact CHK1, as a 2018 paper demonstrated that Rb-deficient cells express higher levels of CHK1 and are more sensitive to CHK1 inhibitors^[3]. They chose to move forward with the MDA-MB-468 (resistant) and MDA-MB-231, which had moderate prexasertib sensitivity, for the remainder of their studies. They investigated the MAPK/PI3K pathways and found EGFR elevated in the resistant MDA-MB-468 cells, while AKT was elevated in both the MDA-MB-468 and the sensitive MX-1 cells. They chose to further investigate the function of EGFR in mediating prexasertib resistance, based on the expression in resistant cells. Using the MDA-MB-231 cells, they show that treatment with EGF increased resistance to prexasertib; however, it would be interesting to know whether this treatment altered receptor level or just downstream signaling. In addition, there is no dose dependence of EGF on prexasertib response, suggesting that they have reached a threshold of EGF/EGFR stimulation. As an aside, this is likely reached in the MDA-MB-468 cells as well, given that the higher dose of EGF increased sensitivity to prexasertib.

To overcome the resistance, they used a combination treatment of prexasertib with an EGFR inhibitor, erlotinib. This combination regimen showed synergy in both the resistant MDA-MB-468 and the moderately resistant MDA-MB-231 cells. Mechanistically, the authors state that there are changes in phosphorylation of Bad; however, the blots appear to show changes in the total protein. In addition to Bad, the MDA-MB-468 cells also show a decrease in phosphorylation of AKT, which is not observed in the MDA-MB-231 cells (likely due to their low baseline levels). *In vivo* studies showed that the combination of both drugs was required to decrease tumor weight in the mice injected with MDA-MB-468 cells, as opposed to single-drug treatments alone^[1]. While these results are contradictory to the *in vitro* results from [Figure 1](#) (reprinted from [Figure 4](#) of [Ref. \[1\]](#)), which show that erlotinib alone could decrease cell survival in the MDA-MB-468 cells, this could be due to cell non-autonomous interactions that would be lacking *in vitro*.

The overall message from the manuscript is that EGFR inhibition can be used to overcome resistance to CHK1 inhibition. The manuscript by Lee *et al.*^[1] gives great promise and lays the foundation for further investigation into this important mechanism of treating TNBC. To aid in the understanding of the relationship between EGFR and CHK1 in TNBC, an investigation of the sensitive MX-1 cells with EGF treatment would be beneficial. A deep dive into the correlation of EGFR and CHK1 in human TNBC would also be interesting to determine potential resistance to CHK1 inhibitors. In addition, previous investigations have shown the benefit of ATR and/or PARP inhibitors with prexasertib^[4] (also discussed in clinical trial NCT04032080), which may provide additional investigative avenues. Regardless, the clinical need for better targeted therapies for TNBC is high, and Lee *et al.*^[1] have identified a novel combination regimen using EGFR inhibition with CHK1 inhibition.

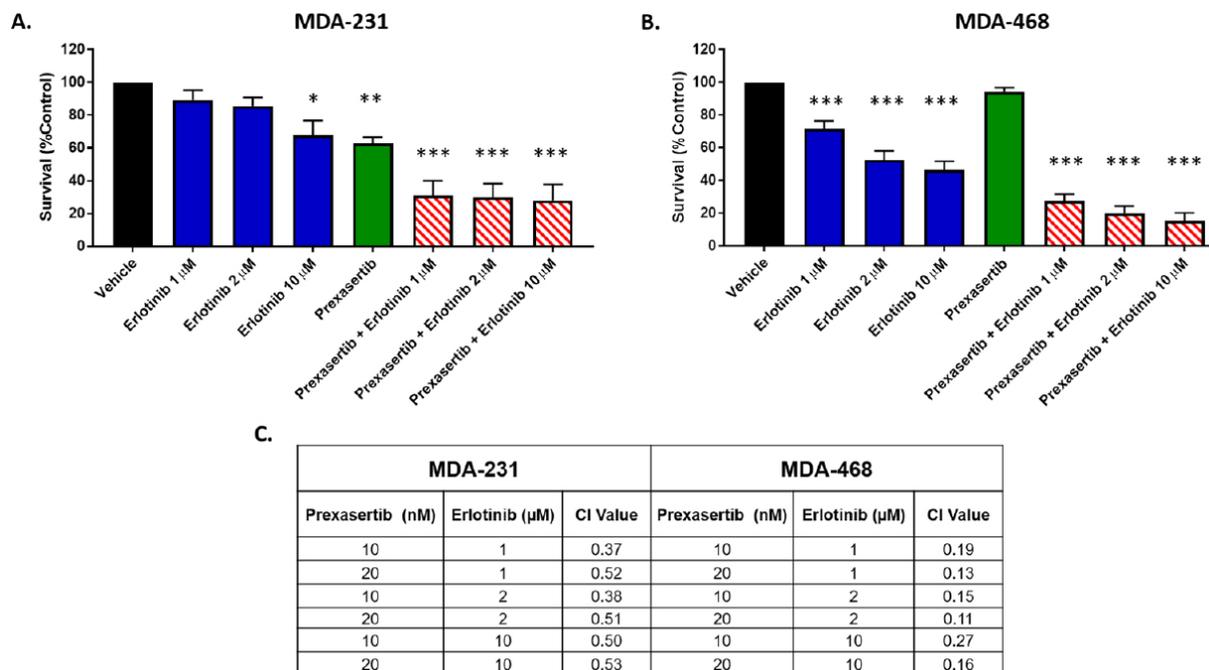

Figure 1. Erlotinib co-exposure with prexasertib synergistically enhanced cell killing. Viability of 3D cultures of MDA-231 (A) and MDA-468 (B) after exposure to prexasertib, erlotinib, and combinations of erlotinib and prexasertib; the combination index (CI) showed synergistic interaction (CI < 1) of erlotinib and prexasertib in both MDA-231 and MDA-468 (C).

Abstract

Despite the outstanding advances in understanding the biology underlying the pathophysiology of acute myeloid leukemia (AML) and the promising preclinical data published lastly, AML treatment still relies on a classic chemotherapy regimen largely unchanged for the past five decades. Recently, new drugs have been approved for AML, but the real clinical benefit is still under evaluation. Nevertheless, primary refractory and relapse AML continue to represent the main clinical challenge, as the majority of AML patients will succumb to the disease despite achieving a complete remission during the induction phase. As such, treatments for chemoresistant AML represent an unmet need in this disease. Although great efforts have been made to decipher the biological basis for leukemogenesis, the mechanism by which AML cells become resistant to chemotherapy is largely unknown. The identification of the signaling pathways involved in resistance may lead to new combinatory therapies or new therapeutic approaches suitable for this subset of patients. Several mechanisms of chemoresistance have been identified, including drug transporters, key secondary messengers, and metabolic regulators. However, no therapeutic approach targeting chemoresistance has succeeded in clinical trials, especially due to broad secondary effects in healthy cells. Recent research has highlighted the importance of lysosomes in this phenomenon. Lysosomes' key role in resistance to chemotherapy includes the potential to sequester drugs, central metabolic signaling role, and gene expression regulation. These results provide further evidence to support the development

of new therapeutic approaches that target lysosomes in AML.

Keywords: Lysosome, chemoresistance, AML, lysosomotropic drug, lysosomal sequestration, refractory AML

INTRODUCTION

Relapse and refractory diseases are major clinical challenges during the management of acute myeloid leukemia (AML) patients, and they prevent an optimized response to current treatments. As relapse refers to reappearance of the disease, relapse episodes are strongly related to refractoriness, both of them leading to poor prognosis^[1]. For the last five decades, the standard AML therapy consisted of a combination of cytarabine and an anthracycline^[2], and improvements in the survival rate are mainly due to optimization of the supportive care and hematopoietic cell transplantation protocols. Recently, new targeted drugs have been approved, incorporating the notion of personalised treatments for AML. Continuous assessment of newly approved drugs over time will provide valuable complete efficacy and safety data that will result in an optimal drug regime, as current clinical benefit is controversial^[3,4]. Thus, acquisition of new biological insight in AML pathophysiology represents an unmet need necessary to expand the targetable therapeutic mechanism repertoire to overcome chemoresistance and, then, significantly improve clinical outcomes for AML patients.

Primary and secondary chemoresistance have been widely explored using conventional approaches, searching for gene mutations, chromosomal aberrations, and dysregulated signaling pathways^[5-8]. Changes in the multidrug resistance gene family affect the intracellular concentration of drugs by either reducing the active transport into the tumor cells or increasing the efflux out to the extracellular space. Other mechanisms of action that affect the response to chemotherapy include: modifications in the chemotherapy molecular targets, preventing the pharmacologic action, increased ability to repair tumor DNA damage, defective response to proapoptotic stimuli, and changes in the tumor microenvironment^[8]. Although several inhibitors targeting drug-resistance mechanisms have been reported, their clinical development is still under evaluation.

Oxidative phosphorylation function, metabolic plasticity, and mitochondrial adaptation contribute to chemoresistance in AML, especially towards cytarabine, as resistant AML cells rely more on mitochondrial oxidative phosphorylation and less on glycolysis^[9,10]. Increased mitochondrial mass, mitochondrial membrane potential, reactive oxygen species production, and a characteristic gene signature associated with oxidative phosphorylation are hallmarks of chemoresistance AML cells^[9,11]. Indeed, inhibition of oxidative phosphorylation induces chemosensitivity^[9,11-13]; and mitochondrial oxidative phosphorylation and respiratory capacity correlate with a better response to cytarabine treatment in AML cells^[11]. This metabolic reprogramming might have an important therapeutic implication and metabolic vulnerabilities might be exploited pharmacologically.

Closely related to mitochondria, lysosomes have attracted special interest in oncology due to their growing importance in transformation processes. The traditional view of lysosomes has been challenged by the recognition that lysosomes are not only “degradative organelles”, but also metabolic sensors and regulators, becoming legitimated as intracellular signaling hubs^[14]. Additionally, recent findings highlight the physical and functional interaction of mitochondria and lysosomes, suggesting that this crosstalk plays a major role in metabolic regulation, based on the transfer of Ca²⁺ between organelles^[15,16], affecting the cellular response to treatment. In this review, the role of lysosomes in chemoresistance in AML is discussed and an overview of the potential therapeutic approaches for overcoming refractoriness in leukemia is provided.

LYSOSOMES

Lysosomes were first described in the 1950s as organelles responsible for the degradation of biological macromolecules from extra- and intra-cellular origins^[17]. Their central role in cellular recycling and homeostasis was revealed later when autophagy was discovered^[18,19]. Recent discoveries confirm lysosomes as crucial modulators of cell homeostasis, regulating both cellular metabolism and clearance (reviewed in Ref.^[20]).

Structurally, lysosomes are acidic organelles surrounded by a phospholipid bilayer. The acidic lumen is maintained by vacuolar-type H⁺ ATPase (V-ATPase) on the lysosomal membrane^[21]. Other key proteins on lysosomal membrane are: lysosome-associated membrane protein, soluble N-ethylmaleimide-sensitive factor activating protein receptors, toll-like receptors, and mammalian target of rapamycin (mTOR)^[22]. Luminal hydrolytic enzymes of lysosomes include proteases, sulfatases, nucleases, lipases, phosphatases, and nucleases, which degrade macromolecules.

Lysosomes belong to the endolysosomal system, a dynamic network of organelles consisting of early, late, and recycling endosomes and lysosomes. Primary lysosomes originate from the Golgi apparatus. Early endosomes formed from the plasma membrane might also progress to late endosomes and lysosomes, as a result of a maturation process. Alternatively, a contact site between lysosomes and late endosomes can be formed, followed by cargo transfer and dissociation (kiss-and-run model), or late endosomes can fuse with lysosomes, creating a hybrid organelle that subsequently evolves in lysosomes (fusion and fission process)^[23].

During malignant transformation, cancer cells adapt their physiological processes to sustain their intrinsic anabolic and catabolic needs. Both lysosomal mass and subcellular localization are widely changed to enable the acquisition of cancer cells' idiosyncratic feature of uncontrolled growth. Recycling of exogenous material provides energy and key molecular components, while autophagy enhances catabolism and, consequently, energy and metabolite precursors are supplied. Nutrient sensing is tightly regulated by lysosomes, based on the activation and translocation of the mTORC1 complex to the lysosome membrane, enhancing lipid catabolism under starving condition in transformed cells (reviewed in Ref.^[24]).

Lysosomes in AML

During leukemogenesis, AML cells increase their lysosomal mass, although their number is not significantly affected^[25]. As AML relies on fatty acids for energy supply, lysosome-dependent fatty acid oxidation rate is higher, inducing an augmented lysosomal mass to support this process^[26]. The gene network that regulates the lysosomal biogenesis is also upregulated, similarly to the expression of key lysosomal enzymes^[27-37]. Indeed, the lysosomal matrix enzyme activity is enhanced in AML, as compared to healthy myeloid cells, probably due to an increase in the quantity of enzymes and the influx rate^[38]. As a consequence of these lysosomal changes, AML cells contain fragile lysosomes due to destabilization of the lysosomal limiting membrane and lower pH.

V-ATPases play both direct and indirect roles in the control of cellular signaling. Growth, survival, and differentiation signaling pathways frequently rely on these ATP-dependent proton pumps. Control of vesicular pH by V-ATPase is essential for proper signaling by many plasma membrane receptors that traffic through the recycling networks, including Notch and Wnt^[39]. Canonical Wnt is required for the development and maintenance of AML^[40-42]. Inhibition of V-ATPase prevents the activating phosphorylation of the Wnt receptor upon ligand binding and dysregulates ligand-mediated internalization of the receptor^[43,44]. Although the importance of Notch as a therapeutic target in AML is still controversial,

this signaling pathway regulates proliferation and cell survival^[45-47]. Activation of the Notch receptor induces the intracellular domain to be cleaved and translocated to the nucleus, a process requiring V-ATPase function^[48-50]. Similarly, PI3K/Akt/mTOR signaling pathway is crucial to many physiological processes, such as proliferation, gene expression regulation, differentiation, cell death, metabolism, cell survival, and migration, and it is frequently hyperactivated in AML^[51-55]. While the precise mechanism involved in the V-ATPase-mediated modulation of mTOR remains widely unknown, inhibition of V-ATPase represses mTOR activation^[56], and mTOR inhibition leads to AML cell death^[57,58].

Lysosomal sequestration of drugs

Lysosomal sequestration or lysosomal trapping is an important mechanism responsible for chemoresistance acquisition^[59]. Many chemotherapeutics used in clinics (i.e., anthracyclines, taxanes, platinum-based drugs) are lipophilic, weak-base drugs and can therefore diffuse freely across lipid membranes, including the plasma membrane and lysosomal membrane. Alternatively, lysosomotropic drugs can be actively transported by inward turned multidrug efflux transporters of the ATP-binding cassette superfamily, embedded in the lysosomal membrane (originally expressed in the plasma membrane and endocytosed into lysosomes), particularly ABCB1^[60-63] and ABCA3^[38]. The acidity of the lysosomal lumen facilitates the rapid protonation of weak-base drugs, impairing their ability to cross back across lipid bilayers, resulting in their marked lysosomal accumulation and compartmentalization^[64,65]. Chemotherapeutics sequestered in lysosomes and associated to drug resistance phenomena include tyrosine kinase inhibitors^[66-68], topoisomerase inhibitors^[69-71], antimetabolites^[72], alkylating agents^[73,74], and microtubule-targeting agents^[75,76]. Lysosomal sequestration severely affects drug subcellular distribution, significantly reducing efficiency, since lysosomes are seldom the target sites for these chemotherapeutics, and the sequestered drugs will not reach their targets^[77]. Therefore, higher concentrations are required to achieve therapeutically relevant concentrations, increasing side effects in patients, and promoting secondary chemotherapy resistance. Treatment with these types of drugs induces expansion of the lysosomal compartment, thereby enhancing their lysosomal sequestration capacity and further increasing chemoresistance, constituting a feedback loop^[78-80].

The transcription factor EB (TFEB) is the master regulator of lysosomal biogenesis, by modulating the expression of genes bearing the coordinated lysosomal expression and regulation motif. In resting conditions, phosphorylated TFEB is retained inactivated in the cytoplasm by the 14-3-3 protein. Calcineurin dephosphorylates and activates TFEB, leading to its dissociation from 14-3-3 and subsequent translocation to the nucleus. mTOR phosphorylates (and inactivates) TFEB, enabling its binding to 14-3-3 in the cytoplasm. The activity of calcineurin is modulated by the release of Ca²⁺ from the lysosomes through the lysosomal Ca²⁺ transporter mucopolin (MCOLN1)^[81]. mTOR can be inhibited by raising the pH, as lysosomotropic drugs do^[82]. Activation of TFEB induces lysosomal biogenesis which increases lysosomal sequestration capacity and exerts a feedback loop.

Clearance of chemotherapeutics sequestered in lysosomes might also provide an additional chemoresistance mechanism. Exocytosis has been proposed as the preferred process^[83], as drug accumulation induces an increase of pH, leading to an activation of exocytosis^[84,85]. Moreover, drug sequestration-induced TFEB activation partially results in the induction of lysosomal exocytosis and clearance of lysosomal content outside the cell^[86,87]. However, once drugs have been released to the extracellular space, they can rediffuse back into the cells, making the exocytosis-mediated chemoresistance a controversial process that requires further clarification.

The anthracyclin daunorubicin (DNR), a backbone chemotherapeutic agent in first-line treatment of AML, displays physicochemical features compatible with lysosomal trapping. Early studies demonstrated that DNR intracellular distribution depends on drug treatment response. Sensitive AML cells preferentially accumulate DNR in the nucleus, where the pharmacology effect is exerted. In contrast, DNR-resistant AML cells tend to sequester DNR in lysosomes^[88]. Indeed, expanded lysosomes are observed in response to DNR treatment, as well as a diminished nuclear drug uptake, exhibiting a 2.5/3-fold less DNR concentration in nucleus in resistant versus sensitive AML cells^[69]. In AML, the relevance of ABCB1 in the active transportation of DNR into lysosomes is limited^[60,69], in contrast to other solid tumor cells^[62,63,89]. Instead, in AML, DNR is actively influxed by lysosomal ABCA3, a transporter upregulated in chemoresistant patients and correlated with poor prognosis^[37,38].

LYSOSOME-BASED THERAPEUTIC APPROACHES

The key contribution of lysosomes to chemoresistance raises increasing interest in lysosome-targeting therapies to either sensitize tumor cells to current approved chemotherapy or as new pharmacologic approaches. The transformation process itself affects the integrity and size of lysosomes, increasing their fragility. Sphingolipid metabolism alterations are also often found in cancer cells, leading to changes in the lysosomal membrane function and structure^[90]. Due to an increased metabolic demand, cancer cells upregulate their lysosomal function, resulting in an augmented lysosomal mass^[91]. Accumulation of lysosomotropic drugs in cancer cells destabilizes lysosomes, causing their failure and eventually activating cell death program. However, healthy lysosomes are fully functional and display compensatory mechanisms that prevent fatal damage. Consequently, a wide therapeutic window is found due to these differences in fragility of lysosomes in cancer cells *vs.* healthy cells. Several strategies have been explored, including lysosomal destabilization. Lysosomotropic compounds can accumulate in lysosomes, causing lysosomal membrane-cell permeabilization, release of cathepsins, and consequently, activation of the cell death program^[92]. Using different screening approaches, the anti-malaria drug mefloquine^[25], cationic amphiphilic antihistamines^[93], and σ_2 receptor agonist siramesine^[94] were described as lysosomal disruptors in AML cells and sensitizers to approved chemotherapeutics. Mefloquine disturbs the lysosomal membrane of AML cells, allowing the release of cathepsins to the cytoplasm and inducing apoptosis^[25]. Cationic amphiphilic antihistamines simultaneously disrupt both lysosomes and mitochondria, based on their physico-chemical properties, inducing both apoptosis and autophagy^[93]. Both the specific cationic amphiphilic antihistamines and mefloquine spare healthy blood cells, confirming the differential effect of lysosomal disruptors in AML and the existence of a preclinically-validated therapeutic window. However, reprofiling of these drugs to AML is difficult due to their pharmacological profile, and no clinical trials have been successfully completed. Medicinal chemistry programs are expected to be necessary to achieve clinically suitable new compounds. Nevertheless, to date, targeting lysosomal integrity is the most promising therapeutic approach to overcome lysosome-mediated chemoresistance in AML [Figure 1].

Accumulation of chemotherapeutics in lysosomes heavily depends on lysosomal lumen pH. Moreover, in resistant AML cells, the pH gradient between the lysosome and cytosol is higher^[95]. Treatment with V-ATPase inhibitor archazolid A induces cell death in leukemic cells, both T-cell acute leukemia and acute myeloid leukemia^[96]. Similar results were obtained with bafilomycin A, another V-ATPase inhibitor, although the mechanism of action responsible for this pharmacological effect is still controversial^[97], as bafilomycin A is unable to resensitize cytarabine-resistant cells^[98]. However, the preclinical data suggest that the therapeutic window was narrow, and their clinical significance might be limited.

As for further lysosome regulators, rapamycin and other mTORC1 modulators, have shown promising results in preclinical assays, specially in combination therapies^[52]. However, mTORC1 regulates key

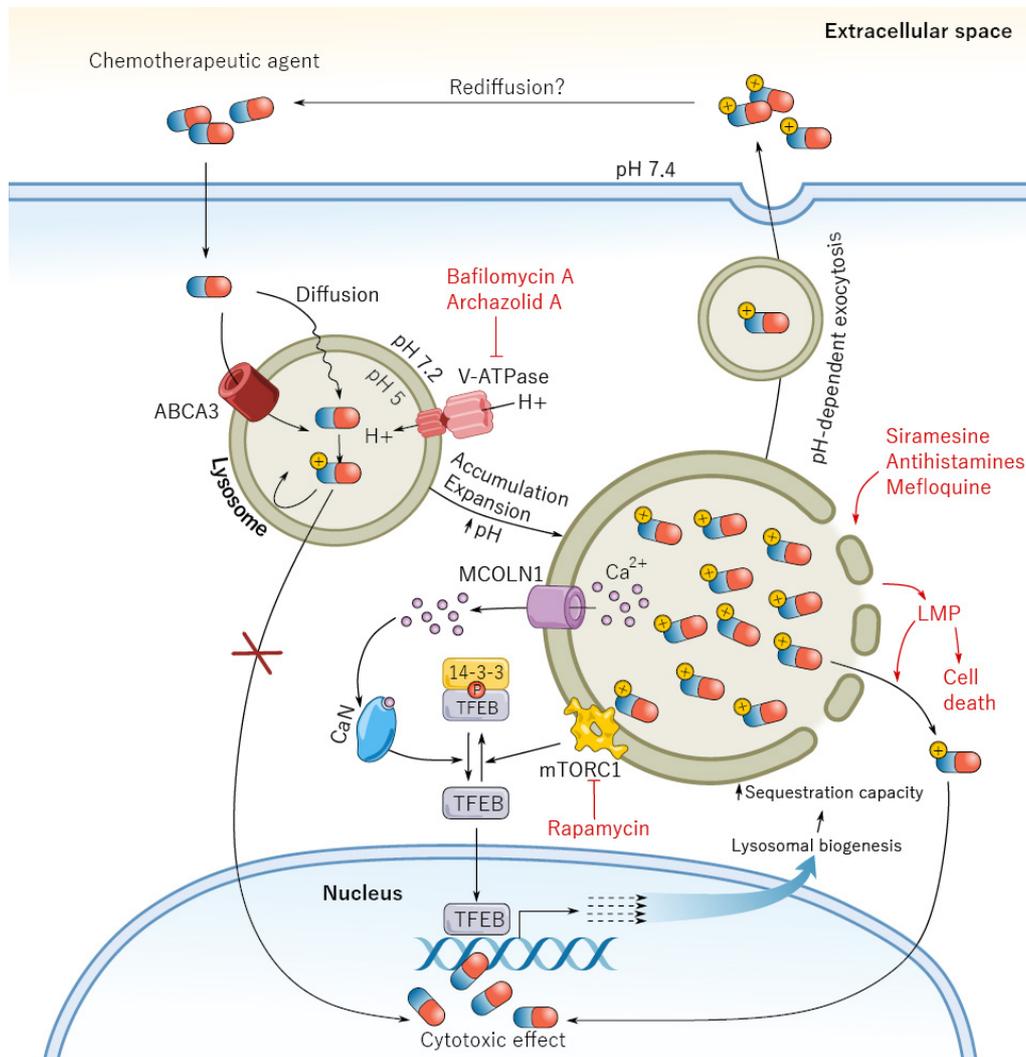

Figure 1. Mechanisms of lysosomal-mediated chemoresistance in acute myeloid leukemia (AML) at a glance. Most chemotherapeutic agents get readily sequestered in lysosomes upon entry in AML cells, causing a remarkable expansion of the lysosomal compartment. Lysosomal expansion is accompanied by an increase in pH, inducing exocytosis and, consequently, clearance of chemotherapy from cells. Both mechanisms prevent chemotherapeutic agents from directly interacting with their molecular targets, commonly located in the nucleus. To revert the undesirable sequestration, two main strategies have been proposed, namely, increasing lysosomal pH by inhibiting V-ATPase or pharmacologically inducing lysosomal membrane leakiness, thus releasing chemotherapeutics and additionally eliciting lysosomal-dependent cell death. Conversely, mTORC1 inhibition contributes to lysosomal biogenesis and sequestration capacity, a mechanism that has been traditionally overlooked in translation of mTORC1 inhibitors and that could partly explain their clinical failure. ABCA3: ATP binding cassette subfamily A member 3; CaN: calcineurin; LMP: lysosomal membrane permeabilization; MCOLN1: mucolipin TRP cation channel 1; mTORC1: mammalian target of rapamycin complex 1; TFEB: transcription factor EB; V-ATPase: vacuolar ATPase.

processes implicated in cellular metabolism and growth. The complexity and broadness of the mTOR signaling networks increase the risk of toxicity due to off-tumor on-target effects, as the therapeutic window is narrow, if existent^[99]. Besides, accumulating evidence suggest that mTOR is not the only specific molecular target for rapamycin. A quantitative chemical proteomics approach has revealed that the rapamycin targetome is extensive, including Stat3, an ubiquitous secondary messenger^[100]. In consequence, the efficacy of mTORC1 modulators in clinical trials is limited^[101-104], probably due to its conserved function of mTOR complex in homeostasis mechanisms in all cell types, preventing their further clinical development [Table 1].

Table 1. Summary of the main lysosome-associated chemoresistance mechanisms and therapeutic approaches

CHEMORESISTANCE MECHANISMS RELATED TO LYOSOMES			
Mechanism	Cause	Effect	Solution
Drug sequestration ^[59]	Drug protonation due to lysosomal acidic lumen ^[64,65]	Changes in subcellular distribution ^[77]	Increase drug concentration ^[78-80]
Exocytosis ^[83]	Drug accumulation due to increased pH ^[84,85] and TFEB activation ^[86,87]	Clearance of lysosomal drug content ^[86,87]	Drugs can rediffuse back into the cells
LYSOSOME-BASED THERAPEUTIC APPROACHES			
Type	Actions	Examples	
Lysosomal destabilizers	Lysosomal membrane permeabilization, cathepsins release, and cell death program activation ^[92]	Mefloquine (anti-malaria drug) ^[25] , cationic amphiphilic antihistamines ^[93] , and siramesine ($\sigma 2$ receptor agonist) ^[94]	
V-ATPase inhibitors	Activation of cell death program ^[96]	Archazolid A ^[96] and bafilomycin A ^[98,96]	
mTOR modulators	Effect on combinatory therapies ^[52]	Rapamycin ^[52]	
Antibody-drug conjugates	Release of the therapeutics coupled to the antibody ^[105]	Gemtuzumab ozogamicin ^[106]	

Gemtuzumab ozogamicin (Mylotarg) is an anti-CD33 monoclonal antibody conjugated to the small molecule chemotherapy drug calicheamicin, recently reapproved for AML. Upon surface CD33 recognition, this antibody-drug conjugate is internalized and translocated to lysosomes. The acidic-labile linker is hydrolyzed in the acidic environment of the lysosome, releasing the cytotoxic drug that is exported to the nucleus, where the pharmacological effect occurs^[105]. Thus, the effectiveness of gemtuzumab ozogamicin greatly depends on lysosome functionality. This targeted therapy was expected to represent a new paradigm in AML therapy; however, the clinical benefit is limited and severe adverse effects are found in a considerable rate^[106]. Discrepancies between expectations and clinical efficacy may be explained based on the lysosomal impairment in AML cells, partially due to the hyperactivation of PI3K/Akt signaling pathway^[51,53,54]. A direct correlation between lysosome function and gemtuzumab ozogamicin-induced cytotoxicity was observed and forced activation of lysosomes led to a synergistic effect with gemtuzumab ozogamicin^[106], demonstrating that these lysosomal-dependent conjugate approaches used as monotherapy may be of limited interest in AML.

CONCLUSION

Refractory and relapse disease are still the main clinical challenges faced in AML. Although new drugs have been approved in the last years, treatment failure and resistance mechanisms remain a major problem in patient management. To date, none of the therapeutic strategies designed to overcome chemoresistance has succeeded in clinics. The identification of lysosomes as key organelles in resistance acquisition opened a new research field and provided new avenues to explore in order to revert the resistant phenotype. The leukemic transformation process results in an augmented metabolic demand, associated with the upregulation of the lysosome function. Consequently, increase in lysosomal mass, pH, and enzymatic activity is induced. Lysosomotropism of several chemotherapeutics enable their sequestration in the lysosomes, becoming “drug-safe house” compartments and reducing their cytotoxic effect in molecular targets. As a consequence of the lysosomal changes induced during leukemogenesis, AML lysosomes are more fragile than those found in healthy cells, with a preclinically demonstrated safe therapeutic window. Developing new drugs that target leukemic lysosome integrity may sensitize AML cells to conventional chemotherapeutics or even constitute a new pharmacological lysosome-centred strategy for relapse and refractory AML patients.

Abstract

Since taking part as leading actors in driving the metastatic process, circulating tumor cells (CTCs) have displayed a wide range of potential applications in the cancer-related research field. Besides their well-proved prognostic value, the role of CTCs in both predictive and diagnostics terms might be extremely informative about cancer properties and therefore highly helpful in the clinical decision-making process. Unfortunately, CTCs are scarcely released in the blood circulation and their counts vary a lot among different types of cancer, therefore CTC detection and consequent characterization are still highly challenging. In this context, *in vitro* CTC cultures could potentially offer a great opportunity to expand the number of tumor cells isolated at different stages of the disease and thus simplify the analysis of their biological and molecular features, allowing a deeper comprehension of the nature of neoplastic diseases. The aim of this review is to highlight the main attempts to establish *in vitro* CTC cultures from patients harboring different tumor types in order to highlight how powerful this practice could be, especially in optimizing the therapeutic strategies available in clinical practice and potentially preventing or contrasting the development of treatment resistance.

Keywords: Liquid biopsy, circulating tumor cells, liquid tumor biomarkers, cell cultures, circulating tumor cell cultures, biomarker evaluation, precision medicine, drug sensitivity

CIRCULATING TUMOR CELLS: WEAKNESS IN RARITY

During the last decades, personalized medicine has progressively gained a crucial role in cancer therapeutics, leading to an increased need to monitor the molecular heterogeneity of neoplastic diseases. Despite representing the gold standard in defining tumor molecular profile and therefore in guiding treatment choices, tissue biopsy is an invasive practice that does not allow to follow the clonal evolution of the tumor, thus being not very informative of the genomic changes that cancer might exhibit at progressive disease^[1]. In this context, the increasing interest showed in liquid biopsies together with the consistent number of studies in this research field have led to a deeper consciousness of the potential impact that liquid tumor biomarkers could have on the clinical decision-making process, especially considering that liquid biopsies are non-invasive, easy to perform, and highly accessible^[1,2]. As the only requirement to obtain information about the tumor mutational status is a simple withdrawal of biological fluids, most frequently blood but also saliva, urine, pleural, and cerebrospinal fluid, liquid biopsies enable a real-time closer look at cancer dynamics, ensuring a more precise monitoring of cancer patients, hopefully offering the best therapeutic option possible^[3].

Circulating tumor cells (CTCs), circulating tumor DNA, and more recently exosomes released from both primary tumor and metastatic sites in the systemic circulation represent the main cancer-derived material studied in liquid biopsy-based analyses, providing prognostic and predictive indications and currently under investigation for their potential role in cancer diagnostics^[1,3].

CTCs were firstly described by Ashworth^[4] in 1869 and, after only twenty years, Stephan Page proposed the “seed and soil” hypothesis, assuming that the metastatic process is not randomly successful, but tumor cells (the “seed”), detaching from the primary tumor, can grow up in selected organs solely in the presence of a suitable microenvironment (the “soil”)^[5]. This theory was not immediately accepted, but only after a century, CTCs were recognized for their relevant role in driving the metastasization^[6]. CTCs, shed actively or passively in the bloodstream, can be found as single cells or aggregated in clusters, with clusters appearing to show up to 50-fold increased metastatic potential compared to single CTCs^[7,8]. The number of CTCs detected through the antigen-dependent CellSearch® system shows a prognostic value for metastatic breast, colon, and prostate cancers^[9-12]. CTCs counts ranging from 0 up to 4 CTCs in 7.5 mL of blood are indicative of a favorable prognosis, while a cut-off of 5 CTCs in 7.5 mL of whole blood indicates an unfavorable prognosis for both metastatic breast and metastatic prostate cancers, while in the case of metastatic colon cancer a cut-off of 3 CTCs suggests poor prognosis^[9-11]. Currently, CTC enumeration through CellSearch® for these three metastatic cancer settings is the only clinical application for CTCs^[13].

Unfortunately, since CTCs isolation through the CellSearch® platform relies on the expression of the epithelial cell adhesion molecule (EpCAM), which is normally found on the surface of cells of epithelial origin, there may be problems related to CTCs discrimination and detectability because CTCs are actually capable of downregulating epithelial characteristics in favor of a mesenchymal-like phenotype^[7,14,15]. Morphological and genetic changes determining this phenotypical switch can be identified in the activation of a biological program termed epithelial-mesenchymal transition^[7,16]. The acquisition of a mesenchymal-like phenotype strongly enhances the migratory and invasive capability of tumor cells, therefore the metastatic competence of these cells is incredibly increased^[16]. Moreover, this phenotypical plasticity is highly associated with stemness properties as well as drug resistance, and it is mainly responsible for the impossibility of CellSearch® to detect and isolate CTCs^[7,14-16].

To overcome this limitation, several alternative devices based on CTCs physical or functional characteristics have been developed over the years^[7]. However, the use of these methods is limited to research purposes and

currently does not find any applications in clinical practice.

A major issue to consider when studying CTCs is their rarity in blood circulation^[3,6,17]. The scarce formation of CTCs in the body together with their variability in different tumor types represent hard challenges in CTC analysis^[3,6,17]. In this context, it is particularly clear the potential usefulness of CTC cultures^[17]. *Ex vivo* expansions of CTCs can possibly enable to obtain a conspicuous number of circulating tumor cells and consequently to study tumors characteristics not only present in the primary site, but also defining the properties of cells able to survive in the blood circulation as well as to form distant metastases and eventually understanding the changes occurring between the first stages of the tumor and the advanced ones, thus implementing the use of liquid biopsies^[18]. This would be strongly important, for example, in elaborating new therapeutic strategies for cancer patients and concurrently overcoming the problems related to the onset of resistance phenomena^[3,19-23]. Despite the huge interest in CTC cultures, only a few groups succeeded in establishing CTC cultures, thus confirming the enormous difficulties that still make this practice extremely challenging today^[12].

CTC BIOLOGY

CTCs have a crucial role in tumor progression, taking part in the intermediate stage of the process known as metastatic cascade^[24]. Indeed, the metastatic evolution of cancer is a sum of several events, starting with tumor cells dissemination from the primary site of the neoplastic mass (or alternatively from an already formed metastatic lesion), followed by a phase of invasion directly into the blood vessels or indirectly passing through the lymphatic circulation, ultimately concluding with the colonization of a distant organ and the new tumor formation^[25,26].

CTCs intravasation can occur both through active and passive shedding^[26]. Cell-intrinsic features, microenvironmental characteristics, and vascular structure could be involved in the generation of CTCs^[26]. The activation of the epithelial-mesenchymal transition program, guided by a group of different transcriptional factors (e.g., Snail, Slug, Twist, and Zeb1), leads tumor cells to lose cell polarity, acquire the capability to degrade components of the extracellular matrix, and downregulate such epithelial characteristics like EpCAM and E-cadherin surface proteins (extremely important for cell-cell adhesion) in favor of mesenchymal-like features, together with the invadopodia formation regulated by the N-WASP protein, concur to the active release of cancer cells in the bloodstream^[25-27]. The presence of a leaky vascular structure, highly associated with tumor growth, can contribute to the generation of CTCs^[26]. The chronic activation of angiogenesis is notably one of the hallmarks of cancer^[28]. The dysregulation of proangiogenic signals, like the fibroblast growth factor (FGF) and the vascular endothelial growth factor (VEGF), promotes the formation of aberrant vessels, thus facilitating both the passive shedding of cancer cells and the active intravasation^[26,28]. Lastly, the tumoral microenvironment plays a key role in inducing the formation of CTCs^[26]. Interestingly, it has been reported that tumor-associated macrophages, expressing the tyrosine kinase with immunoglobulin-like loops and epidermal growth factor homology domains-2 (Tie-2), are capable of producing VEGF, therefore contributing to the increase of vascular permeability and ultimately to tumor cells intravasation^[29].

Once in circulation, it is possible to find CTCs both as individual cells and clusters of 2 to 50 cells^[26]. Several studies regarding CTC clusters detection, their characteristics and functional role have been published during the last decade. Particularly interesting is the work of Aceto *et al.*^[30] demonstrating that CTC clusters derive from oligoclonal groups of cells arising from a single tumor, excluding cluster formation by coalescence of single CTCs in the bloodstream. This study ulteriorly reported the half-life of CTC clusters, ranging from 6 to 10 min, thus considerably shorter compared to single CTCs (estimated to be 25 to

30 min)^[30]. The reduced half-life of CTC clusters, together with the ability to extravasate faster than single CTCs and the enhanced metastatic competency (partly associated with resistance to apoptosis), support their survival and outgrowth^[30].

In 1975, Butler and Gullino^[31] quantified the rate of tumor cells shedding in the bloodstream using a rat model. This study showed that tumors release millions of cancer cells in the blood circulation per 24 h/g of tissue^[31]. Despite the huge amount of tumor cells shed each day, patients commonly develop only few metastases, thus demonstrating the metastatic process as highly inefficient^[32]. Indeed, the cell viability in the blood is compromised by several factors, including shear stress, *anoikis*, the deficit of growth factors, and immune surveillance^[32,33]. The combination of such aspects results in a tremendously limited number of CTCs, commonly 1 to 10 CTCs per mL of blood^[33,34].

Although many factors concur in reducing the survival of CTCs in the circulation, important evidence indicates various blood constituents, including platelets, neutrophils, macrophages, myeloid-derived suppressor cells (MDSCs), or cancer-associated fibroblasts to tightly interact with CTC preserving them from physical damage and helping them in evading the immune system^[35]. Platelets are actively involved in CTCs' protection during their transit into the bloodstream in many ways, for example, defending them from mechanical stress, as well as cancer-associated fibroblasts, and inducing resistance from *anoikis*, which is regulated by the YAP pathway, determining RhoA-(myosin phosphatase targeting subunit 1) and MYPT1-protein phosphatase (PP1)-mediated Yes-associated protein 1 (YAP1) dephosphorylation and nuclear translocation^[35,36]. Most importantly, platelets can recruit either neutrophils and macrophages by the release of chemokines, like CXCL5 or CXCL7^[37]. Together with neutrophils, platelets can shield tumor cells from other immune cells attacks, thus helping CTCs in immune escaping^[35,37]. Similarly, CTC-MDSC clusters seem to be capable of evading T cell immune response^[35]. Moreover, interactions with blood cells can significantly enhance the ability of those CTCs to invade distant sites. It has been reported that platelets can release transforming growth factor β (TGF β), known to be involved in the activation of the epithelial-mesenchymal transition program, thus incrementing the invasion potential of CTCs, and other mediators, like histamine, serotonin, and eicosanoid metabolites among others, determining the modification of blood vessel permeability^[37-39]. On the other hand, cancer cells releasing colony-stimulating factor 1 can activate macrophages, which, in turn, secrete epidermal growth factor, therefore inducing tumor cell migration^[40].

Complex interactions with blood constituents combined with the expression of specific genetic signatures, which seem to be associated with the ability of CTCs to metastasize (e.g., in a study by Zhang *et al.*^[41] breast cancer CTCs expressing the Her2+/EGFR+/HPSE+/Notch1+ genetic signature demonstrated a tendency to metastasize in the brain), allow an extremely small fraction of cancer cells in the bloodstream to complete the metastatic cascade, thus colonizing distant tissues and promoting the generation of new tumor lesions.

Hence, it is clear that CTCs with metastatic competence are definitely rare events, delineating the metastatic cascade as a globally inefficacious process. Furthermore, although it is possible to count a large number of works elucidating the main characteristics of CTCs, there are lots of questions yet unraveled. Futures studies, providing a deeper knowledge of the biology of these circulating cells, are needed to consolidate the clinical value and the use of CTCs, particularly in the field of precision medicine.

CTC CULTURES: A STRENUOUS CHALLENGE

Several strategies are currently available for CTCs isolation and subsequent culturing. The enrichment is a crucial step when it comes to isolating viable CTCs from the rest of the blood constituents, such as platelets, red blood cells and white blood cells, allowing CTCs concentration and thus facilitating the detection

process^[12,17]. It is possible to perform the enrichment step through three different types of technologies: protein expression-based, physical property-based and function-based technologies^[12,17] [Figure 1].

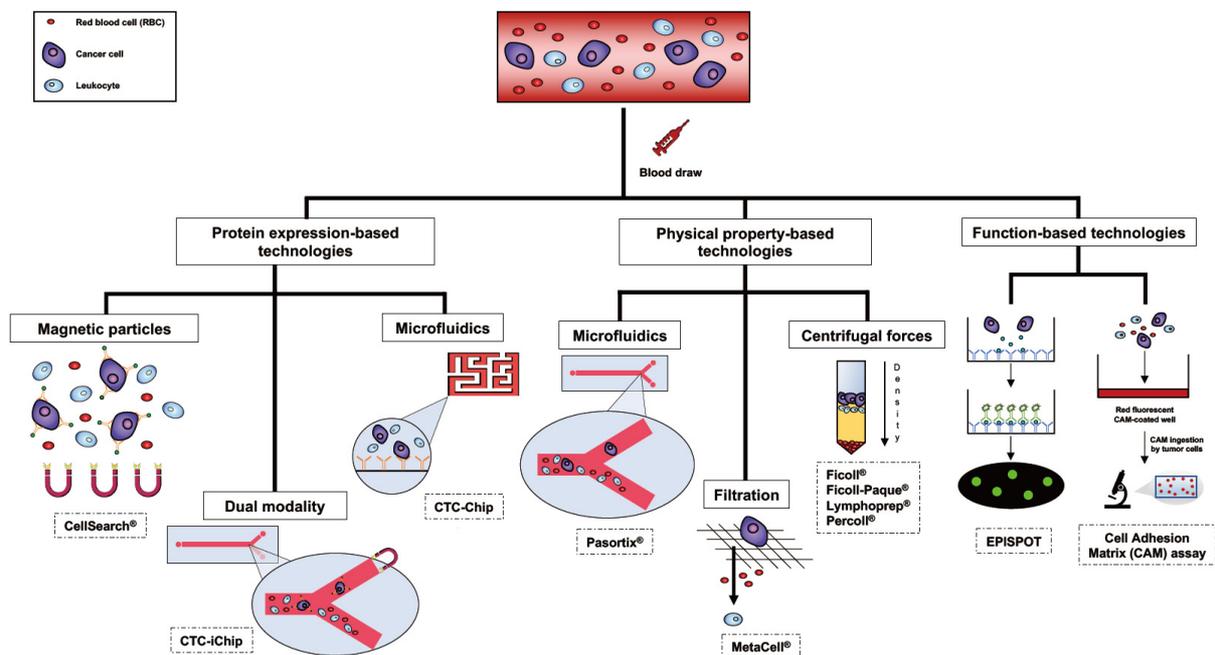

In the first case, the enrichment feasibility is due to the expression or the lack of the expression of specific proteins on the surface of CTCs. In other terms, CTC isolation relies on the presence of certain positive or negative selection markers^[12,17]. EpCAM is one of the most frequently used surface proteins for positive enrichment, while surface antigens, like CD45, serve to guarantee the depletion of leukocytes from the blood sample by negative selection^[12,17]. Among the positive selection-based techniques, immune-magnetic separation, flow cytometry and immuno-affinity based microfluidic platforms, like the CTC-iChip, must be mentioned^[12]. The drawback of these methods is strictly related to the possible loss of CTCs during the isolation, due to the lack of expression of the antigens selected for the positive enrichment^[12,17]. To overcome this problem, CTCs can alternatively be separated by negative selection. RosetteSep[®] antibody cocktail, for example, is an available product currently used to enrich CTCs through tetrameric complexes of antibodies that target the unwanted cells in the blood sample, allowing their removal and eventually CTC purification^[12]. These tetrameric antibody complexes recognize several antigens, including CD2, CD16, CD19, CD36, CD38, CD45, CD66b, and glycophorin A on red blood cells and leukocytes^[42]. After centrifugation using a density gradient medium, purified tumor cells can be found at the interface between the plasma and the medium^[42].

Since CTCs are supposed to be larger and less deformable than other blood cells (even though recent studies showed the existence of small CTCs potentially implicated in metastasis progression) and have different relative densities compared to red blood cells and white blood cells^[43], separation based on the physical properties play a leading role in the field of CTC enrichment^[12,17]. Indeed, it has been generally reported that CTCs exhibit an average size of 30 μm , bigger than red blood cells (6-8 μm) and white blood cells (10-15 μm)^[44,45]. Thus, several size-based platforms have been developed to isolate CTCs, such as MetaCell[®], as well as different microfluidic devices, like the Parsortix[®]^[12]. While MetaCell[®] enables CTC enrichment through an 8 μm -pore polycarbonate membrane, Parsortix[®] is a microchip-based isolation technique^[46-50]. Both methods give the possibility to isolate viable CTCs^[12], with MetaCell[®] also being frequently used to establish short-term CTC cultures^[46-50]. Moreover, in 1959, Seal, observing that red blood cells and white blood cells have higher specific gravities (1.092 and 1.065, respectively) compared to cancer cells (1.056), exploited these differences to separate them using one of the first density-based techniques involving silicone floatation^[51]. To date, it is possible to count on different density gradient media, such as Ficoll[®], a synthetic polymer formed by copolymerization of sucrose and epichlorohydrin^[12], Ficoll-Paque[®] and Lymphoprep[®], both composed of polysaccharides and diatrizoate^[52], and Percoll[®], consisting in a colloidal silica particle suspension^[45]. All these media basically allow the separation of CTCs from blood cells through centrifugation. To optimize this type of CTC enrichment, density gradient media are frequently used with other methods, like the aforementioned RosetteSep[®] antibody cocktail^[53].

Eventually, another opportunity to enrich viable CTCs is offered by the isolation of tumor cells based on their functional properties^[12,17]. Almost ten years ago, the development of a method allowing CTCs enrichment by their invasion ability, known as collagen adhesion matrix assay, represented the first example of this methodological category^[17]. Essentially, this assay is based on the singular propension of tumor cells to disrupt and ingest collagen adhesion matrix fragments, providing information about cancer cells invasiveness^[54]. On the other hand, the detection of proteins secreted, released or shed by viable cancer cells, is the core of the EPithelial ImmunoSPOT (EPISPOT) assay^[55]. These types of techniques enable *in vitro* CTC expansions since they well preserve cell viability^[12,17] [Table 1].

Table 1. Examples of strategies for viable circulating tumor cell (CTC) isolation

Type of technology	System	Method	Type of culture	Ref.
Protein expression-based technologies	RosetteSep®	Antibody cocktail for negative selection	Short-term Long-term	Guo <i>et al.</i> ^[12]
	CTC-iChip	Micro fluidic capture platform with two immune magnetic sorting modes to isolate CTCs	Long-term	Yu <i>et al.</i> ^[19]
Physical property-based technologies	Ficoll® Ficoll-Paque® Lymphoprep® Percoll®	Density gradient media that allow the separation of circulating tumor cells from blood cells through centrifugation	/	Guo <i>et al.</i> ^[12] Li <i>et al.</i> ^[45] Rosado <i>et al.</i> ^[52]
	MetaCell®	8 µm-pore polycarbonate membrane-based technique.	Short-term	Kolostova K. <i>et al.</i> ^[46]
	Pasortix®	Cell size and deformability microchips isolation based technique	/	Guo <i>et al.</i> ^[12]
Function-based technologies	Collagen adhesion matrix assay (CAM)	Method based on tumor cells' ability to attach and ingest collagen adhesion matrix	/	Guo <i>et al.</i> ^[12]
	EPithelial ImmunoSPOT assay (EPISPOT)	Detection of proteins secreted or released by viable cancer cell	Short-term Long-term	Guo <i>et al.</i> ^[12] Cayrefourcq <i>et al.</i> ^[62]

**Figure 1.** Schematic examples of the most commonly used technologies for circulating tumor cell (CTC) enrichment, detection, and isolation.

Despite the numerous methods currently available for CTCs enrichment and therefore the resulting complexity in selecting a more suitable technique to enrich viable CTCs for future cultures, the choice of the culturing conditions is probably the hardest part of the *in vivo* expansion process. In this context, the critical challenge is related to the limited knowledge we have about the biology of the CTCs^[12] and, most of all, the prerogative of CTCs to show a high rate of heterogeneity^[14] that overcomplicate the adoption of certain culturing options and is consequently decisive in succeeding or failing the *ex vivo* CTC propagation^[12]. According to the scientific literature, it is possible to count on a discrete number of studies reporting examples of CTCs *in vitro* cultivations. In 2013, Zhang *et al.*^[41] reported for the first time an *ex vivo* expansion of CTCs for breast cancer, also demonstrating those CTCs to have metastasis initiating properties

in the brain when expressing a specific genetic signature (the aforementioned Her2+/EGFR+/HPSE+/Notch1+). For this study, CTC cultures were monitored over 28 days, therefore it was not possible to establish long-term cultures^[41]. Comparable cultures of circulating cancer cells were obtained from patients with mesothelioma^[56], lung^[57], esophageal^[58], bladder^[59], and head and neck cancers^[60]. In all these cases, CTCs were efficiently maintained in culture for a short period (in most cases, 14 days, with rare exceptions, which, however, did not exceed 50 days of cultivation)^[56-60]. Only a few groups successfully obtained long-term CTC cultures, including Yu *et al.*^[19] and Gao *et al.*^[61] in 2014, respectively for breast and prostate cancers. Additionally, Cayrefourcq *et al.*^[62] in 2015, Grillet *et al.*^[21] in 2017, and Soler *et al.*^[63] in 2018 were able to establish durable CTCs cultures and permanent CTC lines from colorectal cancer patients^[62,63]. Brungs *et al.*^[22] obtained long-term CTC cultures in 2020 for metastatic gastroesophageal cancer, while Hamilton *et al.*^[20] in 2015 and Lee *et al.*^[23] in 2020 obtained successful CTC cultures from small cell lung cancer (SCLC) patients.

The two main strategies adopted to establish *in vitro* circulating cancer cell cultures are represented by two-dimensional (2D) and three-dimensional (3D) cultures^[12]. Adherent conditions are the most common choice, especially for short-term cultures, because it is clearly easier to set up a 2D culture, in terms of time, complexity, and costs^[12,64]. However, even if there are studies reporting data of successful short-term and long-term CTC cultures in both 2D and 3D systems, it has been observed that a non-adherent culturing condition is preferable when the aim is to establish long-term cultures, because following a few cell divisions, CTCs cultured according to a monolayer adherent approach tend to senesce^[19]. Besides this, when cultured in 2D conditions, CTCs actually lose essential morphological characteristics as well as cell-cell and spatial interactions, thus several cellular functions, like proliferation or differentiation, are definitively compromised^[64]. Moreover, the adherent culture condition guarantees unlimited access to nutrients and oxygen, in contrast with the actual *in vivo* situation^[64]. Different studies reported the importance of hypoxic conditions in promoting CTCs growth^[19,62], while other publications showed the capability of CTCs to grow even under a non-hypoxic context^[61].

Although recreating the exact characteristics of a tumor microenvironment is almost impossible, there have been many successful attempts in culturing CTCs as well as mimicking the *in vivo* tumor growth, for example, co-cultures of CTCs from early lung cancer patients together with tumor-associated fibroblasts, collagen I, and Matrigel^[57].

Alternatively, *ex vivo* expansions of CTCs can be implemented by direct inoculation of CTCs in immunodeficient mice. Major brilliant examples of CTC-derived explants were published during the last two decades, starting with the work of Pretlow *et al.*^[65] in 2000, where the authors reported the capacity of cells in peripheral blood of prostate and colorectal cancer patients to form metastasis. In 2013, Baccelli *et al.*^[66] demonstrated the existence of a population of metastasis-initiating cells among breast cancer CTCs that express EPCAM, CD44, CD47, and MET, thus recapitulating the phenotype of patient metastases. Lastly, Hodgkinson *et al.*^[67] elegantly described that CTCs isolated from SCLC patients, either showing sensitivity or resistance to chemotherapy, then inoculated into immune-compromised mice were tumorigenic and mirrored the donor patient's response to treatments. It is important to point out that the feasibility of these *in vivo* assays is associated with the presence of very high concentrations of CTCs in the blood samples (e.g., > 1000 in 7.5 mL of peripheral blood in the case of breast cancer patients), therefore reducing the possibility to successfully realize CTC-derived explants^[62].

However, *ex vivo* propagations of cancer cells are still extremely delicate processes, therefore more and more studies are needed to optimize all the steps involved in this practice.

CTC MOLECULAR CHARACTERIZATION: DIVING INTO PRECISION MEDICINE

Cancer is definitely not a static disease, therefore spatial and temporal tumor dynamics must be considered when analyzing the neoplastic evolution to guide patients towards the best clinical outcome possible^[68]. Since treatment decisions solely rely on primary tumor sampling, there clearly could be a massive loss of information about tumor characteristics that would be otherwise important in the therapeutic evaluation process, especially considering that treatments are actually directed against metastases rather than primary tumors^[68,69]. Indeed, the selective pressure deriving from both the metastatic process and microenvironmental features can induce the formation of subclones presenting properties that highly differ from the primary tumor^[7]. Thus, the analysis of metastatic cells is crucial for clinical practice purposes^[7]. However, in several cases (e.g., lung or brain metastases), tissue sampling is certainly not feasible^[7]. Given that metastatic cells can be constitutive of the pool of CTCs, liquid biopsy can definitely provide a valid alternative to this invasive practice^[69].

The molecular characterization of CTCs might offer details about the changes occurring during the metastasization process and possibly elucidate the reasons for resistance to therapy as well as highlight potential therapeutic targets^[69]. In breast cancer, for example, human epidermal growth factor receptor 2 (HER2) positive CTCs were found in patients with HER2-negative primary tumors suggesting the proper therapeutic regimen based on the HER2-CTC status^[70-72]. Comparably, patients with estrogen receptor (ER) positive primary tumors were found to be characterized by the presence of ER-negative CTCs^[73]. This may predict the onset of resistance to endocrine treatment in the subpopulation of metastatic breast cancer patients who do not benefit from this therapy^[7,73]. Other analyses of CTCs at the single-cell level showed to be informative of the estrogen receptor 1 (*ESR1*) gene mutations, thus allowing the identification of genes involved in endocrine treatment resistance^[74]. In metastatic castration-resistant prostate cancer (mCRPC), an androgen-dependent type of prostate cancer, the cause of a failing response to androgen receptor (AR) inhibitors, enzalutamide and abiraterone, can be identified in the presence of androgen-receptor splice variants^[75]. Androgen-receptor splice variant 7 (AR-V7) was actually found to be expressed on the surface of CTCs isolated from mCRPC patients, thus confirming the association between the detection of AR-V7 in CTCs and the exerted resistance to AR inhibitors in mCRPC patients^[75]. In a study focused on colorectal cancer, genomic analyses conducted on individual CTCs showed the presence of both Kirsten rat sarcoma viral oncogene homolog (KRAS) mutated and KRAS wild-type CTCs in the same patient^[76]. Since the expression of KRAS mutations hinder the use of anti-epidermal growth factor receptor (EGFR) treatments, the presence of CTCs harboring KRAS mutations in wild-type colon cancers might explain the therapeutic EGFR inhibition failure, thus being indicative of treatment resistance^[7,77,78]. Lastly, programmed cell death ligand 1 (PD-L1) expression on CTCs in metastatic lung cancer seems to be predictive of a good response to anti-PD-1 immunotherapy, so it could potentially become a helpful biomarker when evaluating the response to immunotherapies in the context of precision medicine^[79].

IN VITRO CTC CULTURES AS A MODEL TO DECIPHER DRUG SENSITIVITY

Considering the low concentration of CTCs in the bloodstream as well as their high rates of heterogeneity and poor survival, not surprisingly, there are still a lot of open questions about CTC biology, including the timing of their release in the blood, the extravasation and intravasation processes, their ability to survive once in the systemic circulation and which is the genetical relation with the original tumor. Moreover, despite their identification and study in different neoplastic diseases, the aforementioned issues (first and foremost, the poor number of CTCs released in the blood) represent remarkable obstacles to CTCs characterization at genomic, transcriptomic, and functional levels. Therefore, *in vitro* culturing of CTCs can offer the opportunity to overcome these limitations and better elucidate the molecular features of these cells.

Unfortunately, CTCs are definitely not easy to expand *in vitro*, especially when the purpose is to establish long-term CTCs cultures^[8,12,80,81]. However, for those groups who succeeded in culturing CTCs, it was possible to observe that these cell lines they obtained show phenotypical characteristics that partially match those of cells present in tumor tissues from donor patients, but also express molecular features specifically related to CTCs^[19,41,62,82], exhibiting metastatic competency^[66,67] as well as stemness properties including an efficient DNA repair system and an enhanced metabolic rate^[82]. Furthermore, since being representative of the tumor molecular landscape, CTC cultures can be useful in predicting drug sensitivity as well as treatment resistance and eventually became a precious tool in drug screening projects^[83] [Figure 2].

In a ground-breaking study, dated 2014, Yu *et al.*^[19] isolated viable CTCs, using the CTC-iChip technology, and successfully established long-term oligoclonal CTC cultures from six ER-positive breast cancer patients and sustained these cultures for over six months. The analysis of these cell cultures allows exploration of the unique genetic context of single tumors, thus revealing the presence of preexisting mutations in phosphatidylinositol-4,5-bisphosphate 3-kinase (PIK3CA) gene and the acquisition of new tumor-derived mutations in *ESR1* gene, *PIK3CA* gene, and fibroblast growth factor receptor gene 2 (*FGFR2*), among others^[19]. Furthermore, the CTC lines obtained were used for drug sensitivity testing, they resulted concordant with patients' clinical histories, and they were also useful for the identification of new potential therapeutic targets^[19]. More specifically, one of these cell lines, displaying a high allele frequency of mutant *ERS1*, was actually not sensitive to selective ER modulators and the selective ER degrader fulvestrant^[19]. However, since ER strongly depends on the activity of HSP90 protein and the stabilization of mutated receptors relies on this chaperone, the use of HSP90 inhibitor in this *ERS1* mutated cell line was found to be cytotoxic alone and in combination with both raloxifene and fulvestrant^[19]. In another CTC line, harboring both *PIK3CA* and *FGFR2* gene mutations, the combined inhibition of these two targets (not previously tested in clinical settings) showed to successfully enhance the activity of single drugs^[19] [Table 2].

Hamilton *et al.*^[84], who firstly obtained stable CTCs cultures from SCLC patients in 2015, later in the same year conducted a drug sensitivity study using two CTCs lines, BHGc7 and BHGc10, that were established from peripheral blood of SCLC patients with the extended disease^[20]. Since CTCs counts are monitored for prognostic purposes and to evaluate response to cytotoxic therapy, they treated SCLC BHGc7 and BHGc10 CTC cell lines with common second-line therapies for SCLC (cisplatin, etoposide, topotecan, and epirubicin) *in vitro* and compared the chemosensitivities of these cell lines to drug responsiveness of several permanent SCLC cell lines derived from lung and distinct metastases^[20]. The cytotoxicity assays showed that BHGc10 was way more resistant than BHGc7 to cisplatin, while the other SCLC cell lines exerted variable responses to this chemotherapeutic agent^[20]. Both BHGc7 and BHGc10 were sensitive to etoposide as well as two SCLC cell lines^[20]. The remaining SCLC cell lines displayed elevated IC₅₀ values instead^[20]. Either BHGc7 and BHGc10 were found to be highly sensitive when treated with topotecan or epirubicin^[20]. Compared to the CTC cell lines, SCLC cell lines exhibited different susceptibilities to epirubicin and topotecan, showing a significant resistance to epirubicin, while milder to topotecan (with the exceptions of topotecan-sensitive SCLC26A cell line and, conversely, NCI-H526 distinctly topotecan-resistant)^[20]. The heterogeneous responses displayed by CTCs in comparison to primary and metastatic SCLC cells not only highlight the intrinsic difference in terms of drug sensitivities among these cancer cells, but also clearly indicate that the variation in CTCs number can possibly not mirror the response of primary and metastatic SCLC lesions to chemotherapeutic treatment^[20] [Table 2].

Later in 2017, Grillet *et al.*^[21] established three distinct CTC cell lines by isolating and expanding CTCs from chemotherapy-naïve patients with metastatic colorectal cancer. These cell lines, cultured for several months, showed up to have strong cancer stem cell phenotypical traits, with self-renewal and multilineage

Table 2. Patients involved, CTC lines obtained and drug sensitivities

Authors	Type of tumor	n patients involved	n of CTC cell lines obtained	CTC lines name	Molecular signatures	Sensitivity
Yu <i>et al.</i> ^[19]	Metastatic luminal subtype breast cancers	36	6	BRx-33	<i>ESR1, NUMA1</i>	/
				BRx-07	<i>TP53, PIK3CA, FGFR2, CDH1, APC, DGKQ, MAML2</i>	Paclitaxel*, fulvestrant* and doxorubicin* <i>FGFR2</i> inhibitor AZD4547 <i>PIK3CA</i> inhibitors (BYL719 and PD173074) Moderately responsive to the <i>FGFR1</i> inhibitor PD173074
				BRx-68	<i>TP53, ESR1, PIK3CA, MSN</i>	Capecitabine*, fulvestrant* <i>HSP90</i> inhibitor STA9090 alone and in combination with both raloxifene and fulvestrant
				BRx-50	<i>ESR1, IKZF1, BRCA2</i>	Capecitabine*, olaparib*
				BRx-42	<i>PIK3CA, KRAS, IGF1R</i>	/
				BRx-61	<i>TP53</i>	/
Hamilton <i>et al.</i> ^[20]	Small cell lung cancer	2	2	BHGc7	/	Cisplatin, etoposide, topotecan and epirubicin
				BHGc10	/	Etoposide, topotecan and epirubicin Mild resistance to cisplatin
Grillet <i>et al.</i> ^[21]	Metastatic colorectal cancer	/	3	CTC41	<i>BRAF V600E</i> , CSC-related genes (<i>ALDH1A1, CD133, CD26, CD44v6</i>)	Resistant to FIRI (regimen inspired by standard-of-care chemotherapy combinations 5-fluorouracil and SN-38, the active metabolite of irinotecan)
				CTC44		
				CTC45		
Brungs <i>et al.</i> ^[22]	Metastatic gastroesophageal cancer	20	1	UWG01CTC	Genes for neuroendocrine markers (<i>CNTFR, PAX-5, NGF</i>), <i>DLL-3</i>	Synergism at all concentrations of carboplatin and etoposide Carboplatin increase radiosensitivity
				41	1	UWG02CTC
Lee <i>et al.</i> ^[23]	Small cell lung cancer	22	18	/	<i>TTF-1</i> , synaptophysin, <i>PD-L1</i> , variable expression of EMT markers (E-cadherin, N-cadherin)	CTC lines from patients 14 and 20 showed high sensitivity to standard treatment for SCLC patients (cisplatin/etoposide), whereas these drugs exhibited no cytotoxicity in the CTC line from patient 15, reflecting patient lack of response to this therapy

*Sensitivity to these drugs was consistent with clinical history of the patients. CTC: Circulating tumor cells; EMT: epithelial-mesenchymal transition; FIRI: fluorouracil and irinotecan; FGFR 1 and 2: fibroblast growth factor receptor 1 and 2; HSP90: heat shock protein 90; PIK3CA: phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit alpha.

differentiation properties as well as metastatic potential and a robust expression of typical cancer stem cell markers, ranging from aldehyde dehydrogenase (ALDH1A1) and CD133 to CD26 and CD144V6^[21]. Since being genetically heterogeneous is another prerogative of these CTC lines, it has been demonstrated

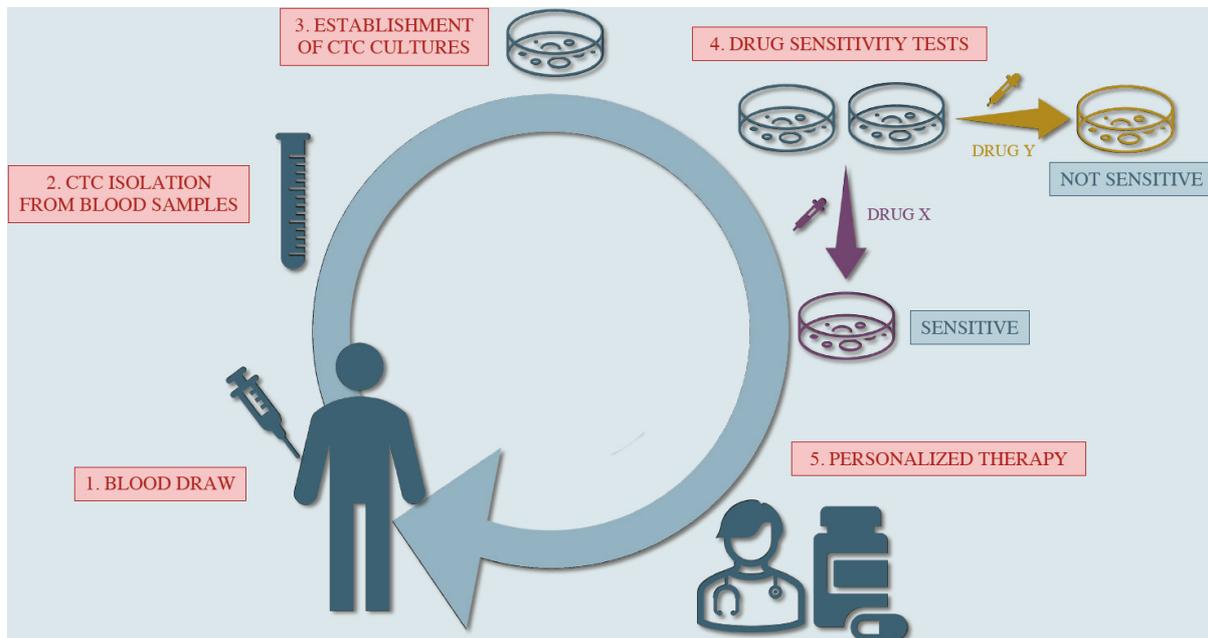

Figure 2. Potential use of circulating tumor cell (CTC) cultures as a predictor for drug sensitivity/resistance, guiding to a more personalized type of therapy.

that they surprisingly harbor the BRAF V600E mutation, although the primary tumors as well as metastatic tissues carried KRAS mutations^[21]. Additional analyses provided data highlighting the differential upregulation of metabolic activity in CTC lines compared to primary tumor-derived cells, with a special regard for the enhanced drug/xenobiotics metabolism, thus suggesting these cells to be strongly resistant to standard cytotoxic compounds^[21]. These findings were confirmed by following drug sensitivity tests, using a chemotherapy regimen (FIRI: 5-fluorouracil and the active metabolite of irinotecan) that basically mimics the standard treatment combinations for colorectal cancer patients^[21]. CTC lines demonstrated more resistance to this therapeutic combination than cells derived from both primary and metastatic tumors^[21]. Lastly, evaluating the multikinase inhibitor regorafenib and the BRAF V600 inhibitor vemurafenib activity on these cell lines, a variable sensitivity to regorafenib was exerted and specifically one of these CTC lines emerged to be responsive to vemurafenib, although this BRAF V600 inhibitor demonstrated a scarce efficacy in BRAF-mutated colorectal cancer patients^[21] [Table 2].

More recently, a study by Brungs *et al.*^[22] reported the establishment of long-term CTC cultures (maintained for over 12 months), with CTCs isolated from metastatic gastroesophageal cancer patients. Profiling the two CTC lines obtained (UWG01CTC and UWG02CTC), data showed these cell lines to display distinct genotypic and phenotypic features, basically reflecting the characteristics of the originating tumor^[22]. As the first CTC line (UWG01CTC) was obtained from a patient whose gastrointestinal cancer rapidly developed into metastatic disease, with metastasis histopathology showing high-grade neuroendocrine carcinoma, UWG01CTC exhibited high levels of neuroendocrine markers (i.e., synaptophysin, CD56, and chromogranin A) and strongly expressed genes encoding for neuroendocrine markers such as the ciliary neurotrophic factor receptor (CNTFR), the B-cell-specific activator protein (PAX-5), and the nerve growth factor receptor (NGFR), although this line was negative when stained for epithelial (e.g., EpCAM) or stem cell markers^[22]. On the other hand, the patient whose CTC sampling generated the UWG02CTC line was affected by a gastric adenocarcinoma, thus robustly expressing cytokeratins (CK), in particular CK-20, as well as EpCAM and E-cadherin proteins, but also gastric cancer stem cell markers CD44, ALDH1, and

CD133, and demonstrating stem cell pathways, like NOTCH and WNT, to be upregulated^[22]. Considering the differences these two CTC lines exhibited, drug and radiosensitivity were evaluated^[22]. Indeed, UWG01CTC and UWG02CTC responded differently to standard chemotherapeutics used for these cancers^[22]. Moreover, harboring distinct molecular landscapes, with UWG02CTC showing higher expression of EGFR, FGFR2, receptor tyrosine-protein kinase erbB-2 (ERBB2), and Janus kinase/signal transducer and activator of transcription (JAK/STAT) pathway genes compared to UWG01CTC, while UWG01CTC having marked expression of the *DLL3* gene, this study highlights potential druggable targets whose activity should be explored in order to define new personalized types of treatment^[22]. Finally, since UWG01CTC displayed lower expression of DNA damage response enzymes than UWG02CTC, it has also been noted that a synergistic effect of radiotherapy when combined with carboplatin for UWG01CTC line^[22] [Table 2].

Later in 2020, Lee *et al.*^[23] succeeded in expanding *ex vivo* CTCs from SCLC patients. For this study, a new system was developed to culture CTCs, involving the implementation of a biomimetic material called binary colloidal crystal^[23]. With the use of binary colloidal crystal, it was possible to build a suitable surface for CTCs expansion, and it was also found that CTC from SCLC formed spheroids, which were observed after 14 days and continued to grow, showing to be still viable after 40 days^[23]. During this period, drug sensitivity tests were performed on these CTC cultures to evaluate the response to standard first-line treatment of SCLC, which basically consists of a platinum doublet: cisplatin or carboplatin combined with etoposide^[23]. This work demonstrated that CTC cultures recapitulate their originating patients' outcomes, thus highlighting the possibility for expansions of CTCs to predict responses to therapy^[23]. Since PD-L1 expression has been detected through immunofluorescence-based analyses, this study also suggests exploring the efficacy of immune checkpoint blockade, which are emerging as a valid treatment for SCLC patients^[23] [Table 2].

CONCLUSIONS

Ex vivo expansions of CTCs clearly represent a potential tool to examine tumor characteristics, unraveling new biomarkers as well as possibly predicting drug sensitivity, eventually leading to optimized and personalized treatment strategies. However, the establishment of CTC lines is still tremendously challenging and currently not capable of informing clinical decisions.

One of the most important limiting factors is the timing of the process, which is not rapid enough to guide therapeutic choices for donor patients^[3,83]. Indeed, the establishment of CTC lines and their consequent stabilization generally require months to be obtained^[3,12]. In this context, several techniques are currently under investigation, such as innovative culture media or support surfaces capable of promoting rapid cell growth and survival^[3].

Secondly, since being an essential prerequisite to successfully yield cell lines from CTCs, high CTC counts (> 300 CTCs) constitute another important obstacle that restricts the use of these models in patients with the advanced-stage disease^[83]. Novel applications of diagnostic leukapheresis^[85] or *in vivo* CTC capture devices^[86,87], allowing the isolation of higher numbers of CTCs than conventional enrichment methods, are expected to be a solution for this impediment.

Furthermore, experimental studies suggested that < 0.01% of cancer cells are supposed to initiate metastasis^[88-90]. The low frequency of metastatic-inducing CTC among highly heterogeneous populations of tumor cells released in the circulation must be considered particularly when performing drug sensitivity or drug screening tests for clinical purposes^[32]. Indeed, as Hamilton *et al.*^[20] demonstrated, CTCs may not

reflect treatment responses of primary and metastatic lesions. Moreover, it is crucially important to assess whether the analyses conducted on a cell population that basically derives from few CTCs can be significantly representative of the entire tumor complexity^[3].

In conclusion, despite being extremely promising, the use of CTC lines, which will hopefully fulfill soon the great expectation of providing the exact information to offer the best therapeutic option possible to cancer patients, still requires further optimizations to allow translation into the clinic.

Abstract

Aim: Circular RNAs are widely and abnormally expressed in human cancer cells, and they participate in cancer progression. However, they have rarely been investigated in the immune evasion of non-small cell lung cancer (NSCLC). Here, we elucidated the function and molecular mechanism of hsa_circ_0020714 in promoting the resistance to anti-PD-1 immunotherapy of NSCLC.

Methods: The expression of hsa_circ_0020714 were examined by qRT-PCR. *In vivo* experiments were executed to investigate the biological function of hsa_circ_0020714 in the sensitivity of NSCLC to anti-PD-1 immunotherapy. The qRT-PCR, fluorescence *in situ* hybridization, RNA pulldown, RNA immunoprecipitation, and western blot were carried out to investigate the potential regulatory mechanisms of hsa_circ_0020714 in NSCLC immune evasion.

© The Author(s) 2022. **Open Access** This article is licensed under a Creative Commons Attribution 4.0 International License (<https://creativecommons.org/licenses/by/4.0/>), which permits unrestricted use, sharing, adaptation, distribution and reproduction in any medium or format, for any purpose, even commercially, as long as you give appropriate credit to the original author(s) and the source, provide a link to the Creative Commons license, and indicate if changes were made.

Results: The expression of hsa_circ_0020714 was upregulated in NSCLC tissues compared to the paired adjacent non-tumor tissues, and an increased expression of hsa_circ_0020714 was significantly associated with a bad prognosis and resistance to anti-PD-1 immunotherapy in patients with NSCLC. Mechanistically, hsa_circ_0020714 functions as an endogenous miR-30a-5p sponge to enhance SOX4 expression, thereby promoting immune evasion and anti-PD-1 resistance in NSCLC patients.

Conclusion: Hsa_circ_0020714 induces the immune evasion and resistance to anti-PD-1 immunotherapy of NSCLC via the miR-30a-5p/SOX4 axis, and may be an promising immunotherapeutic target in NSCLC.

Keywords: NSCLC, immune evasion, circRNAs, PD-1, immunotherapy resistance

INTRODUCTION

Advanced non-small cell lung cancer (NSCLC) with a negative driver gene has a high tendency for distance metastatic and resistance to chemotherapy^[1,2]. Recent evidence suggests a critical role for anti-programmed death-1 (anti-PD-1) immunotherapy in driver gene negative NSCLC. Although anti-PD-1 immunotherapy has improved the prognosis of patients with advanced NSCLC, a larger proportion of patients still did not respond to anti-PD-1 therapy due to primary or secondary resistance and failed to demonstrate clinically effective responses^[3,4]. Therefore, further investigation is necessary to clarify the molecular mechanisms involved in NSCLC immune evasion and develop new immunotherapeutic approaches for patients with NSCLC.

Circular RNAs (circRNAs) are recently a class of novel non-coding RNAs (ncRNAs) with circular configurations and have attracted much attention^[5,6]. With the rapid development of RNA sequencing (RNA-Seq) technology, circRNAs have been confirmed to be dysregulated frequently in most cancers, and to play critical regulatory roles in the process of tumorigenesis and progression^[7]. Several dysregulated circRNAs have been reported to be involved in NSCLC cell proliferation, invasion, migration, immune evasion, and chemotherapy resistance, for example circFGFR1^[8], circNDUFB2^[9], and circMET^[10]. SOX4 is a member of the SOX (Sry-related high-mobility group box) transcription factor family^[11]. The SOX4 gene is frequently amplified and overexpressed in most malignancy tumors. Evidence increasingly demonstrates that SOX4 act as an oncogene in several cancer progression^[12]. Bagati *et al.*^[13] reported that increased expression of SOX4 induced immune evasion and promoted resistance to anti-PD-1 immunotherapy in triple-negative breast cancer.

Here, we reported a novel cancer immune evasion-related circRNA hsa_circ_0020714, which is significantly upregulated in NSCLC tissues compared with nontumor adjacent tissues. And forced expression of hsa_circ_0020714 is associated with immune evasion of NSCLC and predicts a poor prognosis. Functionally, knockdown and overexpression experiments indicated that hsa_circ_0020714 regulates the sensitivity of NSCLC to anti-PD-1 immunotherapy. Moreover, hsa_circ_0020714 acts as a sponge for miR-30a-5p to upregulate SOX4 expression and consequently induces NSCLC immune evasion. This study reveals an innovative new insight into the underlying molecular mechanism of NSCLC immune evasion and sheds light on hsa_circ_0020714 as a promising sensitivity prediction biomarker and a potential therapeutic target for NSCLC immunotherapy.

METHODS

Cell culture

Human NSCLC cell lines (A549, HCC827, NCI-H1299, NCI-H1650, NCI-H226, and NCI-H460) and HEK-293T cells were purchased from Cell Bank of the Chinese Academy of Sciences (Shanghai, China).

These cells were routinely cultured in DMEM medium (HyClone, Logan City, USA) supplemented with 10% fetal bovine serum (Gibco, Carlsbad, USA) and 1% penicillin/streptomycin (100 IU/mL) at 37 °C in a humidified incubator with 5% CO₂.

Patients and tissues

We obtained NSCLC tissues and matched adjacent non-tumoral tissues from patients who underwent surgery at the Zhongshan Hospital of Fudan University and Second Affiliated Hospital of Nanchang University. The tissues from NSCLC patients were counterstained with hematoxylin and eosin and were confirmed independently by two independent pathologists. All patients or their guardians gave written informed consent for the use of their samples before collection. This study received approval from the Ethical Review Committee of the Zhongshan Hospital of Fudan University.

Total RNA extraction and quantitative real-time polymerase chain reaction detection

Total RNA extraction and quantitative real-time polymerase chain reaction (qRT-PCR) analysis were performed according to our previous studies^[8,14,15]. In brief, total RNA from NSCLC tissues, matched adjacent non-tumor tissues, and NSCLC cell lines were extracted using TRIzol (Invitrogen, USA) reagent and then reverse-transcribed into cDNA using a PrimeScript RT Reagent Kit (TaKaRa, Japan). Finally, qRT-PCR was carried out with SYBR Green Real-time PCR Master Mix (Yeasten, Shanghai, China) following the manufacturer's instructions.

Mice xenograft anti-PD-1 therapy study, western blot, circRNA immunoprecipitation, RNA pull-down, and dual luciferase reporter assays

Mice xenograft anti-PD-1 therapy study, western blot, circRNA immunoprecipitation (circRIP), RNA pull-down, and dual luciferase reporter assays were evaluated with SPSS software (19.0, SPSS, Inc., Chicago, IL) as described in our previously studies^[8,10,14]. Experimentation on *C57BL/6* mice were approved by the Animal Experimentation Ethics Committee of Zhongshan Hospital, Fudan University. And the antibody used in western blot and circRIP assays were listed as follows: Tubulin (Abcam, ab52623), AGO2 (Abcam, ab186733), and SOX4 (Abcam, ab70598).

Transfection of lentiviral vectors, plasmids, and miRNA mimics

Transfection of lentiviral vectors, plasmids, and miRNA mimics were evaluated with SPSS software (19.0, SPSS, Inc., Chicago, IL) as described in our previously studies^[10,14]. In brief, Hsa_circ_0020714 overexpression lentiviral vectors, miR-30a-5p mimics, or pLG3 plasmid containing the sequence of wild type/mutant hsa_circ_0020714/SOX4 mRNA 3'-UTR were constructed (Shanghai Genomeditech Co. Ltd., Shanghai, China). Transfectant cells were characterized by qRT-PCR or western blotting.

Statistical analysis

Statistical analysis was conducted using the SPSS software (19.0, SPSS, Inc., Chicago, IL) as described in our previously studies^[10,14]. $P < 0.05$ was considered statistically significant.

RESULTS

Hsa_circ_0020714 is highly expressed in NSCLC tissues and is correlated with poor prognosis

Previous studies have indicated that forced CD151 expression in NSCLC was correlated to poor prognosis^[16]. Importantly, CD151-derived circRNA circ_0020710 was significantly overexpressed in melanoma tissues and its upregulated expression induced melanoma immune evasion^[17]. Therefore, we speculated that the dysregulation of CD151-derived circRNAs may act as oncogenes in NSCLC cells. To explore CD151-derived circRNA expression in NSCLC tissues and matched adjacent nontumor tissues, we examined the CD151-derived circRNAs expression in four pairs of NSCLC tissues and matched adjacent

nontumor lung tissues by using qRT-PCR. The results indicated that hsa_circ_0020714 was upregulated in the NSCLC tissues [Figure 1A]. Next, we examined hsa_circ_0020714 expression in the NSCLC tissues and matched adjacent nontumor tissues and found that hsa_circ_0020714 was significantly increased in the NSCLC tissues (tumor/non-tumor ≥ 2) (74/120) [Figure 1B]. Furthermore, our results demonstrated that patients with upregulated hsa_circ_0020714 expression had a worse prognosis than those with lower levels of hsa_circ_0020714 [Figure 1C and D].

Higher levels of hsa_circ_0020714 expression is correlated with resistance to anti-PD-1 therapy in NSCLC patients

Increasingly, studies have reported the dysregulation of circRNAs execute a critical role in cancer immune evasion^[8,18]. Therefore, we explored whether forced hsa_circ_0020714 expression can decrease the curative effect of anti-PD-1 therapy (Keytruda). Then, we analyzed retrospective data from 42 NSCLC patients (29 cases of lung adenocarcinoma and 13 cases of lung squamous cell carcinoma) with relapse or distant metastasis receiving anti-PD-1 immunotherapy. After six therapy cycles, the efficacy was examined using enhanced computerized tomography and assessed based on iRECIST criterion. For 29 cases of lung adenocarcinoma, the results demonstrated that there were 4 patients with partial response, 14 patients with stable disease, and 11 patients with progressive disease. For 13 cases of lung squamous cell carcinoma, there were 1 patient with partial response, 5 patients with stable disease, and 7 patients with progressive disease. Next, hsa_circ_0020714 expression levels were evaluated via qRT-PCR, and the results demonstrated that the expression levels of hsa_circ_0020714 were higher in the progressive disease group compared with stable disease and partial response groups in both adenocarcinoma and squamous cell carcinoma panels [Figure 2A and B]. These results showed that hsa_circ_0020714 likely participates in the immune evasion and resistance to anti-PD-1 immunotherapy of NSCLC.

Hsa_circ_0020714 upregulates SOX4 expression sponging miR-30a-5p

Increasingly, studies have verified that circRNAs act as miRNA sponges. We therefore analyzed whether hsa_circ_0020714 has the ability to induce immune evasion by sponging certain miRNAs. Through StarBase v3.0 analysis, we found that hsa_circ_0020714 and SOX4 were predicated to be possible targets of miR-30a-5p [Figure 3A]. Importantly, it has been reported that forced SOX4 expression promoted immune evasion and resistance to anti-PD-1 immunotherapy in triple-negative breast cancer^[13]. Based on these results, we speculated that hsa_circ_0020714 promoted NSCLC immune evasion possibly via sponging miR-30a-5p to upregulate SOX4. To further determine the function of hsa_circ_0020714 in immune evasion, we detected hsa_circ_0020714 expression in seven human NSCLC cell lines [Figure 3B]. Next, RIP experiment with argonaute 2 (AGO2) antibody in A549 cells was performed. Our results indicated that hsa_circ_0020714, SOX4 mRNA, and miR-30a-5p, but not circANRIL (a circular RNA that confirmed does not bind to AGO2)^[19], were significantly enriched [Figure 3C]. Furthermore, we performed luciferase assays using miR-30a-5p mimics cotransfected with luciferase reporters (which contained a wild-type or miR-30a-5p-target mutant hsa_circ_0020714 sequence/SOX4 mRNA 3'-UTR) into HEK-293 T cells. Compared with the negative control mimics, miR-30a-5p significantly inhibited the luciferase reporter activity in the cells with the wild-type hsa_circ_0020714/SOX4 mRNA 3'-UTR sequence, but not affect the activity in the cells with the miR-30a-5p-target mutant circFGFR1/SOX4 mRNA 3'-UTR sequence [Figure 3D]. To determine whether hsa_circ_0020714 upregulates SOX4 expression via the miR-30a-5p, we established hsa_circ_0020714 or miR-30a-5p target sequence of mutant hsa_circ_0020714 NCI-H460 overexpression cell lines through lentiviral vectors [Figure 3E]. The mRNA and protein levels of SOX4 were significantly increased in NCI-H460 cells following transfection with hsa_circ_0020714, compared with the mock group and mutant hsa_circ_0020714 group [Figure 3F and G].

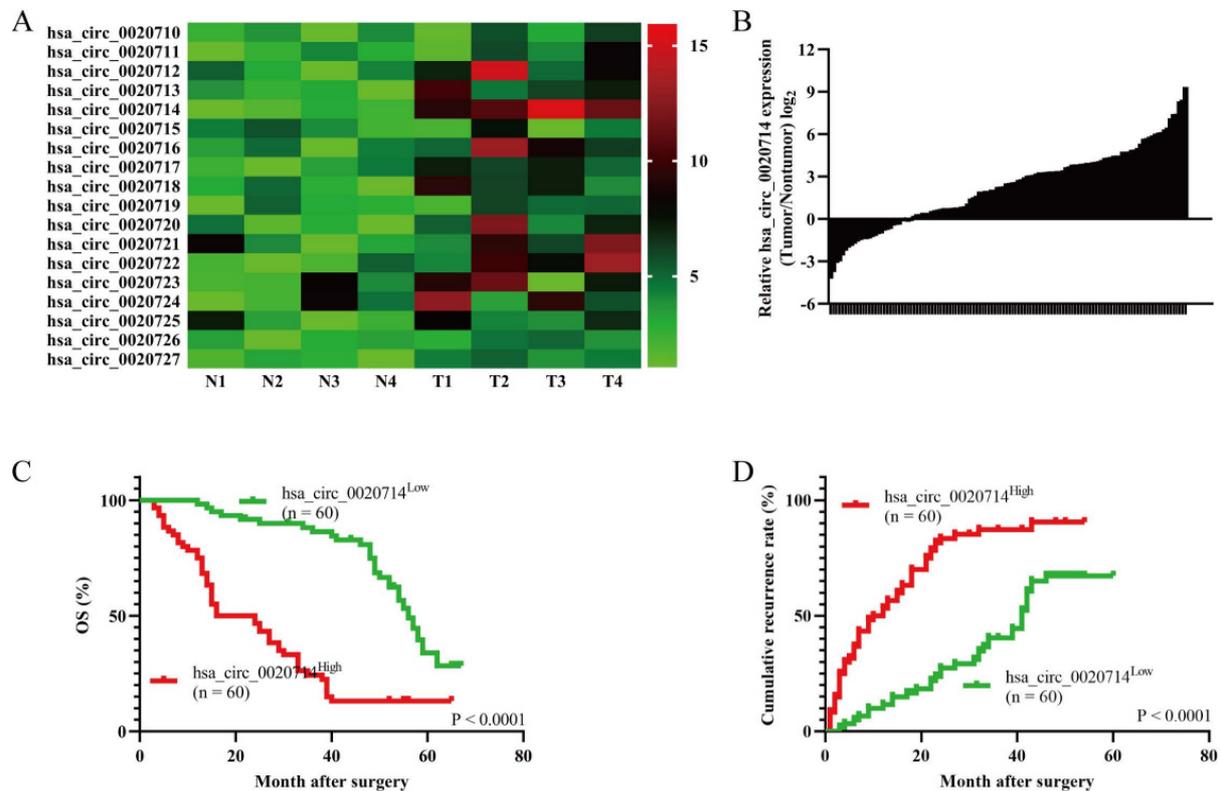

Figure 1. Forced hsa_circ_0020714 expression in the non-small cell lung cancer (NSCLC) tissues correlated with poor prognosis. (A) The heatmap shows *CD151* gene-derived circRNAs in pairs of NSCLC tissues and adjacent nontumor tissues using qRT-PCR. (B) The differential expression of hsa_circ_0020714 in the NSCLC tissues and matched adjacent nontumor tissues of 120 patients, as indicated. (C, D) Prognostic analysis of hsa_circ_0020714 expression in 120 NSCLC patients.

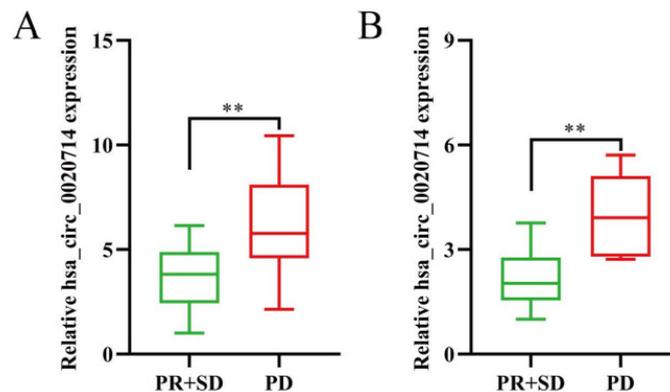

Figure 2. Hsa_circ_0020714 may act as a biomarker for resistance to anti-PD-1 immunotherapy in non-small cell lung cancer (NSCLC) patients. (A) Lung adenocarcinoma. (B) Lung squamous cell carcinoma. $**P < 0.01$.

To further verify whether hsa_circ_0020714 upregulates the SOX4 expression by sponging miR-30a-5p, we detected the expression of miR-30a-5p and SOX4 mRNA in above 120 NSCLC patient tumor tissues. The results demonstrated that there was a negative correlation between miR-30a-5p and hsa_circ_0020714/SOX4 mRNA in the NSCLC tissues. Inversely, positive correlations between hsa_circ_0020714 and SOX4 mRNA was observed in the NSCLC tissues [Figure 4A-C]. Moreover, our results demonstrated that patients with upregulated SOX4 mRNA expression had a worse prognosis than

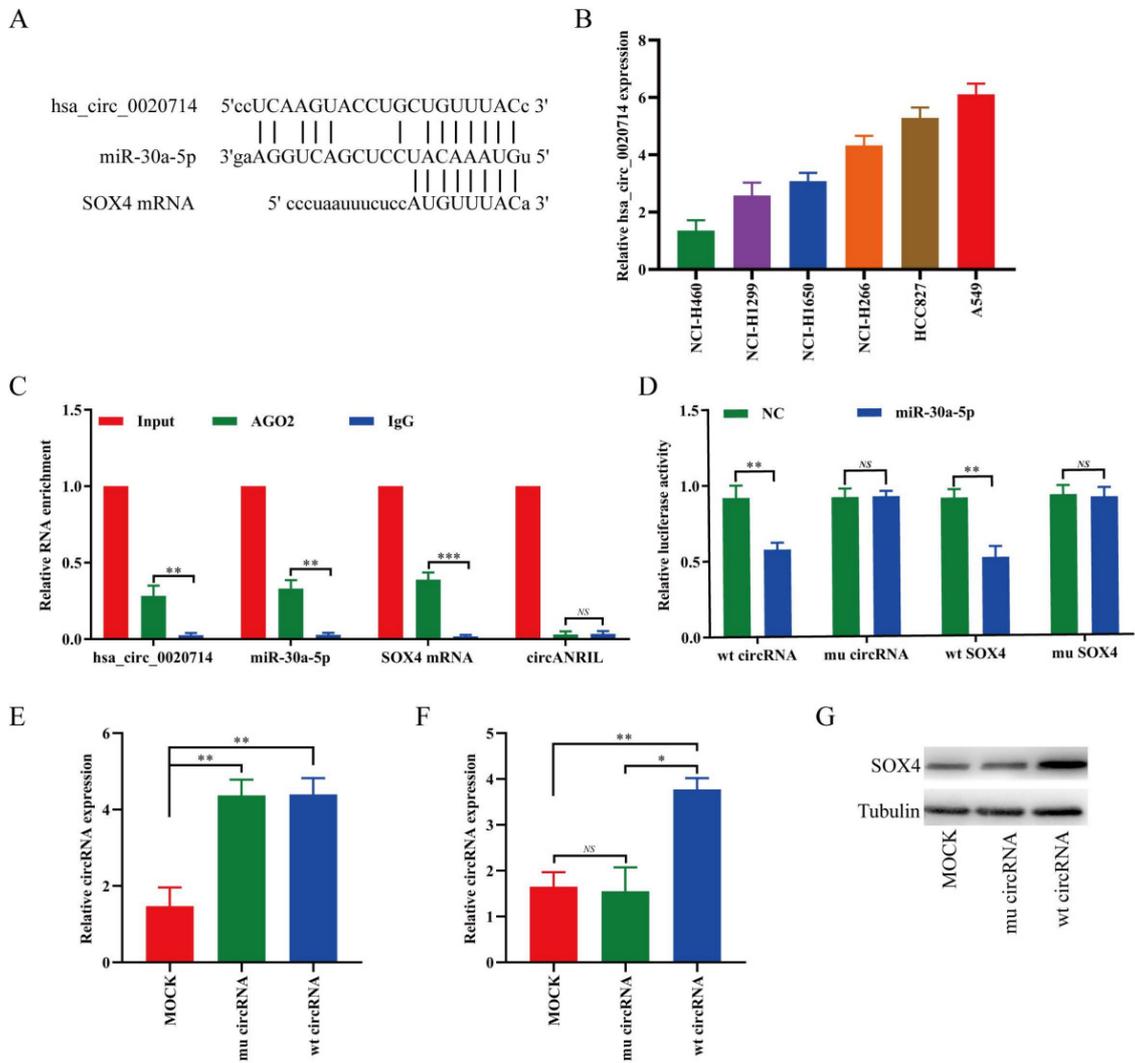

Figure 3. Hsa_circ_0020714 upregulates SOX4 expression via sponging miR-30a-5p in NSCLC cells. (A) Putative miR-30a-5p binding sites to hsa_circ_0020714 and SOX4 were predicted using StarBase v3.0. (B) Hsa_circ_0020714 expression was detected in six NSCLC cell lines using qRT-PCR. (C) CircRIP analysis was carried out using an AGO2 antibody in A549 cells extract. (D) The luciferase activity of wild type (wt) or mutant (mu) pLG3-hsa_circ_0020714/SOX4 mRNA 3'-UTR in the HEK-293T cells after cotransfected with miR-30a-5p. (E) Hsa_circ_0020714 expression was modified in the NCI-H460 cells by lentivirus-mediated cDNA transfection. (F, G) SOX4 mRNA and protein expression levels in wild type (wt) or mutant (mu) hsa_circ_0020714-overexpressing NSCLC cells. $***P < 0.001$, $**P < 0.01$, $*P < 0.05$. NS: Not significant.

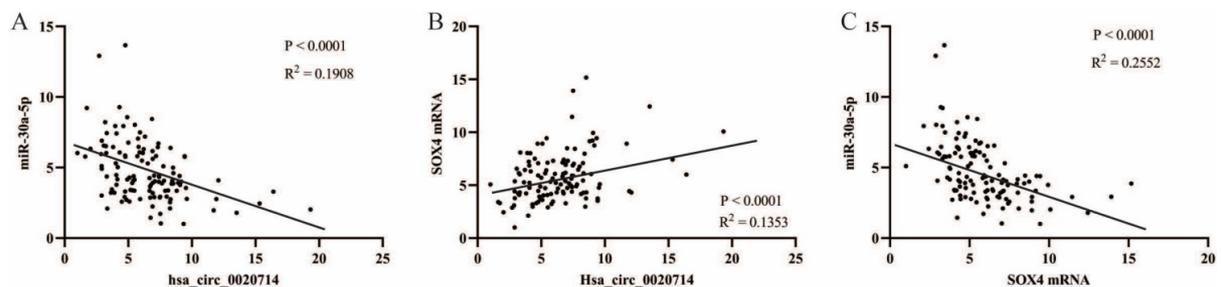

Figure 4. The correlation between hsa_circ_0020714, miR-30a-5p, and SOX4 mRNA was analyzed in NSCLC tissues. (A) The correlation between hsa_circ_0020714 and miR-30a-5p was analyzed in NSCLC tissues; (B) The correlation between hsa_circ_0020714 and SOX4 mRNA was analyzed in NSCLC tissues; (C) The correlation between miR-30a-5p and SOX4 mRNA was analyzed in NSCLC tissues.

those with lower levels of SOX4 mRNA, and patients with increased miR-30a-5p expression had a better prognosis than those with lower levels of miR-30a-5p [Figure 5A-D].

Hsa_circ_0020714-induced resistance to anti-PD-1 therapy in a SOX4-dependent manner

Interestingly, humans and mice have the same miR-30a-5p sequence, and mouse SOX4 mRNA 3'-UTR also has a predicted target sequence of miR-30a-5p [Figure 6A]. Then, we performed a luciferase assay using miR-30a-5p mimics that were cotransfected with luciferase reporters (containing wild-type or the mutant miR-30a-5p target sequence of mouse Sox4 mRNA 3'-UTR) into HEK-293 T cells. Compared with the negative control mimics, miR-30a-5p significantly inhibited the luciferase reporter activity in the cells with the wild-type mouse Sox4 mRNA 3'-UTR, but not the cells with the mutant mouse SOX4 mRNA 3'-UTR [Figure 6B]. In addition, our results indicated that upregulated hsa_circ_0020714 significantly promoted SOX4 expression in mouse lung cancer LLC cell line [Figure 6C]. To further determine the biological function of hsa_circ_0020714 on anti-PD-1 therapy resistance, we detected the anti-tumor effects of the PD-1 antibody in LLC-hsa_circ_0020714 xenograft C57BL/6 mice. Compared to that of the miR-30a-5p target sequence of mutant hsa_circ_0020714 group, the tumor growth increased in the LLC-hsa_circ_0020714 cells group which exhibited resistance to anti-PD-1 therapy and had a shorter survival time [Figure 6D-F].

DISCUSSION

With the rapid development in the fields of bioinformatics and high-throughput sequencing techniques, the researchers have gradually deepened their understanding of circRNAs. Increasingly studies have verified that dysregulated circRNAs expression play critical roles in NSCLC immune evasion and resistance to anti-PD-1 immunotherapy. For example, our previous study demonstrated that forced circFGFR1 promotes resistance to anti-PD-1 treatment in NSCLC immunotherapy via sponging miR-381-3p to upregulate the expression of C-X-C motif chemokine receptor 4^[8]. In another study, our results indicated that circMET overexpression enhanced NSCLC immune evasion via acting as a miR-145-5p sponge to upregulate CXCL3 expression^[10]. Here, for the first time we reported that hsa_circ_0020714 plays a critical biological function in NSCLC immune evasion. We determined that hsa_circ_0020714 was upregulated in NSCLC tissues compared with paired adjacent nontumor tissues, and forced hsa_circ_0020714 expression was associated with a poor prognosis and resistance to anti-PD-1 immunotherapy in NSCLC patients. Mechanistically, hsa_circ_0020714 functions as an endogenous miR-30a-5p sponge to enhance SOX4 expression, subsequently inducing resistance to anti-PD-1 immunotherapy in NSCLC patients.

CircRNAs belong to a novel class of important ncRNAs involved in regulating various pathological and physiological processes. In recent years, they have attracted numerous research attention. Mounting evidence shows that dysregulated expression of circRNAs play a critical role in NSCLC progression and immune evasion^[8,10]. In previous study, we proved that circMET overexpression can promote cancer cell proliferation, metastasis, and immune evasion in NSCLC^[10]. In addition, we found that forced circFGFR1 expression promoted NSCLC progression and resistance to anti-PD-1 by sponging miR-381-3p^[8]. In this study, we found that hsa_circ_0020714 was a critical oncogene that participates in immune evasion of NSCLC.

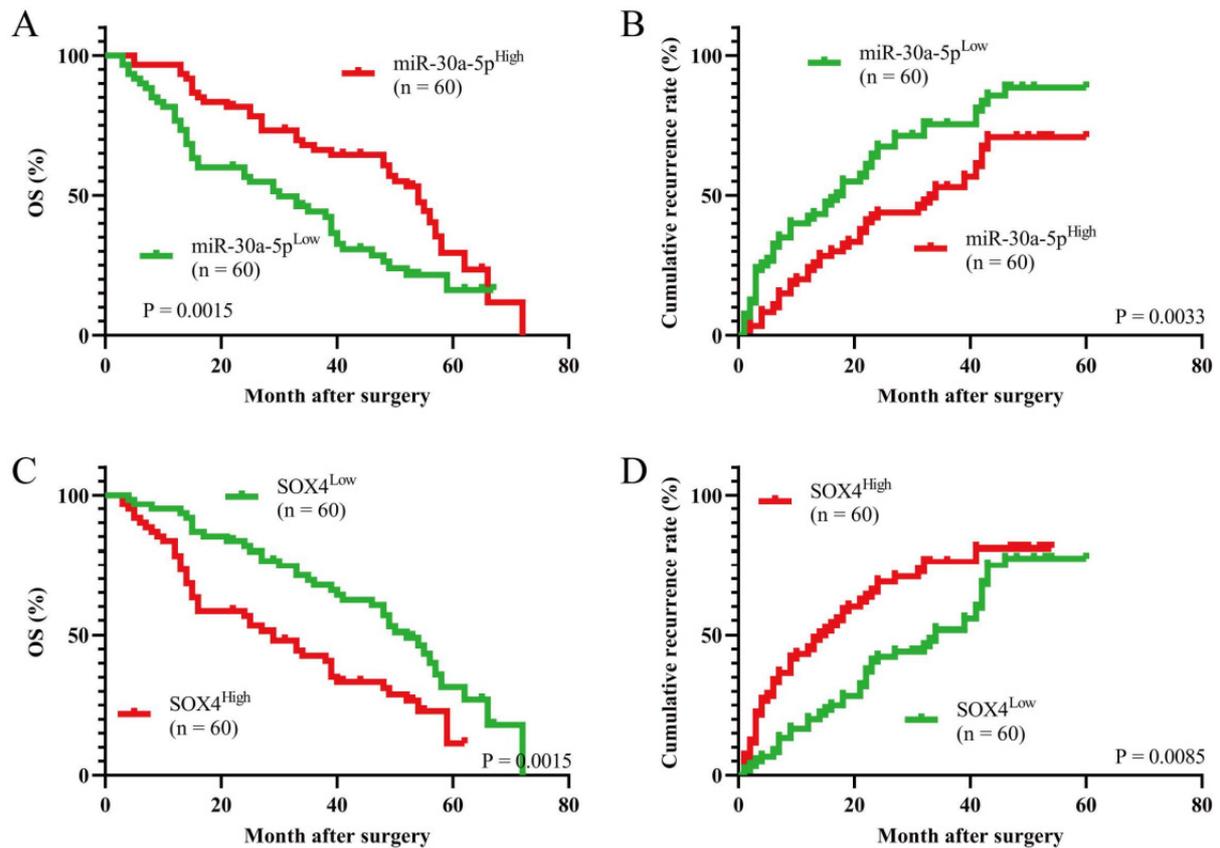

Figure 5. Prognostic analysis of miR-30-5p, and SOX4 mRNA expression in 120 non-small cell lung cancer (NSCLC) patients. (A and B) Prognostic analysis of miR-30-5p expression in 120 NSCLC patients; (C and D) Prognostic analysis of SOX4 mRNA expression in 120 NSCLC patients.

SOX4 is a member of the SOX family of transcription factors. Upregulated SOX4 expression participates in cancer progression, including proliferation, invasion, and migration^[11]. In recent years, increasingly evidence has confirmed that the expression of SOX4 was regulated by a large class of ncRNA^[20-22]. Our study identified SOX4 as a downstream important molecular of hsa_circ_0020714/miR-30a-5p axis in NSCLC cells. Recently, Bagati *et al.*^[13] found that forced SOX4 expression inhibits T cell-mediated anti-tumor immunity in triple-negative breast cancer. Furthermore, PD-1 blockade was verified to efficiently promote proliferation and expansion of CD8⁺ T cells in cancer model^[23]. Over the past years, cancer immunotherapies have been demonstrated effectively therapeutic effect for some patients by blocking immune checkpoint receptors on T cells, restoring T cell-mediated cytotoxicity and recruiting more T cells into the tumor environment^[24]. Here, our results also indicated that hsa_circ_0020714 could sponge miR-30a-5p to upregulate SOX4 expression in the NSCLC cells, thereby promoting NSCLC immune evasion and resistance to anti-PD-1 immunotherapy.

Taken together, our results demonstrate that hsa_circ_0020714 expression is upregulated in NSCLC tissues compared with the paired adjacent nontumor tissues. Mechanistically, hsa_circ_0020714 induces the immune evasion of NSCLC cells via sponging miR-30a-5p to upregulate SOX4 expression, which has been confirmed acted as a oncogene in several malignant tumors, including NSCLC. Therefore, blocking the hsa_circ_0020714/miR-30a-5p/SOX4-related pathway may effectively reverse resistance to anti-PD-1-based immunotherapy in NSCLC.

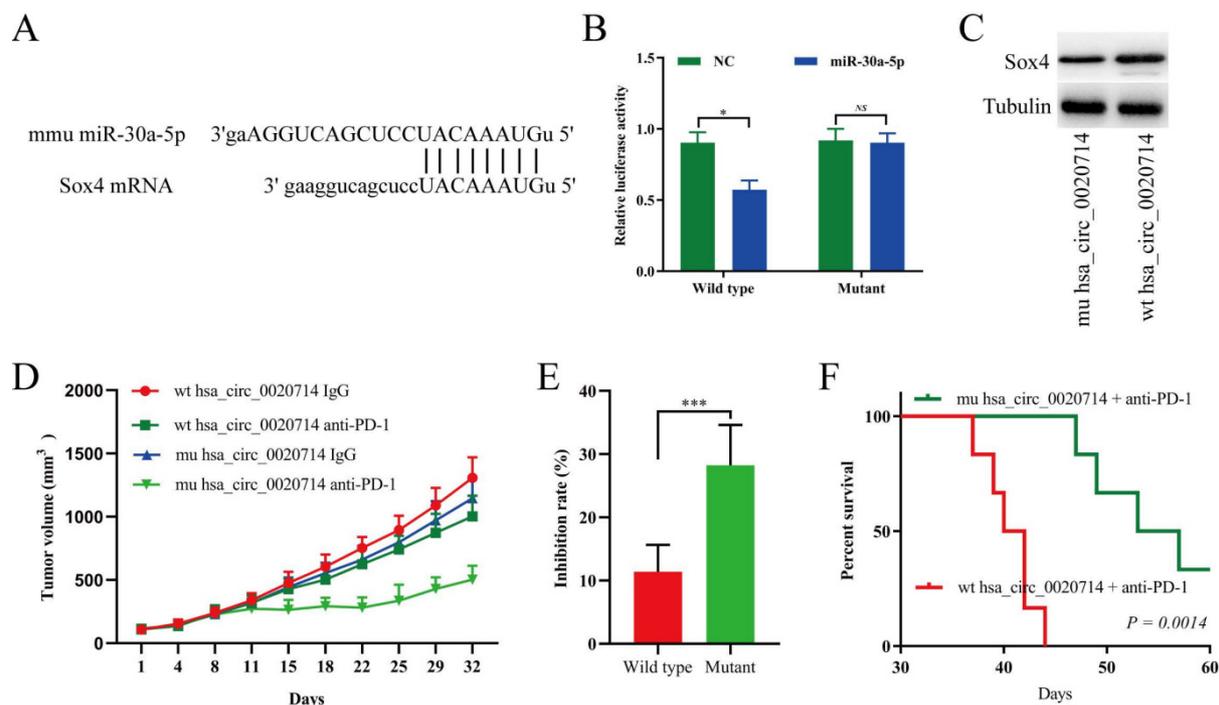

Figure 6. Hsa_circ_0020714 promotes non-small cell lung cancer (NSCLC) resistance to resistance to anti-PD-1 immunotherapy in NSCLC patients. (A) Putative miR-30a-5p binding sites to mouse Sox4 were predicated via StarBase v3.0. (B) The luciferase activity of wild type (wt) or mutant (mu) pLG3-Sox4 mRNA in the HEK-293T cells after cotransfected with miR-30a-5p. (C) Sox4 expression in the wild type or mutant hsa_circ_0020714-overexpressing cells was detected by western blot. (D) LLC cells with mutant or wild type hsa_circ_0020714-overexpressing were subcutaneously injected into 4-week-old C57BL/6 mice. When tumors had reached a mean volume of 100 mm³, the mice were treated with an IgG or PD-1 antibody. The data are presented as the mean tumor volume (n = 6). (E) The data are expressed as the percentage of tumor growth inhibition (the data are presented as the mean ± SD). (F) The survival curves of the mouse lung xenograft tumors formed by mutant or wild type hsa_circ_0020714-overexpressing cells and treated with a mouse antibody against mouse PD-1. ***P < 0.001, *P < 0.05. NS: Not significant.

DECLARATIONS

Authors' contributions

Conceived and designed the experiments: Wu J, Zhu MX, Li KS

Performed the experiments: Wu J, Zhu MX, Li KS, Zhang PF

Analyzed the data: Zhang PF, Peng L

Wrote the paper: Zhang PF, Peng L

All authors read and approved the final manuscript.

Availability of data and materials

All data generated or analyzed in this study are included in this article.

Financial support and sponsorship

This study was funded by the National Natural Science Foundation of China (82072575), Medical Scientific Research Foundation of Zhejiang Province, China (2019KY176).

Conflicts of interest

All authors declared that there are no conflicts of interest.

Ethical approval and consent to participate

Ethical approval was obtained from the Zhongshan Hospital Research Ethics Committee. Experimentation on C57BL/6 mice were approved by the Animal Experimentation Ethics Committee of Zhongshan Hospital, Fudan University. All patients or their guardians gave written informed consent for the use of their samples before collection.

INTRODUCTION

Multiple myeloma (MM) is the second most common hematologic malignancy after non-Hodgkin's lymphoma. Intrinsic and acquired drug resistance of cancer cells to standard drugs is a major obstacle for a more successful survival outcome of MM patients treated on contemporary clinical protocols. The primary purpose of this special issue on "Drug Targets and Resistance Mechanisms in Multiple Myeloma" was to collect new and transformative information regarding new insights about the mechanisms of drug resistance in MM and the role of the tumor microenvironment in treatment failures.

MAIN TEXT

Overcoming inherent and acquired drug resistance of MM cells, especially in the context of the immunosuppressive tumor microenvironment (TME), remains a major challenge to effective therapy of high-risk or relapsed/refractory (R/R) MM^[1-15]. Amplified expression of drug transporters P-glycoprotein (P-gp/ABCB1) and multidrug-resistance-associated protein 1 (MRP1/ABCC1) have been implicated in the resistance of MM cells to drugs that are known substrates for these proteins, such as melphalan, dexamethasone, and anthracyclines [Table 1]^[16-18]. Some studies have indicated that abundant expression levels of the lung resistance protein (LRP), another drug transporter protein, may also confer resistance to chemotherapy drugs and proteasome inhibitors (PIs) in MM^[16-18]. It remains to be seen if a potent and safe inhibitor of these drug transporters can be identified and clinically leveraged to overcome drug resistance in

Table 1. Possible Mechanisms of Cancer Drug Resistance in Multiple Myeloma

Therapeutics	Resistance Mechanism
IMiD	Mutations of proteins in CRBN-IK axis associated with deficient expression
PI	Impaired binding to PSMB5 due to mutations; MIF overexpression; LRP abundance; epigenetic reprogramming; DNA hypermethylation in an active intronic CRBN enhancer
Chemo	Amplified expression of P-gp/ABCB1 and MRP1/ABCC1
MoAb	Low expression level of target antigen; upregulation of the complement inhibitors CD55 and CD59
DEX	GR mutations and deficiency; amplified expression of P-gp/ABCB1 and MRP1/ABCC1

DEX: Dexamethasone; IMiD: immuno-modulatory drug; PI: proteasome inhibitor; Chemo: chemotherapy drugs; MIF: migration inhibitory factor; LRP: lung resistance protein; P-gp: P-glycoprotein; MRP1: multidrug-resistance-associated protein 1.

MM. Several humoral and cellular components of the TME facilitate the immune evasion and subsequent expansion of drug-resistant MM clones, such as myeloid-derived suppressor cells (MDSCs), regulatory T-cells, and MM-derived cytokines including TGF- β , and IL-6, and IL-10^[4]. MYC and hepatocyte growth factor/c-MET signaling networks have also been identified as potential contributors to cancer drug resistance in MM^[15]. Patients with triple-class-refractory MM whose cells exhibit triple-class resistance to PIs, immunomodulatory drugs (IMiDs), and monoclonal antibodies (MoAb) have an OS of < 6 months emphasizing the urgency of this unmet medical need^[19-20].

IMiDs such as thalidomide, lenalidomide, and pomalidomide trigger cereblon (CRBN)-mediated ubiquitination and degradation of important regulatory proteins that contribute to the expansion of drug-resistant clones, including the transcription factor Ikaros^[18]. They also augment the proliferation and effector function of cytotoxic T-cells (CTLs) and natural killer (NK) cells while inhibiting immunosuppressive T-regs. Unfortunately, deficient expression of the target CRBN, as reported for MM cells with certain mutations of the *cereblon* gene or DNA hypermethylation in an active intronic CRBN enhancer, occurs in almost one-third of the patients with R/R MM and causes resistance to the IMiDs [Table 1]^[21,22]. CRBN-independent resistance to IMiDs has also been reported^[1,4]. Ongoing research will explore if the clinical benefit of IMiDs could be augmented by using them in combination with CRBN E3-ligase modulators (e.g., iberdomide) to accelerate the degradation of Ikaros transcription factor proteins IKZF1/IKZF3^[1,4].

In contemporary induction protocols for MM, IMiDs are often combined with PIs such as bortezomib and Carfilzomib^[5,20]. PIs trigger apoptotic death of MM cells by contributing to an exaggerated unfolded protein response (UPR) pathway and ER stress^[1,4]. They further impair the survival-promoting interactions between MM cells and stromal elements in the bone marrow microenvironment, and they promote the immunogenic death of damaged MM cells^[1,4]. Impaired binding of PIs to the target proteasome β 5 subunit (PSMB5) has been associated with PI resistance and can occur due to mutations of the encoding gene that cause conformational alterations at the binding region [Table 1]^[23,24]. MicroRNAs (miRNAs) play important roles in mRNA silencing and regulation of gene expression in MM cells^[25]. CD47 antigen is overexpressed in MM, likely due to miR155 down-regulation, and its abundance was associated with a poor prognosis^[26-28]. Recent studies have implicated CD47 in PI resistance of MM cells^[28]. In view of the promising early clinical experience in patients with myeloid malignancies, evaluation of the anti-CD47 MoAb Magrolimab in R/R MM patients would also seem warranted^[4]. Notably, CD47-targeting with synthetic micro-RNA miR-155 overcame bortezomib resistance and induced phagocytosis as well as apoptosis of MM cells by causing loss of CD47^[28]. Likewise, another micro-RNA, miR-218, is decreased in MM and synthetic miR-218 may help overcome PI resistance^[29]. In the future, nanoformulations of synthetic miR155 and miR-218 could be used for the resensitization of resistant MM cells to PI. Another emerging new strategy to overcome PI resistance

involves the targeting of the macrophage migration inhibitory factor, which has been shown to render MM cells resistant to PI-induced apoptosis^[30]. Clinical biomarker studies have demonstrated that the high-level expression of this target is associated with poor prognosis and survival in MM^[30].

BCL-2 is a predominant anti-apoptotic protein in B-lineage lymphoid malignancies, including MM. Venetoclax is a BCL-2 homology 3 (BH3)-mimetic that disrupts the association of the proapoptotic BH3-only proteins such as BIM and BID with BCL-2^[31]. BCL-2 inhibition by Venetoclax could theoretically damage chemotherapy-resistant MM cells by inhibiting the amino acid metabolism and reducing oxidative phosphorylation like its effects on leukemic cell populations^[1,32,33]. Venetoclax exhibited meaningful single-agent activity in R/R MM patients, especially those with a t(11;14) translocation^[34]. A combination of Venetoclax plus Bortezomib and dexamethasone was more effective than placebo plus bortezomib and dexamethasone in patients with R/R MM, albeit with higher toxicity due to infections^[35]. Besides BCL-2, MCL-1 is also an important survival-promoting anti-apoptotic protein for MM cells, and inhibitors of MCL-1 such as AMG-176 and MIK665 have been developed as potential anti-MM drugs that could be combined with other apoptosis-promoting anti-MM drug candidates including Venetoclax^[36].

A recent prospective clinical study employed longitudinal single-cell RNA-sequencing (scRNA-seq) to study the mechanism and dynamics of drug resistance in MM^[37]. An enzyme of the UPR pathway, peptidylprolyl isomerase A, was identified as a new molecular target demonstrating the clinical potential of this new strategy in identifying clinically relevant new therapeutic targets for overcoming cancer drug resistance in MM^[37]. Another important strategy for further identification of new molecular targets contributing to cancer drug resistance in MM is deep measurable residual disease (MRD) profiling, which is based on the characterization of MRD clones using flow cytometry in combination with whole-exome sequencing^[38].

Precision medicines as well as biotherapeutic agents, including therapeutic monoclonal antibodies such as the anti-CD38 MoAb Daratumumab and isatuximab, and the anti-signaling lymphocyte activation marker F7, antibody elotuzumab, antibody-drug conjugates, and bispecific antibodies (BiAb) have been developed to damage drug-resistant MM clones as well as alter the immunosuppressive bone marrow microenvironment with some very promising clinical data regarding their clinical impact potential^[1,4,39]. T-cell redirecting BiAb and bispecific T-cell engagers (BiTES) targeting CD38, the orphan G protein-coupled receptor GPRC5D, and the B-cell maturation antigen (BCMA)/CD269 on MM cells and CD3 antigen on T-cells facilitate the CTL-mediated destruction of drug-resistant MM cells in cytolytic synapses^[4,40]. They showed promising single-agent activity in early clinical trials of R/R MM patients, and risk mitigation strategies have been identified for their potentially serious side effects such as cytokine release syndrome and neurotoxicity^[4,40]. BCMA-targeting cellular immunotherapy platforms using chimeric antigen receptor (CAR)-T cells or NK cells have also been developed with documented objective clinical responses in single-agent trials^[1,4,6-9,40].

Another area of active clinical research to improve the outcome of cancer drug-resistant MM is related to efforts for overcoming the immunosuppressive TME^[4,40]. BiAb and anti-CD38 MoAb are capable of dual targeting of both MM cells and immunosuppressive elements of the TME such as the MDSC, and are being explored as potential therapeutic platforms^[40].

Each of the new modalities designed to mitigate or overcome cancer drug resistance in MM has faced inherent and acquired resistance mechanisms^[21]. For example, soluble BCMA renders MM cells resistant to the cytolytic actions of BCMA-directed BiAb/BiTES and CAR-T cells by serving as a competing target for

these biotherapeutic platforms. It remains to be seen if this resistance can be overcome by using a γ -secretase inhibitor to reduce the γ -secretase mediated production of soluble BCMA. It will be important to develop multi-modality combination regimens to minimize the risk of escape by drug-resistant MM clones as well as the emergence of MM clones refractory to the new agents with promising activity^[1,4,13,20,21,35,40-45]. The timely definition of optimal strategies for overcoming the cancer drug resistance in MM will require randomized adaptive clinical trials with multiple parallel cohorts, each evaluating a promising new treatment strategy.

Abstract

Multiple drug resistance (MDR) is the tumor's way of escaping the cytotoxic effects of various unrelated chemotherapeutic drugs. It can be either innate or acquired. MDR represents the end of the therapeutic pathway, and it practically leaves no treatment alternatives. Reversing MDR is an unfulfilled goal, despite the important recent advances in cancer research. MDR, the main cause of death in cancer patients, is a multi-factorial development, and most of its known causes have been thoroughly discussed in the literature. However, there is one aspect that has not received adequate consideration - intracellular alkalosis - which is part of wider pH deregulation where the pH gradient is inverted, meaning that extracellular pH is decreased and intracellular pH increased. This situation interacts with MDR and with the proteins involved, such as P-gp, breast cancer resistance protein, and multidrug associated resistance protein 1. However, there are also situations in which these proteins play no role at all, and where pH takes the lead. This is the case in ion trapping. Reversing the pH gradient to normal can be an important contribution to managing MDR. The drugs to manipulate pH exist, and most of them are FDA approved and in clinical use for other purposes. Furthermore, they have low or no toxicity and are inexpensive compared with any chemotherapeutic treatment. Repurposing these drugs and combining them in a reasonable fashion is one of the points proposed in this paper, which discusses the relationship between cancer's peculiar pH and MDR.

Keywords: Multidrug resistance, pH gradient inversion, reversion of the pH gradient, P-gp, pH centered treatment.

INTRODUCTION

For more than 3000 years, trepanations (for unclear reasons) have been performed, since 2000 BC (and a breast cancer tumor was excised approximately at the same date); up to the 20th century, surgery was the only available treatment for solid tumors. During that time, there was nothing to be done for non-solid tumors. Things started to change in the middle of the last century.

Chemotherapy started in earnest in the 1940s, a decade in which two important advances achieved clinical status. In the first of these events, Louis Goodman and Alfred Gilman created the first alkylating agent as a derivative of the poisonous nitrogen mustard gas, a sibling of the sulfur mustard gas used in WWI^[1]. The second event had Sydney Farber as the protagonist. He introduced the first anti-metabolite (aminopterin) for acute leukemia treatment in children^[2]. Interestingly, the title of the first publication by Farber and his associates starts with “Temporary relief...”, thus, incorporating from the first moment one of the main problems of chemotherapy, the limited duration of its benefits. In both cases, the first patients treated by Goodman and Gilman on the one hand and the children with acute leukemia treated by Farber *et al.*^[2] on the other hand, the effects of chemotherapy were not long lived and repeat treatments were usually unsuccessful. Chemotherapy came up against its main adversary, resistance. To prolong the beneficial effects and at the same time reduce toxicity, multidrug chemotherapy protocols were introduced - successfully in many cases. Remissions lasted longer and toxicity was reduced. However, resistance and relapse still persisted at the end of the therapeutic path. Patients receiving chemotherapy can in many cases become resistant to previously effective drugs. Unfortunately, resistance is the proof of concept that cancer cells are the most adaptive cells in eukaryotes.

Resistance is the product of two different sources:

- (a) The malignant cell itself; and
- (b) The stroma and the vascular system.

The most important mechanism is the one in which the cancer cell develops the ability to prevent the drug from entering it or reduces the amount that can enter, simply expels the drug, or can inhibit apoptosis despite the treatment.

The stroma may contribute to resistance through its dense composition (e.g., pancreatic cancer with desmoplastic reaction) or its low vascular supply that decreases drug distribution in the tumor [Figure 1].

A distinction must be made between primary (or intrinsic) and acquired (or secondary) resistance. In the first case, cells are resistant to the drug before they first encounter it. In the latter, acquired resistance, the tumor develops resistance during the course of chemotherapy. This difference implies that, in the second case, tumors evolve from their initial responsive status towards an unresponsive one. The main evolution consists in upregulating the expression of some specific proteins of the ATP binding cassette family (ABC), namely P-glycoprotein (P-gp, also known as MDR1 or ABCB1), multidrug associated resistance protein 1 (MRP1 or ABCC1), and breast cancer resistance protein (BCRP or ABCG2).

The introduction of novel targeted therapies in the last twenty years was expected to dramatically change the resistance problem. That did not happen. Targeted treatments improved survival and progression-free periods in many different cancers - in some, a cure was even achieved - but resistance to treatment remained little changed in most cases.

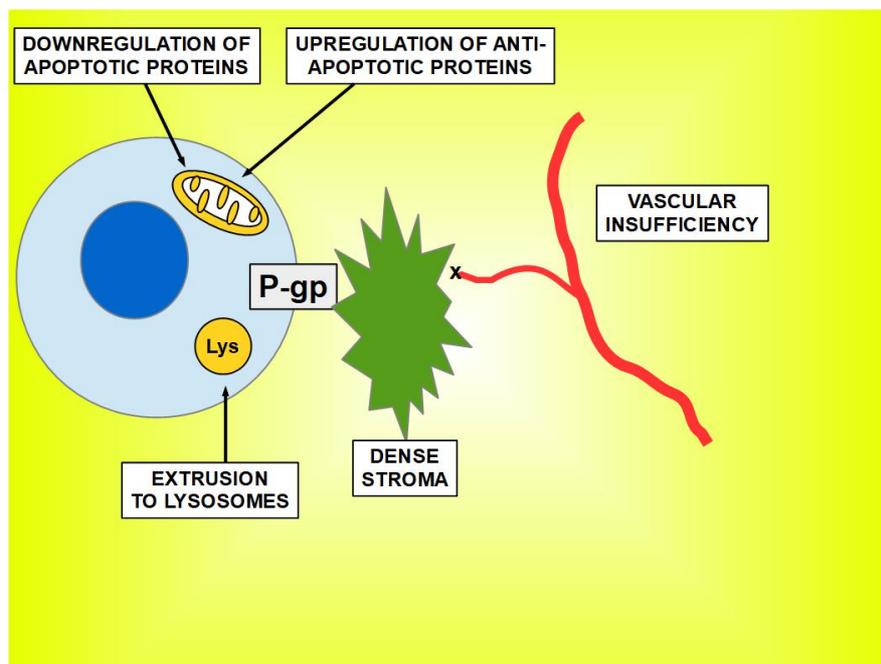

Figure 1. An overview of the main mechanisms of drug resistance. Drug extrusion is represented by P-gp (P-glycoprotein).

In 1958, Burchenal and Holmberg were the first to study the short-lived remission achieved with anti-metabolites in the treatment of leukemia at a cell level^[3]. They expressed the prevailing concept at that moment - a random mutation induced by the drug - but they also established that there were many other biochemical mechanisms leading to resistance.

There is a special form of resistance consisting of invulnerability to many unrelated drugs that were never administered to the patient. This is known as MDR, a situation that severely limits the therapeutic options and consists of increased efflux of drugs. This mechanism was first proposed by Keld Danø, in 1973, as probably the main mechanism^[4]. This drug extrusion hypothesis was followed some years later by the discovery of P-glycoprotein^[5] and other MDR proteins such as multidrug-associated resistance protein 1 (MRP1)^[6] and BCRP^[7], proteins that were not known when Danø proposed his theory. This meant that the extrusion culprits were finally identified.

Multiple drug resistance

Resistance to a drug must be differentiated from multidrug resistance. In the first case, a mutation or clonal evolution can be the cause, supposing that the malignant cells are responsive to other chemotherapeutic drugs. It is the lack of response to many different drugs that signals towards MDR, especially if these drugs were never administered before. In this last case, the most probable cause is the increased expression of one or more of the MDR proteins. Therefore, it is cancer's resistance to many different and unrelated chemotherapeutic drugs that defines MDR, which may be intrinsic (primary) or acquired after chemotherapy. The lack of specificity is still one of the issues that is hard to explain. The causes of MDR are multiple, from poorly drug vulnerable stem cells to clonal evolution, stromal barriers, and mutations. It is not the aim of this paper to discuss MDR mechanisms but to focus exclusively on those related to pH alterations. When chemotherapy initially works, it is able to induce apoptosis in many of the malignant cells. However, tumors are very heterogeneous^[8,9] and not all malignant cells will be eliminated with the treatment. Those that survive repeated cycles of cytotoxic medication are either intrinsically resistant, or

they are located in inaccessible parts of the tumor, such as very hypoxic niches without blood supply or in the middle of dense connective tissue with high interstitial pressure impeding circulation [Figure 1]. The non-resistant cells are gradually killed, while the surviving resistant cells will thrive and progress and, ultimately, fully replace the “weaker” cells, thus heralding the relapse. This is a typically Darwinian evolution where chemotherapy is the selective force for the survival of the fittest.

For extensive reviews on MDR, read the works of Gillet *et al.*^[10], Rascio *et al.*^[11], Mansoori *et al.*^[12] Jayaraj *et al.*^[13], Ruan *et al.*^[14], Aleksakhina *et al.*^[15], and Vasan *et al.*^[16].

This paper does not analyze MDR causes in depth, which is beyond the scope of the review, but rather focuses on the relationship between the tumor dysregulated pH and MDR and explores new therapeutic avenues in this regard.

pH deregulation in cancer

It has been known since the work of Otto Warburg^[17] in the 1920s that tumors are acidic due to excessive production of lactic acid as a consequence of high glycolytic flux and downregulation of mitochondrial oxidative activity. Between the 1920s and the beginning of the 1970s, it was believed that there was no difference between intra- and extracellular pH. Thus, if the tumor was acidic, this concept included both sides of the cell membrane. Only in the late 1970s did it become evident that acidity was limited to the extracellular matrix, while in the intracellular milieu, pH was either unchanged or increased, compared with normal cells. The long time it took to discover the pH differences on the two sides of the cell membrane was due to the lack of adequate instruments that could accurately gauge intracellular pH [Table 1]. The awareness of different intra- and extracellular pH levels also led to the discovery of the channels, exchangers, transporters, and enzymes located on the membrane, which are in charge of maintaining this pH differential (gradient).

In Table 1, the direction of the arrow indicates the pH gradient, and we can easily see that in cancer, the gradient follows exactly the opposite direction compared with non-malignant counterparts. This is the inversion of the pH gradient, a process found in all tumors, which is fundamental for cancer cell survival and progression. This means that in cancer, extracellular pH becomes acidic and intracellular pH becomes more alkaline.

Extracellular acidity, known for a long time, and the more recently discovered intracellular alkalinity were merely considered as a consequence of cancer metabolism and, to a certain extent, innocent bystanders. This notion started to change in the mid-1980s, when researchers found more and more evidence showing that the inverted pH gradient represented an important advantage for growth, proliferation, migration, and invasion. Furthermore, in 2000, Reshkin *et al.*^[18] showed that the first step in cellular transformation consisted in an increase of intracellular pH as a consequence of the enhanced activity of a specialized membrane channel, sodium bicarbonate exchanger 1 (NHE1). This exchanger, one of the main players in intracellular pH homeostasis, has the ability to export hydrogen ions (H⁺, protons) while importing Na⁺ from the matrix into the cells.

Reshkin *et al.*^[18] went one step further; they inhibited NHE1 with a drug that has been in clinical use for more than fifty years, amiloride. Interestingly, NHE1 inhibition impeded malignization. This was clear proof of the importance of pH in cancerization.

Table 1. pH in different compartments in normal and cancer cells

Table 1	Normal cell	Cancer cell
Extracellular (EC) pH (pHe)	7.30-7.35	6.4-7.0
Intracellular (IC) pH (pHi)	7.2	7.25-7.50
pH gradient	EC→IC	IC→EC

Intracellular and extracellular pH are discussed separately below, even though they are part of the same process of pH deregulation. The membrane between both compartments is the tool that keeps this different pH alive. The membrane is not a simple and passive boundary, but rather it is an active player that maintains a different environment inside and outside the cell. This is in part achieved by channels, exchangers, transporters, and enzymes spanning through it.

Extracellular and intracellular pH (pHe and pHi)

Normal extracellular pH, which is very close to the blood pH, decreases by around 8–10% in cancer tissues. It goes from 7.35 (normal tissues) to roughly 6.8 (malignant tissues). In some cases, it becomes even more acid. This is the result of different events:

(a) Increased CO₂ production that produces carbonic acid on the cell surface and immediately ionizes, generating a bicarbonate ion that is reintroduced into the cell and a proton that remains in the extracellular matrix [Figure 2]. Two proteins located in the cell membrane participate in this process, namely membrane carbonic anhydrases (isoforms CAIX and CAXII) and sodium-bicarbonate cotransporter (NBC). CAIX is usually overexpressed in many hypoxic tumors^[19-22]. CAIX is so closely associated with hypoxia that many authors consider its overexpression as a hypoxia marker^[23-29].

CO₂ abandons the cell simply by diffusion. When it reaches the cell surface, there is a tandem activity on CO₂ carried out first by membrane carbonic anhydrase IX or XII and then by NBC [Figure 2].

Since Warburg's work and until 1999, lactic acid was considered the main culprit of extracellular acidosis in cancer. Seminal research by Newell *et al.*^[30] showed that eliminating lactic acid production in malignant cells only minimally modified extracellular acidosis; thus, lactate is not the main and sole origin of a low pHe. It seems that CO₂ production is equally important in pHe descent. Malignant cells produce large amounts of CO₂ through the very active pentose phosphate pathway and fatty acid beta-oxidation.

(b) Increased lactic acid production is extruded from the cell by specialized membrane transporters such as monocarboxylate transporter 1 (MCT1) and monocarboxylate transporter 4 (MCT4). Figure 3 shows the origin of lactic acid from the glucose metabolism, which is strongly deviated towards the glycolytic pathway instead of the oxidative pathway of the Krebs cycle. MCTs can carry monocarboxylates in general; they are not exclusively dedicated to lactate transport. In cancer, these transporters are overexpressed on the cell membrane^[35-38]. Hao *et al.*^[39] found that there was an association of CD44, CD147, MDR1, and MCTs expressions with prostate cancer progression and drug resistance.

(c) There is the extrusion of intracellular protons through NHE1, vacuolar ATPase proton pumps.

(d) There is the extrusion of protons through endosomes that become exosomes or simply release their acidic cargo into the extracellular matrix. Endosomes can follow two pathways: (a) transformation into lysosomes; and (b) becoming carriers of compounds that will be extruded from the cell, such as protons,

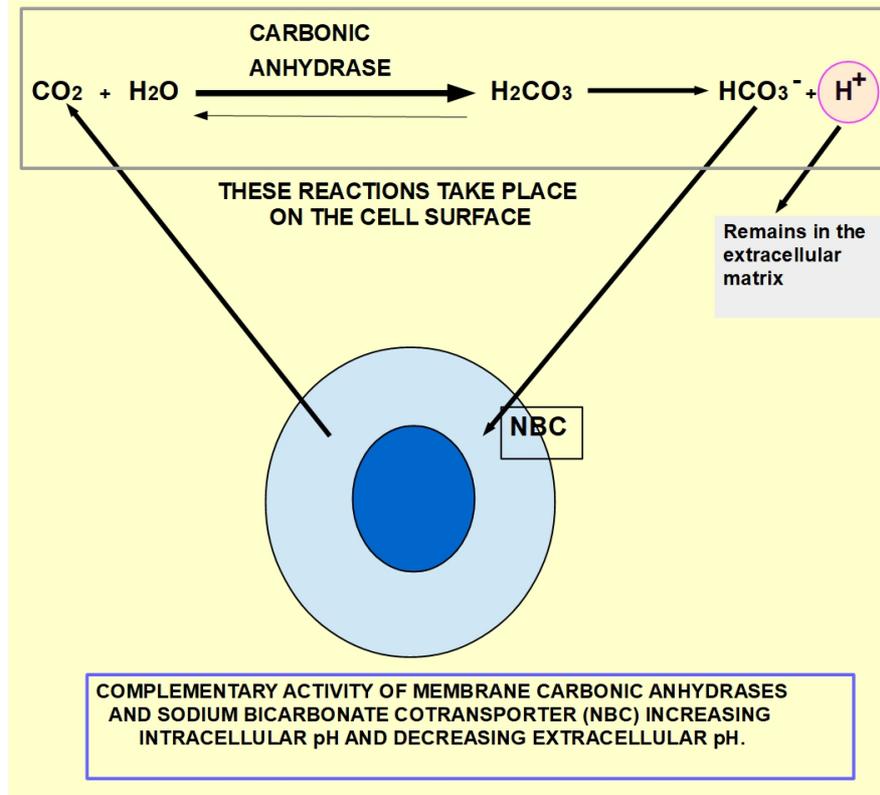

Figure 2. CO_2 of metabolic origin diffuses to the cell surface where it is hydrated to carbonic acid, which spontaneously ionizes to form a proton and a bicarbonate molecule. While the bicarbonate is reintroduced into the cell by NBC, the proton remains in the extracellular matrix, contributing to its acidification. NBC: Sodium-bicarbonate cotransporter.

proteolytic enzymes, etc.

(e) Debris of stromal and tumoral cell death are produced, whether by hypoxia, invasion, chemotherapy, or radiotherapy. Necrotic cells are able to release acidic intracellular compounds, while apoptotic cells are engulfed by macrophages and there is no intracellular content released into the matrix.

Reducing extracellular pH simultaneously increases intracellular pH because the mechanism is essentially based on protons released from inside the cell and into the matrix.

Matrix acidification has advantages for malignant cells because acidity:

- Decreases and inhibits immunological attacks on the tumor;
- Activates proteolytic enzymes needed for invasion; and
- Stimulates migration at the invadopodium level,

As mentioned above, intracellular pH increases through the loss of protons towards the matrix and the import of bicarbonate. This situation is also advantageous for the malignant cell because it:

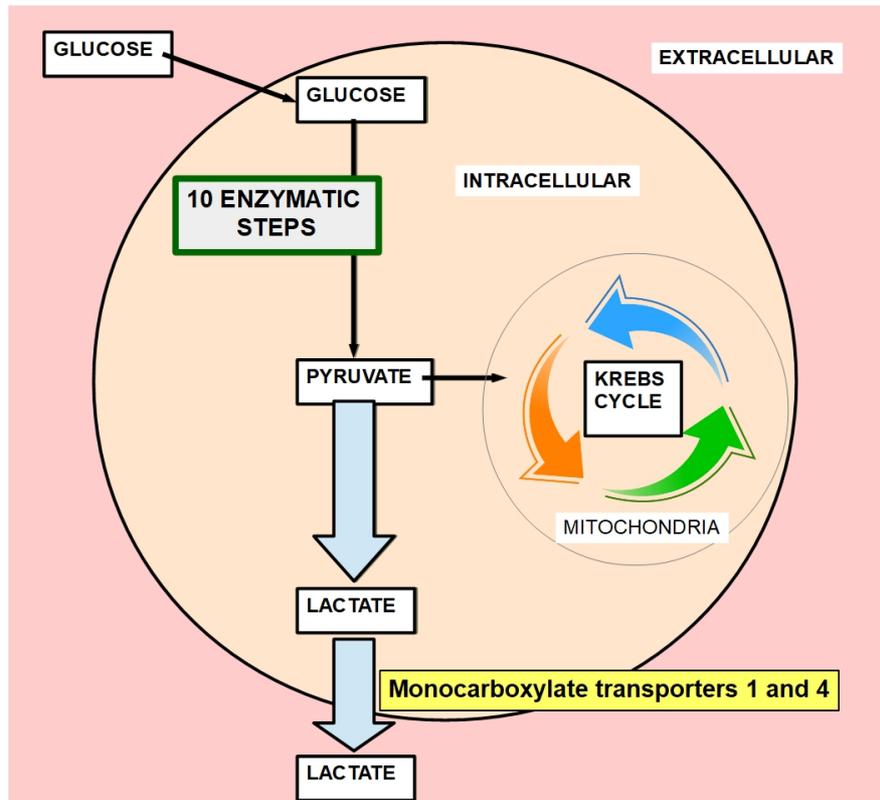

Figure 3. Origin of lactate production. Normal cells do not use the glycolytic pathway beyond pyruvate that goes into the Krebs cycle associated with coenzyme A and converted into acetyl-CoA. Malignant cells follow the glycolytic pathway ending in lactate that is extruded by the activity of monocarboxylate transporters. Lactate cannot stay inside the cell because it would decrease intracellular pH to life-threatening levels, thus it must be swiftly exported. This soft-spot of cancer metabolism transforms MCTs into valid targets^[31-34].

- Increases the activity of glycolytic enzymes, thus enhancing glycolytic flux that allows a higher biosynthetic activity;
- Increases proliferation; and
- Decreases the possibility of apoptosis.

RELATIONSHIP BETWEEN Deregulated pH AND MDR

The relationship between pH and MDR has major participation in the resistance process, as is discussed below. We do not have the evidence to maintain that MDR would not be possible without deregulated pH; however, there are many findings that hint towards this hypothesis. At this point, we are convinced that restoring the normal pH gradient should be an integral part of MDR targeting.

The relationship between extracellular pH and MDR has been extensively studied and is represented by a phenomenon called ion trapping.

Ion trapping

Weakly basic chemotherapeutic drugs, such as doxorubicin, cannot enter the hydrophobic cell membrane because they undergo ionization in the acidic tumor extracellular environment. The lipid bilayer cell membrane is semipermeable, meaning that, while it allows fat-soluble non-ionized moieties to enter, it is

poorly permeable to ionized water-soluble molecules. Anthracyclines and vinca alkaloids are weak basic drugs that are ionized by the microenvironmental acidity, thus substantially reducing their access to the cell^[40-42].

There are many reports that serve as proof of concept regarding the relation between ion trapping and extracellular acidity:

- Reducing extracellular acidity with sodium bicarbonate, mitoxantrone cellular penetration was increase^[43].
- Gu *et al.*^[44] developed a fluorescent probe based on dihydroberberine that showed that ionized berberine had a substantially lower cell penetration than the non-ionized form.
- Proton pump inhibitors, which increase extracellular pH, decrease drug resistance^[45].

Endosomal ion trapping

Martinez-Zaguilán *et al.*^[46] described the trapping of chemotherapeutic drugs in cellular endosomes. A new membrane is rapidly formed around the drug molecules, and these endosomes have a high V/ATPase proton activity, meaning that their interior is highly acidic. According to our criteria, drug release from the endosomes is inhibited by a mechanism similar to ion trapping. That is, the acidic interior ionizes weak basic drugs, impeding their transit through the membrane.

Extracellular acidity induces P-gp expression

This mechanism is independent of ion trapping and consists of the increased P-gp expression when extracellular pH becomes acidic^[47-50]. The mechanism that leads from extracellular acidity to increased P-gp proteins has not been fully clarified as yet.

Intracellular alkalinity and its effects on MDR

The intracellular milieu and its sub-compartments, such as mitochondria, Golgi, endoplasmic reticulum, and endosomes, including autophagosomes and lysosomes, all have different pH, which is set according to the needs of the metabolic processes taking place in them:

- Cytoplasm is the site of glycolysis and fatty acid synthesis.
- Mitochondria are the site of the Krebs cycle, the electron transport chain, and lipid beta-oxidation.
- Golgi and endoplasmic reticulum mature proteins and secretions.
- Autophagosomes recycle organelles and other nutritional agents.
- Lysosomes and endosomes are very acid, degrade biological products, and intervene in the maturation of proteolytic enzymes.

Each of these activities requires a different optimum pH, and the cell's homeostatic machinery maintains these different pHs (gradients) through membranes, e.g., cytoplasmic pH around 7.2, mitochondrial pH around 8, and lysosomal pH below 5.5.

Cell proliferation requires an alkaline cytoplasm, slightly above that of the resting cell.

In an extensive phylogenetic review, Busa and Nucitelli^[51] showed that almost all species increase their intracellular pH before replication. There were also some minor exceptions. This led the authors to consider intracellular pH as a signaling mechanism. High intracellular pH does not seem to be an indispensable mechanism but rather a facilitator for cell replication.

Drug-resistant cells were found to over-express or increase the activity of some of the membrane proteins discussed above^[52]:

- A subunit of a vacuolar H⁺-ATPase proton pump^[53]; and
- NHE1 (sodium hydrogen exchanger 1)^[54-56].

Proton pumps and NHE1 [see [Figure 4](#)] are directly related to the pH gradient inversion: increasing intracellular alkalization and decreasing extracellular pH. P-gp has a direct connection with intracellular and extracellular pH because:

- Intracellular acidification downregulates P-gp^[57]; and
- Extracellular acidity increases P-gp expression by up to 5-10-fold *in vitro* ^[58].

This particular P-gp/pH relationship may explain some cases of intrinsic resistance, where there was no previous contact with any chemotherapeutic drug.

Apoptosis requires intracellular acidosis

The main objective of chemotherapy consists in inducing the programmed death (apoptosis) of malignant cells^[59,60]. If this objective is not achieved, the tumor is resistant^[61]. Tumors have the ability to suppress apoptosis to a certain extent^[62]. There are many different modes for achieving resistance to apoptosis. One of them is increased signaling through the pro-survival PI3K/AKT pathway. This is usually associated with, or may produce a high expression of, the anti-apoptotic Bcl2 proteins.

For example, high expression of the anti-apoptotic Bcl2 protein induces an MDR phenotype in lymphoma cells^[63]. Apoptosis is favored by low intracellular pH and impeded when it is high^[64]. There is abundant evidence showing that the intracellular decrease of pH is favorable for apoptosis:

- Deoxyribonuclease II is an essential enzyme in programmed cell death and requires an acidic environment for its action^[65].
- The first step in apoptosis consists of cytoplasmic acidification mainly due to proton export from mitochondria, thus alkalinizing this organelle and releasing cytochrome C^[66].
- Maximal activation of caspases is only achieved with acidic cytoplasm.
- Pharmaceuticals that decrease intracellular pH induce apoptosis. This is the case of lansoprazole (inhibits the proton pump)^[67], salinomycin^[68], and lonidamine. The antibiotic salinomycin has shown the ability to

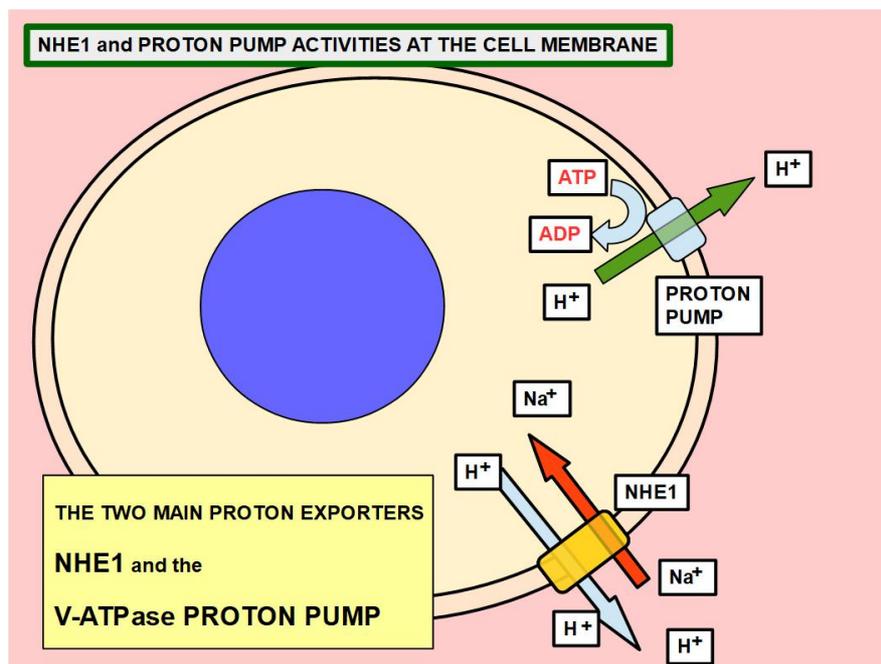

Figure 4. Increase of protons in the extracellular matrix originates mainly from the extrusion of intracellular protons by NHE1 and the proton pump.

decrease the efflux of doxorubicin as well as other chemotherapeutic drugs in MDR^[69-72] through P-gp inhibition^[73]. In addition to these effects, it also has anti-tumor activity independently of MDR inhibition^[74-82]. However, we presume that many of the salinomycin's anticancer effects are directly related to intracellular acidification. Conversely, P-gp has antiapoptotic effects^[83], and prolonged intracellular acidification decreases P-gp expression^[84].

PROOF OF CONCEPT OF THE pH-MDR RELATIONSHIP

It has been known since 1990 that multidrug-resistant cells have a higher pH than their non-resistant counterparts^[85]. This pH is higher on average by 0.1-0.2 and has been found in many different malignant cell lines. Although this is not a universal finding, it is quite frequent. There is also evidence that the increased intracellular pH is partly due to increased NHE1 activity.

MDR1 expressing cells were resistant to complement-mediated cytotoxicity; however, interestingly, malignant cells not expressing MDR1 that were manipulated to increase their pHi also showed similar resistance to complement-mediated cytotoxicity. Complement deposition in the cell membrane was reduced and delayed in both types of cells to a similar magnitude^[86].

Belhoussine *et al.*^[87] confirmed the higher intracellular pH in MDR cells. They also found that these cells had more acidified vesicles, which were more acidic than their sensitive counterparts. According to the authors, these findings suggest that non-MDR cells have a lesser ability to remove protons.

Interestingly, some publications showed the ability of amiloride, an NHE1 inhibitor and cell acidifier, to reverse both the pHi increase and MDR^[88, 89].

Hamilton *et al.*^[90] showed that verapamil, a classic P-gp inhibitor, lowered pHi, but they considered these two factors unrelated.

In 1997, Robinson *et al.*^[91] found that the expression of MDR1 had the ability to delay apoptosis in fibroblasts transfected with the MDR1 gene and exposed to cytotoxic substances, colchicine in particular. The sole increase of pHi in non-transfected cells was able to induce a similar apoptotic delay. This finding suggests at least two things:

- (1) Apoptosis requires low pHi; and
- (2) One of the mechanisms used by MDR to oppose apoptosis is to maintain the increased pHi.

What remains to be seen is whether high pHi is a facilitating mechanism for resistance to apoptosis or a causal one. This report is in line with that by Weisburg^[86] and supports the idea that increased pHi by itself can induce an MDR phenotype.

MDR has a “protective” effect against caspase-dependent apoptosis. Inhibition of P-gp with specific antibodies increased drug- or Fas-mediated apoptosis through caspase activation in drug-resistant cells^[92], and activating caspases requires an acidic cytoplasm. Thus, protection from apoptosis seems to be a synergic activity of MDR proteins plus intracellular alkalinity.

The pH gradient inversion, with its intracellular alkalinity and without MDR proteins, has shown that it can prevent intracellular accumulation of chemotherapeutic agents. In this regard, Simon *et al.*^[52] showed that intracellular alkalinity can substantially decrease accumulation and modify the intracellular distribution of weak alkaline chemotherapeutic drugs without any efflux mechanism in place. Intracellular alkalinity can prevent drugs from binding to their targets. Therefore, it is not only the extracellular ion-trapping effect that impedes the activity of weak alkaline drugs. In the experiments performed by Simon *et al.*^[52], non-resistant myeloma cells had a significantly lower intracellular pH compared with myeloma chemo-resistant cells (7.1 vs. 7.45).

Proton pump inhibitors have shown the ability to decrease or inhibit the MDR phenotype^[93]. Cisplatin treatment increased V-ATPase proton pump expression, and pHi was significantly increased in cisplatin-resistant cells. The DNA-binding ability of cisplatin was significantly enhanced in a more acidic pHi, suggesting that cisplatin's cytotoxicity was modulated by pHi. Proton pump inhibitors such as bafilomycin could synergistically increase cisplatin's cytotoxicity. These findings show that pHi is a key player in cisplatin's effects^[94]. Unfortunately, bafilomycin cannot be used in clinical practice due to its toxicity.

Thiebaut *et al.*^[95] confirmed the higher pHi in resistant cells compared with their non-resistant counterparts. They performed an experiment in which they raised the extracellular pH and found that non-resistant cells maintained a pHi around 7, but the resistant cells markedly increased their pHi. pHi did not increase when they treated resistant cells with P-gp inhibitors, and they suggested that P-gp also behaves as a proton exporter.

Hoffman *et al.*^[96] showed that the level of resistance in MDR cells was correlated with two other parameters, namely pHi and low membrane electrical potential. Resistance was induced when they increased pHi in non-resistant cells. Furthermore, membrane depolarization also conferred a mild chemoresistance without any P-gp participation.

NHE1 is the main proton exporter, albeit not the only one, and it is overexpressed/over-active in cancer cells^[97]. This is particularly so in resistant cells^[97]. Cariporide is a powerful experimental NHE1 inhibitor. Interestingly, cariporide, which acidifies cytoplasm, is also able to sensitize resistant-breast cancer cells to doxorubicin^[54].

NHE1 inhibition with cariporide reversed imatinib resistance in BCR-ABL-expressing leukemia cells^[98-100], and NHE1 knockdown sensitized malignant cells to cisplatin-induced apoptosis^[101]. Inhibiting proton extruders, among them NHE1, increased doxorubicin's cytotoxic effects on breast cancer cell lines^[102].

pH regulation implies the participation of many players, in addition to NHE1. Membrane carbonic anhydrases are among these participants. Interestingly, by inhibiting membrane CAs, MDR can be reversed^[103-108].

The inverted pH gradient has roles at both ends of the gradient: while cytoplasmic acidification downregulated P-gp^[109], extracellular acidity upregulated it^[110]. This finding explains why it is not enough to act pharmacologically on one of the components of pH deregulation; both need to be addressed.

Despite all the evidence supporting the idea that high pHi is an indispensable condition for the MDR phenotype, Young *et al.*^[111] showed that increased intracellular pH is not a necessary condition for P-gp drug extrusion activity. However, we consider that this research has a conclusion bias because it only proves acid extrusion but not drug extrusion. Actually, this research showed that P-gp seems to have proton extruding abilities.

Coley *et al.*^[112] found that drug resistance was related to high electric conductivity. Conductivity is not directly related to pH because it depends on the total ions (including hydrogen ions) in a solution, while pH depends only on hydrogen ions.

Mulhall *et al.*^[113] showed a strong inverse relationship between conductivity and initiation of apoptosis. Thus, increased cytoplasmic conductivity seems to increase the apoptosis resistance found in resistant cells.

From these two last publications, we can deduce that the “ideal” drug-resistant cells seem to be those with:

- (1) high electrical conductivity; and
- (2) markedly elevated cytoplasmic pH.

These “ideal” resistant cells are refractory to apoptosis induction. We can also speculate, at this point, that increased intracellular pH is not mandatory for P-gp drug extruding activity, but it is a valuable resource for resistance to apoptosis.

Confirming the importance of conductivity, it was found that the cystic fibrosis transmembrane conductance regulator (CFTR), another member of the ABC family, decreases plasma membrane electrical potential when it is over-expressed and at the same time generates an MDR phenotype, but with a low intracellular pH. There are some similarities between this regulator and P-gp and a striking difference regarding pH^[114].

NHE1 activity has been found to be increased in many tumors, and its downregulation re-sensitized cells to chemotherapy drugs^[115, 116]. Drug-induced cellular surface tension modifications can impact P-gp activity^[117].

Surface tension (interfacial tension) causes membrane rigidity^[118]; thus, pH plays a fundamental role in this phenomenon. Furthermore, high pH increases membrane lipid electric charges. Phosphatidylethanolamine, a normal component of the cell membrane, is involved in acid-base equilibrium with the medium.

There is abundant evidence showing that modifying cell membrane fluidity (rigidity) can reduce P-gp activity, thus reversing MDR^[119-124]. Surfactants that reduce surface tension, such as Tween 80 (polysorbate 80), are able to reduce P-gp activity^[125] and improve drug delivery into the cell^[126].

HYPOTHESIS/THERAPEUTIC PROPOSAL

Based on the evidence discussed above, a triple approach against MDR is proposed here. This consists of a known P-gp inhibitor such as verapamil associated with a surfactant and a pH gradient reversal scheme.

Verapamil

Verapamil, a calcium channel blocker, was first found to be an inhibitor of MDR in 1981^[127]. It is now a well-known P-gp inhibitor that impedes P-gp protein expression at the transcriptional level^[128] and increases ATP consumption in MDR cells^[129]. Direct binding of verapamil to P-gp has also been described^[130]. There is abundant evidence about this drug's impact against MDR^[131-137].

The surfactant Tween 80

As mentioned above, surfactants reduce cell membrane rigidity, thus counteracting one of the tools employed by MDR proteins to reject chemotherapeutic drugs. In this regard, surfactants reduce chemoresistance^[138]. There is also abundant evidence concerning Tween 80's anti-MDR properties^[139-142].

The pH gradient reversal scheme

This scheme is based on five drugs that target different cell membrane proteins involved in pH homeostasis and in the inverted pH gradient. Its objective is to partially downregulate all the participants in the pH gradient inversion. Full blown inhibition of all of them would be impossible without serious undesired consequences for normal cells. However, partial inhibition is possible with no toxicity. These pH modulators are:

- (a) amiloride;
- (b) acetazolamide;
- (c) lansoprazole;
- (d) quercetin; and
- (e) topiramate.

The appropriate combination of these drugs creates an important decrease of the intracellular pH and at the same time increases extracellular pH. Targeting pH alterations in cancer is becoming a valid strategy in complementary treatments^[143].

- Amiloride is an FDA-approved potassium-saving diuretic in clinical use for the treatment of cardiovascular diseases and is usually associated with other diuretics such as hydrochlorothiazide. Amiloride's main objective in the scheme is the inhibition of NHE1. Although it is a weak NHE1 blocker, at clinical doses, it is the only available approved drug. There are more potent NHE1 inhibitors; however, they are neither on the market nor FDA-approved. Evidence supporting amiloride's anticancer effects is abundant^[144-150] and involves actions derived from its intracellular acidifying properties as well as its ability to inhibit urokinase-type plasminogen activator (uPA)^[151-154]. In addition, amiloride decreases the release of tumor exosomes^[155-158]. This exosome inhibition also reduces proton discharge and blocks an important pathway of cancer cell communication. Specifically, amiloride and its derivatives reversed MDR in different types of tumors^[159-162].

- Acetazolamide is a nonspecific carbonic anhydrase inhibitor. Cytoplasmic pH lowering is a known effect of this diuretic^[163-165] that has been in medical practice for over sixty years and is FDA approved for uses not related to cancer. There is also evidence of its ability to slow cancer growth^[166,167] and inhibit MDR^[168]. Furthermore, Zheng *et al.*^[169] found that MDR in some tongue cancers was not produced by the three known MDR proteins of the ABC family, but rather by over-expression of CAIX. When CAIX was downregulated by antisense oligonucleotides or acetazolamide, the tumor was re-sensitized. Kopecka *et al.*^[170] showed that the other membrane carbonic anhydrase, CAXII, physically interacted with P-gp on the cell surface. Silencing CAXII or inhibiting it with acetazolamide created a low intracellular pH that altered P-gp's ATPase activity and promoted chemosensitization in MDR cells. There is active ongoing research for specific CAIX and CAXII inhibitors that would make it possible to circumvent the side effects of acetazolamide^[171]. For the time being, and until these new molecules are approved, we can only count on acetazolamide as a CA inhibitor.

- Lansoprazole is a vacuolar ATPase proton pump inhibitor approved by the FDA for the treatment of diseases related to excessive gastroduodenal acid production. At the cellular level, lansoprazole has the ability to inhibit proton extrusion from the cell, thus acidifying the intracellular milieu. Proton pumps can be found in intracellular membranes and the cell membrane. Those located in lysosomes keep the intralysosomal space acid while removing protons from the cytoplasm [Figure 5].

Lansoprazole was able to induce apoptosis in breast cancer cells^[172]. Regarding MDR, lansoprazole reversed it in pets^[173]. Other proton pump inhibitors, such as omeprazole, pantoprazole, and esomeprazole, showed incremental effects on different chemotherapeutic drugs^[174-176]. Unfortunately, there are also negative findings, e.g., pantoprazole in a clinical trial for docetaxel in metastatic castration-resistant prostate cancer showed no effects^[177], despite the favorable results in laboratory level cell tests^[178-179]. Pantoprazole even increased tumor growth and decreased chemotherapeutic cytotoxicity in mice^[180]. The benefits or disadvantages of pantoprazole remain controversial. According to Wang *et al.*^[181], proton pump inhibitors increased chemosensitivity and improved overall survival and progression-free survival in patients with advanced colorectal cancer. It is possible that proton pump inhibitors are not all the same regarding their anticancer effects. This is the reason we choose lansoprazole, which is less controversial than pantoprazole. Proton pump inhibitors decreased cisplatin sequestration in endosomes that were finally released from the cell in a melanoma model^[182]. Luciani *et al.*^[183] treated malignant cells with proton pump inhibitors, improving the accumulation of intracellular cytotoxic drugs. Intermittent proton pump inhibitors associated with standard chemotherapy administration improved the clinical outcome in metastatic breast cancer patients^[184].

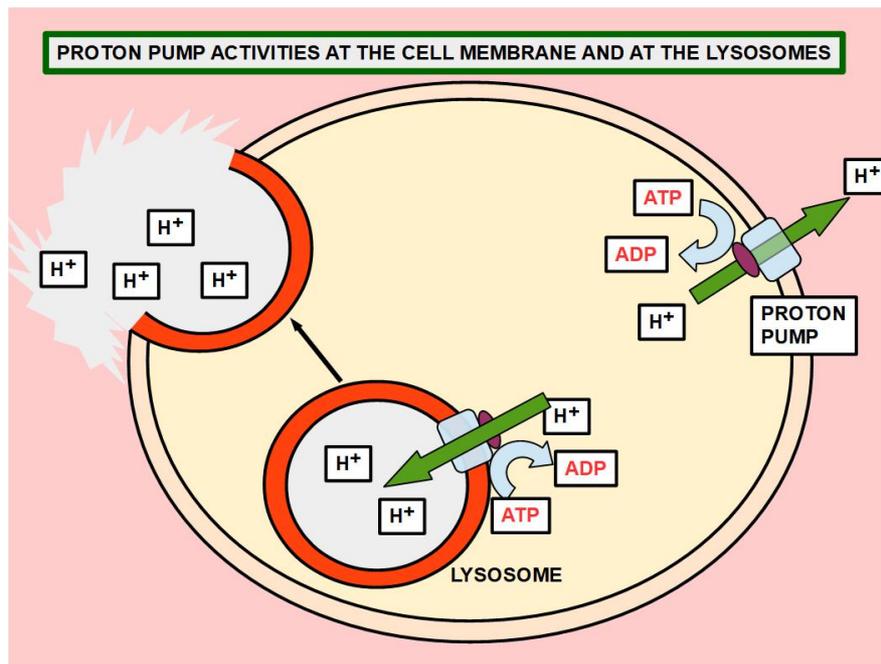

Figure 5. Different arrangements of proton pumps in the cell membrane and lysosomes. While in the cell, membrane the pump extrudes protons towards the extracellular space, in the lysosome, it pumps the protons into it. In a further step, the lysosome releases protons into the matrix. The functional end result is the same in both cases: inversion of the pH gradient.

• Quercetin is a natural flavonoid that is not approved as a drug by the FDA but is available as an over-the-counter nutritional supplement. However, it is the only compound that can be found on the market with a strong ability to inhibit monocarboxylate transporters^[185, 186]. MCT inhibition by quercetin induces important intracellular acidification^[187]. Significantly, there is considerable evidence of its capacity to reverse the MDR phenotype^[188-218]. Despite this large body of evidence, absolute lack of toxicity, and low cost, we could not find clinical trials exploring the substance's ability for MDR reversal. Adverse events using high levels of quercetin (1 g daily) as a nutritional supplement have been rarely reported^[219]. Quercetin also has additional beneficial effects in cancer:

- (a) Inhibition of the PI3K/Akt/mTOR pathway^[220, 221];
- (b) Proteasome inhibition that leads to mTOR inhibition and autophagy^[222, 223];
- (c) Decrease of ROS that diminishes PKC activity^[224];
- (d) Cancer cell-specific inhibition of the cell cycle^[225, 226];
- (e) Downregulation of heat shock protein 90^[227];
- (f) Inhibition of β -catenin signaling^[228];
- (g) Inhibition of pleiotropic kinases^[229]; and

(h) Induction of apoptosis^[230].

- Topiramate is an FDA-approved drug for the treatment of seizures and epilepsy. It has four pharmacological effects that can benefit MDR reversal: (1) carbonic anhydrase inhibition; (2) intracellular acidification; (3) inhibition of voltage-gated sodium channels; and (4) inhibition of aquaporin 1^[231-235]. There are no publications on topiramate having direct effects on MDR; however, refractory epilepsy in rats has been found to be associated with increased expression of P-gp^[236, 237]. Topiramate and other anticonvulsants are substrates for P-gp. Although there is no empirical proof, we suspect that topiramate may saturate P-gp extrusion capacity. The reason for including topiramate in the scheme is mainly for two of its effects: cytoplasmic acidification and voltage-gated sodium channel inhibition.

- Statins are inhibitors of the *de novo* synthesis of cholesterol by blocking hydromethyl glutaryl coenzyme A reductase, an enzyme that is a rate-limiting factor for mevalonate synthesis and the mevalonate pathway. Therefore, statins decrease endogenous cholesterol production. Cell membrane rigidity depends on the amount of cholesterol, among other factors.

DISCUSSION

pH homeostasis is a complex mechanism in which different transporters, exchangers, channels, and enzymes are involved in overlapping proton and ionic trafficking between different cellular compartments. The results of these ionic movements lead to the best possible pH balance for cellular functions. Tumor pH homeostasis is different from that found in normal tissues, and this difference involves a proliferative and progressive advantage for the malignant phenotype. Each enzyme in a complex organism has a specific pH in which it works at the optimum speed and capacity. This is the pK. Tumors, by creating a different pH homeostasis, are signaling which enzymes should be more active and when, thus regulating tumor metabolism.

This essentially means that pH is a signaling molecule. If anyone doubted that pH is a molecule, he or she would be right. It is not a molecule but many molecules, or, even better, many protons. The cell behavior is thus conditioned by the number of protons present. The MDR phenotype shows a slight difference with the drug-sensitive one: a higher intracellular pH. This difference allows for two characteristics of the MDR cell:

- (1) A more rigid cell membrane that plays a role in impeding cytotoxic drug access inside the cell; and
- (2) A higher resistance to apoptotic signals.

A third characteristic must be added to this: the ion trapping produced by the strongly acidic extracellular matrix.

Multidrug resistance is not a one-protein job. At a certain point, P-gp and its sister molecules of the ABC family require adequate cell membrane rigidity, higher apoptosis resistance, and more ion trapping, whether in the matrix or inside lysosomes. This means the appropriate pH. MDR seems to function better with a high intracellular pH. This does not mean that one is the cause of the other. An MDR phenotype can be achieved even with low intracellular pH; this is the case of CFTR. Conversely, a high pH_i can generate an MDR phenotype without over-expressing the MDR proteins.

This evidence hints towards the idea that high pHi and the MDR proteins complement each other, rather than there being a causal relationship. Both come together in one characteristic of the resistant cell: increased cell membrane rigidity. High pHi induces membrane rigidity, which in turn cooperates with MDR.

All this said, it becomes evident that for a successful fight against MDR, it is not enough to downregulate P-gp, etc., but pH and cell membrane rigidity must be tackled as well. The scheme proposed here confronts the three issues:

- P-gp with calcium channel blockers such as verapamil or others;
- pH gradient inversion with the pH-centered treatment; and
- membrane rigidity with surfactants such as Tween 80 and others.

The MDR problem has even further complexities. Balza *et al.*^[238], working with two different breast cancer cells, a triple-negative one and a hormone-sensitive one, found that:

- (1) Associating cisplatin with an amiloride derivative was significantly more effective than treatments with cisplatin plus esomeprazole in triple-negative cells; and
- (2) Esomeprazole alone was more effective in hormone-sensitive cells.

This shows that pH-centered treatments as complementary therapy may differ according to the type of cell.

Importantly, persistent intracellular acidification was able to downregulate the MDR phenotype^[84].

Figure 6 is a summary of concepts discussed in this paper, while Figure 7 shows the site of action of MDR inhibitors.

It is important to note that extracellular acidity per se can induce P-gp expression. Figure 6 shows that the ABC family of drug extruders, intracellular alkalosis, and extracellular acidosis can all generate an MDR phenotype in an independent manner. However, there is evidence supporting the relationships among these three factors. Increased extracellular acidity induces P-gp expression. MDR cells with increased P-gp expression usually show increased intracellular alkalinity^[87, 95]. This, in turn, prevents apoptosis and increases cell membrane rigidity^[112, 113], creating the ideal environment for drug resistance^[117].

CONCLUSIONS

MDR represents the last chapter of chemotherapeutic cancer treatment. It leaves the oncologist on a very narrow path to continue patient care. Unfortunately, there is no accepted treatment protocol. In this review, we propose a multidrug approach that simultaneously targets three important MDR characteristics, namely the MDR proteins, dysregulated pH, and cell membrane rigidity, with a rationally constructed approach.

This scheme has not been tested on clinical grounds. However, each of its components has separately provided successful experimental results, with the exception of topiramate, which has not been tested in the MDR context. This justifies their combination, as each of them targets different aspects of the MDR

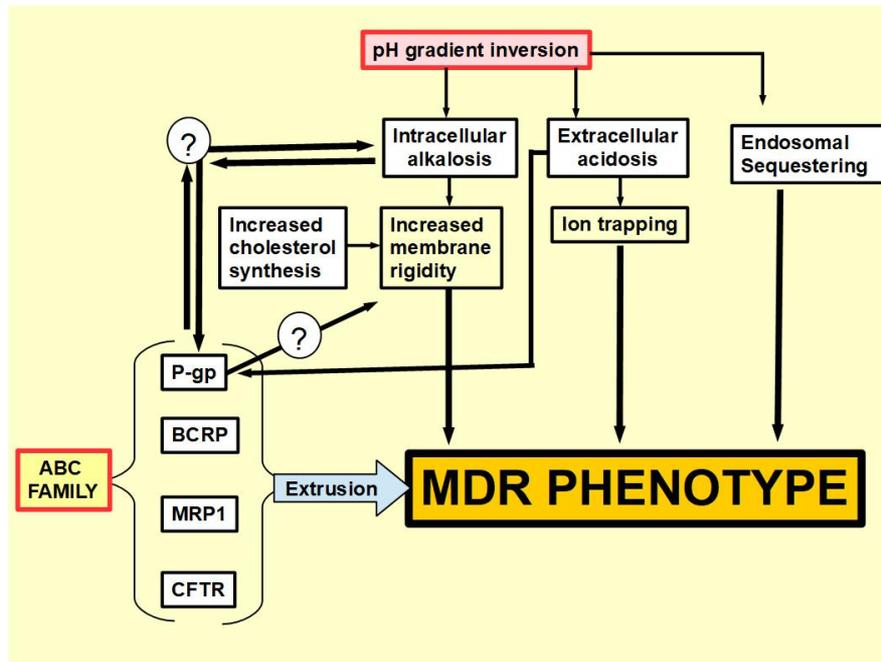

Figure 6. A synthesis of known and unknown relationships between pH and the MDR phenotype. Based on references cited above (Ref. [48-50,239-241]). Multiple drug resistance (MDR)

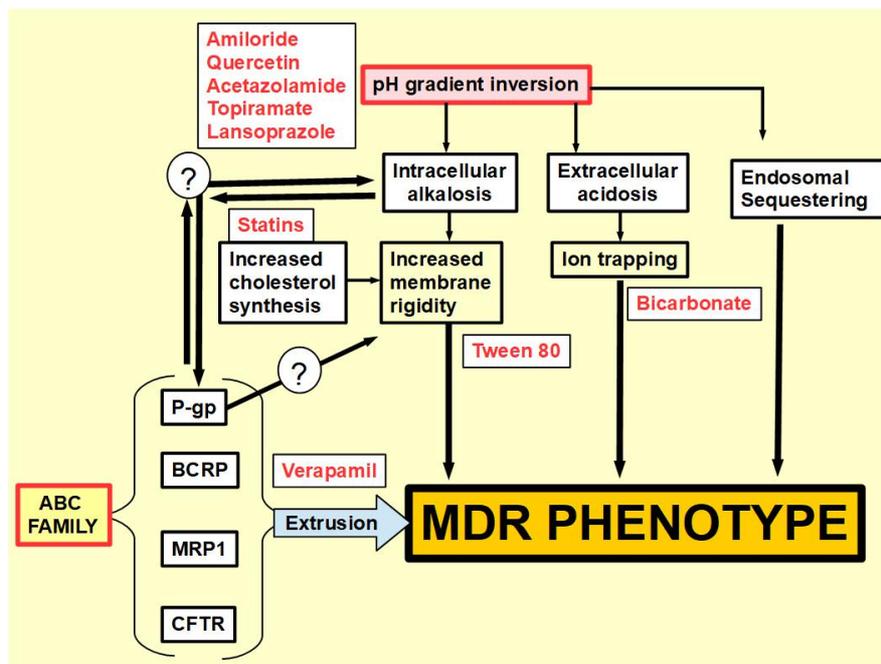

Figure 7. Site of actions of the anti-MDR scheme. Reversion of the deregulated pH gradient is able to act against the MDR phenotype in two ways, by decreasing extracellular acidity and reducing intracellular pH. MDR: Multiple drug resistance.

conundrum. Well-planned clinical trials are needed to evaluate this proposal. Furthermore, the scheme has almost no toxicity for normal cells, and there is ample clinical experience with the use of all these drugs.

Abstract

Ovarian cancer is one of the most lethal gynecologic cancers. The standard therapy for ovarian cancer has been the same for the past two decades, a combination treatment of platinum with paclitaxel. Recently, the FDA approved three new therapeutic drugs, two poly (ADP-ribose) polymerase inhibitors (olaparib and niraparib) and one vascular endothelial growth factor inhibitor (bevacizumab) as maintenance therapies for ovarian cancer. In this review, we summarize the resistance mechanisms for conventional platinum-based chemotherapy and for the newly FDA-approved drugs.

Keywords: Drug resistance, ovarian cancer, cisplatin, carboplatin, paclitaxel, olaparib, niraparib, bevacizumab

INTRODUCTION

Ovarian cancer is one of the most lethal gynecologic cancers, with projected 21,410 cases and 13,770 deaths in the United States in 2021^[1]. The standard treatment for ovarian cancer is platinum-based chemotherapy (carboplatin or cisplatin) in combination with paclitaxel, and it has remained the same for the past two decades. Most patients are initially responsive to these treatments; however, relapse occurs in around 80% of women due to platinum resistance, causing the need to comprehend its molecular mechanisms to improve

treatment efficacy and patient survival^[2].

Cisplatin was first synthesized in 1844 by Michele Peyrone, but it was not until 1965 that Barnett Rosenberg from Michigan State University discovered that cisplatin inhibits cell division. Since then, cisplatin has been widely used for the treatment of bladder, lung, head and neck, testicular, and ovarian cancers^[3]. In 1978, it became the first FDA-approved platinum-based compound for cancer treatment^[4]. Subsequently, a second-generation platinum-drug, carboplatin, was developed and became FDA-approved in 1989^[5,6].

In the 1960s, the National Cancer Institute and the U.S. Department of Agriculture collaborated to identify potential cytotoxic anticancer properties from 115,000 plant extracts^[7]. From screening these samples, Arthur Barclay identified cytotoxic properties in bark extract from the Pacific yew tree, *Taxus brevifolia*, in 1964. Three years later, the active ingredients from *Taxus brevifolia* were identified and named as taxol. A fully synthetic version of the drug, called paclitaxel, was FDA-approved for use as a chemotherapeutic agent for ovarian cancer in 1992. Clinical trials in the early 2000s have shown improved outcomes in women with relapsed ovarian cancer when treated with paclitaxel in addition to platinum-based chemotherapy^[8]. Since then, the standard treatment of ovarian cancer patients continues to be platinum-based chemotherapy in combination with paclitaxel.

Recently, there have been new advancements in treatment recommendations for ovarian cancer patients with the emergence of three new FDA-approved chemotherapeutic drugs. In 2018, the first poly (ADP-ribose) polymerase inhibitor (PARPi), olaparib, was FDA-approved as maintenance therapy for ovarian cancer, followed by the approval of niraparib (another PARPi) in 2020. In 2020, a vascular endothelial growth factor inhibitor (VEGFi), bevacizumab, was also FDA-approved as another maintenance therapy for ovarian cancer. In this review, we will discuss the resistance mechanisms of conventional chemotherapies and provide insights into the resistance mechanisms against the recently FDA-approved chemotherapeutic drugs for ovarian cancer.

MECHANISMS OF RESISTANCE TO PLATINUM AGENTS

Cisplatin and carboplatin target cancer cells by forming adducts/crosslinks with DNA purine bases, with a preference for guanine. These crosslinks result in DNA damage that impedes proper genome replication, transcription, and triggers cell apoptosis^[9]. A prevalent resistance mechanism centers around inhibiting the compound from reaching the DNA, which is mediated by efflux transporters. In addition, once DNA lesions are formed, DNA repair pathways are activated to fix DNA damage caused by the platinum agents, as described below [Figure 1].

Influx and efflux transporters

One of the most widely accepted mechanisms of platinum resistance is the dysregulation of both influx and efflux pumps/transporters, which modulates the transport of platinum in ovarian cancer cells. When the first multidrug resistance transporter, an ATP-binding cassette transporter (also called ABCB1, P-glycoprotein, P-gp, or MDR1), was identified to have a function in the efflux of anticancer drugs out from cancer cells, it was also tested whether cisplatin is pumped out by P-gp^[10-13]. However, it was identified that cisplatin is not a direct substrate of P-gp. Thus, it prompted the investigators to identify transporters that are similar to P-gp but have the ability to efflux cisplatin. This led to the discovery of the influx transporter, copper transporter 1 (CTR1), and efflux transporters, ATPase copper-transporting alpha and beta (ATP7A and ATP7B). Subsequent studies have shown that cisplatin-sensitive A2780 ovarian carcinoma cells have higher CTR1 expression than cisplatin-resistant A2780CP^[14] and that overexpression of CTR1 in A2780 cells increased the influx of cisplatin^[15]. Clinically, patients who had cytoreductive surgery followed by platinum-

Mechanisms of Platinum Resistance

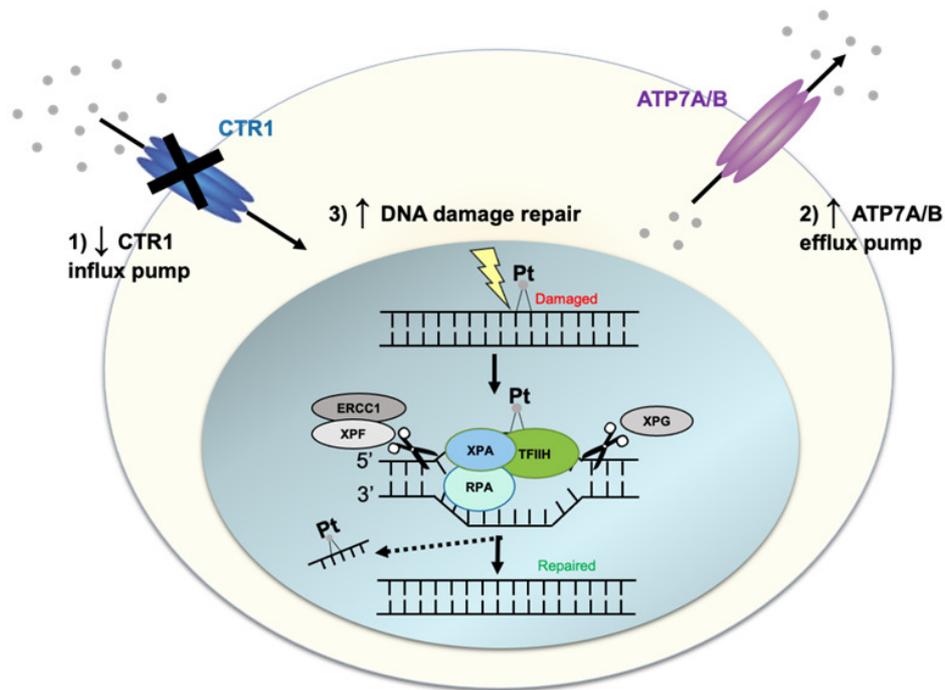

Figure 1. Schematic illustration of platinum resistance.

based chemotherapy had CTR1 mRNA levels that correlated with platinum sensitivity^[16]. Interestingly, cisplatin exposure in A2780 cells triggers rapid downregulation of CTR1, thereby inhibiting further cisplatin accumulation in the cells. This negative feedback loop has been proposed to result in resistance to cisplatin^[17]. Cisplatin-induced downregulation of CTR1 is inhibited by the proteasome inhibitor bortezomib^[18]. A clinical trial (NCT0107441) was recently completed to determine intraperitoneal bortezomib's maximum-tolerated dose and dose-limiting toxicities when administered with carboplatin in an epithelial ovarian, fallopian tube, or primary peritoneal cancer.

On the other hand, ATP7A/B efflux platinum^[19,20]. However, only the silencing of ATP7B, and not in the silencing of ATP7A, in cisplatin-resistant cells (A2780-CP20 and RMG), resulted in increased sensitivity to cisplatin^[21]. Clinical studies have also supported the prognostic value of ATP7B in ovarian cancer patients treated with cisplatin therapy^[22,23]. In addition, a clinical study on 152 ovarian cancer patients has shown that genetic polymorphism in ATP7A is implicated in cisplatin resistance, and genetic polymorphisms in CTR1 is implicated in carboplatin resistance^[24].

DNA repair

After entry of platinum drugs into the cytoplasm via CTR1, the platinum drugs enter the nucleus, where they form intrastrand and interstrand crosslinks with the DNA. Resistance to platinum occurs via DNA repair pathways. Single-strand DNA lesions are repaired by nucleotide excision repair (NER), and double-strand lesions are repaired either by homologous recombination (HR) or non-homologous end-joining (NHEJ) pathway^[25]. In the NER pathway, the site of the DNA lesion is cleaved by ERCC1-XPF and XPG endonucleases to remove the DNA lesion. High ERCC1 expression is associated with platinum resistance in epithelial ovarian cancer but is not associated with patient survival^[26]. Promoter methylation of mismatch

repair (MMR) genes can also lead to cisplatin resistance by downregulating MMR-driven DNA damage response^[27]. The MMR pathway carries DNA repair during DNA replication and recombination and specifically recognizes mismatched base pairing, insertions, and deletions^[28]. In a study using cisplatin-resistant and MMR-deficient ovarian tumor xenografts caused by MLH1 promoter hypermethylation, treatment with the demethylation agent, 2'-deoxy-5-azacytidine, was shown to improve response to cisplatin and carboplatin^[27].

Emerging studies: other resistance mechanisms to platinum agents

More recently, other examples of platinum resistance have been explored. These include upregulating of deubiquitination of proteins targeted for proteasomal degradation^[29], increased cisplatin-induced autophagy^[30], and dependence on mitochondrial oxidative phosphorylation for energy supply^[31]. Metabolic reprogramming and angiogenesis are hallmarks of cancer^[32] that provide tumor supply of nutrients and oxygen, energy efficiency, and drive cell survival; thus, they are also speculated to be involved in chemotherapy resistance. For instance, it has been recently shown that upregulation of the serine/threonine kinase Aurora-1 in cisplatin-resistant ovarian cancer increases glycolysis and suppresses cell senescence by stimulating the transcription factor sex determining region Y-box 8 (SOX-8)^[33]. Another study has shown that fibrillin-1 (FBN1) is significantly upregulated in cisplatin-resistant ovarian cancer organoids and tissues and that FBN1 drives phosphorylation of VEGF2 and nuclear translocation of the transcription factor signal transducer and activator of transcription 2 (STAT2), which affects the expression of genes associated with STAT2-mediated glycolysis and angiogenesis^[34]. A combination of FBN1 knockout and an antiangiogenic drug was demonstrated to improve cell sensitivity to cisplatin. Altogether, there are several emerging studies on mechanisms of platinum resistance in ovarian cancer.

MECHANISMS OF RESISTANCE TO PACLITAXEL

Paclitaxel exerts its effect by binding to the β -subunit of tubulin and causing tubulin polymerization in the absence of GTP, a factor that is normally required for microtubule polymerization^[35]. Once bound, paclitaxel stabilizes microtubules and prevents tubulin depolymerization. This inhibits the shortening of the microtubules during anaphase when it is necessary to pull apart sister chromatids, which results in cancer cell death^[36]. Below, we discuss several mechanisms of resistance to paclitaxel [Figure 2].

Efflux by P-glycoprotein

Like platinum-based chemotherapies, cancer cells can develop resistance to paclitaxel via efflux of paclitaxel out from the cancer cells. However, unlike cisplatin, paclitaxel is the major substrate of P-gp^[11,37]. In order to prevent P-gp mediated efflux of paclitaxel, recent studies have shown that mutations in P-gp can suppress the efflux of paclitaxel^[38], and substitution of 14 conserved residues in homologous transmembrane helices 6 and 12 with alanine resulted in reversal of P-gp from efflux to influx pump^[39], a potential future avenue for preventing efflux of paclitaxel.

Tubulin isotype composition

Paclitaxel is involved in the stabilization of microtubules, and as such, changes in microtubule composition can play a key role in determining cell susceptibility to paclitaxel. While tubulin has multiple isoforms, microtubules composed of mostly the β III isoform show significantly lower stability compared to β I and β II microtubules^[40]. Lower microtubule stability can counteract the microtubule-stabilizing effect of paclitaxel and thus allow cell division to occur despite paclitaxel activity. Paclitaxel-resistant ovarian tumors have been sampled to reveal up to a 4-fold increase in the proportion of β III isoform, indicating that upregulation of β III isoform production may confer paclitaxel resistance^[41].

Mechanisms of Paclitaxel Resistance

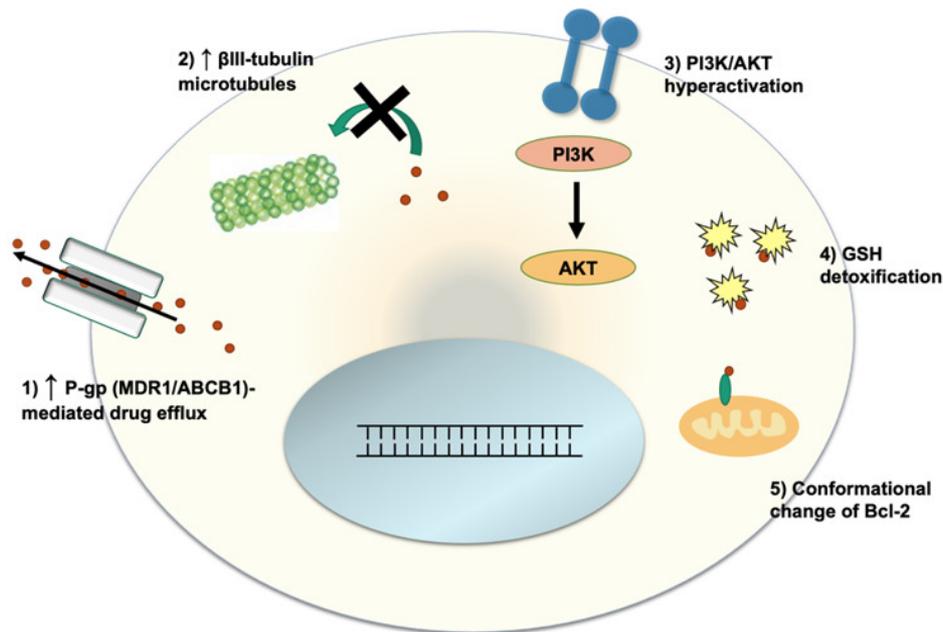

Figure 2. Schematic illustration of paclitaxel resistance.

Phosphoinositide 3-kinase /protein kinase B pathway

The Phosphoinositide 3-kinase/protein kinase B (PI3K/AKT) pathway has been shown to be a key driver of metastasis and drug resistance in many different cancers, including ovarian cancer. Overactivation of this signaling pathway leads to the upregulation of factors involved in cell proliferation and migration. Mechanisms of PI3K/AKT hyperactivation include loss of function in PTEN (a negative regulator of PI3K/AKT), mutations in PI3K that confer constitutive activity, and hyperactivity of AKT^[40]. These mutations cause the activation of pro-mitotic factors that overpower the anti-proliferative signals that result from paclitaxel dosing.

Glutathione S-transferase 1

The detoxifying powers of the glutathione pathways are turned against paclitaxel in this resistance mechanism. In healthy cell conditions, Glutathione S-transferase P1 (GSTP1) production is inhibited by high PRMT6 activity, which inhibits the production of the GSTP1 precursor, G6PD. In this particular resistance mechanism, PRMT6 is downregulated in cancer cells, allowing for increases in G6PD production and higher levels of GSTP1 as a result. Thus, paclitaxel becomes sequestered by GSTP1 and detoxified in the cells before it can bind tubulin^[42]. In the A2780 ovarian cancer cell line model, GSTP1 knockdown suppressed the invasion and migratory properties of the cells and sensitized the cells to cisplatin and carboplatin^[43].

B-cell lymphoma 2 family

In the B-cell lymphoma 2 (Bcl-2) family, there are the pro-apoptotic factors, BAD and BAX, as well as the anti-apoptotic factors, Bcl-2, Bcl-XL, and Mcl-1^[44]. Paclitaxel has been found to alter Bcl-2 activity, transforming it into a pro-apoptotic factor^[45]. Mechanistically, paclitaxel mimics the nuclear orphan receptor Nurr77 to cause this effect. The Nurr77 and paclitaxel have structural similarities that explain this mimicry^[46]. Just like Nurr77, paclitaxel binds to the N-terminal loop of Bcl-2 and induces a conformational

change to expose the Bcl-2-homology 3 domain. Upon phosphorylation of this conformational isoform, Bcl-2 changes from an anti-apoptotic factor to a pro-apoptotic factor by inducing cytochrome c release from the mitochondria^[47]. Resistance to paclitaxel can be attributed to increases in anti-apoptotic Bcl-2 family members, as the anti-apoptotic factors inhibit FasL production, a ligand involved in cell death, by preventing its gene transcription^[44,48].

In addition, genetic differences in Bcl-2 have been attributed to varying rates of paclitaxel treatment success in patients. Recent studies have identified a T>C variant (RefSNP rs1801018) in the Bcl-2 sequence that is highly associated with paclitaxel resistance in multiple tumor types. In a retrospective genomic analysis of cancer patients, 73% of patients with T at location 21 did not respond to the platinum-paclitaxel combination therapy^[49]. Although the exact mechanism facilitating this resistance is currently unknown, the data indicate a vital relationship between the Bcl-2 sequence and paclitaxel susceptibility and resistance.

Paclitaxel and cisplatin cross-resistance

Cisplatin and paclitaxel are commonly used in conjunction since the two drugs bring cytotoxicity by distinct mechanisms and, thus, provide two unique barricades against uncontrolled cell growth^[9]. Yet, as cells become resistant to cisplatin, they can also become resistant to paclitaxel. One such mechanism of this is through upregulation of cell survival pathways. Cells can combat cisplatin- and paclitaxel-induced apoptosis by upregulation of cell survival pathways, such as TNF/NFκB^[50]. It is not yet known whether paclitaxel resistance mechanisms are able to confer cisplatin resistance, but the existence of common resistance mechanisms between the two drugs posits the idea.

MECHANISMS OF RESISTANCE TO PARP INHIBITORS

Olaparib and niraparib are two PARPi recently approved by the FDA for targeted therapy in ovarian cancer in 2018 and 2020, respectively. These drugs are currently used as maintenance therapies or advanced treatments of ovarian cancer in platinum-sensitive patients who have undergone chemotherapy as first-line chemotherapy^[51]. PARPi undermines single-strand DNA (ssDNA) damage repair, more specifically the base excision repair pathway, either by trapping PARP proteins on the DNA site of the lesion or by blocking PARP catalytic domain^[52]. This prevents the binding of NAD⁺, a cofactor necessary for the post-translational modification, named PARylation, onto targeted proteins to happen^[53]. Unrepaired ssDNA breaks lead to double-strand DNA (dsDNA) breaks and genomic instability, triggering cell death^[54]. Approximately 30 - 60% of the patients treated with PARPi respond to the treatment^[55]; however, several cases of resistance have been reported. As the first FDA-approved PARPi, olaparib is the most investigated in terms of resistance mechanisms and will be further discussed below [Figure 3].

DNA repair

Patients with impaired homologous recombination (HR) repair machinery often respond better to PARPi treatment. This combination leads to the accumulation of dsDNA breaks due to deficient DNA repair^[56]. Hence, most resistance to olaparib and other PARPi has been linked to restoring DNA repair activity. Recently, it was shown that olaparib-resistant epithelial ovarian cancer cells harboring BRCA2 mutation had augmented microhomology-mediated end joining (MMEJ) pathway, which allows the cells to overcome PARP inhibition^[57]. The increased expression of the epigenetic reader Bromodomain-containing protein 4 (BRD4) induces upregulation of aldehyde dehydrogenase 1 family member A1 (ALDH1A1), an enzyme associated with chemotherapy resistance through drug metabolism and inhibition of apoptosis signaling mediated by reactive oxygen species (ROS). ALDH1A1, in turn, is proposed to stimulate MMEJ and dsDNA repair. Thus, ALDH1A1 specific inhibition was shown to recover PARPi sensitivity. In another study, BRCA2-mutated high-grade serous ovarian carcinoma cells (HGSOC) resistant to olaparib exhibited

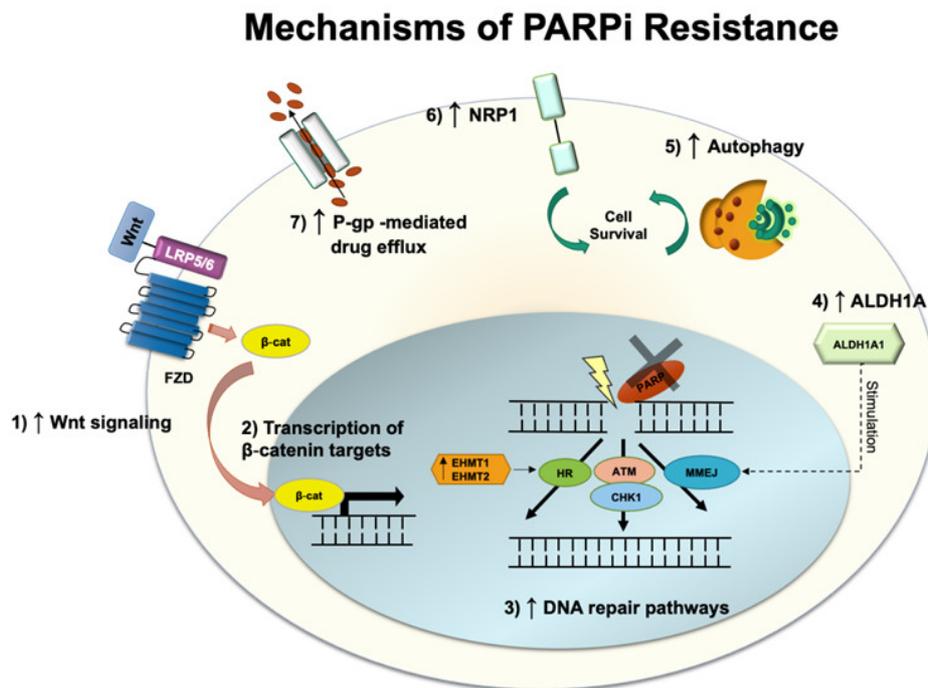

Figure 3. Schematic illustration of PARPi resistance. PARPi: Olymerase inhibitor.

histone-lysine-N-methyltransferase 1 and 2 (EHMT1/2) overexpression and consequent increase in histone H3 lysine 9 dimethylation, which was correlated with poorer overall survival^[58]. As EHMT1/2 has been demonstrated to play a role in DNA repair by directly recruiting DNA damage response factors, the interruption of its activity leads to HR and NHEJ impairment, and disruption of the cell cycle, sensitizing these cells to PARPi. Nonetheless, no increase in cell death rates was observed when EHMT1/2 was inhibited. An alternative mechanism of resistance to olaparib in HGSOc cell lines independent of BRCA reverse mutation was demonstrated to be associated with increased activation of the Wnt signaling pathway^[59]. Although Wnt drives different cell pathways by directly promoting β-catenin accumulation and upregulating β-catenin target-gene transcription, treatment with its inhibitor, pyrvinium pamoate, and olaparib abrogated DNA damage repair^[59]. Furthermore, olaparib-resistant cell lines were shown to have enhanced HR and distal NHEJ induced either by Wnt-dependent or independent mechanisms.

Cell cycle

The cell cycle regulation is critical for the proper execution of DNA repair^[60]. Upon recognition of DNA damage, checkpoint kinases ATM and ATR phosphorylate downstream signaling pathways to determine whether to continue with cell cycle progression or pause for DNA repair^[61]. HGSOc has universal p53 loss, which causes dysfunctional G1/S checkpoint, which makes the tumor be dependent on G2/M cell cycle arrest for DNA repair^[62]. This G2/M cell cycle arrest is mediated by the cell cycle checkpoint kinase 1 (Chk1) and is activated by the DNA replication stress marker ATM and ATR, allowing HR to fix dsDNA breaks in the presence of collapsed replication forks. Moreover, Chk1 phosphorylates BRCA2 and RAD51 recombinase, assisting their nuclear translocation and interaction. RAD51, in turn, mediates invasion and pairing of the broken DNA strand with the homologous chromosome, used as the template for DNA recombination and repair^[63,64].

Inhibition of Chk1 with prexasertib has been demonstrated to attenuate olaparib-induced RAD51 translocation to the nucleus and foci formation leading to HR deficiency in BRCA wild-type or BRCA2-restored function HGSOc^[62]. Thus, Chk1 inhibition was shown to enhance the sensitivity of ovarian cancer cells to DNA damage response inhibitors, such as PARPi, and the combination of both drugs decreases cell viability due to increased DNA damage and apoptosis. In addition, it promotes cell cycle progression to the M phase independent of the BRCA phenotype in cells once arrested in the G₂/M checkpoint by olaparib treatment only. Importantly, over 90% of HGSOc have abnormal function of the tumor-suppressor TP53^[65], meaning that cells rely on the G₂/M checkpoint in the absence of the G₁/S. The combinatory treatment forces the cell to enter the M phase even in the presence of unrepaired DNA breaks, leading to cell death.

Efflux transporters

Apart from DNA damage repair-associated mechanisms, other models were proposed to elucidate ovarian cancer resistance to olaparib. One such example is drug efflux pumps, and they have been widely explored to be involved in multi-drug resistance mechanisms. P-gp, which is encoded by *ABCB1* gene, is associated with first-line chemotherapy resistance to paclitaxel and other taxane drugs^[13]. *ABCB1* gene expression and copy number were shown to be increased in paclitaxel-resistant ovarian cancer cells presenting cross-resistance to olaparib, and both drugs were actively effluxed from the cells^[66]. Inhibition of P-gp with elacridar was able to resensitize the resistant cells to olaparib and paclitaxel, hence a combinatory treatment to improve sensitivity to PARPi. Similarly, targeting neuropilin-1 (NRP1), a transmembrane receptor that contributes to cell contact evasion and tumorigenesis in ovarian tumors, with the miRNA miR-200c, induces sensitization of resistant SKOV3 ovarian cancer cell lines (BRCA wild-type) to olaparib^[56]. In these cells, NRP1 was demonstrated to be present in higher levels compared to the sensitive UWB1.289 BRCA1-null cell line or the partially resistant UWB1.289 in which BRCA1 function was restored.

Autophagy

Regardless of the BRCA phenotype, clinical trials (NCT01847274; NCT02354586) have demonstrated that niraparib leads to better outcomes in patients with wild-type HR^[67]. Although niraparib resistance in ovarian tumors has been reported, whether similar pathways drive this as for other PARPi remains to be elucidated. As the FDA approval of niraparib happened more recently, only a few studies have explored its specific resistance mechanisms to date. Nonetheless, a recent study treating a variety of ovarian cancer cell lines, including the BRCA wild-type OVCAR8 and HEY cells, with four PARPis, olaparib, niraparib, rucaparib, and talazoparib, demonstrated increased autophagy activation^[68]. Autophagy has been described as a common resistance mechanism to overcome anticancer drugs by providing the energy supplies necessary for cell survival under stressful conditions. It also contributes to the hypoxic microenvironment and metabolic stress, two components modulated by cancer cells to escape cell death. Hence, targeting autophagy for downregulation may improve patient response to PARPi. Combining olaparib and inhibitor that can target autophagy may increase ATP phosphorylation and ROS formation. As a consequence, increased cell death and proliferation suppression were observed after the combinatory treatment. Further studies are needed to elucidate whether autophagy itself is enough to drive cell survival in cells containing high genomic instability.

In summary, ovarian cancers have several resistance mechanisms to PARPis. These include stimulating DNA damage response, preventing genomic instability either by upregulating Wnt signaling, inducing EHMT1/2 overexpression, or increasing ALDH1A1 levels. Alternatively, olaparib might be actively effluxed from the cells using the P-gp pump. Resistance to olaparib and niraparib has also been attributed to PARPi-mediated-autophagy, which contributes to the metabolic modulation of cancer cells and prolonged cell survival.

MECHANISMS OF RESISTANCE TO BEVACIZUMAB

Bevacizumab is a humanized monoclonal IgG1 antibody designed to target VEGF^[69] and was recently approved as maintenance therapy for ovarian cancer in 2020. VEGF, an angiogenic growth factor, is often produced by cancer cells to drive blood vessel growth and, consequently, divert nutrients directly to tumors^[70,71]. Bevacizumab binds directly to circulating VEGF, preventing it from interacting with VEGF-receptors, thus inhibiting angiogenesis by starving the tumor from nutrients. Resistance mechanisms against bevacizumab have been discussed in other cancer settings^[72,73]. Here, we discuss resistance mechanisms to bevacizumab in ovarian cancer [Figure 4].

Bevacizumab-induced decreased antibody uptake, increased vessel pericyte coverage, and angiogenesis

When angiogenesis occurs in solid tumors, it forms a defective vasculature with increased tumor permeability. This alters the tumor microenvironment and affects intra-tumoral drug delivery. When ovarian cancer SKOV3 mouse xenograft was evaluated for antibody uptake using PET imaging of ⁸⁹Zr-bevacizumab, it was observed that bevacizumab treatment decreased tumor uptake and lessened intra-tumoral accumulation of bevacizumab with increased vessel pericyte coverage^[74]. Pericyte promotes endothelial cell survival via activation of VEGF-A, and, therefore, may contribute to the resistance to VEGFi^[75,76]. In addition to increased vessel pericyte coverage, ovarian cancer cells can circumvent bevacizumab via angiogenesis. For instance, the crosstalk between endothelial cells and ovarian cancer cells can activate the PI3K/Akt pathway and stimulate the proangiogenic factor FGF2, overcoming VEGF-dependent vascularization as an evasive mechanism^[77].

Ephrin type-B receptor 4

Ephrin type-B receptor 4 (EphB4) is a tyrosine kinase receptor with a functional role in blood vascular morphogenesis and angiogenesis^[78]. While the exact resistance mechanism has not yet been determined, EphB4 is overexpressed in bevacizumab-resistant ovarian cancer SKOV3 xenograft and co-administration of bevacizumab with the EphB4 blocker, NVP-BHG712, results in reversal of resistance and inhibition of tumor growth^[79].

The mechanisms by which cancer cells develop resistance to bevacizumab have yet to be fully characterized. While the resistance mechanisms mentioned above have been identified, the future discovery of additional resistance mechanisms should be anticipated in the ovarian cancer setting.

CONCLUSION

In this review, we have described mechanisms of drug resistance against platinum, paclitaxel, olaparib, niraparib, and bevacizumab in the context of ovarian cancers. While we know many resistance mechanisms against platinum and paclitaxel, we continue to discover novel resistance mechanisms due to technological advancement in the field. There is currently a major interest in the field to understand the resistance mechanisms of new ovarian cancer treatments such as olaparib, niraparib, and bevacizumab. We anticipate more new insights and discoveries in novel resistance mechanisms as well as novel approaches to overcome drug resistance (i.e., nanomedicine^[80]) in the next few years.

Abstract

Pancreatic cancer is ranked as the fourth leading cause of cancer-related mortality and is predicted to become the second leading cause of cancer-related death by 2030. The cause of this high mortality rate is due to pancreatic ductal adenocarcinoma's rapid progression and metastasis, and development of drug resistance. Today, cancer immunotherapy is becoming a strong candidate to not only treat various cancers but also to combat against chemoresistance. Studies have suggested that complement system pathways play an important role in cancer progression and chemoresistance, especially in pancreatic cancer. A recent report also suggested that several signaling pathways play an important role in causing chemoresistance in pancreatic cancer, major ones including nuclear factor kappa B, signal transducer and activator of transcription 3, c-mesenchymal-epithelial transition factor, and phosphoinositide-3-kinase/protein kinase B. In addition, it has also been proven that the complement system has a very active role in establishing the tumor microenvironment, which would aid in promoting tumorigenesis, progression, metastasis, and recurrence. Interestingly, it has been shown that the downstream products of the complement system directly upregulate inflammatory mediators, which in turn activate these chemo-resistant pathways. Therefore, targeting complement pathways could be an innovative approach to combat against pancreatic cancer drugs resistance. In this review, we have discussed the role of complement system pathways in pancreatic cancer drug resistance and a special focus on the complement as a therapeutic target in

INTRODUCTION

Pancreatic cancer is ranked as the fourth leading cause of cancer-related mortality and is predicted to become the second leading cause of cancer-related death by 2030^[1]. About 90% of these tumors are pancreatic ductal adenocarcinomas (PDACs), tumors of the exocrine part of the pancreas. The cause of this high mortality rate is due to PDAC's rapid progression and metastasis, low rate of early detection, and development of drug resistance^[1].

In the last ten years, gemcitabine has been the most common treatment option for advanced-stage pancreatic cancer. However, even with this treatment option, the 5-year survival rate is still incredibly low, only 10% according to the American Cancer Society^[2]. Unfortunately, the survival rate is continuing to decrease due to increased incidences of chemoresistance in pancreatic cancer cells. Researchers have investigated to determine the mechanism of chemoresistance to improve the efficacy of gemcitabine and other chemotherapeutic drugs. It has been found that a multitude of signaling pathways play a role in causing chemoresistance, the major ones being nuclear factor kappa B (NF- κ B), signal transducer and activator of transcription (STAT3), c-mesenchymal-epithelial transition factor (C-MET), and phosphoinositide-3-kinase/protein kinase B (PI3K/AKT)^[1,3,4].

Researchers have investigated these different signaling pathways to find a target they could inhibit to prevent their activation and sensitize the cancer cells to the treatment. However, with multiple pathways and a surplus of stimuli causing the activation, it has proven difficult to successfully inhibit them all. It has been found that inflammation which is a known element of cancer progression, plays a significant role in the activation of these different signaling pathways^[5].

A huge mediator of inflammation within cancer is the complement system which is a part of the body's innate immune response and has been shown to induce a series of inflammatory responses to help fight infection and other diseases^[6,7]. It has been proven that the complement system has a very active role within cancer progression, especially within establishing the tumor microenvironment^[8]. In addition, it has been shown that the downstream products of the complement system directly upregulate inflammatory mediators, which in turn activate these chemo-resistant pathways^[7].

This review article summarizes recent advances related to the role of the complement system in pancreatic cancer chemo-resistant signaling pathways, and the opportunity of targeting the complement system as a novel treatment to overcome drug resistance in pancreatic cancer.

Overview of the complement system

The complement system is an important mechanism that links innate immunity to adaptive immunity and helps the body fight foreign pathogens and abnormal host cells^[9]. The complement system consists of multiple plasma proteins that sequentially interact with one another to mount an attack on the foreign substance. These complement proteins are widely dispersed throughout the body fluids and tissues and remain dormant until an infection or an abnormality is recognized. At that point, they are locally activated

and will trigger a series of strong inflammatory events. Three different pathways can trigger the activation of the complement system: the classical pathway, alternative pathway, and lectin pathway. Though these pathways differ in response to the local stimuli that cause their activation, all of these pathways lead to the cleavage of complement protein C3 into C3a and C3b, and C5 into C5a and C5b. C3a and C5a are inflammatory mediators or anaphylatoxins, and they contribute to inflammation through stimulation of histamine release and activation of other immune cells such as macrophages, eosinophils, and neutrophils^[10]. C3b aids in opsonization which helps with phagocytosis of pathogens, and C5b initiates the assembly of the membrane attack complex, which is an essential mechanism to eliminate bacteria resistant to phagocytosis. Though the complement system is an important arm of the immune system, insufficient stimulation and/or overstimulation can be deadly to the host and is associated with autoimmune problems, chronic inflammation, infections, and even cancer^[9].

Complement system and cancer

The complement system has been regarded as a component of the innate immune response against invading pathogens and “non-self-cells”. However, when a tumor or malignancy is identified, the levels of complement proteins in tissues and fluids appear to vary^[8]. It has been shown that the expression of complement proteins is increased in malignant tumors^[8]. Complement system activation in the tumor microenvironment has been shown to lead to enhanced tumorigenesis and progression^[8].

It has been well established that an inflammatory process is vital for the development of tumors in humans^[11]. It was recognized that cancers develop from “subthreshold neoplastic states” which are caused by carcinogens that elicit a somatic change to the cells, but these altered cells can stay in normal tissues indefinitely, but when the second source of stimulation such as irritation or inflammation arises, these cells start to manifest as cancerous^[5].

Through numerous experiments, it has been established that activation of the complement system is a very important component of tumor-promoting inflammation^[12]. The inflammatory response is caused by the complement system’s anaphylatoxins which are a critical step in the progression of tumorigenesis and cancer^[12]. It was shown that C3a or C5a, which are both anaphylatoxins, can cause inflammation in a variety of ways by releasing histamine, activating other leukocytes, and stimulating the production of inflammatory mediators like TNF-alpha, IL-6, IL-1 β , and IL-1^[13]. It has been shown that these anaphylatoxins generated during tumor-associated complement activation can reshape the tumor microenvironment and play a role in tumor cell proliferation, resistance to chemotherapy, and angiogenesis within pancreatic cancer^[14]. C5a has been shown to upregulate angiogenic factors such as vascular endothelial growth factor (VEGF) in cancer cells which plays a huge role in the development of newly formed blood vessels allowing the tumor to grow. C3a and C5a also play a huge role in the activation of tumor-associated macrophages (TAMs). These macrophages are activated by the anaphylatoxins, just like neutrophils and other leukocytes, but TAMs play a huge role in shaping the tumor microenvironment. TAMs produce a large number of strong angiogenic and lymphangiogenic growth factors, cytokines, and proteases, all of which increase neoplastic progression^[5]. TAMs also produce IL-10, which dampens the anti-tumor response of cytotoxic T cells. In addition, TAMs cause an increase of inflammatory cytokines, which help with the invasiveness of the cancer cells allowing them to invade more tissues and spread easily.

Bonavita et al. reported that mice deficient in complement C3 were safe against chemical carcinogenesis in mesenchymal and epithelial tissue due to reduced inflammation^[15]. It was also shown that the long pentraxin *PTX3* gene is a very important negative regulator of inflammation and complement activation. Mice deficient in this gene had a much higher susceptibility to chemical carcinogenesis, an increase in the

number of TAM's, and an increase of inflammatory chemokines inside the tumor^[12]. The prolonged inflammation caused by the complement system in a tumor microenvironment increases the risk of neoplastic transformation by causing the accumulation of cytokines, chemokines, growth factors, and reactive oxygen species, all of which can fasten the creation of a tumor-supportive microenvironment^[16]. Further, the complement system also plays a significant role in creating cancer's defense mechanisms, especially with drug resistance. The complement's anaphylatoxins and downstream products like the activated macrophages have specifically been identified in upregulating specific chemoresistance signaling pathways^[13].

Drug resistance pathway overview in pancreatic cancer

Drug resistance is one of the many reasons why the mortality rate of pancreatic cancer is so high. Through multiple experiments, it was shown that more than 165 genes are related to drug resistance^[17]. These genes are involved with antioxidant activity, regulation of the cell cycle, signal transduction, and apoptosis. The four major chemo-resistant signaling pathways are NF- κ B, C-MET, STAT3, PI3K/AKT^[18] [Figure 1].

Gemcitabine has been the standard treatment for advanced-stage pancreatic cancer since it inhibits cell proliferation and causes apoptosis of tumor cells through the activation of the adenosine monophosphate-activated protein kinase/mammalian target of rapamycin (AMPK/mTOR) pathway^[17]. For gemcitabine to function properly, after its uptake into the cell, it must be phosphorylated by deoxycytidine kinase^[1]. The transport, phosphorylation, and activation of gemcitabine are all governed by numerous enzymes and proteins. One protein, in particular, which is essential for the function of gemcitabine is nucleoside transporter protein such as Human Concentrative Nucleoside Transporter (hCNT1), which is responsible for taking the drug into the cell allowing for it to inhibit cellular growth and cause apoptosis^[1]. Further, it has been demonstrated that chemo-resistant signaling pathways cause downregulation of these nucleoside transporters and inactivate deoxycytidine kinase which decreases the efficacy of gemcitabine. In addition, these signaling pathways not only inhibit the activation and transport of gemcitabine but also improve the tumor microenvironment to better protect itself from damage.

Furthermore, another major cause of resistance to gemcitabine comes from inactivity of the human equilibrative nucleoside transporter 1 (hENT-1). Gemcitabine is a pyrimidine analog, and it relies on membrane transporters for its uptake. That is why "The presence and activity of the nucleoside transporters were considered as possible important determinants of gemcitabine cytotoxicity and clinical efficacy"^[19]. hENT-1 and hCNT-1 are the most efficient transporters, but hENT-1 is the most widely expressed in human tissues and is overexpressed in different tumor types. Without the facilitated transport function of hENT-1, the entrance of gemcitabine into the cell and its ability to cause an effect is markedly decreased. It was shown that inhibition of the facilitated, diffusion-mediated nucleoside transport by the dipyridamole derivative BIBW22BS, resulted in a 30-100-fold decrease in activity for gemcitabine in various human cancer cell lines^[20]. Whereas, high hENT-1 levels were associated with prolonged disease-free status and overall survival in patients receiving gemcitabine adjuvant chemotherapy^[19].

After the entrance into the cell, gemcitabine is metabolized to active gemcitabine diphosphate and triphosphate by the enzyme deoxycytidine kinase, which leads to the inhibition of ribonucleotide reductase subunits 1 and 2, whose expression is associated with gemcitabine resistance^[21]. In addition, gemcitabine is capable of inducing apoptosis in cancer cells primarily with a pathway involving caspase-8 and a mitochondrial-dependent caspase-9. The cascade led by caspase-8 is involved in death receptor-mediated apoptosis, whereas caspase-9 was thought to mediate chemical-induced apoptosis through the formation of an apoptosome. It was further reported that unlike inhibition of caspase 9, inhibition of caspase-8

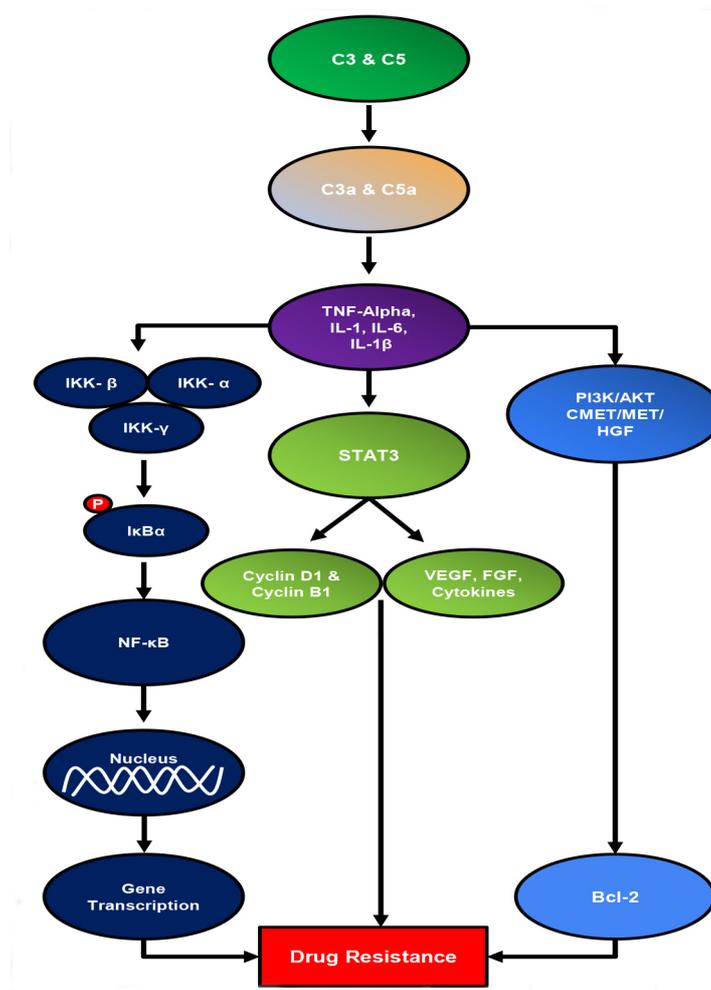

Figure 1. Complement system causes drug resistance through multiple signaling pathways in pancreatic cancer.

significantly decreases apoptosis. Furthermore, stable overexpression of the caspase-9 inhibitors, caspase-9S and X-linked inhibitor of apoptosis (XIAP) in the NSCLC cell line H460 failed to suppress apoptosis induced by various chemotherapeutic drugs; however, drug-induced apoptosis was blocked in H460 transfectants that expressed known inhibitors of caspase-8^[22]. Researchers have studied the following signaling pathways as a way to better combat the chemoresistance that they cause to improve the survival rates of patients afflicted with pancreatic cancer.

NF-κB and complement system and its role in pancreatic cancer

Nuclear factor kappa B (NF-κB) has been shown to cause cancer progression, angiogenesis, and drug resistance in cancer, especially pancreatic cancer^[4,23]. Ease of invasion and metastasis is one of the reasons which make the fatality rate of pancreatic cancer so high. It was shown that NF-κB was constitutively activated in about 67% of pancreatic adenocarcinoma but not in normal pancreatic tissue^[24,25]. It has been previously reported that pancreatic cancer causes an upregulation of complement proteins, which in turn create more anaphylatoxins^[26]. NF-κB is a transcription factor that can be activated through a classical signaling pathway or an alternative signaling pathway. The classical/canonical signaling pathway involves TNF-alpha, pro-inflammatory cytokines, and IL-1β, which will lead to the activation of the IKK-β. Then phosphorylates IκBα, which will then cause the NF-κB dimer to be translocated into the nucleus so that it

can activate gene transcription^[27]. It was previously shown that the anaphylatoxins C3a and C5a upregulate inflammatory mediators and cytokines, and cause direct stimulation of TNF- α and IL-1 β ^[9]. In addition, these anaphylatoxins cause more macrophages to be recruited, which have also been shown to play a huge role in inflammation^[13]. The complement system activates NF- κ B through more than just direct inflammatory mediators. The extracellular signal-regulated kinase (ERK), which is a member of the MAPK family of signaling molecules, is shown to be activated by inflammatory cytokines which are stimulated by the anaphylatoxins such as IL-6 and TNF- α ^[28]. Following this activation, ERK causes changes in the tumor microenvironment by producing downstream effectors such as Ribosomal S6 Kinase (RSK). RSKs have been shown to change cell proliferation and survival through the activation of NF- κ B^[29].

Once NF- κ B is activated, translocated into the nucleus, and able to affect gene expression which causes a variety of pro-tumor effects. NF- κ B can cause the secretion of CXCL14 which is a chemokine that not only promotes angiogenesis and tumor growth but also plays a role in translocating NF- κ B into the nucleus^[27] [Figure 1]. With CXCL14 and the complement system synergistically activating NF- κ B, the possibility for chemoresistance rises significantly. Gastrin, a normal digestive hormone has very high levels in pancreatic cancer cells but low levels in normal tissue and is involved with metastasis through altering the expression of ABCG2 which is known as the breast cancer resistance protein through the actions of NF- κ B^[4]. However, invasion and metastasis are only a few of the many negative effects caused by the activation of this transcription factor, the most harmful being chemoresistance. Gemcitabine has been noted as the first line of defense for pancreatic cancer, but its efficacy is being decreased by the chemoresistance caused by NF- κ B, which prevents improvements in survival rates and prognosis. NF- κ B through a signaling pathway can cause inhibition of human concentrative nucleoside transporter 1 and 3 and human equilibrative nucleoside transporters necessary for the uptake of gemcitabine into a tumor cell^[30]. Without the ability to properly uptake the gemcitabine, the tumor cells will continue to survive and grow, decreasing the survival rate at a steadfast rate. It was also shown that NF- κ B can induce drug resistance through the upregulation of the *MDR1* gene in cancer cells. The *MDR1* gene encodes for an integral membrane protein, P glycoprotein, which has a specific role in drug efflux, which is the ability of the cell to regulate its internal environment and remove harmful toxins or metabolites^[31]. This is how the cancer cells can protect themselves from chemotherapeutic treatments. It was shown that inhibiting NF- κ B would downregulate this gene and the P glycoprotein which would sensitize the cells to apoptosis. NF- κ B has a multitude of pro-cancerous effectors, and it has been demonstrated that the complement pathway and its downstream effectors play a role in its activation.

Complement system and C-MET/MET/ hepatocyte growth factor pathway and its role in pancreatic cancer

C-MET is the mesenchymal-epithelial transition factor gene encoded for membrane-bound receptor tyrosine kinase RTKs. They are expressed by epithelial cells such as the liver, pancreas, prostate, and kidney, and this receptor binds with a ligand hepatocyte growth factor (HGF). Afterwards it activates a wide range of different signaling pathways, one being chemoresistance and tumorigenesis^[32]. There is an aberrant activation of C-MET in tumors exhibiting malignant properties. Pancreatic cancer cells are one of the most malignant neoplasms across the world, so C-MET activation would be highly expressed in this cancer^[33]. It has been shown that C-MET expression levels are 5-7 times higher in individuals with PDAC than with normal pancreatic tissue^[34]. Interestingly, aberrant activation of C-MET can be caused by inflammatory cytokines^[32]. The complement anaphylatoxins can cause this aberrant activation and initiate the signaling cascade that leads to chemoresistance and other pro-tumor effects [Figure 1].

HGF-MET signaling has been shown to encourage angiogenesis in cancer by inducing VEGF expression. In addition, HGF-MET stimulation induces apoptosis protection for non-self-lung cancer cells by down-regulating apoptosis-inducing factors^[35]. It has also been shown that over-stimulation of C-MET causes non-self-cell lung cancer resistance to an EGFR inhibitor. Further, the HGF-MET pathway supports resistance through the PI3K/AKT signaling pathway. It has been shown that C-MET deletion in pancreatic neoplasia enhanced chemosensitivity to gemcitabine. The complement systems downstream inflammatory mediators activate the C-MET pathway, which causes chemoresistance through cross-talk with other signaling pathways such as PI3K/AKT.

Complement system and STAT3 and its role in pancreatic cancer

STAT3 play a major role in many signaling pathways and have been proven to play a role in promoting pancreatic cancer progression^[36] [Figure 1]. STAT3 activation is dependent on the phosphorylation of tyrosine residue, Tyr705, which then allows dimerization of STAT3 allowing it to translocate into the nucleus and affect gene transcription^[36]. Growth factors and oncogene proteins like Src and RAS have the ability to induce the phosphorylation of the Tyrosine residue and cause STAT3 activation. However, it was shown that inflammatory cytokines such as IL-6 and TNF-alpha also have the ability to cause activation of STAT3^[37]. It has also been reported that these inflammatory cytokines are upregulated by the anaphylatoxins which have been shown to be in higher levels within pancreatic cancer patients. The anaphylatoxins produced by the complement system have proven to play a pivotal role in inflammation and cancer progression, and its downstream effectors, like Interleukin 6, cause the constitutive activation of STAT3^[36]. It has also been shown that C3 complement overexpression showed a clear increase in STAT3 expression in gastric cancer cell lines^[38].

Once the STAT3 signaling cascade has been activated, it can affect multiple aspects of cancer progression. For example, through the expression of angiogenic growth factors such as VEGF and FGF, angiogenesis of the tumor cell can be upregulated, which increases the ability to create its blood vessels and fasten the growth process. In addition, apoptosis can be inhibited through the upregulation of Cyclin D1 and Cyclin B1, which are regulatory proteins that have been implicated in tumorigenesis and the development of malignancy^[39]. In concert with the complement system, STAT3 can upregulate inflammatory cytokines to increase inflammation and immune evasion. STAT3 can also enable the inhibitory functions of Treg cells^[37]. Treg or T regulatory cells are responsible for maintaining peripheral tolerance and regulating the immune response. Now, if their inhibitory functions are upregulating, this in turn, causes an increase in the immunosuppressive environment in which cancer cells thrive. Finally, STAT3 plays a major role in energy metabolism for cancer cells. Cancer cells need the energy to replicate, so STAT3 upregulates glycolysis to make more ATP^[40]. It has been shown that the energy cancer cells utilize, nearly 50%, comes from glycolysis, so the upregulation is a crucial prerequisite to tumor growth and cancer progression^[40]. Finally, STAT3 plays an important role in chemoresistance in cancer cells. Further, STAT3 alters ATP-binding cassette membrane transporters, which are crucial to the process of drug uptake into the cell. If the drug is not able to breach the cell, then the therapeutic effect cannot be achieved^[41]. Therefore, all the above reports suggest that STAT3 has been proven to enhance cancer progression and chemoresistance, and its phosphorylation can be initiated by the complement pathway's anaphylatoxins.

Complement system and PI3K/AKT and its role in pancreatic cancer

PI3K is a lipid kinase that regulates multiple cellular processes with its downstream effector, AKT. The PI3K/AKT signaling pathway has been considered a significant cause of chemoresistance in cancer therapy, inhibition of apoptosis, stimulation of cell growth, and modulation of cellular metabolism^[42] [Figure 1]. This signaling pathway causes multi-drug resistance through interactions with ABC transporters, NF-κB, and others.

The PI3K/AKT pathway is activated by the production of 3-phosphorylated phosphoinositide which initiates the signaling cascade. However, it was shown that C3a binding to the C3a receptor leads to transduction of intracellular signals through various G-proteins and phosphorylation of the PI3K/AKT pathway, which causes chemokine synthesis in humans. Furthermore, C3a and C5a binding to their receptors cause an influx of calcium which initiates signaling cascades such as MAPK and AKT pathways^[10,13]. Not only does the complement pathway use the PI3K/AKT pathway to help with the formation of their chemokines, but the binding of anaphylatoxins to their respective receptors also causes the activation of this pathway. In addition, IL-6, which is released by the anaphylatoxins, is required for pancreatic cancer progression through the activation of MAPK and PI3K/AKT signaling pathway^[43]. One of the ways to activate the PI3K/AKT pathway is through the activation of the mutated *Kras* gene synergistically acting with IL-6. *Kras* mutation is shown to be the most commonly mutated gene in pancreatic cancer and drives the formation of pancreatic intraepithelial neoplasia^[43]. It was also shown that without IL-6, cancer progression slows even in the presence of the *Kras* mutation^[43].

Once the PI3K/AKT pathway has been activated, numerous downstream effectors cause cancer progression. For example, abnormal activation of the PI3K/AKT signaling pathway contributes to the upregulation of Bcl-2 expression, which causes cell survival by inhibiting the release of cytochrome c from the mitochondria^[42]. This type of apoptosis prevention only adds to the multi-drug resistance already previously seen. Further, another downstream effector seen in many cancers is XIAP which has played a role in chemoresistance by inhibiting autophagy-induced apoptosis. It was shown that abnormal activation of PI3K/AKT induces XIAP expression^[42]. Especially in pancreatic cancer cells, there is a cross-talk and activation between PI3K/AKT and NF- κ B which results in multidrug resistance through the stimulation of Cyclin D1 to accelerate cell progression and tumor growth leading to drug resistance. Finally, pancreatic ductal preneoplastic lesions come from the differentiation of acinar cells to ductal cells, and the process of this occurring is called acinar to ductal metaplasia (ADM). This process is accelerated by mutated *Kras* and inflammation. However, p110-alpha, which is a catalytic subunit of PI3K- α can cause ADM in the presence or absence of pancreatic inflammation^[44].

The complement-induced PI3K/AKT pathway not only acts with the *Kras* mutation to fasten the cancer progression, but also with NF- κ B and other mediators to promote cell survival and chemoresistance.

CONCLUSION

The complement pathway is a part of the body's innate immune response capable of attacking pathogens and foreign abnormalities. However, with cancer, the complement pathway does more harm than good. It allows for increased inflammation through the release of anaphylatoxins, the activation of different signaling cascades through the induction of inflammatory mediators, and finally a nourishing tumor microenvironment. The most detrimental side effect of the complement system's activation would be the chemoresistance caused by the anaphylatoxins.

Pancreatic cancer has had one of the highest cancer-related mortality rates due to its fast metastasis and chemoresistance. The major signaling pathways discussed in this review article discussed have all been targets of therapeutic treatment in order to combat chemoresistance. Though these treatments have been shown to cause higher sensitivity to gemcitabine and other chemotherapeutic drugs, the problem has not been solved. The fact of the matter is that all of these signaling pathways are activated by different stimuli and can a cross-talk, therefore, inhibiting each one yields a futile response. However, it has been shown that targeting the complement pathway has been successful as a therapeutic treatment option for lung cancer in a few pre-clinical studies which indicate that inhibition of either C3a or C5a signaling inhibits cancer

progression in lung cancer models and other malignancies^[45]. However, even with all the current evidence showing how the complement system upregulates inflammation and mediators that enable tumorigenesis, as of 2019, no clinical trials are targeting the complement system as a therapeutic approach. It has been shown that the complement system upregulates these signaling cascades, and targeting each main pathway has proven to be ineffective. If the complement's anaphylatoxins were targeted and the inflammatory response was removed, then there would be fewer inflammatory mediators upregulating these pathways. This could yield a more successful chemotherapeutic treatment without the obstacle of chemoresistance.

Abstract

The emergence of immunotherapy as a cancer therapy has dramatically changed the treatment paradigm of systemic cancer therapy. There have been several trials evaluating immune checkpoint blockade (ICI) in soft tissue sarcoma. While there is generally a limited response in sarcoma, a subset of patients has durable responses to immunotherapy. This is attributable to a variety of factors including histologic subtype, tumor-infiltrating lymphocytes, and the tumor microenvironment among others. There is ongoing translational and clinical research evaluating ICI resistance in sarcoma and identifying therapeutic strategies to overcome this resistance. Herein, we provide a review of the current data, proposed mechanisms of resistance, and potential approaches to overcome this resistance.

Keywords: Sarcoma, soft tissue sarcoma, checkpoint inhibitor, immunotherapy, resistance

INTRODUCTION

Soft tissue sarcomas (STS) are a heterogenous group of cancers of mesenchymal origin^[1]. They represent 1% of cancer diagnoses in the United States, with 13,130 diagnosed in 2020^[2]. The prognosis of soft tissue sarcoma is poor, with up to 50% of patients with localized disease developing metastases and a median

survival of 12-24 months in the advanced setting^[3,4]. There are more than 50 histologic subtypes of soft tissue sarcoma, each with a distinct clinical profile, prognosis, and response to treatment.

Sarcomas are generally divided into two categories based on genetics, simple and complex. Many simple subtypes are translocation driven and have limited neoantigens, such as synovial sarcoma (SS) and myxoid/round cell liposarcoma^[5]. Complex sarcomas have more complex genetics, with potentially mutated protein targets for T-cells^[5]. The most common of these include Undifferentiated Pleomorphic Sarcoma (UPS) and Leiomyosarcoma (LMS), and they have been found to have higher gene expression levels related to antigen presentation^[5,6].

First-line therapy consists of anthracycline-based cytotoxic chemotherapy, and Doxorubicin remains the most active single agent with a response rate of up to 20-25%^[7-11]. There have been attempts to improve this treatment approach with dose intensification and combination therapies, but these have had a limited impact on overall survival^[4,8]. With the emergence and success of immunotherapy in other cancer subtypes, there has been interest in using this modality to treat soft tissue sarcomas^[6]. While there are several modalities of immunotherapy, including T-cell transfer therapy, monoclonal antibodies, cancer vaccines, immune system modulatory and ICI, our review will focus on ICI^[12]. This has led to multiple clinical trials of ICI and ICI combination therapy in advanced soft tissue sarcoma [Table 1].

An early phase II study evaluated the CTLA-4 inhibitor, ipilimumab, in advanced synovial sarcoma given their high expression of cancer testes antigen NY-ESO-1. Patients were treated with ipilimumab 3 mg/kg intravenously every 3 weeks for three cycles and then restaged. Six patients were enrolled and received 1-3 cycles of ipilimumab. All patients showed clinical or radiological evidence of disease progression after no more than three cycles of therapy. This study was stopped due to slow accrual and lack of activity^[20].

SARC028 was a multicenter, two-cohort, single-arm, open-label phase II study evaluating the anti-PD-1 antibody, pembrolizumab, in 40 patients with advanced soft tissue sarcoma^[13]. Patients received 200mg pembrolizumab IV every 3 weeks until progression or unacceptable toxicity. Histologies enrolled included UPS, dedifferentiated liposarcoma (DDLPS), SS, LMS. 18% (7/40, 95%CI: 7-33) of patients with soft tissue sarcoma achieved an objective response. This is clinically meaningful, although the prespecified objective response rate to meet their endpoint was 8/40 responses. The majority of these responses were in patients with UPS or DDLPS, and one patient with UPS achieved a confirmed complete response. The 12-week PFS in the soft tissue sarcoma cohort was 55%. The median duration of response was 49 weeks and overall survival (OS) was not reached in patients with UPS. In this study, adequate tumor biopsies were obtained from 81% of patients during treatment and were analyzed for pre-treatment PD-L1. PD-L1 was positive at the 1% threshold in only three samples, all of which were from patients with UPS. Two of the three were evaluable for response, and one had a complete response and the other had a partial response^[13].

There was also a single center, phase II study evaluating nivolumab, an anti-PD-1 antibody, in twelve patients with advanced uterine leiomyosarcoma^[21]. Patients received 3 mg/kg every 2 weeks intravenously of nivolumab until progression or unacceptable toxicity. There were no responses noted in this cohort, and the second stage was not opened due to lack of benefit^[21].

The Alliance A091401 trial was an open-label, non-comparative, randomized, phase II study of nivolumab with or without ipilimumab, an anti-CTLA-4 antibody, in metastatic or locally advanced sarcoma^[14]. Patients received intravenous nivolumab 3 mg/kg every 2 weeks or nivolumab 3mg/kg plus ipilimumab 1mg/kg every three weeks for four doses followed by nivolumab 3 mg/kg every two weeks for up to two

Table 1. Studies of checkpoint inhibition in sarcoma

Authors	Year	Study Type	Treatment	N	ORR	mOS	PFS
Tawbi HA, et al. ^[13]	2017	Phase II	Pembrolizumab	N = 80	18% (7/40 STS)	12.25m (8.50-18.25)	4.5m (2-5.25)
D'Angelo SP, et al. ^[14]	2018	Phase II	Nivolumab	N= 38	5% (2/38)	10.7m (5.5-15.4)	1.7m (1.4-4.3)
D'Angelo SP, et al. ^[14]	2018	Phase II	Nivolumab plus Ipilimumab	N = 38	16% (6/38)	14.3m (9.6-NR)	4.1m (2.6-4.7)
Wilky BA, et al. ^[15]	2019	Phase II	Axitinib plus Pembrolizumab	N = 33	25% (8/32)	18.7m (12-NR)	4.7m (2-9.4)
Martin-Broto J, et al. ^[16]	2020	Phase Ib/II	Sunitinib plus Nivolumab	N = 68	21% (12/58)	24m	5.6m (3.0-8.1)
Pollack S, et al. ^[17]	2020	Phase I/II	Pembrolizumab plus Doxorubicin	N = 37	19% (7/37)	27.6m (18.7-NR)	8.1m (7.6-10.8)
Kelly CM, et al. ^[18]	2020	Phase II	Talimogene laherpavec plus pembrolizumab	N = 20	35% (7/20)	18.68m (12.25-NR)	4.28m (3.15-NR)
Gordon, et al. ^[19]	2020	Phase II	Ipilimumab, Nivolumab, Trabectedin	N = 41	19.5% (8/41)	> 12.5m	> 6.0m

years. The most common sarcoma subtypes across both groups were leiomyosarcoma (34%), liposarcoma (6%), spindle cell sarcoma (13%), undifferentiated pleomorphic sarcoma (13%) and bone sarcoma (11%). In the nivolumab group (38 patients), the response rate was 5% (2/38, 92%CI: 1-16) and thus, did not meet its primary endpoint of objective response rate. The combination group (42 patients) had an overall response rate of 16% (6/38, 92%CI: 7-30) with a median PFS of 4.1 mo and OS 14.3 mo^[14].

The results of clinical trials using checkpoint inhibition in soft tissue sarcoma have been varied, and there is an ongoing study into which sarcoma subtypes are more responsive to checkpoint inhibitors and if there are predictive biomarkers that can be used. This remains a challenge given the heterogeneity of different sarcoma subtypes and the rarity of each disease. Unlike other cancer types, biomarkers such as tumor mutational burden and PD-L1 expression have failed to identify good responders in soft tissue sarcoma. Although a small proportion of patients do respond to checkpoint inhibitors, the majority do not, likely due to primary resistance to checkpoint inhibition. In those who do respond, most will progress, which is likely due to acquired resistance.

Herein, we will highlight here mechanisms of resistance, research evaluating predictive biomarkers in STS and current approaches to overcome resistance to checkpoint inhibition.

RESISTANCE MECHANISMS

Unlike other more immunogenic cancer types such as melanoma, only a minority of patients with soft tissue sarcoma develop durable clinical responses to ICI (primary resistance) and most of those who do respond will eventually progress (acquired resistance). In order for the immune system to respond effectively, cancer cell-specific antigens that are recognizable by antigen-presenting cells are required, T cells must be primed and activated with the ability to infiltrate tumors, and cancer cells must recognize and destroy cancer cells^[22]. There also must be a balance of stimulatory and suppressive signaling that favors continued cytotoxicity by T-cells within the tumor microenvironment (TME)^[15,22].

Tumors are generally thought of as immunogenic (or hot) or non-immunogenic (or cold). Sarcomas are generally characterized as non-immunogenic, cold tumors with limited immune cell infiltrate, low tumor mutational burden (TMB) and low PD-L1 expression, which is thought to contribute to their primary resistance to ICI^[23,24]. This is by tumor intrinsic or extrinsic mechanisms. Tumor intrinsic mechanisms

include lack of antigenic proteins, lack of antigen presentation, genetic T-cell exclusion or insensitivity to T-cells^[25,26]. Oncogenic signaling pathways also contribute to tumor intrinsic resistance to ICI^[26]. Tumor extrinsic mechanisms include the absence of T cells, inhibitory immune checkpoints and immunosuppressive cells including tumor-associated macrophages (TAMs) and T-regulatory cells (Tregs)^[25]. Upregulation of Tregs can induce immunologic tolerance and an increase in M2 TAMs suppress the TME and correlate with progression^[12]. Within STS, there is wide heterogeneity, with response rates that are variable among histologies. Prior studies have shown an increase in sensitivity to ICI among such histologies as ASPS, UPS and DDLPS^[14,27,28].

Given that T cell responses are central to the efficacy of ICI, there have been several studies evaluating tumor infiltrating lymphocytes (TILs) within sarcomas prior to and on treatment. D'Angelo^[29] and colleagues evaluated TILs in 50 sarcoma specimens to further evaluate the immune milieu. They noted infiltration of TILs and TAMs in 98% and 90% of tumors, respectively. They evaluated subsets of TILs with the median number of each subset and noted CD3+ cells 3.3% (0%-33.2%), CD8+ cells 1.2% (0%-14%), CD4+ 0.2 (0%-13.6%), and FOXP3+ 0.1 (0-3.6%)^[29]. There was an increased number of CD8+ cells in larger tumors or those who presented with metastatic disease, which is potentially indicative of T-cell exhaustion^[29]. This study found that low CD3+ and CD4+ correlated with better survival, although contrary findings have been noted in other studies. In a cohort of 128 high-grade STS, increased density of CD8+ and CD3+ TIL infiltrates were associated with favorable OS, DSS and DFS when compared to low-density CD8+ and CD3+ infiltrates^[30]. SARC028 correlative analysis evaluated changes in tumor-associated immune infiltrates from baseline to early on-treatment biopsies. They found that both effector memory cytotoxic T-cells and Tregs were subsequently increased after PD-1 blockade ($P = 0.054$)^[28]. Analyses also showed that higher Treg percentages and higher density of cytotoxic T-cell infiltrates at baseline had longer median PFS^[28]. A retrospective study of 81 patients with liposarcoma, LMS, UPS, and SS found that more highly mutated STS subtypes expressed higher levels of genes related to antigen expression and T-cell infiltration and inflammation^[5]. Higher expression was seen in UPS and LMS compared to SS. They also had higher levels of *CD3D*, a marker for T cell infiltration, and *CD8A*, a marker for CD8+ T-cells^[5].

PD-L1 expression in sarcoma is varied, and the data regarding the correlation between PD-L1 expression and responsiveness to ICI in STS is variable, and at this time there is not a consistent correlation^[5,29,30]. In a cohort of resected UPS, SS, AS, ASPS, and ES, any level of PD-L1 expression in tumor cells was positive in 28.1% ($n = 36/128$) of cases. The highest level was found in UPS and the patients with UPS who were PD-L1 positive were noted to have better OS and PFS compared to those patients who were PD-L1 negative^[30]. An analysis of 50 sarcoma specimens noted tumor cell PD-L1 expression of 12% and lymphocyte and macrophagic PD-L1 expression in 30% and 58% of specimens respectively with no correlation with prognostic indicators^[29]. Pollack and colleagues evaluated PD-1 expression by immunohistochemistry (IHC) in common STS subtypes and scored them from 0 to ≥ 5 . 35% ($n = 28$) of tumors had PD-L1 expression, and 51% ($n = 41$) had PD-1 expression of ≥ 2 , with UPS associated with higher expression levels of both PD-L1 and PD-1. Although this study was not designed to evaluate survival outcomes, no correlation was found^[5]. A pooled analysis of sarcoma clinical trials evaluated PD-L1 expression ($\geq 1\%$) in soft tissue sarcoma. This was observed in 13.6% ($n = 21/156$) of patients with available data, and in this group, there was a corresponding ORR of 30% in PD-L1 positive tumors. In the PD-L1 negative tumors, the response rate was 7%^[31]. Correlative analysis from the SARC028 trial noted PD-L1 positivity in 5% of tumors. Both of the PD-L1 positive tumors were UPS and responded to pembrolizumab, although five other patients responded and were PD-L1 negative^[28]. Given the varied expression of PD-L1, particularly between different histologic subtypes, the prognostic and predictive significance of PD-L1 expression remains indeterminate^[12].

The sarcoma TME varies widely by histology and can influence outcomes in patients with sarcoma^[23]. Within the TME, immunosuppressive cytokines, abnormal perfusion from tumor angiogenic networks and metabolic conditions can inhibit T-cell infiltration and function. LMS have poor responses to ICI, and previous studies have shown poor T-cell infiltration in these tumors^[29,31]. Gene expression profiling has also revealed high-level expression of macrophage-associated genes, such as CD 163 and CD68, which was associated with worse disease-specific survival in nongynecologic LMS^[32]. Petitperez and colleagues studied TME gene expression profiles within STS based on immune classifications from immune low to immune high and highly vascularized^[33]. They found most LMS classified to the low immune classes (classes A&B), DDLPS in the highly vascularized group (class C) and immune high (classes D&E) distributed across a variety of histologies^[33]. The immune high group (E) is characterized by tertiary lymphoid structures rich in B-cells. Despite high or low CD8+ cell density, the presence of B-cells was the strongest prognostic factor with improved survival and high response to pembrolizumab therapy.

In those patients who initially respond to ICI, a proportion will eventually progress after ICI. Many of the mechanisms are similar to de novo resistance, but much remains unknown regarding the mechanism behind acquired resistance within sarcoma. There are several potential mechanisms including downregulation of tumor antigen presentation and subsequent lack of T-cell recognition, loss of T-cell function and development of escape mutation variants^[25]. The immunoediting hypothesis refers to the interactions between the immune system and tumor cells that eventually lead to the inability of the immune system to recognize the tumor^[34,35]. Anagnostou and colleagues matched pre-treatment and ICI resistant non-small cell lung cancer and found that resistant tumors had a loss of 7-18 putative neoantigens, many of which generated peptides responsible for host immune response^[36]. There have been studies in melanoma regarding acquired resistance to PD-1 blockade. Zaretsky and colleagues performed whole-exome sequencing on the paired baseline and relapsing biopsy samples in four patients with melanoma who had initially responded to pembrolizumab therapy^[37]. Two of the four patients revealed loss-of-function mutations in genes encoding interferon-receptor-associated Janus Kinase 1 (JAK1) or JAK2. This resulted in insensitivity to the antiproliferative effect of interferon on cancer cells. They also noted mutations in beta-2-microglobulin which led to the loss of major histocompatibility complex class 1 surface expression^[37].

BIOMARKERS OF RESPONSE

A focus of sarcoma research has been on predictive biomarkers which may delineate those who are likely to respond to ICI [Table 2], although predictive biomarkers remain elusive, and to date, there are no clearly defined biomarkers for soft tissue sarcoma.

Prior studies have noted that a high baseline neutrophil-to-lymphocyte ratio was associated with a worse prognosis in sarcoma^[27,38,39]. The increased neutrophil-to-lymphocyte ratio has also been associated with inferior PFS in sarcoma patients who were treated with axitinib and pembrolizumab, but further elucidation of whether this is specifically predictive in the setting of ICI^[27]. Sarcoma patients who were treated with axitinib and pembrolizumab were also noted to have improved outcomes if they had higher plasma angiogenic activity at baseline^[27]. There is still further investigation to elucidate the prognostic implications of this finding.

There is interest in the emergence of DNA methylation profiles as predictive biomarkers in sarcoma patients, particularly those treated with ICI. DNA methylation has been implicated in tumorigenesis in a variety of tumors including sarcoma. A recent retrospective analysis of 35 recurrent sarcoma patients who were treated with anti-PD-1 ICI, most of which were treated with Pembrolizumab, noted DNA methylation differences between responders and nonresponders^[23]. The most prominent pathway differences were seen

Table 2. ICI biomarkers in soft tissue sarcoma

Sarcoma Immune Class

in Rap 1 signaling, focal adhesion, adherens junction, pathways in cancer and extracellular matrix -receptor interaction^[23]. In this study, PD-L1 expression and density of TIL subsets were evaluated and there was no correlation with response to ICI^[23]. DNA methylation profiling was evaluated in 36 angiosarcoma specimens and revealed two subtypes (A and B) which were divided into four subclusters. Survival analysis showed better overall survival in cluster A at 22 months compared to cluster B at 6 months ($P = 0.046$)^[40].

In other cancer types, there have been established biomarkers that predict response including tumor mutational burden and expression of the immune checkpoint molecules PD-1/PD-L1^[26].

A retrospective study by Lu and colleagues of 18 metastatic sarcoma patients receiving anti-PD 1 therapy low TMB in all patients (range 1.12-3.45 mutations/MBs)^[41]. Within sarcoma, PD-L1 positivity rates are low and have not been noted to be a consistent biomarker^[28,29]. Data has been inconsistent with some studies noting improved survival in PD-L1 positive patients^[31] and several without correlation between PD-L1 expression and outcomes^[5,28]. A retrospective study of 18 metastatic sarcoma patients receiving anti-PD 1 therapy noted a PR in 22.2% (4/18) and SD in 50% (9/18) at 12 weeks with an ORR of 18.3% in soft tissue sarcomas. Whole exome sequencing was performed pre-treatment in 8 patients and did not note associations of PD-L1 expression with clinical response^[41]. These studies highlight the unreliability of PD-L1 as a biomarker in STS.

Rates of TILs and TAMs have also been evaluated as potential biomarkers for response. Correlative analysis of SARC028 noted a higher percentage of tumor immune cell phenotypes in those patients who had responses to pembrolizumab^[28].

Immunohistochemical staining can be used to confirm CD68 and CD163 positive macrophages. As noted above, a subset of non-gynecologic LMS has been noted to have dense infiltrates of these TAMs were found to have shorter disease-specific survival, although this was not seen in uterine LMS^[32]. LMS has been noted to have high levels of T-cell-related gene expression, and it is postulated that TAMs are likely critical to immune invasion in these tumors given the poor clinical outcomes with single-agent ICI in LMS^[5,21,32].

The TME has also recently been of interest as a prognostic indicator of response to ICI. STS biopsies from the SARC028 clinical trial were placed into their sarcoma immune classes and the ORR in group E was 50% ($n = 5/10$), followed by group D of 25% ($n = 3/12$) and group C of 22% (2/9)^[33]. These are all higher than the ORR of 21.2% in the overall cohort. There were no responders in groups A and B. Group E also had improved PFS when compared to groups A & B ($P = 0.023$ and $P = 0.0069$, respectively)^[33]. This study has laid the groundwork for potentially risk stratifying patients prior to treatment and identifying those who would be more likely to respond.

OVERCOMING RESISTANCE

Given the relatively low response rates to ICI in soft tissue sarcomas, there has been interest in manipulating the immune environment to increase responses [Figure 1]. Many sarcomas have limited neoantigens and therefore, limited immunogenicity without the generation of tumor-specific T-cells. There are several approaches that are combined with ICI to overcome this limitation including cytotoxic chemotherapy and oncolytic viruses. There is also interest in using drugs, such as tyrosine kinase inhibitors (TKIs) in combination with ICI to target the TME and overcome its suppressive influences which is mediated through immunosuppressive immune cells and cytokines.

Cytotoxic chemotherapy is an effective inducer of immunogenicity and increases inflammatory cytokines. There is evidence, using lung adenocarcinoma models, that chemotherapy can sensitize tumors to host antitumor T-cell immunity^[42]. A lung adenocarcinoma mouse model was able to show that an antitumor CD8(+) T-cell response could be induced with immunogenic chemotherapy^[42]. Within sarcoma, there have been several trials combining chemotherapy with immunotherapy to this end. The SAINT trial evaluated the combination of trabectedin (1.2 mg/m² IV q 3 weeks) with nivolumab (3 mg/mg q 2 weeks) and Ipilimumab (1 mg/m² q 12 weeks)^[19]. Forty-one patients with previously untreated advanced or metastatic soft tissue sarcoma were included. The overall response rate was 19.5% with a disease control rate of 87.8%. Median PFS was > 6.0 months and median OS was > 12.5 months^[19]. These data suggest synergy with trabectedin and Ipilimumab and Nivolumab. A phase 1/2 study by SM Pollack and colleagues evaluated the combination of doxorubicin (45 and 75 mg/m² q3 weeks) and pembrolizumab (200 mg q3 weeks) in 37 patients with advanced sarcoma who had not received prior anthracycline^[17]. The ORR was 13% for phase 2 patients and 19% overall with a median PFS of 8.1 months (95%CI: 7.6-10.8) and median OS 27.6 mo (95%CI: 18.7-not reached). While this study did not reach its primary endpoint (ORR of 15% with 85% power), there was a clinically significant increase in PFS compared to historical studies. Two of three patients with UPS and two of four patients with dedifferentiated LPS had durable partial responses. In 29 patients, there was evaluate IHC for correlatives. 66% had a PD-L1 score of 0, and PD-L1 was not associated with PFS or OS. Tumor-infiltrating lymphocytes were present in 21% of evaluable tumors and associated with inferior PFS (p=0.03). They assessed serum cytokine levels before treatment and during the first two cycles. Granulocyte macrophage colony-stimulating factor levels increased each cycle, and IL-15 levels dropped following doxorubicin treatment. Circulating IL-2R, IP10, and CD30 levels rose sharply after cycle one and levels of IL-8 dropped^[17].

Oncolytic viruses, engineered viral vectors that selectively infect and replicate within cancer cells, are also being combined with checkpoint inhibitors in the treatment of sarcomas^[15]. The innate immune system is also able to recognize these viruses as foreign and initiate an immune response^[43]. A recent phase II study evaluated the combination of intralesional talimogene laherparepvec (T-VEC, the first dose, $\leq 4 \text{ mL} \times 10^6$ plaque-forming units [PFU]/mL; second and subsequent doses, $\leq 4 \text{ mL} \times 10^8$ PFU/mL injected into palpable tumor site(s) on day 1 of each 21-day cycle) with pembrolizumab (200 mg/dose q 3 weeks) in 20 patients with locally advanced or metastatic sarcoma^[18]. The best ORR at 24 weeks was 30 % ($n = 6$, 95%CI: 12%-54%) and overall was 35% ($n=7$, 95%CI: 15%-59%). Median PFS was 17.1 weeks (95%CI: 12.6-NR weeks) and median disease-specific survival was 74.7 weeks (3-sided 95%CI: 49.0-NR weeks). Two of the patients who responded to treatment had disease progression while on ICI prior to entering the study, which may suggest synergism between ICI and T-VEC. There were 11 patients with paired evaluable tumor samples and 55% ($n = 6$) converted from PD-L1 negative at baseline to PD-L1 positive after treatment. Six of the seven patients who responded had evaluable tissue, and in this cohort, there were one PD-L1 positive baseline tumor and four PD-L1 positive post-treatment tumors^[18]. No patient tumors in the refractory group ($n = 13$) were PD-L1 positive at baseline and five were positive after treatment. They also evaluated

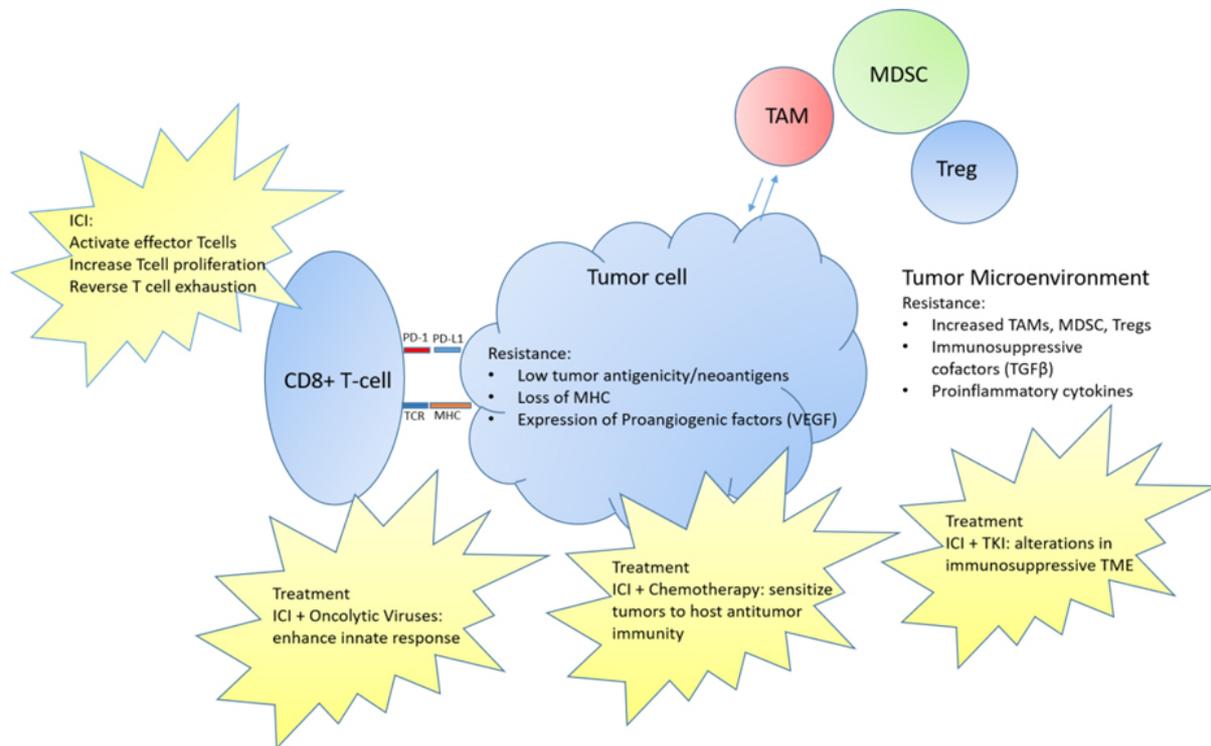

Figure 1. Resistance mechanisms to immunotherapy in soft tissue sarcoma with current treatment mechanisms aimed at overcoming resistance. tumor-infiltrating lymphocyte (TIL) scores which were higher in the response groups (mean TIL score 3) compared to the unresponsive group (mean TIL score 2)^[18]. Responsive patients also had the presence of aggregates of CD3+/CD8+ TILs in the tumor on the pre-treatment biopsy, particularly at the infiltrating edge, and this number increased in the post-therapy samples. Comparatively, there were minimal CD3+/CD8+ infiltrates in the nonresponsive patient tumors. This is a potentially promising therapy and additional investigation is ongoing in sarcoma.

There have been several studies evaluating TKIs in combination with ICI to overcome the immunosuppressive microenvironment. There are several well-known mediators of this environment including vascular endothelial growth factor (VEGF) and Transforming growth factor-β. VEGF and other proangiogenic cofactors are necessary for tumor growth and spread. TKIs with activity against these factors have produced responses in metastatic sarcoma in prior studies^[44-46]. An in vitro study of cocultures of sarcoma evaluated the role of TKIs and PD-1 based therapy^[47]. In this study, human osteosarcoma and SS cell lines were treated with sunitinib. They were then cocultured with dendritic cells (DCs) and the phenotype of these DCs was determined by flow cytometry. Mature DCs were cultured with autologous T cells and the T cells were evaluated for PD-1 expression, proliferation, Treg induction, and IFN-γ production, before and after nivolumab exposure. They found that treatment with sunitinib induced upregulation of PD-L1 on sarcoma cells, induced maturation of DCs, and reduced Treg induction. There was no effect on T cell proliferation or T cell subpopulations. Treatment with nivolumab induced IFN-γ-producing effector T cells^[47].

A phase II single-arm study by Wilky *et al.* combined axitinib (5mg twice daily), an oral TKI, with pembrolizumab (200mg/dose on day 8 and every 3 weeks for up to 2 years) in 33 patients with advanced sarcoma^[27]. ORR was 25% ($n = 8$, 95%CI: 12.1-43.8) with clinical benefit rate of 53.1% ($n = 17$; 95%CI: 35.0-70.5). In the intention to treat analysis, median PFS was 4.7 months (95%CI: 3.0 to 9.4) and median OS was 18.7 months (95%CI: 12.0 to NR). In this study, 11 patients had alveolar soft part sarcoma (ASPS). ASPS is a rare translocation-driven sarcoma subtype that frequently presents in adolescents and young adults. There is a growing body of evidence that these tumors are responsive to both TKIs and ICI and several studies are ongoing^[48]. In this study, the ORR in the ASPS cohort was 54.5% (95%CI: 24.6-81.9). The response rate in the ASPS was greater than that would be expected with either axitinib or pembrolizumab alone, and four of five patients who achieved a partial response had not achieved a partial response with at least on previous TKI. Correlatives and exploratory analyses are still underway.

A recent phase Ib/II trial evaluated the combination of nivolumab (3 mg/kg IV on day 15, then every 2 weeks) with sunitinib (37.5mg for the first 14 days, then 25mg per day) in 68 patients with advanced soft tissue sarcoma who had progressed on prior therapy^[16]. The 6-month PFS was 48% (95%CI: 41-55%) with a median PFS of 5.6 months (3.0-8.1). The median overall survival was 24 months with an 18-month survival of 67% (95%CI: 59-74%). The ORR was 21%, with 100% of responding patients alive at 18 months. These response rates, PFS and OS are favorable compared with activity in anti-PD-1 or sunitinib monotherapy in previous trials^[13,49].

These combination trials show promise in the quest to overcome resistance innate to many sarcomas. Further combination trials are underway.

CONCLUSION

Treatment of sarcomas remains difficult given the heterogeneity in immunogenic features of histologic subtypes and varied responses to ICI due to underlying primary or acquired resistance. There remains interest and promise in combining ICI and immunosensitizing agents to overcome underlying resistance mechanisms within sarcomas and the TME. Further, identifying reliable biomarkers to determine who responders to ICI will be remains an important but complex undertaking. Ongoing studies to better define the immunologic landscape, the immunosuppressive role of the TME and subsequent resistance mechanisms will improve understanding of this complex disease with the goal of improving clinical outcomes.

Abstract

Bladder cancer (BC) is the tenth most common cancer, and its incidence is steadily rising worldwide, with the highest rates in developed countries. Neoadjuvant cisplatin-based chemotherapy followed by radical cystectomy is the standard therapy for patients with muscle-invasive bladder cancer. However, less than 50% of patients initially respond to this treatment and nearly all of them eventually develop resistance, which is an important barrier to long-term survival. Therefore, there is an urgent need to understand the mechanisms of cisplatin resistance in BC and develop ways to counteract them. Several preclinical studies have demonstrated that naturally derived bioactive compounds, such as phytochemicals and flavonoids, can enhance the antitumor activity of cisplatin, with minimal side effects, by targeting different pathways involved in cisplatin sensitivity and resistance. However, their poor bioavailability has been one of the main problems for their successful introduction into clinical practice. At present, however, many new formulations with greatly increased bioavailability are under study in several clinical trials with encouraging results.

Bladder cancer (BC) is a current clinical problem due to its high incidence, prevalence, and mortality^[1,2]. At diagnosis, 70% of patients present with non-muscle-invasive BC, a highly recurrent tumor treated by transurethral resection followed by BCG instillation. However, a high proportion of patients have recurrence and progress to muscle-invasive BC (MIBC), which is also present in 30% of patients at diagnosis^[3]. At present, the treatment of MIBC has several limitations. Cisplatin-based neoadjuvant chemotherapy followed by radical cystectomy is the standard therapy, with the highest level of evidence, but it is only effective in 25%-50% of patients and confers a limited survival benefit^[4]. Moreover, this survival benefit is only observed in patients with pathological response, while the delay in cystectomy in those who do not respond has a negative prognostic impact, highlighting the need for predictive biomarkers to identify those patients likely to benefit from cisplatin-based neoadjuvant treatment^[5]. In addition, adjuvant chemotherapy has been recommended for patients with high-risk MIBC, although randomized trials have not provided conclusive evidence on the impact of this approach^[6-8]. Furthermore, nearly 50% of patients will develop metastatic disease after undergoing radical cystectomy^[3], and platinum-based chemotherapy is considered the cornerstone of treatment for these patients as well^[9]. Nevertheless, immunotherapy - especially immune checkpoint inhibitors (ICIs) - are potentially effective in metastatic BC (mBC)^[10,11], although only 20%-30% of mBC patients respond and there are no reliable predictive biomarkers of response^[12]. Importantly, with the approval of ICIs for the treatment of mBC, they are now being studied in the neoadjuvant setting for MIBC with promising results^[13]. Thus, based on this evidence, it is clear that cisplatin still plays an essential role in the treatment of MIBC. However, less than 50% of patients initially respond, and nearly all of them eventually develop resistance, which represents an important barrier to long-term survival.

In this issue of *Cancer Drug Resistance*, Rajendran *et al.*^[14] elegantly reviewed the mechanisms of cisplatin activity and resistance in BC and the potential of bioactive natural compounds, such as phytochemicals and flavonoids, to overcome this resistance and improve therapeutic response. As they pointed out^[14], resistance to cisplatin is a complex, multifactorial process that can be attributed to specific mechanisms intrinsic to BC biology or to general mechanisms common to different tumor types or drug pharmacokinetics. Several factors have been associated with resistance to cisplatin, including decreased intracellular drug concentration mediated by drug efflux pumps, alterations in DNA repair genes, and increased drug cytosolic inactivation^[15]. I fully support their argument^[14] that a greater understanding of the mechanisms of cisplatin activity and resistance, as well as the identification of potential biomarkers of response, is required so that we can select patients likely to respond to cisplatin and to improve strategies to fight resistance mechanisms. One such strategy is based on targeting the effectors and pathways involved in chemoresistance with natural compounds that can potentially synergize with platinum drugs, such as cisplatin. The antitumor effects of natural products are generally attributed to suppression of cell proliferation and metastasis, induction of apoptosis, and stimulation of autophagy, with minimal side effects^[16].

Based on our group's experience in different tumor types, including mBC^[17-19], we can highlight the potential and promising role of curcumin and its derivatives as chemosensitizing agents^[20]. Curcumin (*diferuloylmethane*) is a hydrophobic polyphenol. It is the major curcuminoid in the spice turmeric (77% curcumin, 17% demethoxycurcumin, and 3% bis-demethoxycurcumin) and is derived from the rhizome of the herb *Curcuma longa*. Many of curcumin's antitumor properties have been attributed to its role as an anti-inflammatory and antioxidant or to its ability to modulate the cell cycle, several pathways, and transcription factors involved in proliferation, apoptosis, migration, invasion, angiogenesis, metastasis, and chemoresistance. Moreover, it has a very low toxicity profile in humans^[20]. In particular, several studies have demonstrated that curcumin can enhance cisplatin sensitivity and prevent drug resistance in different

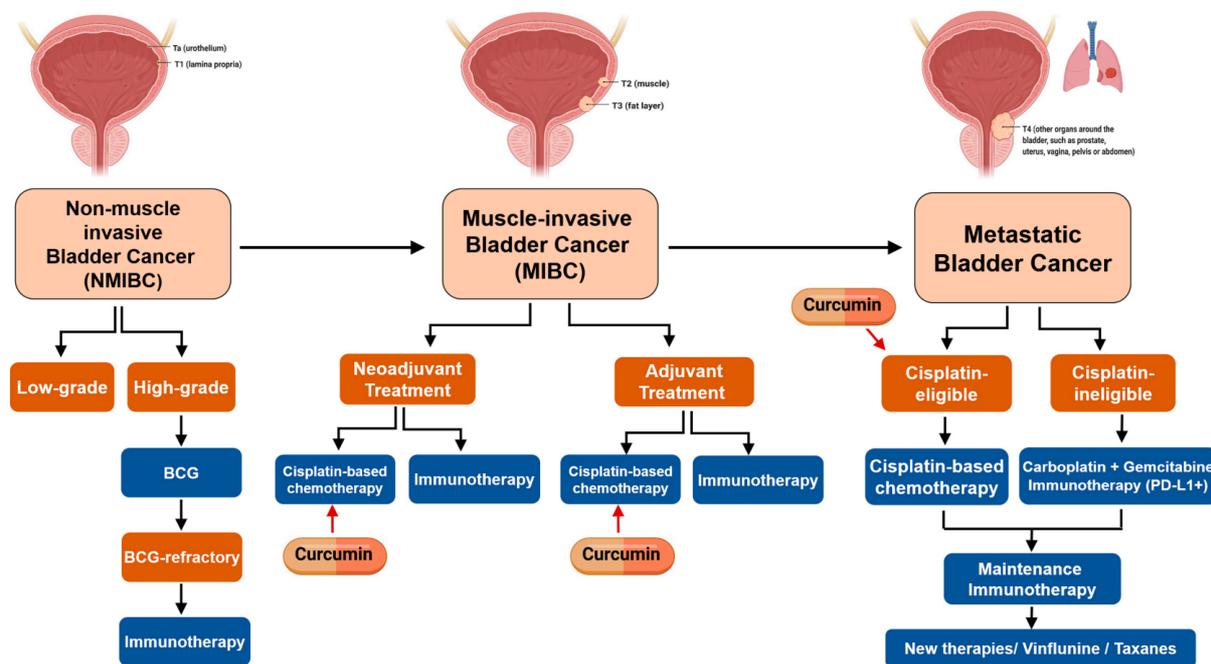

Figure 1. Potential clinical settings for the combined treatment of cisplatin plus curcumin in BC. Created with BioRender.com. BC: Bladder cancer.

tumor types^[21]. Interestingly, Park *et al.*^[21] demonstrated that co-treatment with curcumin and cisplatin synergistically induced apoptosis through ROS-mediated activation of the MEK/ERK pathway and the downregulation of survival proteins in BC cell lines and xenograft mouse models. More recently, it has been shown that the curcuminoid demethoxycurcumin enhanced the chemotherapeutic efficacy of cisplatin on HER2-overexpressing BC cells and inhibited the HER2-induced drug resistance of tumor cells through the inhibition of the PI3K/AKT signaling pathway^[22]. Furthermore, it is well known that a major obstacle for the clinical use of cisplatin is its associated toxicities, including renal damage, deafness, and peripheral neuropathy, which negatively affect the overall efficacy of treatment^[15]. Interestingly, curcumin not only increases the efficacy of cisplatin in several cancer models but also decreases cisplatin-related toxicity^[16,23,24]. The potential clinical scenarios for the combined treatment of cisplatin plus curcumin in BC are depicted in [Figure 1](#).

However, although it is true that *in vivo* and *in vitro* data are promising, the clinical application of these naturally derived bioactive compounds has been limited by their poor bioavailability in humans due to poor absorption and water solubility as well as to their rapid metabolism and systemic elimination^[25,26]. Nevertheless, to solve this problem, in recent years, many efforts have been focused on obtaining new promising bioavailable formulations or delivery strategies: liposomes, micelles, phospholipid complexes, microemulsions, nano-emulsions, emulsions, solid lipid nanoparticles, nanostructured lipid carriers, biopolymer nanoparticles, and microgels^[27,28]. Nonetheless, as proposed by Rajendran *et al.*^[14], high quality pharmacokinetic and pharmacodynamic studies are required for proper dosing of these new compounds. Moreover, increasing our understanding of how these compounds work is critical to developing synthetic derivatives with improved pharmacokinetics and greater bioavailability and efficacy.

In conclusion, although cisplatin is a clinical mainstay for the treatment of MIBC, many tumors unfortunately develop resistance and are refractory to treatment. As Rajendran *et al.*^[14] pointed out,

combination therapies using natural products represent a promising effective and novel strategy to overcome this resistance. For instance, the combination of curcumin and cisplatin could be a potential synergistic strategy to attenuate cisplatin-related adverse effects and decrease resistance. Finally, improved delivery strategies and new formulations offer encouraging ways to increase the bioavailability of these natural products. Hopefully, these strategies will be tested in further randomized, double-blind, placebo-controlled clinical trials in BC patients and incorporated into clinical practice. Nevertheless, although clinical trials using new bioavailable curcumin formulations are certainly mandatory to evaluate the optimal dosage, safety, and antitumor activity, based on our group's previous preclinical results^[19] as well as on those presented by Rajendran *et al.*^[14], I suggest that the combination of curcumin plus a platinum agent, such as cisplatin, could be an effective and reliable approach for the management of several cancers, including BC.

Abstract

In acute myeloid leukemia (AML), a small cell population that contains stem cell features such as lack of differentiation, self-renewal potential, and drug resistance, can be identified. These so-called leukemic stem cells (LSCs) are thought to be responsible for relapse initiation after initial treatment leading to successful eradication of the bulk AML cell population. Since many studies have aimed to characterize and eliminate LSCs to prevent relapse and increase survival rates of patients, LSCs are one of the best characterized cancer stem cells. The specific elimination of LSCs, while sparing the healthy normal hematopoietic stem cells (HSCs), is one of the major challenges in the treatment of leukemia. This review focuses on several surface markers and intracellular transcription factors that can distinguish AML LSCs from HSCs and, therefore, specifically eliminate these stem cell-like leukemic cells. Moreover, previous and ongoing clinical trials of acute leukemia patients treated with therapies targeting these markers are discussed. In contrast to knowledge on LSCs in AML, insight into LSCs in acute lymphoid leukemia (ALL) is limited. This review therefore also addresses the latest insight into LSCs in ALL.

INTRODUCTION

Acute leukemia is a rapidly progressing hematological malignancy that causes more than ten thousand deaths per year in the United States alone^[1]. Acute leukemia can be subdivided into two main classes: acute myeloid leukemia (AML) and acute lymphoid leukemia (ALL). AML is a heterogeneous malignancy characterized by the proliferation and accumulation of myeloid progenitor cells in the bone marrow (BM) and peripheral blood^[1,2], while in ALL lymphoid progenitor cells accumulate in the BM and peripheral blood^[3]. Based on the immunophenotype, ALL can be subdivided into different types; B-cell acute lymphoid leukemia (B-ALL) and T-cell acute lymphoid leukemia (T-ALL), with B-ALL being the most common type^[4]. The median age of onset differs between AML and ALL. While ALL is most commonly diagnosed in children, AML occurs most frequently in patients older than 65 years of age^[1,5]. Despite standard treatment with intensive cytotoxic induction chemotherapy and various clinical trials, five-year overall survival (OS) rates remain poor, especially in adults^[6-8]. For treated AML patients between 60 and 70 years old, the OS rate is about 25%, and for ALL patients aged 70 years and older, it is only 15%. This is much lower compared to OS rates in children: around 80% in ALL and 70% in AML, depending on the risk group classification^[9,10]. A major cause of dismal outcomes for both AML and ALL patients is the high relapse rate^[7,8]. The prevention of relapse remains one of the most complicated challenges in the treatment of acute leukemia. However, the discovery of a rare so-called leukemia stem cell (LSC) population in AML has led to more insight into the mechanisms of relapse development and thereby novel therapeutic opportunities.

In the 1990s, a detailed investigation of AML subpopulations provided the first proof of a rare LSC population, with a CD34+/CD38- phenotype, within AML capable of establishing leukemia in nonobese diabetic/severe combined immunodeficiency (NOD/SCID) mice: leukemic stem cells (LSCs)^[11,12]. This subpopulation of cells shares several properties with normal hematopoietic cells (HSCs). For example, AML LSCs are, similar to HSCs, self-renewing cells that remain undifferentiated themselves but are capable of giving rise to both a stem cell copy and more differentiated progeny cells through mitotic cell division^[13]. In addition, direct evidence shows that AML consists of three distinct LSC classes with heterogeneity in their self-renewal potential: short-term, long-term, and quiescent long-term LSCs^[14]. Since HSC compartments have a similar hierarchical structure of heterogeneous cell classes, it is indicated that LSCs in AML originate from normal HSCs^[12]. In concordance with these functional characteristics, it is suggested that AML LSCs share specific stem cell transcriptional programs with HSCs^[15]. Altogether, this provides strong evidence for a hierarchical organization in AML with LSCs at the apex. Only these LSCs have the ability to initiate and fuel the disease, distinguishing them from more differentiated non-tumorigenic leukemic cells and healthy cells^[13,16]. The stem cell features that distinguish LSC from healthy cells or more differentiated leukemic cells not only provide the capacity to initiate and maintain leukemia but are also thought to contribute to relapse. For example, drug-resistant properties due to changes in the expression of drug resistance genes are attributed to the stem cell phenotype^[13,17-19]. The clinical relevance of LSCs is underlined by studies that showed an increased chance of relapse and worse overall survival in AML patients with a high CD34+/CD38- LSC frequency at diagnosis and after induction therapy compared to patients with a low LSC frequency^[20]. These data suggest that eliminating LSCs during or after induction therapy will be crucial in improving the clinical outcome of AML patients.

Besides functional similarities, LSCs and HSCs also differ in many characteristics, such as cell surface protein expression or activation of intracellular signaling pathways, which may be exploited to specifically eliminate LSCs while sparing HSCs. Some of the key signaling pathways that play a role in the regulation of self-renewal, survival, proliferation, and differentiation are dysregulated in LSCs vs. HSCs. Examples of such signaling pathways include JAK/STAT, Wnt/ β -catenin, Hedgehog, and Notch^[21-24]. The dysregulation of these key signaling pathways in LSCs not only contributes to their oncogenic potential and cancer

progression, but some of them also contribute to drug resistance, illustrating the importance of therapeutically targeting these pathways.

Other factors suggested to be involved specifically in drug resistance of LSC and therefore promising targets are intracellular enzymes such as aldehyde dehydrogenase (ALDH) and histone deacetylase (HDAC)^[25,26]. In addition, the overexpression of drug efflux transporters such as ATP-binding cassette transporters is also suggested to be an important intrinsic resistance mechanism (comprehensively reviewed in^[27]), but treatment with specific inhibitors remains controversial for acute leukemia. Recently, there has been a revival of the research into the metabolic rewiring of resistant cancer cells. For LSCs specifically, the pathway of mitochondrial oxidative phosphorylation seems to be very distinct, as comprehensively reviewed by de Beauchamp *et al.*^[28]. Extrinsic factors, including proteins involved in the cell-to-cell interactions between LSCs and the tumor microenvironment, could sensitize LSCs for eradication^[29,30]. In addition to these intrinsic and extrinsic mechanisms, identification of aberrantly expressed surface markers on LSCs in AML is also a technique of interest in order to specifically eradicate these cells. Due to surface markers uniquely expressed on AML LSCs and not on HSCs, specific drug delivery to the rare population of LSCs is feasible without harming normal stem cells^[31,32].

While knowledge on LSCs in AML has rapidly increased over the past few years, less is known about the nature of LSCs in ALL. There are even contradictory results on the existence of an LSC population in ALL. Several studies support a similar hierarchical organization in ALL as AML, while other studies provide evidence suggesting that the stochastic model may fit better^[33,34]. This model states that all tumor cells are biologically equal and have the same tumor initiating potential. Their intrinsic characteristics cannot predict their behavior, so enrichment of these cells by sorting them based on these characteristics is impossible according to this model^[16]. Therefore, besides summarizing the most important AML LSC specific markers and recent clinical trials targeting these markers, evidence and important markers of a stem cell population in ALL are also discussed.

LEUKEMIC STEM CELL TARGETS IN ACUTE MYELOID LEUKEMIA

AML LSCs cell surface protein targets

Similar to what is seen for AML LSCs, HSCs also have a CD34+/CD38- phenotype. The challenge in eliminating LSCs while sparing HSCs is therefore to find unique markers on LSCs that distinguish them from HSCs. Several studies have shown markers that are aberrantly expressed on LSC but not or very lowly expressed on normal HSC^[32,35]. These markers can be used to isolate LSCs for further characterization, as well as monitored during therapy^[20]. In addition, these markers are investigated for specific targeting by therapeutics, such as antibody-drug conjugates (ADCs) and chimeric antigen receptor (CAR)-T cells directed to these LSC-specific markers. The most important LSC specific cell surface markers are detailed below.

CD123

One of the surface markers that has been shown to be overexpressed in primary AML blasts and LSCs is CD123 [interleukin-3 receptor alpha (IL-3R α)]. CD123 expression was not detectable on normal CD34+/CD38- hematopoietic cells, HSCs, discriminating LSCs from HSCs^[36]. Despite the lack of CD123 expression on HSCs in healthy subjects, several other studies did find CD123 expression on HSCs and more differentiated hematopoietic cells such as monocytes^[37,38]. For instance, NOD/SCID mice injected with patient cells from cord blood and BM revealed that not only human AML LSCs expressed CD123, but also a small proportion of normal human HSCs were positive for CD123^[37]. However, since the percentage of CD123+ HSCs in the bone marrow was relatively low and only a relatively small part of HSCs expressed

CD123, most HSCs should not be harmed by CD123-targeted therapy^[37].

Elevated levels of CD123 in AML are correlated to an increased number of leukemic blasts at diagnosis, a decreased chance to achieve complete remission and poor survival rates^[39]. Moreover, high CD123 expression was associated with more cell cycle activity in the leukemic blasts, apoptotic resistance, and elevated signal transducer and activator of transcription 5 (STAT5) activation by IL-3^[39]. The biological basis explaining this poor survival, when blasts have high CD123 expression, is enhanced signaling via the IL-3R in the CD123 overexpressing AML LSCs, resulting in increased proliferation and cell viability and decreased CXCR4 expression^[30]. CXCR4 is a receptor expressed by HSCs/LSCs that interacts with stromal-derived factor 1 (SDF1), a chemokine constitutively expressed by BM stromal cells^[40]. This interaction plays a major role in the homing and preserving of the stem cells in the BM niche. Downregulation of CXCR4 *in vitro* impaired the migration of LSCs to SDF1, suggesting that high CD123 expression and downregulated CXCR4 in LSCs releases them from the chemoprotective BM niche into the circulation^[30]. A promising strategy to eliminate CD123-expressing AML LSCs could therefore be to combine CXCR4 antagonists with CD123 antibodies, since the antagonists would release more cells from the BM, leading to more effective targeting of LSCs by CD123 antibodies.

CD33

Another surface marker identified on LSCs is CD33, also known as sialic acid-binding Ig-like lectin 3^[37]. Since CD33 shows similar homogeneous expression in relapsed AML samples as CD123, it was suggested that both these surface markers are promising drug targets^[38]. Gemtuzumab ozogamicin (GO), a humanized anti-CD33 monoclonal antibody attached to a cytotoxic agent, has been used in the clinic and has shown clinical efficacy in the treatment of AML. However, since CD33, similar to CD123, shows expression on HSCs, healthy BM myeloid progenitor cells, and more differentiated myeloid cells, the risk of unwanted on-target off-tumor toxicity increases after targeting these molecules^[38]. This is especially seen in ADCs targeting CD33, since the expression of CD123 is more restricted in healthy BM cells compared to CD33 expression^[41]. In addition, the clinically effective GO revealed severe toxicities such as liver and hematological toxicities^[41,42]. Therefore, targeting of more specific surface markers is required to reduce such toxicities.

T cell immunoglobulin mucin-3

T cell immunoglobulin mucin-3 (TIM-3), a transmembrane protein initially found on differentiated CD4+ Th1 and CD8+ Tc1 cells, is a membrane marker expressed on AML cells^[43]. TIM-3 is expressed on multiple immune cells, such as regulatory T cells, natural killer cells, dendritic cells, monocytes, and macrophages^[44-46]. Transcriptional profiling of LSCs and HSCs derived from human AML samples showed that TIM-3 is highly expressed on most LSCs, with the exception of acute promyelocytic leukemia LSCs, but not expressed on normal HSCs^[47]. In addition, only TIM-3-positive AML cells, and not TIM-3 negative ones, were able to regenerate AML in immune-deficient mice. A similar differential expression of TIM-3 between LSCs and HSCs was observed in a study performing flow cytometry on primary human AML samples^[48]. This differential expression allows for prospective separation of LSCs from normal HSCs, and it is also promising for the successful elimination of LSCs in AML^[48]. Moreover, the number of TIM-3 expressing LSCs after allogeneic stem cell transplantation seems to be predictive for relapse^[49].

That LSCs can effectively be eliminated by targeting TIM-3 is supported by *in vivo* experiments in human AML xenograft mice using the anti-human TIM-3 mouse antibody named ATIK2a. This antibody induces antibody-dependent cell-mediated cytotoxicity and complement-dependent cytotoxicity, which resulted in the effective eradication of LSCs without harming HSCs. The outcome of this was a strong decrease in

leukemic burden in treated mice^[47]. Altogether, these studies provide evidence that TIM-3 is a promising target in the elimination of LSCs and suggest that targeting of TIM-3 results in fewer side effects compared to the targeting of, e.g., CD33.

C-type lectin-like molecule-1

C-type lectin-like molecule-1 (CLL-1), a transmembrane glycoprotein, was first identified on AML cells in 2004^[50]. CLL-1 is expressed in 92% of primary AML samples^[50] and expressed on LSCs in the majority of AML patients, but it is absent on HSCs from healthy and regenerating BM from patients who received chemotherapeutic treatment^[51,52]. It was recently published that CLL-1 expression can also be bimodal in AML samples^[53], which warrants further investigation into effective elimination of LSCs including those negative for CLL-1. Despite this, CLL-1 is still a promising target in the treatment of AML. Zheng *et al.*^[54] studied the efficacy and safety of an anti-CLL-1-ADC in which a CLL-1 antibody is conjugated via a self-immolative disulfide linker to a pyrrolobenzodiazepine (PBD) dimer. Xenograft mice and cynomolgus monkeys were treated with this anti-CLL-1 ADC and showed an effective decrease in AML cells. Despite the fact that CLL-1 is expressed on healthy myeloid progenitors, its expression pattern is more restricted on healthy cells than that of CD33, resulting in less toxicity and faster recovery from side effects such as cytopenia^[54]. Anti-leukemic effects were also observed in xenografted mice engrafted with human AML and treated with CAR-T cells targeting CLL-1^[52]. The results show both *in vitro* and *in vivo* compelling anti-leukemic effects.

CD47

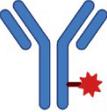

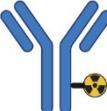

CD47 is a surface marker widely expressed on both hematopoietic cells and other cell types^[55]. The interaction between CD47 and SIRP α , a protein expressed on phagocytic cells such as dendritic cells and macrophages, leads to inhibition of phagocytosis^[56]. The CD47 surface marker is, compared to the other mentioned surface markers, not as stem cell-specific and therefore not used to identify and monitor stem cells. However, since it was found that CD47 has elevated expression on AML LSCs compared to normal HSCs, blocking monoclonal antibodies have been used in multiple studies as a strategy to eliminate LSCs^[56,57]. The results show that these blocking anti-CD47 antibodies enable phagocytosis, resulting in the eradication of LSCs without affecting normal cells^[55-57].

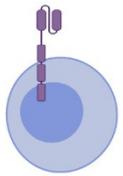

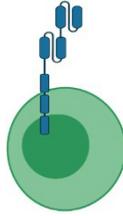

Targeting LSCs via one protein is a big challenge, since even a low expression of a cell surface marker on HSCs leads to unwanted toxicities; thus, more specific targeting of LSCs is required to prevent this. One option to increase efficacy and decrease toxicity is by targeting surface marker combinations that are highly co-expressed on AML cells but not co-expressed on healthy cells. Haubner *et al.*^[38] showed that this is valid for the CD33/TIM-3 and CLL-1/TIM-3 combinations.

Different therapies have been developed to target these surface markers specifically expressed on LSCs [Table 1]. Besides the described surface markers, other commonly investigated surface markers are also included in the table.

The surface markers in Table 1 are all surface markers of AML LSCs that have been investigated by many different studies. Recently, two novel and less thoroughly investigated candidate AML LSC surface markers have been identified. First, CD9, a member of the tetraspanin family, was found to be highly expressed on LSCs in AML patients, and CD9-positive AML cells were capable of initiating AML *in vivo*^[87,88]. Since CD9 is hardly expressed on normal HSCs, it was suggested that this surface marker could be a promising new target for the eradication of LSCs. Second, AML cells positive for c-MPL, a thrombopoietin receptor regulating processes such as self-renewal and HSC proliferation, showed more chemoresistance than the c-

MPL negative AML cell population in a mouse leukemic model^[89]. Moreover, the c-MPL+ cells had a higher self-renewal potential and were significantly better at initiating AML *in vivo* compared to the c-MPL- cell population. Although these results suggest that c-MPL could be a potential target to eradicate AML LSCs, more research is needed regarding unwanted toxicities since c-MPL is also a long-term HSCs marker^[90].

Signal transduction pathways and transcription factors involved in AML LSC survival

Besides the previously described surface markers, there are intracellular proteins such as transcription factors that are differentially expressed between LSCs and HSCs^[91]. Several of these factors are involved in drug resistance mechanisms, making them important therapeutic targets for elimination of AML LSCs.

JAK/STAT signaling pathway

High CD123 expression is associated with elevated STAT5 activation by IL-3, suggesting that the Janus kinase/signal transducer and activator of transcription (JAK/STAT) signaling pathway plays a role in the fate of LSCs [Figure 1A]^[39]. The JAK family of intracellular non-receptor tyrosine kinases can be activated via extracellular cytokine or growth factor binding, resulting in the phosphorylation and activation of STAT proteins^[92]. This STAT protein family consists of transcription factors that interfere with proliferation, differentiation, and apoptosis. Previous research has shown that STAT3 and STAT5 are constitutively activated in AML leukemic blasts, which is not seen in HSCs^[93]. This may contribute to the uncontrolled proliferation of these blasts and resistance to chemotherapy-induced apoptosis. The role of JAK/STAT signaling in AML LSCs growth and survival was investigated several years later by evaluating the expression levels of JAK and STAT in AML patient samples at diagnosis and relapse^[94]. An ATP competitive inhibitor of JAK1/2 kinases named AZD1480 was used in both *in vitro* and *in vivo* experiments to analyze its effect on AML stem/progenitor cells. Inhibitor treatment of AML CD34+ cells *in vitro* showed decreased levels of JAK2 and STAT3/5 activity and reduced AML CD34+ cell proliferation and survival, but it did not affect normal CD34+ cells^[94]. Similar results were seen in NOD/SCID mice treated with AZD1480: the number of AML LSCs was reduced, but normal human HSC numbers were not affected. To further investigate the role of JAK1, JAK2, STAT3, and STAT5 in CD34+ AML cells, an RNA interference-mediated knockdown of these proteins was performed. JAK2, STAT3, and STAT5 knockdown resulted in a significant decrease of colony-forming cells, cell numbers, and survival, while this was not observed with downregulation of JAK1, indicating that inhibition of JAK2 is more effective in decreasing growth and survival of AML CD34+ cells than inhibition of JAK1.

Nuclear factor-kappa B signaling pathway

Nuclear factor-kappa B (NF-κB) is a proinflammatory transcription factor that plays an essential role in cellular processes such as proliferation, survival, stress responses, and inflammation^[95]. NF-κB is suggested to be involved in drug resistance, as NF-κB has anti-apoptotic activity and increased levels of NF-κB have been seen after chemotherapy and radiotherapy^[96,97]. Electrophoretic mobility shift assays on primary AML samples showed constitutively activated NF-κB in AML LSCs. In contrast, in normal human stem/progenitor cells, there was no NF-κB expression^[23]. Multiple studies have investigated the effect of NF-κB inhibitors on AML (stem) cells. For example, AML LSCs treated with MG-123, an NF-κB inhibitor, initiated cell death *in vitro*^[23]. Micheliolide (MCL), a natural sesquiterpene lactone, had cytotoxic effects on LSCs via the inhibition of NF-κB^[98]. *In vitro* MCL treatment initiated apoptosis in AML LSCs but not in normal HSCs. *In vivo*, treatment with DMAMCL, the pro-drug form of MCL, improved survival rates of NOD/SCID mice engrafted with human AML^[98]. A third NF-κB inhibitor, BMS-345541, conferred an altered expression of genes involved in a previously described 17-gene LSC score to primary AML patient samples^[15,95]. This gene signature contains 17 stemness-related genes differentially expressed between LSC-positive and LSC-negative AML samples. The NF-κB pathway is illustrated in Figure 1B, including drugs recently used in clinical trials targeting this pathway. In addition, it has to be noted that this pathway may

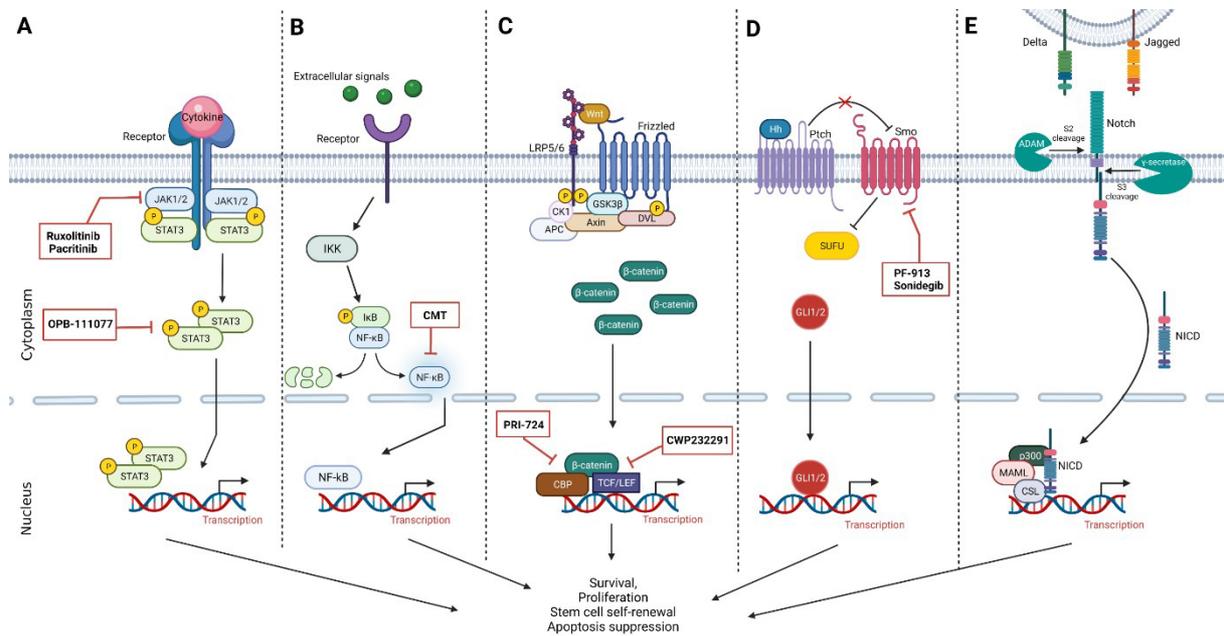

Figure 1. Intracellular signaling pathways dysregulated in AML LSCs, including agents recently used in clinical trials inhibiting pathway activity. (A) JAK/STAT signaling pathway. Therapeutic agents either target elevated JAK1/2 levels or constitutively active STAT3. (B) NF- κ B signaling pathway. Therapeutic agents recently used in clinical trials directly inhibit the constitutively activated NF- κ B. (C) Wnt/ β -catenin signaling pathway. Therapeutic targets prevent constitutive activation by inhibiting the interaction between β -catenin and CBP or TCF. (D) Hh signaling pathway. Small molecule inhibitors target Smoothed (Smo), decreasing pathway activation. (E) Notch signaling pathway. There are currently no clinical trials inhibiting or activating the Notch pathway as a treatment in AML patients. Created with BioRender.com. also be linked to the PI3K/Akt/mTOR pathway, which has also been suggested to be involved in the drug resistance of AML LSC^[99].

Wnt/ β -catenin signaling pathway

The Wnt/ β -catenin signaling pathway is a highly conserved signaling pathway involved in the development and tissue homeostasis^[100]. The Wnt/ β -catenin pathway plays a role in the cellular processes of HSCs, including cell proliferation, differentiation, survival, and stem cell renewal^[101]. The transcriptional coactivator β -catenin plays a central role in this pathway; when the Wnt ligand binds to its cognate receptor Frizzled, β -catenin degradation is blocked, causing an accumulation of β -catenin and subsequent translation to the nucleus. There, β -catenin binds to nuclear transcription factors that belong to the T-cell factor/lymphoid enhancer factor (TCF/LEF) family, which recruits coactivators including the CREB-binding protein (CBP), resulting in the transcription of target genes involved in self-renewal and proliferation^[102]. A study evaluating the activity of Wnt/ β -catenin signaling by transfecting AML and normal progenitors with a TCF/LEF reporter construct, found that in the majority of the AML samples, the TCF/LEF pathway was constitutively active, which was supported by other studies showing overexpression of β -catenin both in AML cell lines and patient samples^[101,103]. Moreover, the promoter regions of Wnt pathway inhibitor genes were frequently methylated in cell lines, and in 89% of AML patient samples with normal cytogenetics one or more of these inhibitor genes were methylated. Methylation of two Wnt pathway inhibitor genes named *sFRP2* and *sFRP5* was associated with elevated relapse risk, suggesting that enhanced Wnt activity has adverse outcomes in AML patients with normal karyotypes^[104].

Wang *et al.*^[105], using an AML mouse model, showed that LSCs require β -catenin in order to maintain their self-renewal capacity. Several studies have shown the overexpression of β -catenin in LSCs; however, the expression of β -catenin in normal HSCs was also observed^[106]. Cobas *et al.*^[107] provided evidence that β -catenin did not show to be crucial for self-renewal of adult HSCs, since depletion of β -catenin in mice showed no impairment in hematopoiesis and lymphopoiesis. Targeting β -catenin is therefore suggested to be promising in the eradication of LSCs, while sparing HSCs [Figure 1C]. Nevertheless, targeting the Wnt/ β -catenin pathway remains a challenge due to its complexity. First, mammals contain 19 different Wnt ligands and over 15 Frizzled receptors and co-receptors. In addition, targeting β -catenin is also complex since it can bind to many other transcription factors besides TCF/LEF^[108]. Numerous small molecule inhibitors or antagonists with different targets within the Wnt/ β -catenin pathway have been investigated, including inhibitors targeting the interaction between β -catenin and TCF^[109]. Treatment with these inhibitors and antagonists is indicated to be relevant in LSC depletion by impairing their self-renewal capacity.

Hedgehog and Notch signaling pathways

Besides the Wnt/ β -catenin pathway, the Hedgehog (Hh) and Notch signaling pathways are also highly evolutionarily conserved pathways involved in the development and tissue homeostasis^[110]. A study in zebrafish treated with a Hh inhibitor suggested that Hh signaling is necessary for HSC homeostasis and differentiation^[111]. A few years later, a study addressed Hh function specifically in adult HSCs, revealing that the deletion or overexpression of Smoothed, a G-protein coupled receptor playing a key role in Hh signaling, did not affect adult HSC self-renewal *in vivo*^[112]. Studies investigating Notch signaling in HSCs showed controversial results as well. Notch signaling is activated in HSCs, but it decreases when HSCs differentiate. Inhibition of Notch signaling demonstrated increased HSC differentiation *in vitro* and depleted HSC levels *in vivo*, indicating that Notch signaling is essential for the self-renewal of HSCs^[113]. This is contradictory to the results of follow-up studies that showed that inhibition of Notch signaling had no effect on HSCs^[114,115].

Aberrant Notch and Hh signaling has been detected in AML LSCs. LSCs that exhibited active Hh signaling showed enhanced survival and chemoresistance^[116]. This, together with the knowledge that inhibiting Hh does not affect HSCs^[112], suggests that targeting Hh in AML patients could specifically eliminate AML LSCs [Figure 1D]. This idea was supported by a study that showed induction of apoptosis in CD34+ leukemic cells after treatment with a Hh neutralizing antibody or Smoothed antagonist^[116]. Besides Hh signaling, the role of Notch signaling has also been investigated in AML, showing controversial results. Depending on the context, Notch signaling could exhibit both oncogenic and tumor suppressor functions *in vivo*^[117]. In AML, Notch signaling has been shown to be mainly tumor suppressive. For instance, CD34+/CD38- LSCs, harvested from an MLL-AF9-driven AML mouse model, contained silenced Notch activity^[118]. Both *in vivo* and *in vitro*, activation of the Notch pathway, by a gain of function models or treatment with a Notch ligand, respectively, led to decreased proliferation and increased apoptosis of this CD34+/CD38- LSC population^[118]. However, despite several studies showing a tumor suppressive role of Notch signaling in AML LSCs, there were also studies providing evidence for an oncogenic role. For example, an oncogenic role of Notch signaling was observed in a pre-leukemic acute promyelocytic leukemia mice model^[119]. In addition, crosstalk between the Wnt/ β -catenin and Notch pathways displayed a promoting role of Notch signaling in AML development^[120]. When β -catenin is activated, osteoblasts in the BM start to express the Notch ligand Jagged-1, resulting in activated Notch signaling in pre-leukemic hematopoietic stem/progenitor cells^[120]. This led to the malignant transformation of these cells, providing evidence that activated Notch has an oncogenic function. However, in contrast to these results, constitutive low Notch and high Wnt signaling in LSCs was demonstrated to play a role in maintaining AML^[121]. This result

suggests that promoting Notch signaling while blocking Wnt signaling could be a promising approach to eliminate LSCs in AML. The Notch signaling pathway and a promising therapeutic agent recently used in clinical trials is shown in [Figure 1E](#).

In addition to the described signaling pathways, there are many other factors identified as being promising LSC targets, including miRNAs^[122]. Examples of the most important markers and therapeutics targeting them are shown in [Table 2](#).

LEUKEMIC STEM CELLS IN ACUTE LYMPHOID LEUKEMIA

Although AML is proven to be maintained by a rare population of LSCs, for ALL it is not clear if it is organized similarly. Several studies support a similar hierarchical organization in ALL as AML, while other studies provide evidence that contradicts this.

Leukemic stem cells in B-ALL

Two early studies from Cox *et al.*^[149,150] evaluated the long-term proliferation of childhood B-ALL cells *in vitro* and *in vivo*. The expression of several surface markers, such as CD34, CD38, CD19, CD133, and CD10, on the B-ALL cells were investigated on their potential to initiate B-ALL. Only a minority of B-ALL cells, those with a primitive CD34+/CD10-/CD19-/CD38- phenotype, were capable of engrafting B-ALL in NOD/SCID mice. Since CD19 is known to be a B-lymphocyte antigen and CD10 a marker of lymphocytic differentiation, this result suggests that B-ALL arises, as in AML, from a primitive immature cell instead of a committed B cell^[34,149]. A few years later, this group performed a follow-up study on the expression of the primitive cell antigen CD133. They found that only cells within the CD133+/CD19- and CD133+/CD38- phenotypes were capable of initiating B-ALL in children, which supported their previous findings^[150,151].

Besides studies indicating that only cells with a primitive phenotype are able to engraft B-ALL in NOD/SCID mice, several other studies found contradictory results showing that exclusively the more mature CD19+ B-ALL cells were capable of engrafting^[152,153]. In this latter study, both the CD34+/CD38-/CD19+ and the CD34+/CD38+/CD19+ B-ALL cell populations had the capacity to engraft B-ALL. Furthermore, in high-risk childhood ALL patients, including patients with *MLL* gene rearrangement, blasts cells were within three different maturation stages (CD34+CD19-, CD34+CD19+ and CD34-CD19+), which all had the capacity to re-establish and reconstitute the original leukemia phenotype in NOD/SCID mice^[154]. That cells within different maturation stages have the capacity to engraft B-ALL and contain stem cell activity was confirmed by showing that both CD19+/CD20- and CD19+/CD20+ cells are capable of B-ALL engraftment. However, a study specifically looking at *MLL-AF4*+ infant B-ALL showed that exclusively the more mature CD34+CD19+ and CD34-CD19+ B-ALL cell populations could engraft^[155]. Similar results were seen in standard-risk patients, such as patients with a *TEL/AML1* fusion gene, in whom engraftment of B-ALL was restricted to cells containing the CD19+ phenotypes^[154]. These controversial findings highlight that the LSCs in B-ALL are heterogeneous and indicate that several cytogenetic aberrations are involved in driving LSCs.

Since in AML the enrichment of LSCs is well established and the CD34+CD38- fraction is suggested to contain the most important LSCs^[17], the surface markers CD34 and CD38 have also often been used to enrich for LSCs in B-ALL^[156]. However, there is a highly dynamic expression of CD34 and CD38 on leukemia-initiating cells in B-ALL^[157], which could be an explanation for the controversial results found in the above-mentioned studies and also suggests a non-hierarchical organization of B-ALL.

dODN: Decoy oligodeoxynucleotide; CBP: CREB-binding protein; Sam68: SRC-associated in mitosis 68; CK1 α : casein kinase 1 α ; Dll4-Fc: delta-like 4 extracellular domain fused to the IgG-Fc-fragment; NMHC: N-methylhemeanthidine chloride; AZA: azelaic acid; GSI: gamma-secretase inhibitor; GLI: glioma-associated oncogene homolog; IKK: I κ B kinase; GSL: guaianolide sesquiterpene lactone; CMT: choline magnesium trisalicylate; NSAID: non-steroidal anti-inflammatory drug; DIMATE: dimethyl ampal thiolester; HDAC: histone deacetylase; ALDH: aldehyde dehydrogenase.

Taken together, accumulating evidence shows that there are several different ALL LSCs with a variety of immunophenotypes, making it impossible to isolate these cells based on their surface markers. Moreover, this indicates that there is not just a rare subset of B-ALL cells with an enhanced leukemogenic potential, and that the stochastic model, rather than the hierarchical LSC model observed in AML, applies for B-ALL^[33,158].

Leukemic stem cells in T-ALL

The identification of LSCs in human T-ALL is, as in B-ALL, a major challenge. Cox et al.^[159] tried to identify LSCs in pediatric T-ALL patients by performing *in vitro* suspension culture assays and *in vivo* NOD/SCID mice model experiments. T-ALL cells with the expression of CD34, in combination with CD4 and CD7, were investigated for their potential to be LSCs. CD4 is a co-receptor of the T cell receptor and CD7 is a marker of early T cell differentiation^[160,161]. Exclusively cells within the rare CD34+/CD4- and CD34+/CD7- subfractions were capable of T-ALL engraftment in mice, suggesting that pediatric T-ALL arises from cells with a primitive immunophenotype, and that T-ALL is similarly organized as in AML^[159]. Contradicting results were found in a study that investigated cortical/mature T-ALL patient samples. In these T-ALL patients, the LSC activity was limited to cells within the CD34+/CD7+ subpopulation both *in vitro* and *in vivo*, while the primitive CD34+/CD7- cells only grew out into normal HSCs^[161].

The previous two studies suggest that LSC activity in T-ALL is limited to the CD34+ phenotype. However, it was revealed that the CD34+ fraction in some T-ALL samples also contained LSC activity, while in other samples the LSC activity was in the CD34- population^[162]. This indicates that, as seen in B-ALL, CD34

is not a universal marker to identify LSCs in all adult T-ALL patients. Interestingly, Chiu *et al.*^[162] found that a CD7+/CD1a- T-ALL cell subset was enriched for LSC activity, suggesting that adult T-ALL arises from immature thymocytes and is organized as a hierarchical CSC model. Moreover, these CD7+/CD1a- cells were shown to be resistant to glucocorticoids such as dexamethasone and prednisone^[162]. These drugs are commonly used for the treatment of ALL, and particularly in T-ALL, resistance to glucocorticoids is the most important driver of treatment failure^[163]. Together, these results indicate that the CD7+/CD1a- T-ALL cell fraction is functionally different from the bulk of the T-ALL, and that it might be important to eliminate these cells to overcome treatment failure.

Besides studies investigating possible surface markers in T-ALL, there are also studies focusing on signaling pathways that could play a key role in T-ALL relapse. Since the majority of patients have T-ALL with oncogenic *Notch1* mutations, a recent study explored the significance of interleukin-7 receptor (IL-7R) signaling, a transcriptional target of Notch1, in LSC potential in T-ALL cell lines, human pediatric samples, and one adult T-ALL sample^[164]. Expression of functional IL-7R is crucial for the emergence of Notch1-induced T-ALL, and IL-7R was demonstrated to be a biomarker for LSCs in T-ALL. Besides human T-ALL, IL-7R is also essential in B-ALL cells containing LSC activity and promoting B-ALL progression, suggesting that targeting IL-7R could prevent relapse in both pediatric T-ALL and B-ALL patients^[164].

Despite a less well-characterized ALL organization compared to AML, there are several clinical trials that focus on targeting populations of cells that have a high initiating potential in ALL such as CD34+CD38+CD19+ cells^[153]. Besides these ALL trials, numerous clinical trials targeting AML LSCs are currently active.

CLINICAL TRIALS TARGETING LSCS

Many different surface markers, transcription factors, and other factors have been described to be differentially expressed between HSCs and LSCs. These are all promising targets in the treatment of acute leukemia, and therefore currently, several clinical trials are investigating the effect of drugs targeting them. The clinical trials in [Supplementary Table 1](#) are examples of recent clinical trials investigating the effects of these anti-LSC compounds, either as a monotherapy or in combination with other therapies.

Summary and important remarks of recent clinical trials targeting LSC-specific markers

[Supplementary Table 1](#) shows many clinical trials focusing on the markers mentioned in the previous sections. Most of these trials, investigating novel therapeutic compounds targeting AML LSCs, are phase I or II trials; however, some compounds are already in phase III: CD123/CLL-1 CAR-T cells, Hh pathway inhibitor PF-913, and HDAC inhibitors pracinostat and panobinostat. Besides the majority of these clinical trials focusing on LSCs in AML, a few have investigated compounds targeting cells capable of initiating B-ALL or T-ALL: anti-CD25 ADC ADCT-301, bispecific anti-CD19/CD3 BiTE blinatumomab, anti-CD19 CAR-T cells, anti-CD7 CAR-T cells, JAK1/2 inhibitor ruxolitinib, Notch inhibitor BMS-906024, and CXCR4 antagonists. The use of CAR-T cells is an often-used strategy to target surface markers in ALL as well as AML. Interestingly, the use of CAR-T cells is one of the few therapeutic strategies in clinical trials with patients under the age of 18. Clinical trials using other compounds or targeting LSC-related pathways are exclusively performed in adults.

Although some clinical trials are investigating the safety and efficacy of novel therapeutics as a monotherapy, most of the compounds are tested in combination with other drugs, such as chemotherapy and hypomethylating agents. A few clinical trials have been terminated [[Supplementary Table 1](#)], either due to a lack of efficacy or slow enrollment, but not because toxicities were seen. Despite this, many recent

clinical trials are still recruiting and some clinical trials targeting LSC-related surface markers or pathways have even been completed with published results.

Published results from recent clinical trials targeting LSC-specific markers

Results from two recent clinical trials involving the targeting of AML LSC surface markers have been published. The clinical trial evaluating the safety and efficacy of anti-CD33 (ADC SGN-CD33A) in newly diagnosed AML patients (NCT02326584) demonstrated that ADC SGN-CD33A is safe both as a monotherapy and in combination with standard high-dose cytarabine (HiDAC) therapy. As a single agent, it resulted in on-target myelosuppression with mild non-hematologic side effects when administered after chemotherapy and/or after allogeneic stem cell transplantation^[165]. Besides CD33, the surface marker CD47 has been tested as an LSC target. Relapsed/refractory AML patients treated with the anti-CD47 monoclonal antibody Hu5F9-G4 (NCT02678338) showed decreased hemoglobin levels in all patients and difficulties with blood compatibility testing^[166]. This could be explained by the fact that CD47 is also expressed on red blood cells, suggesting that HU5F0-G4 is capable of clearing these red blood cells. This therapeutic can only be used safely by carefully monitoring patients receiving Hu5F9-G4.

To investigate the effect of targeting CD19+ B-ALL blasts, blinatumomab, a bispecific anti-CD19/CD3 BiTE, has been used in multiple clinical trials. Results from a phase III clinical trial (NCT02013167) have shown that, compared to chemotherapy, blinatumomab results in improved minimal residual disease remission and longer overall survival in adult B-ALL patients^[167,168], suggestive for eradicating B-ALL LSCs. In addition, a recent study (NCT02143414) showed benefits for older patients with newly diagnosed Ph chromosome-negative B-ALL, including patients with poor-risk cytogenetics^[169]. Besides antibody therapy, CAR-T therapy targeting CD19 has been shown to be effective in B-ALL^[170,171], although it is not specifically shown to be particularly directed against LSCs. An overview of all recent therapeutic strategies targeting LSC-specific surface markers in both AML and ALL is shown in [Figure 2](#).

In addition to clinical trials investigating drugs against the LSC surface markers, results from several clinical trials targeting LSC-related signaling pathways [[Figure 1](#)] have been published. First, two JAK inhibitors, ruxolitinib and pacritinib, showed promising results. Patients with relapsed/refractory AML treated with ruxolitinib (NCT00674479) revealed that this JAK inhibitor has limited toxicities and modest anti-leukemic activity^[172]. Combining the JAK inhibitor pacritinib with chemotherapy in AML patients with *FLT3* mutations (NCT02323607) gave similar results as ruxolitinib, since it was well tolerated and showed anti-leukemic activity^[173,174]. Second, Hh pathway inhibitors, such as PF-913 and sonidegib targeting Smoothed, have been investigated. In a phase II study (NCT01546038), the combination of PF-913 and low-dose cytarabine improved the overall survival of AML patients when compared to low-dose cytarabine alone. This improved outcome was predominantly seen in patients with secondary AML^[175]. Notably, sonidegib combined with the hypomethylating agent azacitidine (NCT02129101) did not show such an improvement, compared to single azacitidine treatment, in patients with previously treated or advanced myeloid malignancies. However, in the relapsed/refractory AML patient population, the combination of sonidegib with azacitidine showed an increase in OS rates and an absence of progression^[176]. Finally, the Wnt/ β -catenin pathway inhibitor CWP232291 has been investigated as a single agent in relapsed/refractory AML patients (NCT01398462). This inhibitor was well tolerated but only minimally effective^[173]. Despite this disappointing result, CWP232291 has great potential in the elimination of LSCs when used in combination with other drugs such as chemotherapy, since this Wnt/ β -catenin pathway inhibitor may be very efficient in killing leukemia cells with self-renewal potential such as LSCs.

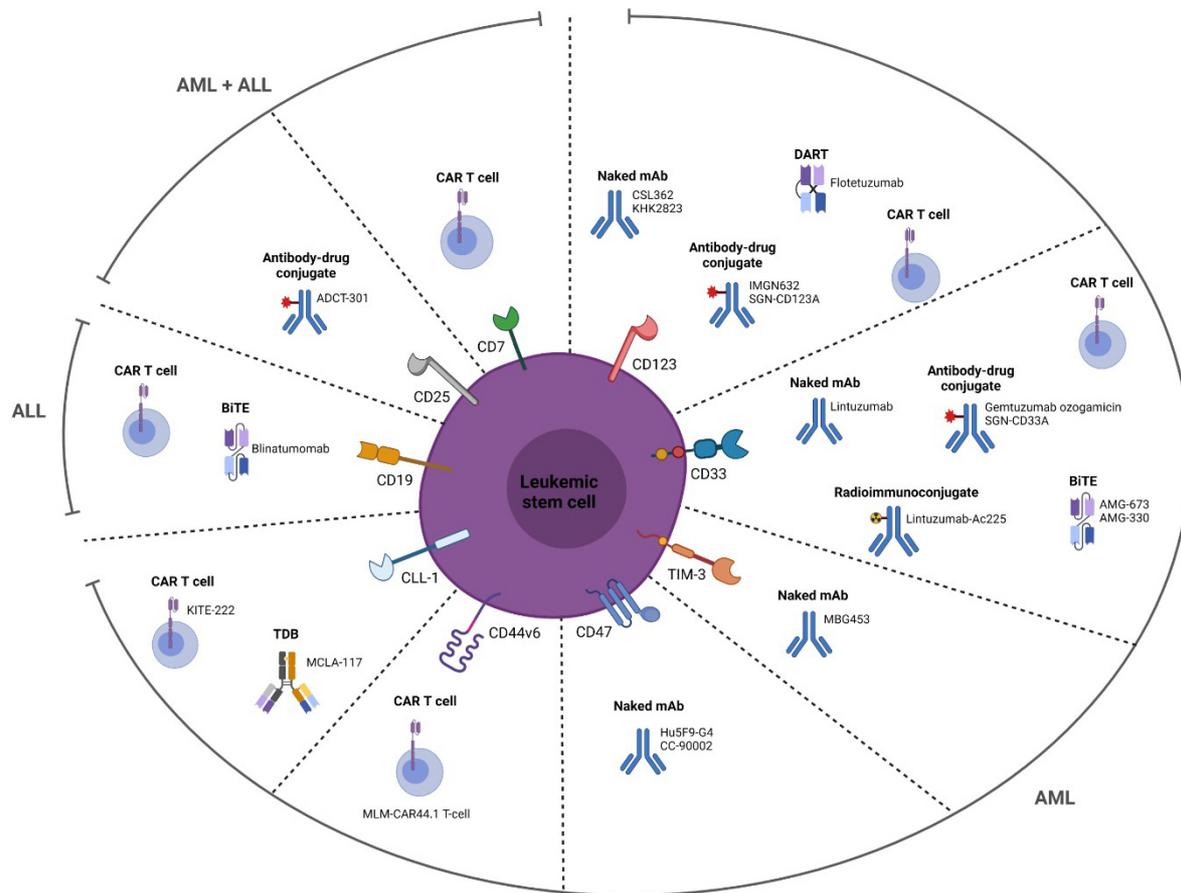

Figure 2. LSC-specific surface markers and the different types of drug agents targeting these markers. All depicted surface markers except CD19 are differentially expressed on AML LSCs. CD19 is a marker specific for B-ALL blasts. In addition, CD7 and CD25 have also been used as targets for ALL treatment. The depicted agents have recently been used in clinical trials. Created with BioRender.com. LSC: Leukemic stem cell; AML: acute myeloid leukemia; CAR: chimeric antigen receptor; TDB: T cell-dependent bispecific; DART: dual-affinity re-targeting antibody.

DISCUSSION

The substantial number of recent studies investigating an LSC population in AML has led to the general acceptance of AML being hierarchically organized. The rare population of LSCs at the apex of this hierarchy plays a key role in the relapse development of the disease due to their drug-resistant mechanisms and self-renewal capacity^[17]. Several common surface markers have been identified that enable both the specific eradication and isolation for further analysis of this LSC population [Table 1]. In addition, different pathways regulating LSCs “stemness” are often dysregulated, making them highly promising targets for the elimination of these cells [Table 2]. The focus of current clinical trials is on novel therapies targeting LSC specific markers by using immunotherapy-based drugs such as CAR-T cells directed to LSC specific surface markers or small-molecule inhibitors/agonists directed to “stemness” pathways [Supplementary Table 1]. However, the multiple resistance mechanisms contained by LSCs are a major challenge in achieving an effective eradication of these cells. Therefore, many clinical trials in AML patients test the effectiveness of targeting LSCs using several therapies, both as a monotherapy and in combination with other drugs.

Accumulating evidence shows that the interaction between BM niche and LSCs plays a role in the survival and acquired drug resistance of AML LSCs^[177]. For instance, inhibiting the CXCR4/SDF1 interaction

involved in HSC/LSC homing releases LSCs from their chemoprotective niche, making them more sensitive to chemotherapy^[30]. This indicates that, besides specifically targeting LSCs, targeting the pathways involved in the BM/LSC interaction could also be a useful strategy to increase LSC eradication. However, this strategy has to be executed carefully, since releasing leukemic cells from the BM into the peripheral circulation could possibly increase the risk of these blasts infiltrating other organs. Future studies on AML should therefore focus on gaining better insight into the factors involved in LSC homing and the effectiveness and safety of targeting these factors.

Compared to AML, research on the LSC population in ALL has been less successful with highly contradicting results. When comparing AML with T-ALL, pathophysiological similarities are seen within both diseases^[162,178]. However, it is still not fully understood if T-ALL follows the same stem cell model as AML. The majority of B-ALL cells containing different immunophenotypes have the capacity to initiate ALL, indicating that B-ALL lacks a clear hierarchy as in AML^[158]. Hence, the term LSC as used in AML might not be correct to define the cells being able to cause relapse in ALL. For ALL, the term leukemia-initiating cells (LICs) is more preferred. Due to the dynamic phenotypes of LICs, their prospective purification has not been possible up to now^[33]. More research is needed to investigate ALL LIC plasticity and discriminating factors that make one population of cells more likely to result in relapse than the other. However, since this has shown to be highly challenging, the focus on interfering with the leukemic cells and BM interaction could be a more promising approach to eliminate ALL LICs in the near future. For all these novel LSC-targeted agents, it is difficult to assess whether specifically the LSC are really eliminated. Monitoring the LSC using flow cytometry during and after therapy might be an option^[179,180] but is not standardly investigated yet.

Despite many different surfaces and other markers being promising targets in eradicating LSCs, there are some important considerations that need to be taken into account before applying anti-LSC therapeutics. First, it is extremely important that healthy cells, especially HSCs, are not targeted by the treatment. Since some surface markers and intracellular pathways involved in “stemness” are expressed in LSCs and HSCs, there is a concern that targeting LSCs can harm healthy stem cell populations. This might cause severe and dangerous side effects, so more research is needed to evaluate how many healthy cells are affected in patients treated with these therapies. Secondly, a major challenge is the heterogeneity of acute leukemia. For instance, in AML, heterogeneous phenotypes of LSCs have been identified between patients^[181]. In addition, it is possible that there are multiple populations of LSCs with different phenotypes present within one patient. Targeting only one marker may therefore not be effective, and more research focusing on simultaneously or subsequently targeting multiple markers is needed.

DECLARATIONS

Authors' contributions

Planned the conception and design of this review article: Hansen Q, Cloos J

Performed the literature search and wrote the manuscript: Hansen Q

Supervision of the research and editing of the manuscript: Bachas C, Smit L, Cloos J

Availability of data and materials

This review article was based on previously published research and reviews, which were collected by using a search of the literature, and they are cited in the review.

Financial support and sponsorship

None.

Conflicts of interest

All authors declared that there are no conflicts of interest.

Abstract

Cancer drug resistance is one of the main barriers to overcome to ensure durable treatment responses. While many pivotal advances have been made in first combination therapies, then targeted therapies, and now broadening out to immunomodulatory drugs or metabolic targeting compounds, drug resistance is still ultimately universally fatal. In this brief review, we will discuss different strategies that have been used to fight drug resistance from synthetic lethality to tumor microenvironment modulation, focusing on the DNA damage response and tumor metabolism both within tumor cells and their surrounding microenvironment. In this way, with a better understanding of both targetable mutations in combination with the metabolism, smarter drugs may be designed to combat cancer drug resistance.

Keywords: Cancer drug resistance, drug resistance, metabolism, DNA damage, DNA repair, hypoxia, synthetic lethality, overcoming resistance

INTRODUCTION

Over the past decades, our understanding of cancer as a disease has increased immensely. The realization of using DNA damaging agents to inhibit the growth of fast-dividing cells with chemotherapy was a game-changing step in treating many types of cancers^[1]. However, as cancer cells are in a more plastic state with increased genomic instability, resistance to single-agent chemotherapy became prevalent. Therefore, following the steps of infectious disease protocols, combination therapies have evolved to combine multiple chemotherapeutic agents to elicit a longer-lasting effect^[2]. While this is more beneficial than single-agent treatments, drug/therapy resistance in cancer is still inevitable and universally fatal^[3].

Targeted therapies have emerged to combat the rapid drug resistance of broad DNA damaging chemotherapy compounds, which use our increased knowledge of specific vulnerabilities in different types of cancers^[4]. Success has been seen targeting specific proteins, such as BCR-ABL, the estrogen receptor^[5], the androgen receptor (AR)^[6], HER2^[7], the epidermal growth factor (EGFR)^[8], and others. More recently, targeting the immune system via checkpoint inhibitors, like PD1/PD-L1^[9] and CTLA4^[10], have produced cures in a subset of patients. Nevertheless, in patients where a cure cannot be achieved with targeted or conventional chemotherapy, cancers will recur and become drug-resistant which ultimately leads to patients' death. Therefore, drug resistance is the principal limiting factor in patient overall survival.

In this review, we discuss relevant resistance mechanisms tumor cells use to adapt to both chemotherapy and targeted therapies. Furthermore, we summarize some of the promising avenues that are currently being investigated to target the tumor resistance pathways and mutations that arise from the treatments. Overall, a better mechanistic insight into drug-resistant cells will hopefully allow for smarter drug design to help combat the major problem of drug resistance and extend patient survival.

MECHANISMS OF RESISTANCE

Changes in the drug-induced DNA damage response

DNA damage continues to be an effective target for cancer therapy as the definition of cancer is uncontrolled cell growth^[4]. In this way, increased cell cycling can lead to more error-prone DNA replication, which relies on DNA damage repair pathways to ensure cell fitness. Therefore, targeting DNA replication via chemo- and radio-therapy to induce DNA damage and ultimately cell death is still the most common - and sometimes the most effective - in cancer treatment^[11]. However, while chemo- and radio-therapy can be initially successful, therapy resistance in cancer is common and ultimately fatal. For this reason, extensive efforts have been focused on both determining and targeting the protein or pathways involved in chemo- and radio-resistance.

In glioblastoma (GBM) - an extremely deadly brain cancer with a ~14-16-month median survival rate - the standard of care includes radiation therapy (RT), maximal surgical resection, and the chemotherapeutic agent temozolomide (TMZ)^[12]. The mechanism of action of TMZ was later shown to create O⁶-methylguanine adducts, which would create double-strand breaks (DSBs) post replication. However, TMZ-resistance is rapid and was found to be partly due to the DNA damage repair protein O⁶-methylguanine-DNA methyltransferase (MGMT)^[13]. MGMT is the suicide DNA repair protein responsible for removing the O⁶-methylguanine adducts and allowing for its damage repair over DSB formation and cell death^[14]. In this way, MGMT inhibitors have been reported that inhibit the function of MGMT. MGMT inhibition has also been shown, to reverse pancreatic tumor gemcitabine resistance via suppressing the expression of survivin in animal models^[15]. However, little clinical success has been realized with MGMT inhibitors with or without TMZ treatment^[16].

DNA-protein kinase (DNA-PK) is a DSB DNA damage sensing complex composed of Ku70, Ku80, and the DNA protein kinase catalytic subunit (DNA-PKcs)^[17]. After a DSB has occurred, DNA-PK binds to the broken end of the DSB to protect it from nuclease degradation and recruits the other DNA damage repair proteins to initiate DSB repair via non-homologous end joining (NHEJ)^[18]. RT has been shown to induce DSBs of which DNA-PK can identify and repair with NHEJ, thereby preventing radiation-induced cell death^[19]. Cells which have a decreased expression of DNA-PKcs have also been shown to be more sensitive to RT^[20]. In this way, many DNA-PKcs inhibitors have been developed to overcome radiation resistance and/or enhance radiation-induced cell death. Radio-sensitization via DNA-PKcs inhibition has been observed with DNA-PK inhibitor VX-984 in GBM^[21], NU7441 in cervical and breast cancers^[22], and NU7026 in non-small cell lung cancer^[23]. Another DNA-PK inhibitor, NU5455, has also been shown to enhance the killing of doxorubicin in lung cancer models^[24].

Lastly, it has been shown that chemotherapy can modulate pro-survival pathways like increasing the expression of drug efflux pumps, apoptosis defects, DNA adduct tolerance, cellular detoxification, and inducing a hypoxic environment^[25]. While the metabolic effects of hypoxia will be discussed in more detail below, Chen *et al.*^[26] have taken advantage of intracellular hypoxia in cisplatin-resistant cells and created a hypoxia-amplifying DNA repair-inhibiting (HYDRI) nanomedicine. HYDRI specifically targeted cancer cells because of their drug-induced hypoxic environment, and then released its payload of hypoxia-activatable chemotherapeutic tirapazamine. In this way, previous studies which determined upregulated pathways in cisplatin resistance could be used to create a smarter therapy that bypassed drug efflux pumps, induced a unique DNA damage profile, and relied on the inevitable hypoxic environment created by cisplatin resistance to target these drug-refractory models^[26].

Synthetic lethality

In 2005, the idea of synthetic lethality in the DNA damage repair pathway, via BRCA1 mutation, was published by two groups^[27,28]. Poly ADP ribose polymerase (PARP) 1 is a key activating protein in the single-strand break (SSB) or base excision repair DNA damage repair pathway^[29]. In parallel, a double-strand break (DSB) can be fixed by two major DNA damage repair pathways - homologous recombination (HR) or NHEJ. HR utilizes a sister chromatid and has a lower error rate, with BRCA1/2 playing a major activating role for proper DNA damage repair, whereas NHEJ is more error-prone, but quicker in repairing a DSB in interphase^[30]. Upon the advent of genetic profiling of tumors, it was discovered that many breast and ovarian cancers had either germline or tumor-specific mutations in the *BRCA1* or *BRCA2* gene^[27]. With the knowledge that SSBs that were unresolved by PARP1 became DSBs with replicative stress that requires BRCA1/2 for repair, the idea of cancer DNA damage response (DDR) synthetic lethality was tested^[31] [Figure 1]. PARP1 inhibition (PARPi) in BRCA1/2 mutated tumors has been successful in many types of cancers, including breast, ovarian, prostate, pancreatic, colon, and lung^[32]. One of the main advantages of tumor specific BRCA mutations is the decreased toxicity of single-agent PARPi treatment. Combination therapies to mimic this synthetic lethality by combining both a BRCA inhibitor with PARPi have proven to be toxic^[33].

Currently, there are at least five PARPi - veliparib (Abbvie), rucaparib (Pfizer/Clovis), Olaparib (KuDOS/AstraZeneca), niraparib (Merck/Tesaro), and talazoparib (Lead/Biomarin/Medivation/Pfizer)^[32] - where the most common mechanism of action is the “trapping” of PARP on the DNA to induce DSBs^[34]. Talazoparib is the newest PARPi and has the highest ability to “trap” PARP on the DNA with ~100 times greater efficacy than the next best PARPi^[35]. Nevertheless, this increased trapping of PARP increases the toxicity of talazoparib - compared to other PARPi^[36]. In clinical results, the phase 3 trial EMBARCA had 431 BRCA1/2 mutant patients with advanced breast cancer, where the talazoparib group had a 62.6% response rate compared to the 27.2% of the standard chemotherapy group^[37].

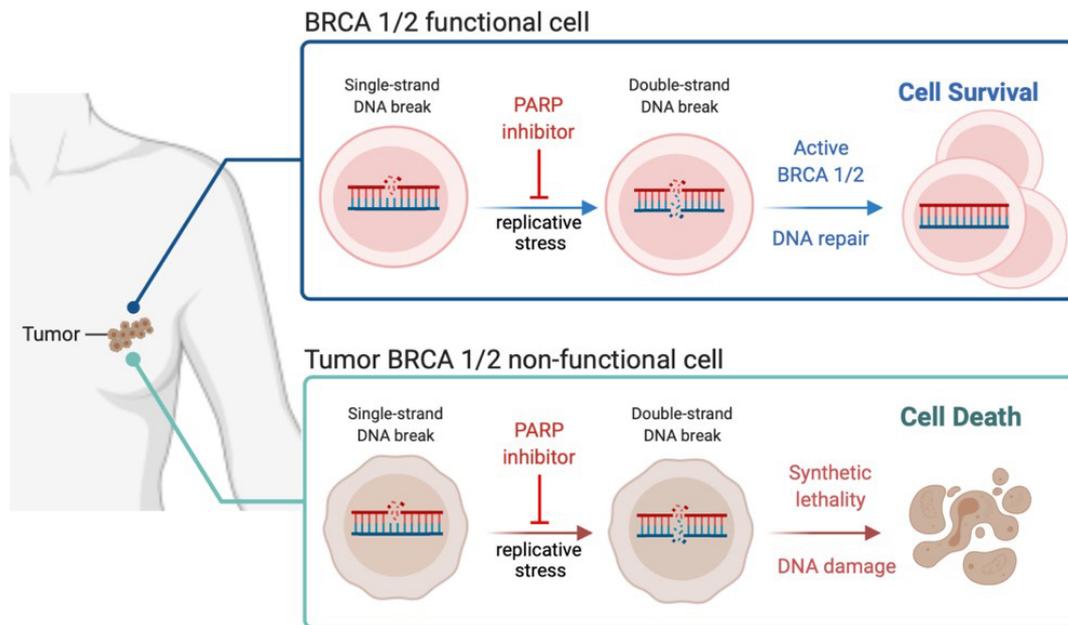

Figure 1. PARPi synthetic lethality in BRCA 1/2 non-functional tumors. BRCA 1/2 functional tumor cells will repair the double-strand break (DSB) induced by PARP inhibition and sequential replicative stress allowing cell survival and growth, whereas BRCA 1/2 non-functional cells cannot repair the DSB and therefore succumb to DNA damage-induced cell death. Figure created with BioRender.

The synthetic lethality success story has other groups actively looking for other synthetic lethal interactions with the many abundant cancer-associated mutations. While not dependent on DDR mutations, AR signaling and PARPi have also been shown to give rise to a synthetic lethal phenotype in preclinical models. However, it is important to note that 19% of primary prostate cancers and 23% of metastatic castration-resistant prostate cancer (mCRPC) have DNA damage repair gene mutations. BRCA2 mutations also have increased levels of prostate specific antigen, a larger percentage of high Gleason scored tumors, and elevated rates of distant and nodal metastases^[38]. Clinically, prostate cancer patients treated with abiraterone plus olaparib showed improved radiographic progression free survival over abiraterone alone in a phase 2 trials which was independent of DDR mutations^[39]. This has also led to an interest in combining PARPi with androgen deprivation therapy alone or in combination with AR signaling inhibitors, which is currently ongoing in mCRPC, and should be considered even in a non-DDR altered state^[38].

DNA damage response with immunotherapy

Immune checkpoint inhibitors (ICI) had great initial promise, with early clinical trial results showing obvious tumor shrinkage, initially. However, after further evaluation, ICI can have about a ~10%-20% durable response rate, depending on the types of cancer^[40]. Therefore, like what we previously described with chemotherapy and targeted therapy, combinatorial studies have been designed to determine whether ICI efficacy can be improved when combined with other conventional therapies^[41,42].

Melanoma was the first cancer to show preliminary success with ICI, and it is well-known that melanoma has one of the highest rates of tumor mutation burden (TMB)^[43]. This brought about the hypothesis that higher rates of TMB in cancer would increase the number of neo-antigens which were predicted to produce a stronger immune response and increase sensitivity to ICI. Radiation and ICI have been tested in combination as radiation treatment for cancer will induce DNA damage, neo-antigens, and immune response^[44]. Furthermore, it was shown in 1979 that the effect of radiation is linked to the immune system when twice the dose of radiation was needed to control tumor growth in thymectomized mice compared to

mice with an intact immune system^[45]. Within the clinic, overall survival of concurrent radiation and ICI - compared to radiation before or after ICI - was shown to improve overall survival (OS) in a retrospective review of lung cancer patients with distant brain metastases^[46].

Other chemotherapy agents are currently being combined with ICI to determine combinatorial efficacy, where one combination - PARPi + ICI - is the most developed. PARPi have shown great promise in many avenues, as shown above with synthetic lethality strategies^[47]. With the increasing characterization of PARPi pathway changes, it was noted in breast cancer that PARPi induced PD-L1 expression^[48]. Not only has PD-L1 been shown to increase with PARPi, but also an increase in cytoplasmic DNA, which activates the cyclic guanosine monophosphate-AMP synthase (cGAS)/stimulator of interferon genes (STING) pathway^[47]. PARPi has also been shown to inactivate the glycogen synthase kinase 2 beta (GSK3)^[36]. An *in vivo* model of BRCA-deficient triple-negative breast cancer also demonstrated that PARPi activated the cGAS/STING pathway and increased CD8⁺ T cell infiltration^[48], as well as decreasing T-cell activation resulting in enhanced cancer cell apoptosis^[36]. Currently, biomarkers are being investigated to select non-BRCA patients that would respond to PARPi + ICI, where the mutational signature 3 - associated with HR deficiency - positively predicted patient responses^[49]. Both the TOPACIO trial and MEDIOLA study are investigating feasibility of immune checkpoint blockade with PARPi^[36].

Reactive oxygen species in drug resistance

Reactive oxygen species (ROS) play a well-known role in cell growth and proliferation in cancer cells, where an increase in ROS can enhance cell growth and post-treatment survival^[50]. One way in which ROS can increase cancer cell survival is genetically by oxidizing nucleic acids, which will cause random mutations and increase genomic instability^[51,52]. ROS can also affect the normal redox balance within the cell. Cysteine is a readily oxidizable amino acid containing a thiol (-SH) group^[53]. Many enzymes have active sites that contain necessary cysteine residues to assist in biochemical reactions^[54]. In Fms-related receptor tyrosine kinase (FLT)3-ITD (a mutation in the tyrosine kinase domain) expressing acute myeloid leukemia, NADPH oxidase 4 generated ROS will inactivate the protein-tyrosine phosphatase (PTP) DEP-1/PTPRJ, which negatively regulates FLT3-ITD transformation^[55]. PTP phosphatase and tensin homolog (PTEN), a PTP family member and potent tumor suppressor, has also been shown to be susceptible to H₂O₂-mediated oxidation and inactivation^[56]. As PTEN is a negative regulator of PI3K and Akt pathways, oxidation and inactivation of PTEN augments downstream signaling and cell growth^[57].

While ROS have been used to create DNA damage via chemotherapy and are necessary byproducts of radiation, drug-resistant cells have been shown to increase their intracellular ROS levels, and thereby adapt to this intracellular hypoxic environment^[58]. Initially, when naïve cells are exposed to chemotherapy, an increase in ROS is noted, as well as a concomitant increase in the antioxidant systems to combat this onslaught of oxidants^[58]. However, this seems to differ in some drug-resistant, or persister, cells where an increase in ROS is still true, but antioxidant genes like glutathione peroxidase (GPX) 4 are now downregulated^[59]. One hypothesis is that these cells use this ROS to their advantage as the hypoxia response element (HRE) shows a higher binding of HIF1 when the G's of the HRE are modified via ROS^[60]. Accordingly, in a new study which dives into the metabolic and transcriptional changes between untreated and persister cells post drug treatment, two of the main upregulated pathways in their model, osimertinib-treated Trp53-knockout with a lung-specific EGFR (L858R) mutation, were ROS and fatty acid metabolism (FAM)^[61]. Furthermore, the cells that had the increased ROS/FAM gene signature were also the cycling persister cells, compared with the non-cycling persister cells. In post-treatment patient samples, 8 out of 11 melanoma samples had an increase in either ROS or FAM signatures, as well as 50% of HER2⁺ breast cancer samples, but the increase in HER2⁺ samples was only in the post-treatment samples^[61].

In these ways, ROS-induced metabolic reprogramming has been an active non-mutational target. The most promising area of research is ferroptosis - or iron-dependent cell death - induction^[62]. As drug-resistant cells have been shown to increase ROS and decrease their antioxidant gene expression, this leaves the cells exquisitely sensitive to ferroptosis via GPX4 or xCT inhibition^[59]. GPX4 is the main regulator to decrease lipid oxidation, and xCT is a cystine/glutamate antiporter, where cysteine is a necessary component for the reducing agent glutathione^[63]. While ferroptosis induction has shown promising initial results in drug-resistant cell and animal models, most drugs never reach the target in cancers such as pancreatic cancer. In this largely drug-refractory cancer, Badgley *et al.*^[64] showed that a cyst(e)ine degrading enzyme - cyst(e)inase - was able to deplete cyst(e)ine from the extracellular environment, thereby decreasing intracellular cyst(e)ine and preventing GSH production. In both *in vitro* and *in vivo* models, cyst(e)ine deprivation led to robust induction of ferroptosis, cell death, and longer animal survivals^[64].

Drug resistance via lipid metabolism and import

Fatty acid (FA) metabolism plays a host of roles within the cell. FAs may be most well-known for being membrane building blocks with the synthesis of glycerophospholipids^[65]. Interestingly, the lipid composition of membranes has garnered recent interest as chemotherapy-resistant cancer cells, in preclinical models, show reduced fluidity of their membranes. These membranes have an increase in saturated fatty acyl chains and are especially enriched for monounsaturated fatty acyl chains in glycerophospholipids^[66]. While this may seem inconsequential, one of the most promising therapeutic targets of drug-resistant cells - ferroptosis - can depend on poly-unsaturated fatty acyl chains to induce toxic lipid peroxidation and cell death^[67]. Furthermore, in chemotherapy-resistant leukemia or ovarian cancer cell lines, the reduced membrane fluidity can come from an increase of cholesterol and/or sphingomyelin within the membrane^[68,69]. This stiffened membrane has been shown to decrease passive diffusion of drug uptake and enhance detergent-resistant membrane domains, which can activate the family of ATP-binding cassette multidrug efflux transporters - including p-glycoprotein - potentiating the multidrug-resistant (MDR) phenotype. However, modulation of membrane fluidity was able to alter the drug efflux transporters, suggesting a potential for diet interventions^[70].

Targeting lipid synthesis itself may also have a benefit in re-sensitizing cells to chemotherapy. Fatty acid synthase (FAS) inhibitors have re-sensitized ovarian cells *in vitro*^[71,72], *ex vivo*^[71], and *in vivo* for T cell lymphoma and ovarian cancer models^[73,74]. In breast cancer cells, overexpression of FAS was able to confer chemoresistance *in vitro*^[72]. While the mechanism by which FAS inhibition can alter chemotherapy sensitivity is unknown, a decrease in MDR proteins has been observed, suggesting membrane composition may be important^[75]. Fatty acid oxidation has also been shown to increase with chemotherapy resistance. GBM cellular and patient-derived xenograft models showed an increase in fatty acid beta-oxidation post-TMZ treatment^[76]. In breast cancer patient samples, the necessary beta-oxidation enzyme carnitine palmitoyltransferase I (CPT1) was increased in tumors that recurred and was also higher in chemo-resistant tumors^[77]. CPT1 inhibitors have also been shown to re-sensitize tumor cells to chemotherapeutic agents^[78].

Lastly, lipid droplet (LD) number and function play an important role in chemotherapy resistance. LDs may directly assist in cell survival by providing an energy reserve of lipids to be oxidized in case of nutrient deprivation^[79]. Hydrophobic drugs can also be sequestered within lipid droplets, creating a drug “sink” for detoxifying chemotherapeutic agents^[79]. Interestingly, LDs were found to co-localize with the mitochondria more frequently in chemo-resistant breast cancer cells, where the LD protein perilipin 4 (PLIN4) was increased. PLIN4 assists in mobilizing lipids for oxidation from LDs, where silencing of PLIN4 decreased the growth of the chemotherapy-resistant, but not the parental, breast cancer cells, suggesting that lipid beta-oxidation is necessary for the sustained growth of chemotherapy-resistant cells^[80] [Figure 2]. Inhibition of long-chain fatty acyl-CoA synthetase via triacsin C blocked fatty acid activation and LD biogenesis which

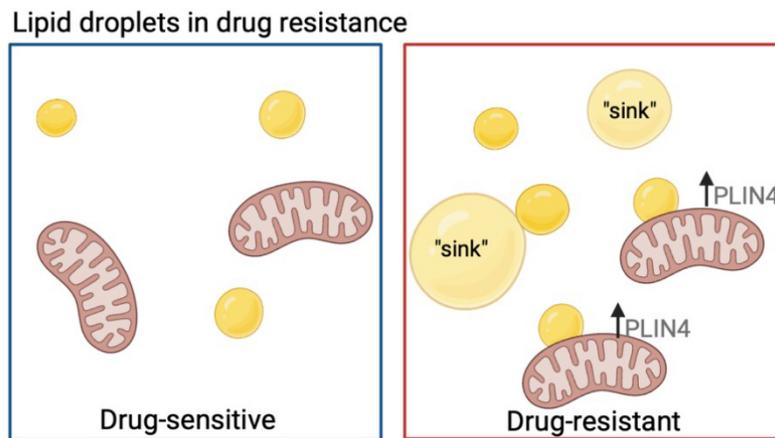

Figure 2. Lipid droplet usage in drug-resistant cells. Drug-resistant cells have been shown to increase lipid droplet accumulation (yellow circles) and have a higher percentage co-localized to the mitochondria, where an increase in PLIN4 helps to better utilize lipids for fatty acid beta-oxidation. Lipids can also be used as drug “sinks” for hydrophobic drugs. Figure created with BioRender.

rendered drug-resistant colorectal cancer cells sensitive to chemotherapy treatment both *in vitro* and *in vivo*^[81].

Hypoxia and drug resistance

The 2019 Nobel Prize was awarded to Kaelin, Ratcliffe, and Semenza for their seminal work on discovering how oxygen is sensed in the cell and the way in which cells are able to adapt to changing oxygen concentrations^[82,83]. Hypoxia-inducible factor (HIF) and HIF signaling are now realized as both a hallmark of cancer, and also affect the surrounding microenvironment^[4]. Through large data analyses, Bhandari *et al.*^[84] used the Buffa-defined hypoxia signature to determine the breadth of hypoxia amongst 1188 samples from 27 types of cancer. They found that hypoxia was varied both between cancers and even within a single patient. The most hypoxic tumors were cervical squamous cell carcinoma and lung cancer, with thyroid adenocarcinoma and chronic lymphocytic leukemia being the least hypoxic^[84]. This study corroborated the findings of The Cancer Genome Atlas. Furthermore, higher hypoxia scores also correlate to both lower overall survival and progression-free survival in multiple cancer types^[85]. A forced hypoxic environment in GBM models has also been shown to decrease the sensitivity of cells to the standard of care chemotherapeutic agent TMZ^[86].

As cancer cells grow faster than normal cells, they quickly outgrow their nutrient supply, which creates a lower level of oxygen in the tumor microenvironment (TME). This low oxygen, or hypoxic TME, affects gene signatures and pathways activated within the tumor cells^[87]. Carbonic anhydrases and CO₂ levels are increased, which leads to increased cellular acidification^[88]. However, cancer cells depend on a higher intracellular pH (~7.4 *vs.* ~7.2) and acidify their TME, decreasing the extracellular pH (~6.0~7.1 *vs.* ~7.4)^[89]. This acidic niche has been shown to increase the expression of MDR genes and decrease drug import into cancer cells^[90]. A highly acidic TME can also prevent proper immune profusion and cause resistance to ICI^[91]. Acidity can increase the immune checkpoint protein expression, CTLA-4 on T cells, raise the threshold for T cell activation^[92], and decrease CD8⁺ memory T cell lifespan^[93]. Long-term exposure to an acidic environment can decrease natural killer cell function, activation, and survival^[92]. Therefore, modulation of TME pH has been an active area of research.

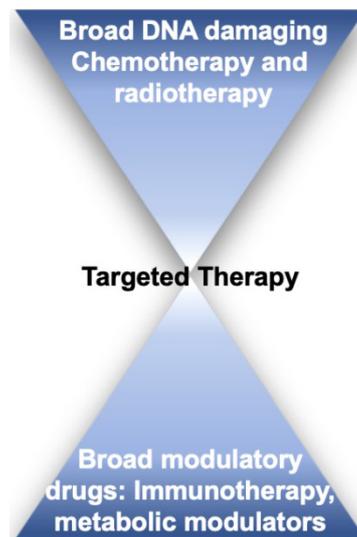

Figure 3. Therapy schematic. Broad-reaching drugs may lend to more durable responses as resistance can arise more rapidly to targeted therapy. Modulating more broad cancer hallmarks - like immune and metabolic targets - may offer smarter drug targets.

To neutralize the acidic TME, oral bicarbonate was given and artificially increased the pH of the TME, which allowed for a better response to ICI in multiple cancer models^[94]. In an effort to maintain normal levels of pH, Na^+/H^+ exchanges, like sodium-hydrogen exchanger isoform (NHE), are upregulated to uptake sodium and pump out protons^[95]. The Na^+/H^+ exchangers are the most common membrane proteins and attempt to regulate the hypoxia-induced pH changes within the cell^[96]. As intracellular acidosis can induce necroptosis and apoptosis, NHE1 inhibitors have been found to modulate intracellular pH and lead to cell death^[97]. Cariporide, an NHE1 inhibitor, can induce apoptosis in breast cancer, reduce MDR1 expression, and decrease tumor volume^[98]. Another NHE inhibitor, amiloride, increased ROS abundance, thereby stimulating PAR synthesis and inducing the PAR-dependent cell death termed parthanatos^[99]. In GBM, Na^+ was shown to be increased almost 3-fold between cancer and normal cells, while NHE1 overexpression is noted and increased NHE1 correlated to worse overall survival^[97].

CONCLUSIONS AND FUTURE PERSPECTIVES

Cancer drug resistance remains the biggest challenge in successfully treating cancer patients today. Here we have outlined some of the current strategies to target the DNA damage repair proteins via chemo-induced dependencies, synthetic lethality, and combination with immunotherapy. More research insight into cancer-specific deficiencies can only lead to better responses, or third-line therapeutic options. Tumor metabolism and the microenvironment may also prove to be promising drug targets as uncontrolled cell growth will always be a hallmark of cancer. Therefore, if we are truly able to understand the metabolic changes and vulnerabilities of cancer, we may be able to develop biomarkers to help dictate metabolic status and treatment plans.

As a whole, we may be better off looking at broad regulatory pathways, as we seem to be at the far end of an hourglass curve [Figure 3]. In the beginning, broad DNA damaging agents were game-changing as they targeted the quintessential cancer dependency - cell growth. Then we narrowed the focus to specific proteins with either activating mutations or cancer-driving functions. While some success has been achieved with targeted therapy, new avenues like modulating the immune system, or using HYDRI-like methods to target broad cancer hallmarks may lead to more durable and smart therapeutic designs.

Abstract

Acute myeloid leukemia (AML) is historically associated with poor prognosis, especially in older AML patients unfit for intensive chemotherapy. The development of Venetoclax, a potent oral BH3 (BCL-2 homology domain 3) mimetic, has transformed the AML treatment. However, the short duration of response and development of resistance remain major concerns. Understanding mechanisms of resistance is pivotal to devising new strategies and designing rational drug combination regimens. In this review, we will provide a comprehensive summary of the known mechanisms of resistance to Venetoclax and discuss Venetoclax-based combination therapies. Key contributing factors to Venetoclax resistance include dependencies on alternative anti-apoptotic BCL-2 family proteins and selection of the activating kinase mutations. Mutational landscape governing response to Venetoclax and strategic approaches developed considering current knowledge of mechanisms of resistance will be addressed.

Keywords: Venetoclax, acute myeloid leukemia, hypomethylating agents, Azacitidine, Decitabine, resistance, BCL2 protein, human

INTRODUCTION

Acute myeloid leukemia (AML) is the most common type of acute leukemia in adults^[1]. The disease often affects older adults with a median age of 68 years at diagnosis^[1]. Conventional treatments using intensive chemotherapy are less beneficial for older patients with poor tolerance and modest outcome^[2,3].

Introduction of Venetoclax (ABT-199), a selective inhibitor of BCL-2, has advanced the treatment options for AML patients, especially older patients^[4]. Venetoclax in combination with hypomethylating agents (HMA) or low-dose cytarabine (LDAC) was approved by US FDA for newly diagnosed AML patients who are either unable to receive intensive chemotherapy or older than 75 years old. Nowadays, this has become the standard therapy for such a population^[5]. However, the prevalent use of Venetoclax comes with a new challenge of resistance, particularly in the relapsed/refractory setting^[6,7]. Here, we review the mechanisms of Venetoclax resistance in AML and discuss strategies to overcome resistance.

MECHANISM OF ACTION OF VENETOCLAX

BCL-2 family proteins and mechanism of action of Venetoclax

Venetoclax (ABT-199) is an oral, selective antagonist of the B-cell lymphoma 2 (BCL-2), a key protein modulating intrinsic (mitochondrial) apoptosis^[8]. Apoptosis is regulated and balanced by protein-protein interactions among BCL-2 family members^[9]. Different members of the BCL-2 family share BCL-2 homology motifs (BH1 to BH4)^[9]. Anti-apoptotic proteins (BCL-2, BCL2A2, MCL-1, and BCL2L1 (BCL-xL), BCL-w, BFL-1/A1) sequester pro-apoptotic proteins by binding to its BH3 motifs^[9-13]. Pro-apoptotic proteins consist of BH3-only proteins and effector proteins, BAK and BAX, which have BH1-4 motifs. BH3-only proteins act as sensitizers (BAD, BIK, HRK, NOXA) or activators (BIM, BID, PUMA) of apoptosis^[10,11,13]. BH3-only sensitizer proteins are unable to activate downstream effector proteins (BAX, BAK) directly. However, they are able to “sensitize” cells toward apoptosis by binding to BCL-2 anti-apoptotic protein, releasing bound BAX or BAK or BH3-only activator protein^[14]. Upon activation by bound BH3-only activator proteins, effector protein oligomerizes, leading to increase mitochondrial outer membrane permeabilization (MOMP) and initiation of cytochrome *c* mediated intrinsic apoptosis^[9-13].

Dysregulation and imbalance of BCL-2 family members controlling apoptosis are commonly found in multiple hematologic malignancies^[12]. Likewise, the BCL-2 family has an essential role in mediating AML survival and chemoresistance. Previous studies have demonstrated that an increase in the level of anti-apoptotic proteins, including BCL-2, is associated with chemotherapy resistance^[15-17]. BCL-2 also supports the survival of leukemic stem cells in AML, and its inhibition induces the death of quiescent leukemic stem cells^[18]. Hence, BCL-2 is an important therapeutic target. Venetoclax, a BH3 mimetic, binds to a BH3-binding groove of BCL-2 protein with high selectivity^[8]. This relieves inhibition of BCL-2 toward BAX and BAK, resulting in cell death^[9]. Preclinical studies demonstrated high anti-tumor activity of Venetoclax in AML, which facilitated further clinical studies^[16,19]. In an initial phase 2 study, Venetoclax monotherapy produced modest responses in heavily treated relapsed or refractory (R/R) AML patients with an overall response rate (ORR) of 19%^[4]. As AML may not depend on BCL-2 for its survival or the dependency may evolve during tumor progression and after therapy^[20], a method to assess BCL-2 family dependency is critically needed to predict sensitivity to Venetoclax^[4,13,21,22]. BH3 profiling is performed by exposing mitochondria to a specific BH3 peptide, followed by measurement of cytochrome *c* release and MOMP^[23]. Addition to a specific BCL-2 anti-apoptotic protein is inferred from cellular apoptotic sensitivity when exposed to different BH3 peptides^[23].

Genomic biomarkers associated with Venetoclax sensitivity

Early phase 2 study on Venetoclax monotherapy suggested spliceosomal mutation in SRSF2/ZRS2 and IDH1/2 as predictors for Venetoclax sensitivity^[4]. Ten out of 11 patients with baseline SRSF2 or ZRSR2 mutation had a measurable reduction in bone marrow (BM) blast after treatment with Venetoclax^[24]. SRSF2 genes were found to induce alternative splicing of apoptosis regulating genes and modulate the expression of BCL-2 family proteins, which may increase sensitivity to Venetoclax^[24,25].

In preclinical models, IDH mutation in AML conferred high BCL-2 dependence and sensitivity to BCL-2 inhibition. The mechanism involved oncometabolite (R)-2 hydroxyglutarate (2-HG), which inhibits mitochondrial cytochrome *c* oxidase, causing a reduction of mitochondrial threshold for apoptosis induction^[26]. A recent study by Stuani *et al.*^[27] described additional mechanisms behind IDH mutant sensitivity to BCL-2 inhibitor through inhibition of mitochondrial respiration. Mutant IDH cells and patient-derived xenografts (PDX) were found to have a larger capacity for mitochondrial oxidative phosphorylation (OXPHOS), as evident by increased electron transport chain (ETC) complex I activity, NADH production by tricarboxylic acid cycle enzymes, mitochondrial ATP content and oxygen consumption rate^[27]. Gene set enrichment analysis on IDH1 mutant cells also showed enhanced fatty acid oxidation (FAO) gene signature, especially CPT1a, an acyl-carnitine transporter during FAO, and its transcriptional regulator, CEBP α ^[27]. While 2-HG was shown to drive CPT1a and CEBP α -dependent FAO and OXPHOS, abrogation of 2-HG production by IDH inhibitor did not impact FAO rate or OXPHOS in the treated AML cell lines, suggesting maintenance of OXPHOS phenotype independent of 2-HG^[27]. Inhibition of OXPHOS and IDH1 mutation subsequently showed synergistic cytotoxic activity and improved cell differentiation *in vitro* and *in vivo*^[27].

Venetoclax, a BCL-2 inhibitor, was reported to target leukemia stem cells (LSCs) metabolism through reduction of ETC complex II activity and OXPHOS^[28]. Consistent with preclinical data, IDH mutant cells showed heightened sensitivity upon OXPHOS inhibition by Venetoclax therapy^[27]. In the phase 2 trial of a single agent Venetoclax, IDH1/2 mutated R/R AML subset reached a higher objective response rate of 33% as compared to 10% ORR in the IDH-wildtype AML subset^[4]. Mirroring synergy seen in preclinical study^[27], a preliminary analysis from an ongoing phase 1/2 clinical trial demonstrated encouraging composite complete remission of 75% with median overall survival (OS) of 9.7 months in the R/R cohort upon treatment with a combination of Ivosidenib (an IDH1 inhibitor), Venetoclax and Azacitidine “triplet”^[29]. Future updates are anticipated to evaluate clinical characteristics and molecular predictors of response. In parallel, a phase 1b/2 study of Enasidenib (an IDH2 inhibitor) and Venetoclax combination is underway (NCT04092179) after demonstrated efficacy in preclinical studies^[30,31].

Utilizing highly sensitive quantitative reverse transcription polymerase chain reaction (RT-qPCR), a clinical study by DiNardo *et al.*^[32] found a strikingly high rate of mutation clearance in NPM1 mutated patients upon treatment with a combination of Venetoclax and HMA or LDAC (4/4 cases). As expected, a high molecular remission rate translated into an excellent survival with relapse-free survival not reached after a median follow-up of 20 months in patients who initially had persistent mutation despite intensive chemotherapy^[33]. Unlike IDH mutated AML, the mechanistic basis of Venetoclax sensitivity in NPM1 mutated AML is not well understood^[32]. However, clinical findings indicate NPM1 (without FLT3 co-mutation) as an important predictor of Venetoclax sensitivity.

ASXL1 mutation was recently found to drive response to Venetoclax *in vitro*. ASXL1 acts as an epigenetic regulator via PRC2-mediated chromatin modification to keep various genes in a repressed state^[34]. Thus, ASXL1 mutation leads to aberrant activation of its target genes, including BCL2^[34]. In preclinical study of Rahmani *et al.*^[34], ATAC-sequencing analysis suggested higher chromatin accessibility on the BCL-2 locus of ASXL1 mutant KBM5 cells due to failure of PRC2 complex recruitment, resulting in BCL-2 overexpression^[34]. BH3 profiling further showed higher BCL2 anti-apoptotic protein dependency in ASXL1 mutant cells, which explained ASXL1 sensitivity to Venetoclax *in vitro*^[34]. Rahmani *et al.*^[34] also demonstrated enhanced global cytosine methylation, which led to sensitivity to Azacitidine, a DNMT inhibitor. Thus, treatment of ASXL1 mutant cells with single agent Venetoclax or Azacitidine resulted in increased cell differentiation, decreased cell growth and viability^[34]. Analysis of data from clinical trials is

needed to prove this finding in the clinical setting.

VENETOCLAX RESISTANCE: PRECLINICAL STUDIES

Cellular mechanism of resistance to Venetoclax: other BCL-2 family proteins

Dependencies on other anti-apoptotic BCL-2 family members, including BCL2-A1, MCL-1, and BCL-xL, have been demonstrated as the key contributors to primary or adaptive Venetoclax resistance^[4,7,13,35-37]. Venetoclax resistance is associated with sequestration of BIM freed from Venetoclax binding to BCL-2 by other Bcl-2 family members, which consequently prevents apoptosis [Figure 1]^[38,39]. Preclinical work demonstrated lower expression of MCL-1 and BCL-xL in Venetoclax sensitive AML cell lines and lower BCL-2 protein levels in resistant cells^[13]. When resistance was induced in AML cell lines through exposure to Venetoclax over several months, a shift was seen toward upregulation of MCL-1 and or BCL-xL with less dependency on BCL-2^[35,40]. To investigate this potential mechanism, BCL-xL and MCL-1 were inactivated with BCL-xL inhibitor (WEHI-539) and short hairpin RNA (shRNA), respectively, which resulted in the restoration of Venetoclax sensitivity in resistant AML cell lines^[35]. Utilizing BH3 profiling, a phase 2 study of Venetoclax monotherapy for R/R AML showed shorter durability of Venetoclax responses in patients with MCL-1 or BCL-xL dependence, suggesting that these mechanisms are operational in the clinical setting^[4].

The knowledge around common co-dependencies in leukemia and cancer led to the exploration of selective BCL-xL and MCL-1 inhibitors. Navitoclax (ABT263), a predecessor of Venetoclax, possessed a high affinity for BCL-2, BCL-xL and BCL-w^[41]. However, its clinical use has been limited by on-target toxicity of thrombocytopenia due to reliance on BCL-xL for platelet survival^[42]. Recently there is a growing interest in the exploration of MCL-1 inhibitors, which have shown striking synergy with BCL-2 inhibitors in resistant AML cell lines and xenograft models^[40,43,44]. Multiple MCL-1 inhibitors are under development, and several are being evaluated in clinical trials^[45-47].

In recent studies, transcriptomic analysis of AML patients' samples showed differential expression of BCL2A1 in resistant cells^[36,37]. Upregulation of BCL2A1 expression correlated with higher Venetoclax's area under the curve (AUC) and less apoptosis after treatment with Venetoclax with or without Azacitidine and Cytarabine. Knockdown of BCL2A1 restored apoptosis and reduced cell growth in the resistant AML cells without substantial effect on the CD34+ hematopoietic stem and progenitor cell (HSPC)^[37]. Therefore, there is a potential for synergy between Venetoclax and BCL2A1 inhibitor in selective AML subsets, similar to Venetoclax and MCL-1 inhibitor^[37,44].

Mutations in activating kinases and Venetoclax resistance

Activation of intracellular signaling pathways by KRAS/PTPN1 or FMS-like tyrosine kinase 3 (FLT3) mutant proteins is postulated to induce Venetoclax resistance. Genomic biomarkers were analyzed before and after treatment with Venetoclax monotherapy^[24]. Three out of 14 patients with pre-treatment FLT3-internal tandem duplication (ITD) and 4 out of 14 patients with PTPN11 mutation failed to achieve bone marrow blast reduction, suggesting intrinsic resistance to Venetoclax. In addition, a subset of patients at the time of relapse were found to harbor FLT3-ITD and/or PTPN11 mutations not identified prior to therapy, strongly indicating the emergence or selection of these mutations as secondary or acquired resistance^[24].

FLT3-ITD mutation occurs in about 25% of adult AML cases and confers an adverse prognosis^[27]. FLT3-ITD mutation promotes survival via activation of PI3K-protein kinase B (Akt), RAS-MAPK, and STAT5 pathway^[14,38]. While the precise downstream molecular pathways are yet to be defined, FLT3-ITD mutation is known to induce higher expression of BCL-xL and MCL-1, which may contribute to Venetoclax

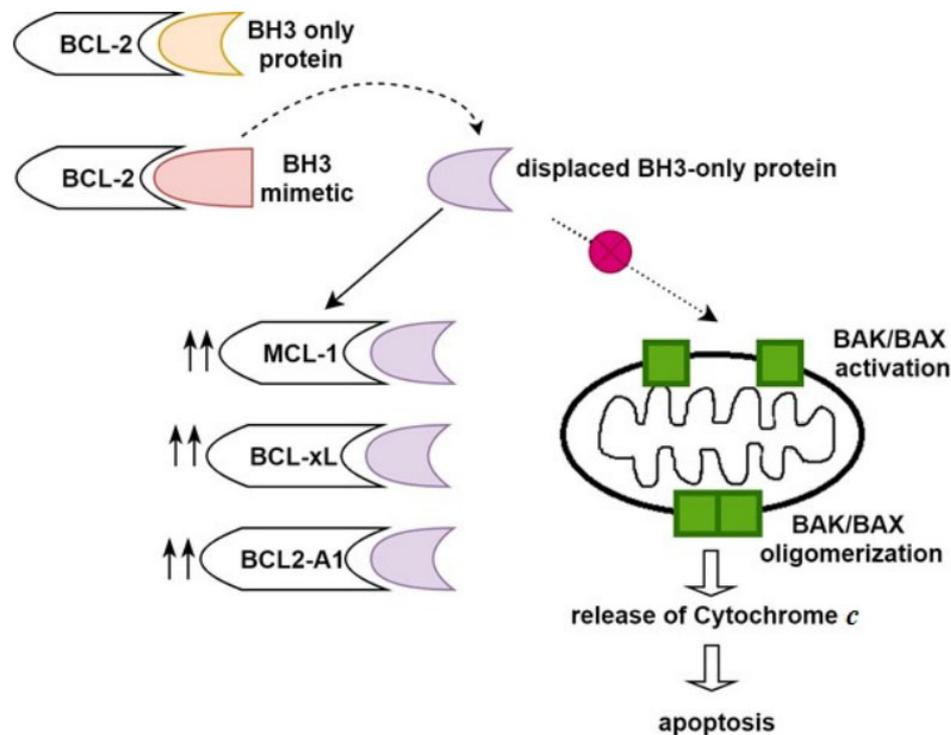

Figure 1. Binding of BH3 mimetic, Venetoclax to BCL-2 anti-apoptotic protein releases bound BH3-only protein, subsequently allowing interaction between BH3-only protein and BAK/BAX. Upregulation of MCL-1, BCL-xL, and BCL2-A1 confers Venetoclax resistance by sequestration of BH3 only proteins, preventing them from interacting with BAK/BAX and avoidance of apoptosis^[35-40].

resistance [Figure 2]^[48-50]. Several studies demonstrated the involvement of the molecular pathway downstream of FLT3 in modulating BCL-xL and MCL-1 expression. STAT5, which was activated by FLT3-ITD, but not by their wild-type counterpart^[50], was found to regulate transcription of the *BCL-xL* gene^[51]. Akt, a downstream substance of PI3K pathway, was shown to influence MCL-1 stabilization by inactivation of glycogen synthase kinase 3 (GSK3), leading to sequestration of BIM and prevention of MOMP^[52]. Yoshimoto *et al.*^[50] further reported the role of STAT5 and Akt in MCL-1 upregulation. Suppression of STAT5 by small interfering RNA (siRNA) reduced the level of MCL-1 protein and mRNA in FLT3-ITD⁺ MV4-11 cell lines. In addition to direct stimulation of MCL-1 transcription, STAT5 also enhances phosphorylation of Akt, which indirectly increases MCL-1 expression in FLT3-ITD cells^[50].

Several preclinical studies evaluated the efficacy of combining FLT3 inhibitor and Venetoclax in FLT3-ITD⁺ cell lines, patient samples, and xenograft models. Ma *et al.*^[38] assessed the efficacy of Midostaurin (1st generation type 1 FLT3 inhibitor)^[3] and Gilteritinib (2nd generation type 1 FLT3 inhibitor)^[3] in combination with Venetoclax. Midostaurin or Gilteritinib in combination with Venetoclax synergistically induced apoptosis in FLT3-ITD⁺ cell lines and patient samples^[38]. The combination of Gilteritinib and Venetoclax also resulted in higher survival of the MV4-11 xenograft model compared to either drug alone, with four out of five treated mice remaining disease-free on day 190^[38]. A similar finding was reported by Zhu *et al.*^[14] The combination of Gilteritinib with Venetoclax outperformed their respective monotherapy in halting the proliferation of FLT3-ITD⁺ cells and reducing tumor burden in the FLT3-ITD⁺ patient-derived xenograft (PDX) and resistant MOLM-14 model^[14]. Another set of experiments with a combination of 2nd generation type 2 FLT-3 inhibitor (Quizartinib)^[3] and Venetoclax *in vitro* and *in vivo*, resonated with prior studies^[49]. Co-treatment with Quizartinib and Venetoclax in the xenograft model produced a longer response with a delay in tumor resurgence for up to three months post-treatment^[24].

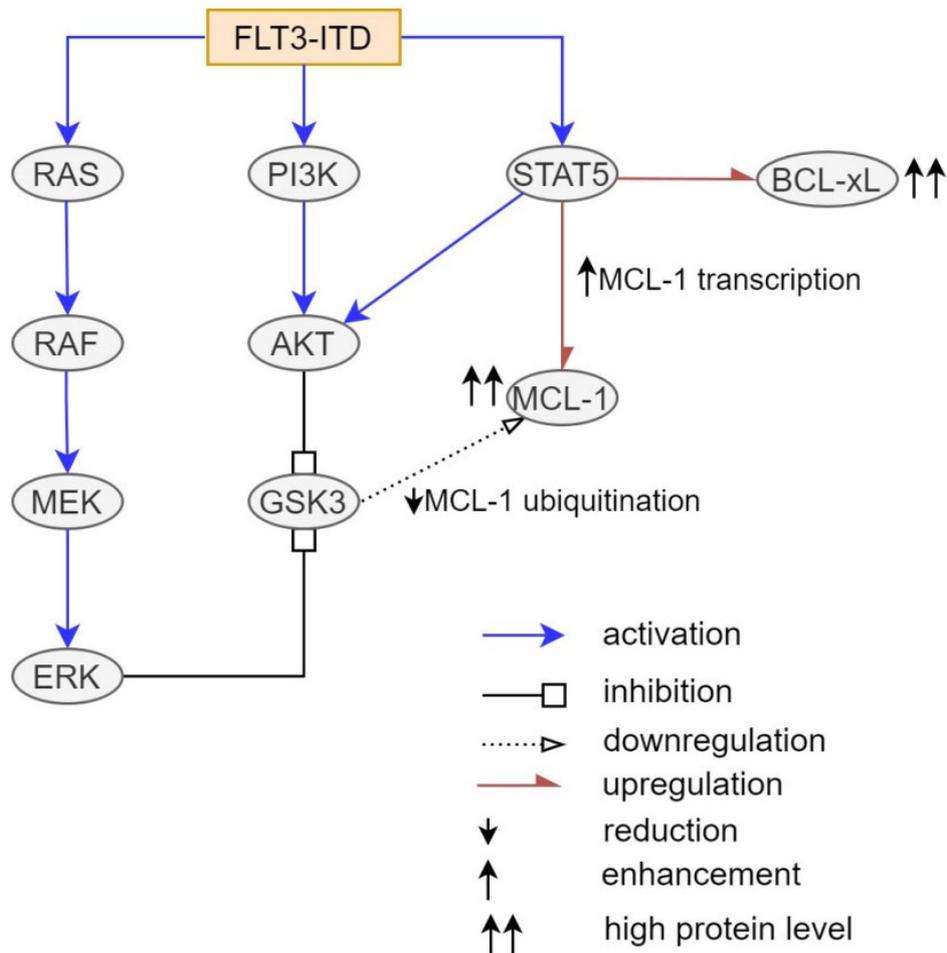

Figure 2. FLT3-ITD mutation causes an increased level of BCL-xL and MCL-1 via activation of downstream PI3K-AKT, RAS-MAPK, and STAT5 pathways. AKT and ERK promoted inhibitory phosphorylation of GSK3, leading to a reduction of MCL1 ubiquitination and degradation. In addition to upregulation of MCL-1 and BCL-xL, STAT5 also increases MCL-1 indirectly through AKT activation. In summary, FLT3-ITD mutation confers Venetoclax resistance by upregulation of BCL-xL and MCL-1^[48-53].

In these studies, mechanisms driving the synergy between FLT3 inhibitor and Venetoclax were interrogated. Ma *et al.*^[38] and Zhu *et al.*^[14] demonstrated that treatment with FLT3 inhibitor (Midostaurin or Gilteritinib) alone or in combination with Venetoclax reduced the expression of MCL-1 *in vitro*^[14,38]. Utilizing western blot, reduced phosphorylation of ERK, AKT, STAT5 was seen after 24 hours of treatment with Gilteritinib or Quizartinib. This finding suggests FLT3 inhibition modulates MCL-1 by simultaneous suppression of multiple kinase pathways including RAS-MAPK, PI3K-AKT, and STAT5^[14,38]. Co-immunoprecipitation assay in FLT-ITD⁺ cell lines further revealed decreased binding of BIM to MCL-1 and increased binding of BIM to BCL-2 after Gilteritinib treatment, while the opposite was seen with Venetoclax treatment^[14,38]. Interestingly, co-treatment with Gilteritinib and Venetoclax also increased the binding of BIM to BAX without increasing BIM binding to other BCL-2 anti-apoptotic proteins, specifically BCL-xL^[14]. Thus, combination therapy with FLT3 inhibitor and Venetoclax *in vitro* reduced BIM binding to both BCL-2 and MCL-1, liberating BIM to interact with BAX and induce apoptosis^[14].

In addition to FLT3, mutations in other activating kinases can confer resistance to Venetoclax (so-called “signaling” mutations). Genomic data from primary patient samples in the BEAT AML database was analyzed along with Venetoclax AUC established *in vitro*^[37]. Samples with KRAS or PTPN11 mutations

were found to have higher Venetoclax AUC. Venetoclax resistance was reproduced when AML cell lines were transduced to overexpress G12D KRAS and A72D PTPN11^[37]. Analysis with RT-PCR and immunoblot showed decreased BCL-2 and BAX with increased MCL-1 and BCL2A1 levels in G12D KRAS cells, as well as increased MCL-1 and BCL-xL levels in A72D PTPN11 cells [Figure 3]^[37]. G12D KRAS cells showed a reduction in cellular viability after treatment with MCL-1 inhibitors (AZD5991)^[37]. However, neither BCL-2 blockade nor simultaneous blockade of BCL-2, BCL-w, and BCL-xL by ABT263 and ABT737 produced a similar response^[37]. This finding implied KRAS mutation dependency on MCL-1 to drive Venetoclax resistance. In A72D PTPN11, AZD5991 was also capable of suppressing PTPN mutant cells, while partial response only was seen with BCL-2/Bcl-XL dual inhibitors ABT-263 and ABT 737. This finding suggests partial dependence of PTPN-induced Venetoclax resistance on MCL-1 and BCL-xL^[37]. As expected, the combination of AZD5991 and Venetoclax showed synergy and fully rescued mutant cell lines from KRAS- and PTPN11-mediated resistance. Hence, combinatorial therapy with Venetoclax and MCL-1 inhibitor is expected to demonstrate high efficacy in AML patients harboring these mutations^[37].

Roles of TP53, BAX, and mitochondria in Venetoclax resistance

In a recent report, BAX variants were found by deep sequencing performed on samples derived from AML patients who relapsed after initially achieving remission with Venetoclax-based regimens, signifying acquired BAX mutation as adaptive Venetoclax resistance^[54]. Reduced survival was also seen when BAX deficient OCI-AML3 cells were transplanted into the AML xenograft model^[54]. BAX deficient cells and xenograft model were resistant to cell death induced by Venetoclax, MCL-1 inhibitor (S63845), or a combination of both^[54]. This is contrary to a prior study which showed sensitivity of BAX knockout (KO) cells to a different MCL-1 inhibitor (AZD-5991) with similar resistance to Venetoclax and BCL-2/BCL-xL inhibitor (AZD-4320)^[55]. Hence, particular attention to BAX mutant subsets is warranted in future studies to evaluate its impact on response to BH3 mimetics as single agents or combinations.

Genome-scale CRISPR/Cas9 screening identified BAX along with TP53 and PMA1P1 (NOXA) as genes whose inactivation confers Venetoclax resistance^[40,55,56]. Gene enrichment and protein-protein interaction analysis identified these genes as an essential part of the mitochondrial apoptosis pathway^[55,56]. TP53 is activated by cellular stress and functions as a transcription factor for genes controlling various cellular processes, including apoptosis and cell cycle arrest^[55]. Several BH3-only proteins, including BAK, BAX, PUMA, and NOXA, are also TP53 target genes^[55,57,58]. As expected, a lower level of BAK1, PUMA, and NOXA was observed in TP53 KO cells^[55]. Interestingly, transcriptional changes were observed outside TP53 target genes with an increased ratio of BCL-xL/BCL-2, which may further confer Venetoclax resistance in TP53 KO cells^[55].

Several preclinical studies demonstrated that TP53 mutated cells and xenograft models are resistant to single-agent therapy with Venetoclax^[55,59] or MCL-1 inhibitor^[55,59,60]. Contesting these findings, Thijssen *et al.*^[60] reported observation that the lack of TP53 function did not preclude cell killing by sub-lethal BCL-2 or MCL-1 inhibitor monotherapy. However, this response was not durable as surviving TP53 deficient cells outgrew TP53 wild-type cells over a longer period of exposure, indicating a competitive survival advantage^[60]. Delayed activation of BAX/BAK and subsequent apoptosis upon BH3 mimetics treatment was thought to cause reduced BH3 mimetics efficacy by lifting the early apoptosis threshold in the absence of TP53. Notably, simultaneous inhibition of BCL-2 and MCL-1 was able to overcome the apoptotic delay with improved durability of response^[60], resonating with synergistic action described in past studies^[55,59].

The impact of TP53 and BAX on mitochondrial function and morphology was evaluated. TP53 and BAX KO cells demonstrated less mitophagy when exposed to stress by a mitochondrial uncoupler and increased

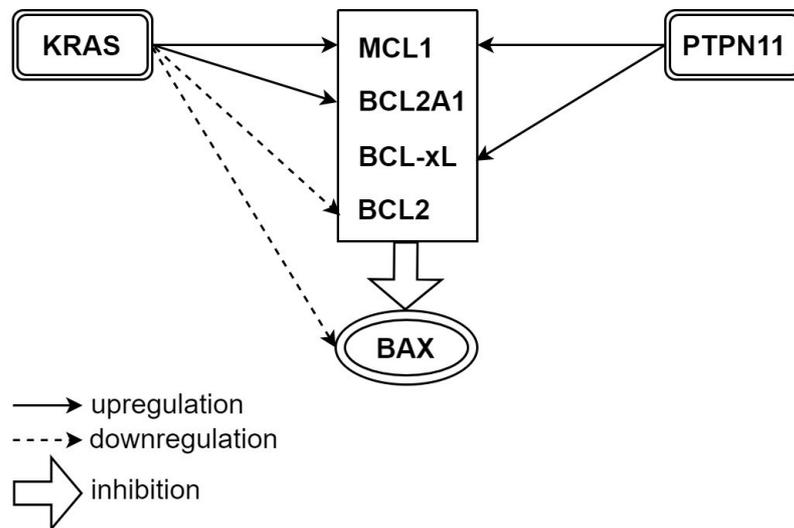

Figure 3. Both KRAS and PTPN11 mutations confer Venetoclax resistance. KRAS mutation causes upregulation of MCL-1 and BCL2A1, while PTPN11 mutation causes upregulation of MCL-1 and BCL-xL. KRAS mutation also downregulates BCL-2 and BAX^[37].

cellular respiration, reflected by higher production of cellular reactive oxygen species (ROS)^[55]. Furthermore, TP53 and BAX KO cells also showed aberrant metabolic profiles with increased nucleotide synthesis and parallel decreases in glucose, pyruvate, amino acids, and urea cycle intermediates levels, suggesting priority shifting on carbon usage to support cancer cell proliferation^[55]. These findings highlight the crucial role of mitochondria in mediating sensitivity or resistance to Venetoclax.

A deeper dive into mitochondrial biology found that aberrant mitochondrial architecture and bioenergetics were implicated in the apoptotic response to Venetoclax^[56]. CRISPR/Cas9 screening further identified a negative association between Venetoclax resistance and mitochondrial chaperonin CLPB, which regulates mitochondrial cristae and metabolism^[56]. Chen *et al.*^[56] reported overexpression of CLPB in AML which led to tighter mitochondrial cristae lumen. On the other hand, loss of CLPB resulted in wider crista and stimulation of mitochondrial stress response, which in turn triggered cell cycle arrest and lowered the mitochondrial threshold for apoptosis^[56]. A combination of CLPB deletion and Venetoclax was found to rescue Venetoclax resistant AML cells even in the presence of TP53 mutation^[56]. Another genomic CRISPR-Cas9 knockout screen demonstrated a negative selection of *DAP3*, *MRPL54*, *MRPL17*, *RBFA* genes, which are part of the mitochondrial translation machinery^[61]. When mitochondrial protein synthesis was blocked by tedizolid or doxycycline, reduction of AML cell viability was only observed upon co-treatment with Venetoclax, but not with Venetoclax or tedizolid or doxycycline alone^[61]. A subsequent investigation by Sharon *et al.*^[61] demonstrated that the combination of Venetoclax and tedizolid led to augmentation of the integrated stress response with associated reduction of OXPHOS, and decreased glycolytic capacity, resulting in ATP consumption and cell death.

Monocytic AML in Venetoclax resistance

Several preclinical studies suggested that AML may respond differently to Venetoclax-based therapies, depending on the blast differentiation stage. In the studies discussed below, AML was classified based on cell morphology according to the French, American, and British (FAB) classification system^[62]. Guided by flow cytometry, ex vivo drug sensitivity testing on patient samples with primary AML showed a progressive increase in Venetoclax resistance through the cell maturation phase from the most primitive AML (Mo) to monocytic AML (M5)^[63,64]. Aligned with this observation, analysis of the BEAT AML dataset also noticed

higher Venetoclax AUC in the leukemic blasts with high expression of CD14 and CLEA7A (gene encoding CD369) that are usually present in M4/M5 AML, suggesting Venetoclax resistance in AML with myelomonocytic or monocytic differentiation^[37].

Further analysis also indicated different expression levels of alternative BCL-2 anti-apoptotic protein at the selected stages of cell maturation, which correlates with Venetoclax resistance. For instance, a gradual decline in BCL-2 expression with a concurrent increase in MCL-1 expression from M0 to M5 was observed, suggesting a lineage-associated switch to MCL-1 in monocytic AML^[63,64]. In addition, the link between high expression of CD14 and CLEA7A, presence of KRAS mutation and increased BCL2A1 were seen in M4/5 AML^[37,63,64]. Hence, Venetoclax resistance in AML with myelomonocytic differentiation may additionally be governed by BCL2A1 through upstream mutant KRAS^[37,63].

Consistent with these laboratory predictions, analysis of matched patient samples at diagnosis and relapse post-Venetoclax revealed the coexistence of primitive and monocytic features at diagnosis, suggesting developmental heterogeneity within the leukemic blast^[64]. Monocytic clone subsequently expanded under the selective pressure of Venetoclax and Azacitidine, with the contemporaneous vanishing of primitive population at the time of relapse^[64]. Interestingly, a portion of relapsed monocytic subclone also showed increased HOXA9 expression (similar to that observed in MLL-rearranged leukemia)^[65], which was not present in their parental clone^[64]. However, both diagnosis and relapsed monocytic clone retained their MCL-1 dependency^[64]. These findings suggest the potential role of menin inhibitor or MCL-1 inhibitor to overcome Venetoclax resistance in monocytic disease^[64,65].

VENETOCLAX-BASED COMBINATION THERAPIES: LESSONS FROM CLINICAL STUDIES

Venetoclax-based combination therapies

Given low response rates to Venetoclax as a single agent in R/R AML Phase II study, further studies focused on combination regimens. Several lines of clinical trials investigated the combination of Venetoclax with HMA or low-dose cytarabine in both frontline and R/R settings^[66-69]. Monotherapy with HMA was commonly used in unfit or older patients with AML, but its benefit is limited by low response rates of ~30% and modest median survival at 8-10 months^[70-73]. The synergy between Venetoclax and HMA therapy was reported in preclinical studies. Bogenberger *et al.*^[74,75] demonstrated increased sensitivity of HMA after inhibition of BCL-2 family proteins in AML samples. Tsao *et al.*^[76] suggested Azacitidine has activity against MCL-1, and it induces synergism with Venetoclax. Subsequent clinical trials validated the clinical efficacy of these regimens.

In a phase 1b study, Venetoclax was combined with either Decitabine or Azacitidine to treat 145 older, newly diagnosed patients unfit for induction chemotherapy. Sixty-seven percent of patients achieved CR/CRi, including 60% of CR/CRi rates in patients with poor cytogenetics risk. The median OS in the study was 17.5 months, and the median duration of response was 11.3 months, with a tolerable safety profile^[66]. Following phase 2 study of 10-day decitabine and Venetoclax for intensive chemotherapy ineligible patients, including 70 newly diagnosed AML and 55 R/R AML, confirmed acceptable safety profile and high efficacy with CR/CRi rate of 74%. The study showed a median OS of 18.1 months in newly diagnosed de-novo AML and six months in R/R AML^[68]. A randomized phase 3 clinical trial (VIALE-A) comparing Azacitidine monotherapy to combination therapy with Azacitidine and Venetoclax as a frontline treatment confirmed improved response rate and survival in Azacitidine/Venetoclax treated patients compared with Azacitidine alone. CR/CRi rate was 66% in the combination therapy arm compared to 28% in patients who received single Azacitidine^[77]. OS was longer in the combination group at 14.7 months with a median event-free survival (EFS) of 9.8 months compared to 9.6 months of OS and seven months of EFS in the single-agent

Azacitidine group.

Cytarabine, a commonly used cytotoxic chemotherapy agent in AML, was likewise shown to have synergism with Venetoclax through inhibition of MCL-1, increased BH3 activity, and upregulation of pro-apoptotic protein, Bim^[78]. A phase 1b/2 study of low-dose Cytarabine (LDAC) combined with Venetoclax in newly diagnosed older AML patients demonstrated excellent safety data and a high response rate with CR/CRi of 54% and median OS of 10.1 months^[69]. This is encouraging compared to results from prior clinical studies of low-intensity cytotoxic therapy, which showed response rates of less than 20% and median OS of less than six months. Thus, the combination of LDAC and Venetoclax showed significantly improved efficacy compared to conventional chemotherapy^[72,79]. In a randomized phase 3 trial in 211 newly diagnosed AML patients ineligible for intensive treatment, the combination of Venetoclax and LDAC was compared to LDAC with placebo. The combination group had a higher CR/CRi rate of 48% compared to 13% of the control group, with an EFS of 4.7 months in the combination group compared to 2 months in the control group^[80]. The combination group also had longer OS at 7.2 months compared to 4.1 months in the control group, with a 25% reduction in risk of death^[80].

In a phase 1b/2 study of Venetoclax with high-intensity chemotherapy FLAG-IDA (Fludarabine, Cytarabine, granulocyte colony-stimulating factor and Idarubicin), 68 younger AML patients with a median age of 46 years old were enrolled, with 29 de novo and 39 R/R patients^[81]. The study demonstrated high clinical efficacy of the combined regimen with median survival not reached at the 12 months median follow-up, and a high minimal residual disease (MRD) negative CR rate of 96% in ND-AML patients and 69% in R/R AML patients. The majority of patients treated with this regimen proceeded towards allogeneic stem-cell transplant (69% of de novo AML and 46% of R/R AML patients)^[81].

In another phase 1b study, Venetoclax was given in a dose-escalated fashion up to 600 mg prior to Cytarabine and Idarubicin infusion (5 + 2) in fit older patients with AML age 60 years and above (CAVEAT study)^[82]. The combination regimen was well tolerable and efficacious, with ORR of 97% and 43% in de novo AML and secondary AML, respectively. Median OS was 11.2 months, with longer median OS seen in de novo AML of 31.3 months and 29.5 months in patients who achieved CR^[82]. This study proved the acceptable tolerability and high efficacy of Venetoclax when given in combination with standard intensive chemotherapy in fit older adults with AML^[82].

An ongoing phase 2 trial of the combination of Venetoclax with Cladribine plus LDAC alternating with hypomethylating agents in 48 newly diagnosed older AML patients demonstrated a high CR/CRi rate of 94% with MRD-negativity of 92%. Median OS was not reached over the 11-month median follow-up, and 24% of patients received an allogeneic stem-cell transplant^[83].

Molecular landscape associated with response to Venetoclax combination therapies

Analysis of pre-treatment patients' characteristics and paired AML samples pre-treatment and at the time of progression was performed to delineate the molecular patterns associated with treatment response to the combination of Venetoclax with HMA or with low dose Cytarabine (LDAC). In the frontline setting, AML patients with NPM1 or IDH1/2 mutations achieved high rates of CR/CRi and had sustained response for > 12 months^[32,66]. Median duration of CR/CRi and median OS was not reached in IDH1/2 or NPM1 mutated patients^[66]. Real-world experience supported the observations of IDH1/2 and NPM1 mutations as molecular predictors of response, even in the R/R setting^[84,85].

It is noteworthy that deep molecular remissions were seen in patients with NPM1 mutation^[32,33]. Highly sensitive RT-qPCR demonstrated MRD clearance in all recruited patients with NPM1 mutation upon treatment with Venetoclax and HMA or LDAC (4/4 cases)^[32]. A subsequent study by Tiong *et al.*^[33] also reproduced this finding in NPM1 mutated patients with molecular persistence or relapse after treatment with standard intensive chemotherapy. In addition, there was no molecular or hematological relapse observed in NPM1 mutated patients who achieved MRD negative remission after a median follow-up of 11.8 months^[33]. Notably, two of the older adult patients unfit for stem cell transplantation (SCT) in this study were alive at 6 and 12 months of follow-up^[33], validating Venetoclax-based therapy as a safe and well-tolerated therapy in the frail older adult population. This finding further highlights Venetoclax as a highly efficacious agent to treat NPM1 mutated AML even after intensive chemotherapy failure. A longer follow-up would be needed to evaluate the duration of MRD clearance with Venetoclax based therapy. If indeed durable, a Venetoclax-based regimen could be a well-tolerated and effective option in lieu of SCT in the unfit older population with NPM1 mutated AML. As deep remission was produced by Venetoclax-based therapy after failure of intensive chemotherapy treatment, further studies would be needed to assess Venetoclax-based therapy as a non-inferior or even a superior alternative to intensive chemotherapy in NPM1 mutated younger AML patients prior to transplantation.

Despite the general association with improved response to Venetoclax-based regimens, several points need to be taken into consideration with respect to NPM1 and IDH2 mutations. Despite responding well to combination therapy with Venetoclax and HMA or LDAC, persistent IDH2 mutation is commonly detectable in remission^[32]. Although infrequent, new IDH2 mutation has been found at the time of relapse^[84], raising questions if adding IDH inhibitor as part of maintenance or consolidative therapy would result in deeper remissions and longer survival. Future studies are needed to address these questions. While NPM1 mutation is generally eliminated by Venetoclax-based therapies, concurrent mutation with FLT3-ITD may confer resistance^[32,65]. As NPM1 mutation is associated with heightened HOX/MEIS1 signature^[32], the possible role of menin inhibitor merits further investigation and has been shown to enhance anti-AML efficacy of Venetoclax in NPM1-mutant AML models^[86]. A combination of menin inhibitor (DS-1594) with Azacitidine and Venetoclax will be evaluated for NPM1c mutated R/R AML in an ongoing phase 1/2 clinical trial (NCT04752163)^[65].

In keeping with the response seen with Venetoclax monotherapy, patients with spliceosomal mutation (SRSF2, U2AF1, SF3B1, ZRSR2) obtained a higher response rate to Venetoclax and HMA therapy compared to wild-type patients (CRi/CRh of 28% vs. 11%)^[87]. Interestingly, the presence of co-mutation seems to influence differential responses seen among genes encoding spliceosome complex. SRSF2 appeared to be enriched with IDH mutations, especially IDH2, compared to the rest of spliceosomal genes cohort^[87]. The impressive outcome was seen among SRSF2/IDH1/2 mutated patients with 1-year OS of 100% and 2-year OS of 88%^[87]. Patients with SRSF2/IDH1/2 co-mutation also had statistically significant higher survival compared to SRSF2 mutated patients without concurrent IDH mutation, further substantiating the important presence of IDH mutation in driving Venetoclax sensitivity in the SRSF2 group^[87]. On the other hand, U2AF1 mutation was enriched with RAS mutation with lower CRc and MRD negative CR rates^[87].

Molecular determinants of resistance to Venetoclax combination therapies

In multiple clinical trials of Venetoclax and HMA or LDAC, TP53 mutation was found to be the predominant mutation in the AML patients that did not respond to Venetoclax-based therapy (7/20 cases)^[32]. While most of the cases harbored a mutation in the DNA binding domain^[88,89], different forms of TP53 abnormalities were observed, including single mutation without TP53 deletion (deletion 17p) and multiple mutations with or without chromosomal abnormality in the TP53 or non-TP53 domain^[88]. Complex cytogenetics was seen in the majority of TP53 mutated cases^[32,88,89], aligned with a known high

prevalence of TP53 mutation in AML with complex karyotype^[90]. These findings underscore TP53 mutation and complex cytogenetics as the most common cause of primary resistance to Venetoclax combination therapy.

Validating preclinical findings^[55,59,60], TP53 mutation was associated with significantly lower response rates to Venetoclax and Decitabine combination therapy compared to wild-type group (ORR of 66% *vs.* 89%, CR/CRI of 57% *vs.* 77%, and MRD negative rate of 29% *vs.* 59%)^[88]. There was a trend toward improved survival in patients who responded or initially responded prior to relapse compared to primary refractory cases. In responder cases, TP53 mutated AML cohort had a shorter duration of response of 3.5 months *vs.* not reached in the TP53 wild-type AML cohort^[88]. These lower responses translated into poor survival with 60-day mortality and median OS of 26% and 5.2 months in the TP53 mutated patients compared to 4% and 19.4 months in the wild-type patients. Interestingly, TP53 mutation burden [variant allele frequency (VAF)] was not proven to be a predictor of response in this mutation cohort, although gain in VAF may be seen at relapse^[88]. In line with this finding, single-cell DNA sequencing on AML patient samples upon relapse to Venetoclax-based therapy showed expansion of clones containing TP53 mutation under the selective pressure of therapy with a Venetoclax-based regimen^[32]. While TP53 mutation may be detected at diagnosis, expansion of new TP53 variants is frequently detected at the time of relapse, with or without concurrent structural loss of 17p locus, suggesting a selection of clones with biallelic TP53 perturbations^[32]. Given lower response rates, shorter duration of response, and poor survival, TP53 mutated patients do not derive long-term benefits from Venetoclax-based therapies and should be offered clinical trials whenever feasible. Research to develop novel agents and treatment strategies is urgently needed given the poor prognosis with limited treatment options in this population.

A focused analysis of relapse patterns after Venetoclax-based combination therapy reported the most common emerging mutations in genes involved in signaling pathways (NF1, FLT3-ITD, NRAS, JAK1), in line with the above-mentioned preclinical findings; RNA splicing (U2AF1, U2AF2, SRSF2, ZRSR2), and transcription factors (IKZF1, SETBP1, RUNX1, STAT5A), followed by tumor suppressors (TP53, WT1), and epigenetic modifiers (BCOR, CREBBP)^[7]. At relapse, concurrent expansion of clones with different types of activating kinase mutations was shown, including FLT3-ITD, FLT3-TKD, FLT3 N676, RAS, CBL^[32]. The emergence of multiple new mutations was also observed in a study by Stahl *et al.*^[84], corroborating previous findings. These observations indicate that adaptive resistance may be governed by the complex interaction between various clones rather than single driver mutation. The polyclonal nature of the clonal expansion adds a tremendous challenge to salvage management of AML patients relapsing post Venetoclax-based induction, which is currently associated with extremely poor outcomes and median survival of less than three months^[7,32].

Future directions and strategies to mitigate resistance

Current understanding of the mechanisms behind Venetoclax resistance identified in preclinical studies led to the development of several combination strategies that have entered clinical trials, as summarized in [Table 1](#). Amongst these regimens, the combination of Venetoclax with FLT-3 tyrosine kinase inhibitors (TKIs) is under rigorous clinical investigation^[91,92]. In a phase 1b trial, the combination of Gilteritinib and Venetoclax reached an ORR of 90% in FLT-3 mutated R/R AML, with similarly high responses in patients who failed prior TKIs^[91]. Preliminary result from the “triplet” with Quizartinib, Decitabine and Venetoclax is promising, with a composite response rate (CRc) of 69% and median OS of 7.1 months in the R/R setting, while median OS was not reached in the frontline setting^[92]. Recruitment is ongoing for Quizartinib as Venetoclax “doublet” (NCT03735875) or “triplet” (NCT03661307) therapy, and updated results are eagerly anticipated^[92,93].

Table 1. Clinical trials evaluating venetoclax-based combination regimens

Drug Regimen	Treatment Category	Mutation (if required for eligibility)	Clinicaltrials.gov identifier	Target Number of patient enrollment ⁺⁺	Phase	Year of study initiation
Azacitidine + Venetoclax	Frontline		NCT03466294	42	II	2018
Venetoclax + Decitabine	Both ⁺		NCT03404193	400	II	2018
ASTX727 (Decitabine and Cedazuridine) + Venetoclax	Both ⁺		NCT04657081	124	I/II	2021
ASTX727 (Decitabine and Cedazuridine) + Venetoclax	Both ⁺		NCT04746235	40	II	2021
Venetoclax + Cladribine + LDAC induction followed by Cladribine+ LDAC + Azacitidine	Frontline		NCT03586609	85	II	2018
LDAC + Venetoclax ^{^^}	Frontline		NCT02287233	94	I/II	2014
LDAC + Venetoclax vs LDAC + placebo	Frontline		NCT03069352	211	III	2017
CPX-351 (Liposome-encapsulated Daunorubicin-Cytarabine) + Venetoclax	Both ⁺	In RR subset, (+) RAS pathway activating mutation: KIT, HRAS/NRAS/KRAS, BRAF, CBL or PTPN11 or loss of function mutation of NF1	NCT03629171	52	II	2018
Ivosidenib (IDH1 inhibitor) + Venetoclax +/- Azacitidine	Both ⁺	IDH1+	NCT03471260	30	I/II	2018
Enasidenib (IDH2 inhibitor) + Venetoclax	Both ⁺	IDH2 (+)	NCT04092179	48	I/II	2020
Gilteritinib (FLT3 inhibitor) + Venetoclax ^{^^}	Salvage		NCT03625505	61	I	2018
Gilteritinib (FLT3 inhibitor) + Azacitidine + Venetoclax	Salvage	FLT3	NCT04140487	42	I/II	2019
Gilteritinib (FIT3 inhibitor) + ASTX727 (Decitabine and Cedazuridine) + Venetoclax	Salvage (phase I), Both (phase II) [†]	FLT3	NCT05010122	42	I/II	2021
Quizartinib (FLT3 inhibitor) + Venetoclax	Salvage	FLT3	NCT03735875	32	I/II	2019

MCL-1 undoubtedly plays an important role in mediating Venetoclax resistance through numerous upstream mediators, both genomic and epigenetic. Hence, targeting MCL-1 directly or indirectly is rational to improve sensitivity to Venetoclax^[38-40,46]. The progress in replicating the success of direct MCL-1 inhibitor from bench to bedside has been hindered by observed troponin leak, possibly related to the regulation of mitochondrial homeostasis by MCL-1^[47,94,95]. S64315, a direct MCL-1 inhibitor, is being evaluated in the early phase of clinical trial in combination with Venetoclax (NCT03672695)^[46,47,93], and additional data on safety profile and efficacy is anticipated.

Several approaches have been pursued to target MCL-1 indirectly, including inhibition of MCL-1 transcription by CKD9 inhibitors, upregulation of NOXA to increase MCL-1 neutralization by NEDD8-activating enzyme (NAE) inhibitor, and targeting RAS-RAF-MEK-ERK (MAPK) pathway to promote MCL-1 degradation by MEK inhibitor and MDM2 inhibitor (a P53 activator)^[53,96-98]. Based on synergy seen in the preclinical studies^[53,96,98], multiple clinical trials evaluating the combination of Venetoclax and these novel small molecule inhibitors are being conducted, as summarized in Table 1. Several clinical trials have published their preliminary finding. In the newly diagnosed secondary AML population, the combination of Pevonidostat (NAE inhibitor), Azacitidine and Venetoclax (NCT03862157) was safe and efficacious with a CR/CRi rate of 70% and 6-months OS of 82%^[99]. A phase 1 clinical trial (NCT02670044) of Venetoclax and Cobimetinib (MEK inhibitor) or Idasanutlin (MDM2 inhibitor) is completed. In R/R/ AML, a preliminary result showed an ORR of 18% in Venetoclax and Cobimetinib cohort^[100]. However, Venetoclax 600 mg and Idasanutlin 200 mg arm achieved an ORR of 38%^[100]. This finding is encouraging as the achieved response rate was higher compared to Venetoclax monotherapy or combination with LDAC or HMA in R/R population^[4,84]. In terms of toxicity, gastrointestinal side effects were predominant with diarrhea, nausea, and vomiting, more with the Cobimetinib combination than idasanutlin^[100].

TP53 mutation confers Venetoclax resistance and is associated with worse outcomes^[55,84]. MDM2 inhibitor activates wild-type p53 by disrupting p53-MDM2 interaction, which consequently prevents proteasomal p53 degradation, increases p53-regulated, and reduces p53 nuclear export^[53,101]. However, MDM2 inhibitor depends on intact p53 function to exert apoptotic activity^[102]. In the setting of mutant TP53, APR-246 (eprenetapopt) was developed^[103]. Through covalent binding of its reactive electrophile form (methylene quinuclidinone) to mutant p53, APR-246 (methylated PRIMA-1) restores its function and induces p53-dependent apoptosis^[103]. A combination of APR-246, Venetoclax and Azacitidine is being evaluated in phase 1 clinical trial (NCT04214860)^[93].

Another strategy is harnessing the innate immune system. Leukemic cells evade macrophage-mediated phagocytosis by overexpressing CD47 which binds to the signal regulatory protein alpha (SIRP α) receptor on the macrophage to produce a “do not eat me” signal^[3,104]. CD47 becomes a potential therapeutic target as it is highly expressed on LSCs^[105]. Several compounds have been developed to block CD47 and SIRP α interaction^[104]. Magrolimab (Hu5F9-G4), an anti-CD47 antibody, was the first one to enter the clinical phase^[104]. In a phase 1 study, Magrolimab was well tolerated and reduced LSC fraction in patients who achieved a response^[106]. Anemia was a notable on-target effect managed by priming and maintenance dose^[106]. Importantly, Magrolimab was not observed to augment Azacitidine’s toxicity when used in combination^[104,106]. This suggests that adding another cytotoxic agent like Venetoclax in combination with Magrolimab is likely safe and synergistic due to the enhanced pro-phagocytic signal^[104,106,107]. Clinical trials on the combination of Venetoclax and anti-CD47 antibody (Magrolimab, ALX148), or SIRP α Fc fusion protein (TTI-622) are ongoing to validate the safety and efficacy of this novel immunotherapy regimen [Table 1].

Being protected by the bone marrow microenvironment (BMM), eliminating leukemia stem cells (LSCs) is challenging to any cytotoxic regimen, including Venetoclax^[108]. In addition to protection, BMM also provides a survival signal and promotes stemness features in resistant AML cells^[109,110]. Yu *et al.*^[110] recently discovered the role of CD44, an adhesion molecule expressed by LSCs, in governing Venetoclax resistance induced by stimulation of the CXCR4-CXCL12 pathway. Higher MCL-1 expression was also observed after CXCL12 stimulation, which was abrogated by CD44 knockout^[110]. Loss of CD44 function also reduced the viability of Venetoclax resistant cells^[110]. With several small molecule inhibitors in development^[111], a combination of CD44 or CXCR4-CXC12 pathway blockade with Venetoclax-based therapies may be worth pursuing.

CONCLUSIONS

The advent of Venetoclax as a BCL-2 inhibitor has transformed AML management. Multiple Venetoclax-based combination therapies are developed based on current knowledge about mechanisms of responsiveness and resistance to Venetoclax. The heterogenous nature of the disease with rapid and divergent clonal evolution poses a unique challenge when it comes to designing an optimal maintenance or salvage therapy. Molecular profiling would be helpful in personalizing treatment plans, especially in selecting a frontline regimen and prior to changing therapy upon MRD persistence, refractoriness or disease relapse.

Several treatment approaches are being evaluated in clinical trials, with remaining questions to be addressed in the future, all to tackle resistance and improve the durability of response. Current strategies are directed toward maximizing induction therapy by the introduction of “triplets” therapy which incorporates several novel targeted therapies to produce a deeper response upfront with the hope to prevent the emergence of mutation from the surviving clone. Sequential therapy is also of great interest, which can be done

empirically [such as Cladribine + LDAC + Venetoclax alternating with Azacitidine+Venetoclax (NCT03586609)] or adaptively tailored to the molecular signature of the resistance clones. Each approach, however, comes with its own challenge. Triplets therapy may only be suitable for selected genomic subsets and may require Venetoclax's dose adjustment to avoid prolonged myelosuppression. Adaptive sequential therapy is an attractive option. However, this strategy requires sensitive molecular techniques for early detection of rising clone(s), which are not readily available at the moment. Reliance on the limited targetable options further hinders its applicability. Hence, the most feasible option currently is a “shot-gun” combo approach aiming at avoiding resistance through the rotating nature of chemo- or immune-therapy agents with different mechanisms of action, aided by Venetoclax as a universal sensitizer.

Considering these limitations, intensive multi-agent chemotherapy and Venetoclax combination would be the best approach for fit younger AML patients currently as a bridge to stem cell transplantation. Immune-based therapy is another promising approach, given its theoretical efficacy across genomic subsets. Current research is focusing on the benefit of immune-based therapy as “MRD erasers” in maintenance or consolidation therapy in patients with a low disease burden^[2,3]. Several agents are currently in development, such as bispecific T-cell engagers (BiTEs), NK engagers, cancer antigen vaccines, and cellular therapies^[2,3]. With multiple novel agents added to the AML armamentarium, additional questions remained unanswered, including the efficacy and duration of response of new combination regimens, the molecular pattern of drug response and resistance, duration of therapy after achieving response to treatment, and response to prior regimen after therapy interruption or discontinuation. Future research would be crucial in addressing these questions to evaluate how to optimally use these different types of therapeutic strategies and to identify patients that benefit the most.

Abstract

Aim: The transcription factor RIP140 (receptor interacting protein of 140 kDa) is involved in intestinal tumorigenesis. It plays a role in the control of microsatellite instability (MSI), through the regulation of *MSH2* and *MSH6* gene expression. The aim of this study was to explore its effect on the expression of *POLK*, the gene encoding the specialized translesion synthesis (TLS) DNA polymerase κ known to perform accurate DNA synthesis at microsatellites.

Methods: Different mouse models and engineered human colorectal cancer (CRC) cell lines were used to analyze by RT-qPCR, while Western blotting and luciferase assays were used to elucidate the role of RIP140 on *POLK* gene expression. Published DNA microarray datasets were reanalyzed. The *in vitro* sensitivity of CRC cells to methyl methane sulfonate and cisplatin was determined.

Results: RIP140 positively regulates, at the transcriptional level, the expression of the *POLK* gene, and this effect involves, at least partly, the p53 tumor suppressor. In different cohorts of CRC biopsies (with or without MSI), a strong positive correlation was observed between *RIP140* and *POLK* gene expression. In connection with its effect on *POLK* levels and the TLS function of this polymerase, the cellular response to methyl methane sulfonate was increased in cells lacking the *Rip140* gene. Finally, the association of RIP140 expression with better overall survival of CRC patients was observed only when the corresponding tumors exhibited low levels of *POLK*, thus strengthening the functional link between the two genes in human CRC.

Conclusion: The regulation of *POLK* gene expression by RIP140 could thus contribute to the maintenance of microsatellite stability, and more generally to the control of genome integrity.

Keywords: Colorectal cancer, genome stability, translesion DNA synthesis polymerase, Pol Kappa, RIP140

INTRODUCTION

Colorectal cancer (CRC) is one of the most frequent cancers worldwide and genetic instability exerts a driving role in this malignancy^[1]. The mismatch repair (MMR) system is one of the various cellular systems involved in the maintenance of genome integrity through the correction of mistakes that occur during DNA replication. Once impaired (as occurs in 2%-3% of CRC cases with an inherited component including Lynch syndrome^[2,3]), it generates microsatellite instability (MSI) and a hypermutated tumor phenotype with a high frequency of point and frameshift mutations^[4,5].

In addition to molecular machineries that cope with DNA repair, mammalian cells possess enzymes with translesion DNA synthesis (TLS) activity. The *POLK* gene encodes Pol κ , one of the Y-family TLS polymerases, which possesses unique DNA damage bypass capability^[6]. Interestingly, despite any associated proofreading exonuclease activity, Pol κ was shown to display high accuracy during dinucleotide microsatellite DNA synthesis^[7], and *Pol κ -/-* mice display a spontaneous mutator phenotype in various tissues^[8]. This could be linked to its less open active site compared to other inaccurate specialized DNA polymerases from the Y family^[9]. In fact, Pol κ possesses a unique structural feature, an extension of its N-terminal region, called N-clasp, that protrudes from the thumb domain and encircles DNA in proximity to a primer terminus^[10]. This results in a much more stable complex once Pol κ binds to a mismatched DNA substrate, facilitating the extension step across various minor groove distortion or lesion. Besides its role in MSI maintenance together with MMR^[7], Pol κ seems to prevent DNA damage-induced toxic effects of methylnitrosourea, another process dependent on the MMR system^[11]. This link between MMR and Pol κ is reinforced by the findings that *POLK* interacts with MSH2^[12] and partially protects human cells from the MMR-dependent cytotoxicity of O6-methylguanine lesions^[11].

Our laboratory recently reported that the RIP140 (receptor interacting protein of 140 kDa) gene was involved in the normal and tumoral development of the intestinal epithelium. RIP140, also known as NRIP1 (nuclear receptor-interacting protein 1), was first identified as a transcriptional repressor of nuclear hormone receptors^[13,14]. We and others then characterized RIP140 as a coregulator of various transcription factors, including, for instance, E2F^[15] or NF κ B^[16]. The repressive activity of RIP140 involves several inhibitory domains interacting with histone deacetylases^[17] and is controlled by different post-translational modifications^[18]. Using a mouse model lacking the *Rip140* gene, various physiological processes were shown to be regulated by RIP140, including female fertility^[19] and mammary gland morphogenesis^[20], fat metabolism^[21], pro-inflammatory cytokine response^[22], or cognition^[23].

In the intestinal epithelium, our laboratory demonstrated that RIP140 inhibits the Wnt/ β -catenin signaling pathway and, as a consequence, exerts an anti-proliferative effect^[24]. In line with this result, we found that this transcription coregulator inhibits the Paneth cells lineage through the regulation of SOX9 expression and activity^[25]. In addition, RIP140 expression decreased in CRC samples compared to the adjacent healthy tissue. In sporadic CRC, RIP140 mRNA and protein levels significantly correlated with better overall survival of patients and were identified as good prognosis markers^[24]. More recently, we demonstrated that RIP140 was acting as a transcriptional regulator of *MSH2* and *MSH6* gene expression and was involved in the regulation of the MSI and hypermutator phenotype in CRC cells^[26]. Interestingly, a frameshift mutation in the RIP140 coding sequence identified in MSI CRC tumors exhibits a dominant negative activity and correlates with shorter overall survival of patients with advanced CRC.

In the present study, we explored whether RIP140 could regulate POLK as a factor involved in microsatellite stability. We demonstrated that, in both engineered mouse models and human CRC cells, RIP140 positively regulates the *POLK* gene expression at the transcriptional level, at least partly *via* a p53-dependent mechanism. A strong correlation was observed between the expression of the *RIP140* and *POLK* genes in CRC biopsies. Moreover, cells knocked out for the *Rip140* gene were shown to be more sensitive to methyl methane sulfonate (MMS), a drug known to induce DNA lesions activating a POLK response. Finally, our data demonstrate a significant impact of *POLK* gene expression on the prognosis value of RIP140 in human CRC. We propose that the modulation of *POLK* gene expression by RIP140 could reinforce its effect on the maintenance of genome integrity and, more particularly, on the stability of microsatellite sequences.

METHODS

Plasmids

pRL-CMV-renilla and pGL promoters were obtained from Promega (Charbonnières, France). pEF-cmyc-RIP140 was previously described^[27]. pEGFP-RIP140 was a kind gift of Dr. Johanna Zilliacus, (Karolinska Institutet, Huddinge, Sweden)^[28]. pEF-cmyc-RIP^{MSI} was generated by mutagenesis using the QuikChange® Site-Directed Mutagenesis Kit (Stratagene). pEF-cmyc-RIP^{MSI} was digested with AflIII and EcoRV enzymes, and the resulting insert was cloned into pEGFP-RIP140 to create pEGFP-RIP^{MSI}. GFP, GFP-RIP140, and GFP-RIP^{MSI} were PCR amplified and cloned into pTRIPZ previously digested with AgeI and MluI to create pTRIPZ-GFP, pTRIPZ-RIP140 and pTRIPZ-RIP^{MSI}, respectively. All the engineered PCR constructs were sequenced.

Cell culture and transfections

Mouse embryonic fibroblasts (MEFs) derived from wild-type or RIPKO mice previously described^[24], and the stably transfected MEFs described by Palassin *et al.*^[26] were grown in DMEM-F12 medium supplemented with 10% FCS, 100 U/mL penicillin, 100 mg/mL streptomycin, and 100 mg/mL sodium pyruvate, with 40 μ g/mL puromycine for selection of stably transfected cells. HCT116, RKO, SW480, and HT29 human colon cancer cells were grown as previously described^[26] and stably transfected with the empty pEGFP vector (Clontech®) or with the same vector containing the full-length human RIP140 cDNA. The SW620 human cell line was grown identically. HCT116-GFP and HCT116-RIP140 cells were previously described^[24] and grown in McCoy medium and 750 μ g/mL G418. Small interfering RNA (siRNA) transfections were performed using INTERFERin® on cells seeded the day before in a 6-well plate (3×10^5 cells per well). Each transfection was performed in triplicate, and interference efficiencies were tested by quantitative RT-PCR.

Animals

C57BL/6J Rip140^{-/-} (RIPKO) mice^[19] were given by Pr MG Parker (Imperial College London, London, UK). C57BL/6/129 RIP140 transgenic (RIPTg) mice were generated using the Speedy Mouse® Technology

(Nucleis) by insertion of a single copy of the human RIP140 cDNA at the HPRT locus^[24]. All animals were maintained under standard conditions, on a 12 h:12 h light/dark schedule and fed a chow diet ad libitum, according to European Union guidelines for the use of laboratory animals. In vivo experiments were performed in compliance with the French guidelines for experimental animal studies (agreement B34-172-27).

Luciferase assays

HCT116 cells were plated in 96-well plates (2.5×10^4 cells per well) 24 h prior to DNA transfection with Jet-PEI[®] (275 ng of total DNA). The pGL3-POLK Luc and its truncated mutant pGL3-83 vectors were previously described^[29]. The pGL3-29 vector was constructed for this work and co-transfected in HCT116 cells. The pRL-CMV-renilla plasmid (Ozyme[®]) was used to normalize transfection efficiency. Firefly luciferase values were measured and normalized by the Renilla luciferase activity. Values were expressed as the mean ratio of luciferase activities.

Cell proliferation and cytotoxicity assays

Cells were seeded in quadruplicate at a density of 2×10^3 cells per well. At the indicated time, 0.5 mg/mL of 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) (Sigma-Aldrich[®], St Louis, MO, USA) was added and incubated at 37 °C for 4 h. Formazan crystals were solubilized in DMSO and absorbance read at 560 nm on a spectrophotometer. The results were normalized to the cell density at Day 1. For cytotoxicity assays, cells were seeded in quadruplicate in a 96-well plate (2.5×10^3 cells per well) and exposed the day after to increasing concentrations of cytotoxic drugs or to vehicle alone. The cells were exposed to the drug during six days and cell proliferation was quantified each day using MTT assay. The results were normalized to the mean optical density of the control for each day. MMS and cisplatin were obtained from Sigma-Aldrich[®].

Real-time quantitative PCR

Total RNA was extracted from cells using Quick-RNA kit (Zymo Research) according to the manufacturer's instructions. Total RNA (1 µg) was subjected to reverse-transcription using qScript cDNA SuperMix (QuantaBio, VWR). Real-time quantitative PCR (RT-qPCR) were performed with the Roche LightCycler[®] 480 instrument and the PerfeCTa SYBR Green FastMix (QuantaBio, VWR) and were carried out in a final volume of 10 µL using 0.25 µL of each primer (25 µM), 5 µL of the supplied enzyme mix, 2.5 µL of H₂O, and 2 µL of the template diluted at 1:10 [see [Supplementary Table 1](#) for primer sequences]. After pre-incubation at 95 °C, runs corresponded to 35 cycles of 15 s each at 95 °C, 5 s at 60 °C, and 15 s at 72 °C. Melting curves of the PCR products were analyzed using LightCycler[®] software to exclude amplification of unspecific products. The results were normalized to different housekeeping gene transcripts (mouse RS9 or human 28S)^[30].

Immunoblotting

RIPA solution was used to extract whole-cell proteins. Cell extracts were analyzed after migration of 30 µg protein extract by Western blotting using a primary polyclonal antibody against Polk (1/1000, Abcam ab57070). Protein quantifications were normalized with the β-actin signal (1/1000, Millipore).

DNA microarray analysis

Published DNA microarray datasets, GSE39582^[31] and GSE42284^[32], were reanalyzed for RIP140 and POLK expression using the Cancertool database^[33]. A transcriptomic dataset from the TCGA-COAD RNA-seq data was also used^[4]. Another published DNA microarray study obtained on a cohort encompassing 396 colon tumor samples with MSS and MSI CRC^[34] was also reanalyzed for RIP140 and POLK mRNA expression. Statistical significance was assessed using a Spearman correlation analysis. Correlation between

RIP140 and *POLK* gene expression was also studied using another cohort^[35]. RNA sequencing data from the TCGA^[4] were reanalyzed using Cox proportional hazard regression^[36]. RNAseq data obtained from CRC samples from the TCGA dataset were analyzed as described previously^[37]. The Kaplan-Meier method was used to estimate overall survival (OS) calculated from the diagnosis until death. Patients lost to follow-up were censored at the time of last contact.

Statistical analysis

All experiments were conducted independently at least three times. The results were expressed as the mean \pm standard deviation (S.D.). Statistical comparisons were performed with Mann-Whitney or Spearman tests. For the Cancertool database analysis, a Pearson's test was performed for the correlation analyses. A probability level (*P*-value) of 0.05 was chosen for statistical significance.

RESULTS

RIP140 regulates *POLK* gene expression in mouse models

To explore the role of RIP140 on the regulation of the *POLK* polymerase gene expression, we first used transgenic mice in which the *Rip140* gene was either knocked out (RIPKO mice) or overexpressed (RIPTg mice)^[24]. As shown in [Figure 1A](#), a significant decrease in the levels of *Polk* mRNA was observed in the intestinal epithelium of RIPKO mice, whereas an increase was noted in RIPTg mice as compared to wild-type animals (WT). These regulations appeared specific since the expression of other TLS polymerase genes from the Y subfamily such as *PolI* did not vary between the different genotypes [[Figure 1A](#) and data not shown]. The steady-state levels of *Polk* mRNA were also significantly reduced in immortalized MEFs derived from the RIPKO mice as compared to cells isolated from WT animals [[Figure 1B](#)]. Altogether, these results demonstrate that RIP140 positively controls the expression of the *Polk* gene in mouse cells and tissues.

RIP140 regulates *POLK* gene expression in CRC cells

To check whether this regulation can be observed in human cells, we then analyzed the effect of RIP140 on *POLK* gene expression in human CRC cell lines. We confirmed the increased expression of the *POLK* gene at the mRNA levels in HCT116 cells either stably overexpressing RIP140 [[Figure 1C](#)] or transiently transfected with a RIP140 expression vector [[Figure 1D](#)]. We also unveiled that silencing the expression of the *RIP140* gene in HCT116, RKO or HCT29 CRC cells significantly affected *POLK* mRNA abundance [[Figure 1E](#) and [F](#) and [Supplementary Figure 1](#)] as well as the *Polk* protein levels in RKO cells [[Figure 1G](#)].

Transcriptional regulation of *POLK* gene transcription in CRC cells

To decipher the mechanisms underlying the positive regulation of *POLK* gene expression by RIP140, we set up transient transfection experiments of HCT116 cells using the *POLK* Luc reporter construct encompassing the proximal promoter region of the *POLK* gene [[Figure 2A](#)]. As observed in [Figure 2B](#), RIP140 significantly increased, in a dose-dependent manner, the luciferase activity driven by the *POLK* gene promoter, thus supporting a positive transcriptional regulation by RIP140. The same effects were observed in other CRC cells including RKO, SW480, and SW620 cells [[Figure 2C](#)].

Mechanism of the transcriptional regulation by RIP140

Although RIP140 was first identified as a transcriptional repressor, we and others reported positive regulation of gene expression (for a review, see Ref.^[38]). In particular, we described a transcriptional activation of gene expression by RIP140 through Sp1-mediated mechanisms^[39]. Since the *POLK* gene promoter exhibits Sp1 binding sites, we tested if the deletion of these sites affected the transcriptional response to RIP140 ectopic expression. As shown in [Figure 2D](#), the induction of luciferase activity by RIP140 was significantly reduced when we used a short reporter construct (*POLK* 29 Luc), suggesting that

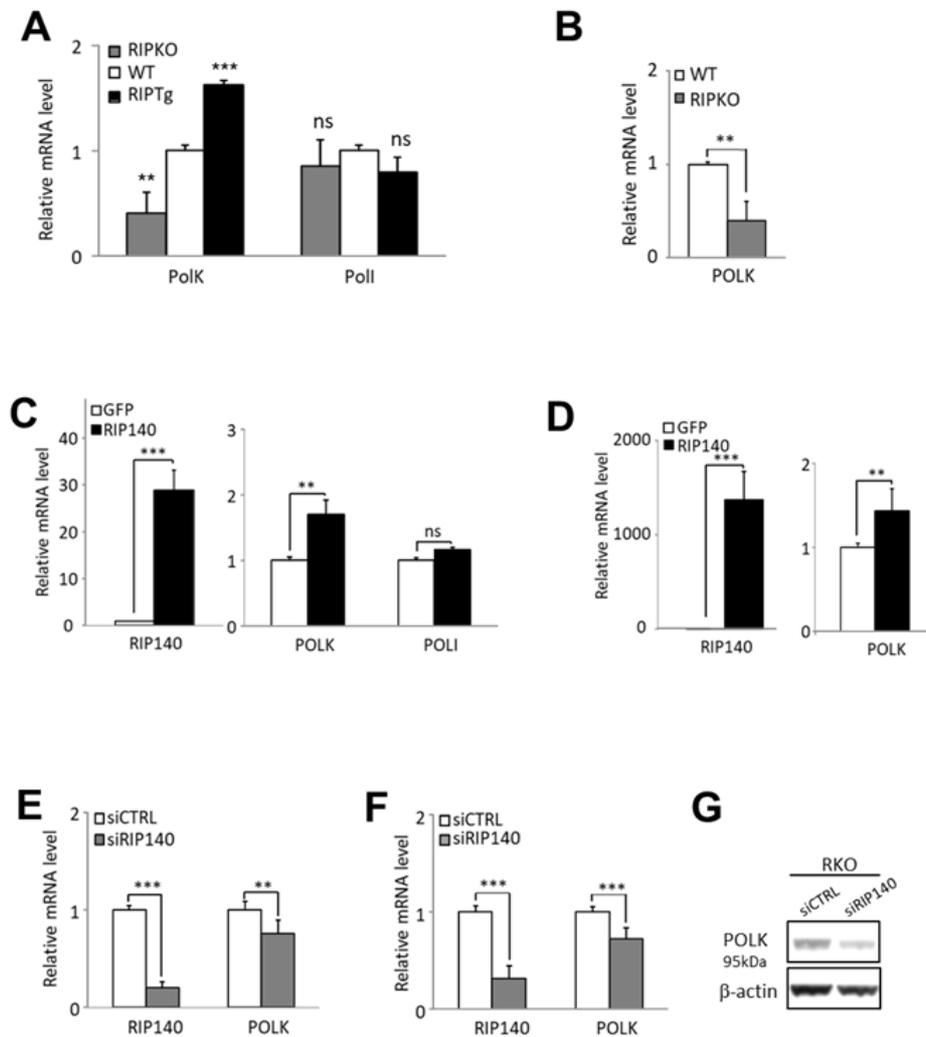

Figure 1. RIP140 regulates *POLK* gene expression. (A) RT-qPCR analysis of *Polk* and *Poll* mRNA in the intestinal epithelium of mice lacking the *Rip140* gene (RIPKO) and in transgenic mice overexpressing RIP140 (RIPTg) as compared to their WT littermates. The results for each gene are given in arbitrary units (AU) and expressed in fold change \pm S.D. relative to WT after normalization to mouse RS9 mRNA. (B) The same as in (A) in immortalized MEFs from WT or RIPKO mice. (C) HCT116 cells were stably transfected with the pEGFP-RIP140-expressing vector (HCT-RIP140) or pEGFP alone (HCT-GFP). RIP140, *POLK*, and *POLI* mRNA levels were quantified by RT-qPCR. The results are expressed relative to GFP cells after normalization to human 28S mRNA. (D) The same as in (C) in HCT116 cells transiently transfected with a RIP140 expression vector. (E) RIP140 and *POLK* mRNA levels were quantified by RT-qPCR in HCT116 cells transiently transfected with siCTRL or siRIP140 siRNAs as indicated. The results are expressed as fold change \pm S.D. relative to siCTRL after normalization to 28S mRNA ($n = 3$ independent experiments for each condition). (F) The same as in (E) performed in RKO CRC cells. (G) *POLK* expression analysis by Western blot of whole cell extract from RKO cells 48 h after transient siRNA transfection. Quantifications are expressed in AU after normalization to β -actin, used as a control of protein migration. A Mann-Whitney test was used for statistical analysis (ns = not significant, ** $P < 0.01$, *** $P < 0.001$).

the regulation of *POLK* gene expression by RIP140 might be, at least in part, mediated by Sp1.

Interestingly, a close correlation between elevated *POLK* expression and p53 inactivation was previously reported in lung cancer tissues^[40]. This effect is likely due to the direct role of p53 on the *POLK* gene since p53 strongly inhibits the *POLK* promoter activity in lung cancer cells, while this activity is much higher in p53^{-/-} MEF than in p53^{+/-} and p53^{+/+} MEFs^[40]. Therefore, we checked whether the positive regulation of *POLK* gene expression by RIP140 was dependent on p53. By using HCT116 cells expressing or not the *TP53* gene,

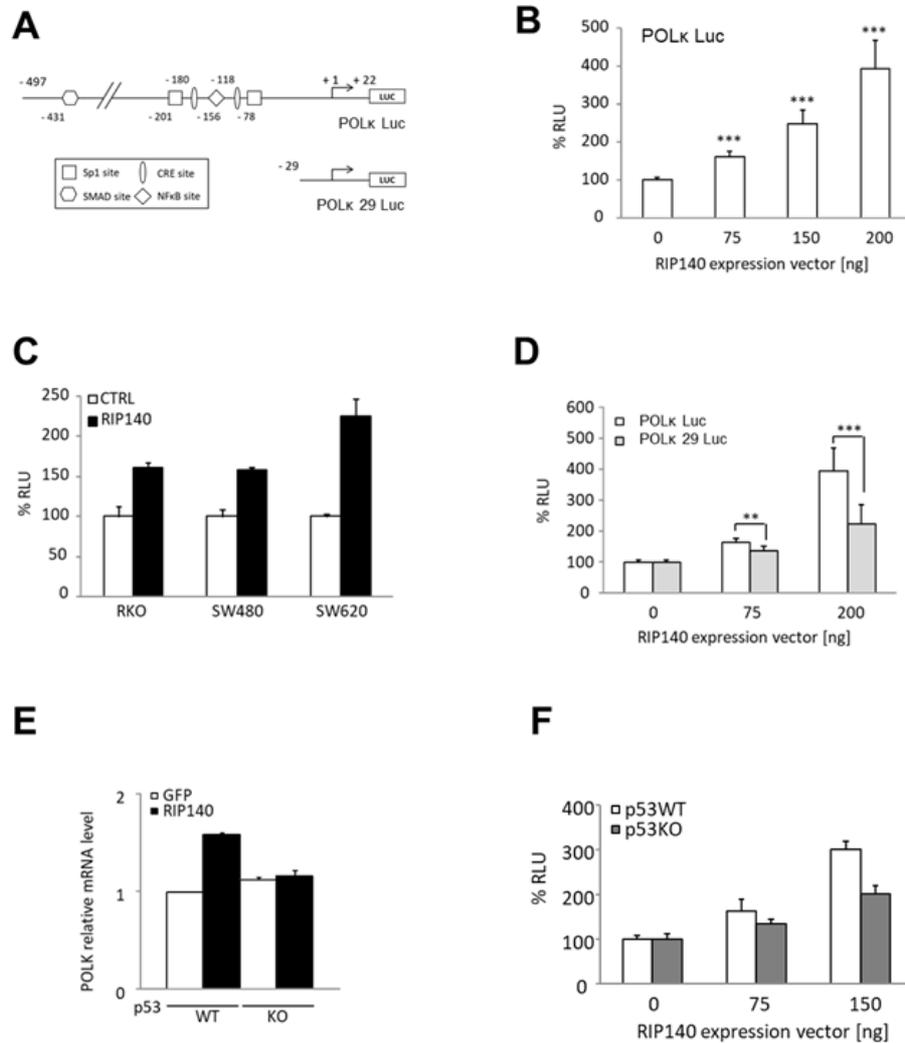

Figure 2. RIP140 regulates POLK at the transcriptional level in CRC cells. (A) Schematic representation of *POLK* proximal promoter cloned in a pGL3 promoter and the putative regulatory sites identified as well as the *POLK* 29 Luc deletion mutant. (B) The *POLK* Luc construct was transiently co-transfected into HCT116 cells with increasing doses of a pEF-cmyc-RIP140 expression vector and pRL-CMV-renilla as an internal control. The reporter activity is presented as relative luciferase activity (RLU) as mean \pm S.D. ($n = 3$ independent experiments). (C) The same reporter assay as in (B) performed in RKO, SW480, and SW620 cells. (D) Luciferase reporter assay performed with the two reporter vectors described in (A), in HCT116 cells. Values, expressed as a percent of control, are means \pm S.D. ($n = 3$ independent experiments). (E) The effect of RIP140 ectopic expression on *POLK* mRNA levels after transient transfection in p53WT or p53KO HCT116 cells. (F) Transactivation of the *POLK* gene promoter by increasing doses of a RIP140 expression vector in p53WT or p53KO HCT116 cells. A Mann-Whitney test was used for statistical analysis (** $P < 0.01$ and *** $P < 0.001$).

we found that, indeed, the regulation of the *POLK* gene by RIP140 was abolished in HCT116 p53^{-/-} cells when monitored at the mRNA level [Figure 2E] or using a luciferase reporter assay [Figure 2F], supporting that p53 is involved in the RIP140-mediated regulation of *POLK* levels.

Correlation of gene expression in human CRC biopsies

To validate in human CRC biopsies the expression data obtained in mouse tissues and in CRC cells *in vitro*, we used the Cancertool database^[33] to reanalyze the published Affymetrix DNA microarray data from two cohorts, namely GSE39582 containing 585 tumors^[31] and GSE42284 with 188 samples^[32]. As shown in Figure 3A and B, and in perfect agreement with the data from mice, the results clearly show a significant positive correlation of *RIP140* mRNA levels with those of *POLK* in CRC biopsies. We also reanalyzed

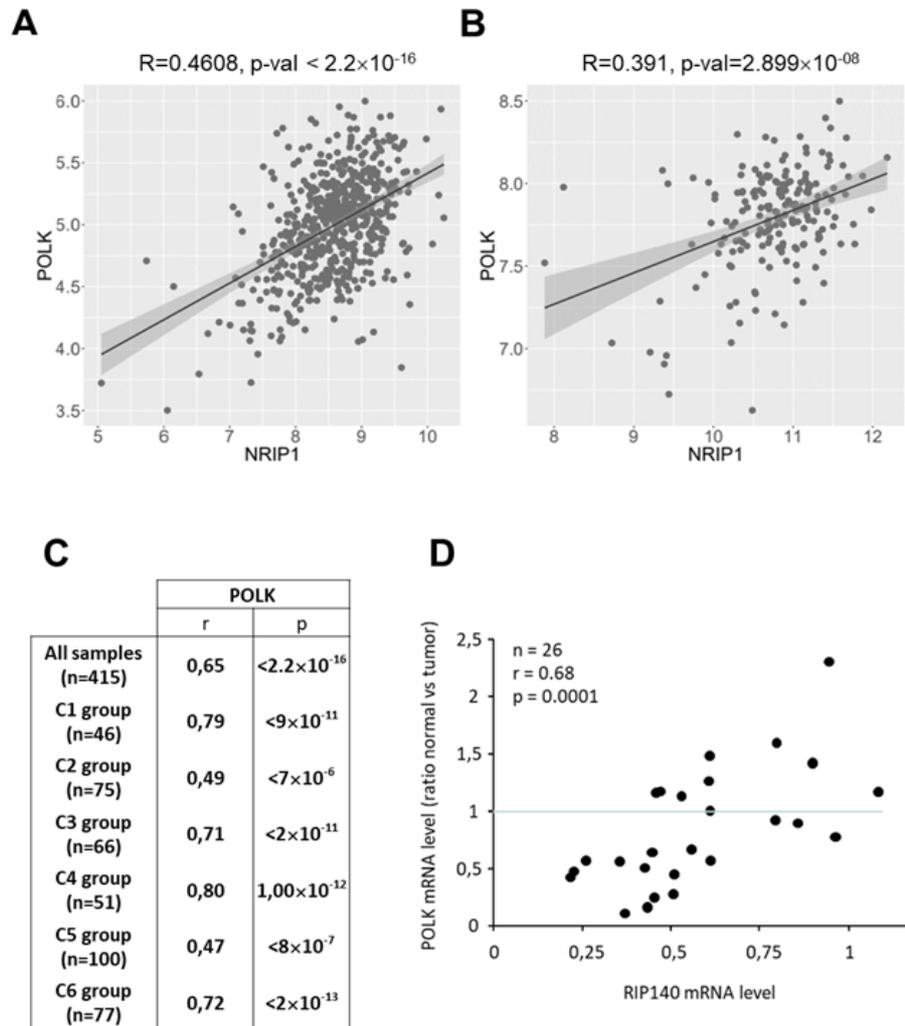

Figure 3. Correlation of *RIP140* and *POLK* gene expression in human CRC samples. (A) Analysis of *RIP140* and *POLK* correlation using the mRNAs expression from the Cancertool database in the GSE39582 cohort^[31]. The correlation coefficient and the p-value (Pearson's test) are indicated. (B) Same as in (A) with the cohort GSE42284^[32]. (C) Correlations between *RIP140* and *POLK* gene expression performed with TCGA RNA-Seq cohort ($n = 415$)^[4] showing the correlations found in the different CRC molecular subtypes described in this cohort. (D) Correlation between *POLK* and *RIP140* gene expression in a cohort comparing the expression of "DNA replication" genes in CRC and in the adjacent normal mucosa ($n = 26$)^[35].

another transcriptomic dataset from the TCGA-COAD RNA-seq data^[4] obtained on 415 samples, which confirmed a significant correlation between *RIP140* and *POLK* mRNA levels ($r = 0.65$; $P < 2.2 \times 10^{-16}$) [Figure 3C]. This dataset was further reanalyzed, taking into account the different molecular subtypes^[31]. This allowed us to show a significant correlation of *RIP140* gene expression with that of *POLK* in the six different subgroups, in particular in the C2 group which corresponds to the MMR deficient subgroup. Finally, we confirmed these data in another cohort comparing the expression of "DNA replication" genes in CRC and in the adjacent normal mucosa^[35]. We confirmed that *RIP140* gene expression strongly decreased in the tumor (data not shown) and that there was a strong correlation in the expression ratio (normal vs. tumoral) of the two genes ($r = 0.68$; $P = 0.0001$) [Figure 3D].

Effect of the RIP^{MSI} mutation on the regulation of *POLK* gene expression

We recently demonstrated that RIP140 plays an important role in controlling microsatellite instability through the regulation of *MSH2* and *MSH6* genes^[26]. To compare the correlation between *RIP140* and *POLK* gene expression in microsatellite stable (MSS) and unstable (MSI) CRC tumors, we reanalyzed a transcriptomic dataset from 396 human CRC with both types of tumors^[34]. As shown in [Figure 4A](#), we observed a very significant positive correlation between *RIP140* and *POLK* mRNA levels in the whole cohort ($r = 0.74$; $P = 5.2 \times 10^{-69}$), thus confirming the results shown in [Figure 3](#). Interestingly, *POLK* and *RIP140* gene expression were significantly correlated in both MSS and MSI tumors [[Figure 4B](#)].

In MSI CRC, we identified a frameshift mutation in the RIP140 coding sequence^[26]. This mutation (called RIP^{MSI}) generated a truncated protein which impaired the biological activity of the RIP140 protein. As shown in [Figure 4C](#), the RIP^{MSI} protein was found to be less efficient than the WT protein to increase *POLK* gene expression. The same results were obtained on endogenous gene expression in HT29 CRC cells overexpressing wild-type or mutated RIP140 [[Figure 4D](#)]. Interestingly, the RIP^{MSI} mutant exhibited a dominant negative effect since its ectopic expression significantly decreased *POLK* mRNA accumulation only in WT MEFs, which express normal levels of RIP140, and not in RIPKO MEFs, which no longer express the *Rip140* gene [[Figure 4E](#)].

Functional consequences of the regulation of *POLK* by RIP140

Since the *POLK* gene is involved in the cellular response to cytotoxic drugs including MMS and cisplatin through a TLS replication process^[41], we next measured the importance of RIP140 on MMS and cisplatin sensitivity by comparing IC₅₀ ratios between RIPKO cells and their WT counterparts. As shown in [Figure 5A](#) and [B](#), we observed a significant increase of sensitivity to MMS and cisplatin when the *RIP140* gene was knocked out (IC₅₀ ratio WT/RIPKO = 9.7, $P < 0.05$ for MMS and IC₅₀ ratio WT/RIPKO = 1.9, $P < 0.001$ for cisplatin). Altogether, these data suggest that the regulation of *POLK* gene expression by RIP140 can affect the cellular responses to various alkylating agents, including anticancer drugs.

POLK expression impacts the prognosis value of RIP140 in CRC tumors

Using the Kaplan-Meier Plotter database, we then investigated whether *POLK* levels contribute to the good prognosis value of RIP140 that we previously reported in CRC patients^[24]. We reanalyzed RNAseq data obtained from 452 patients with colon adenocarcinoma that we separated into two groups of 226 patients, each with low and high *POLK* gene expression in the corresponding tumors using the median as a cutoff value. As shown in [Figure 6A](#) and [B](#), a statistically significant association of high expression of RIP140 with a decreased risk of death in CRC patients was observed when their tumor exhibited low *POLK* gene expression [[Figure 6A](#)] but not in tumors with high *POLK* gene expression [[Figure 6B](#)]. As a control, no differences were observed when the 452-patient cohort was stratified based on the median value of *POLK* expression [[Figure 6C](#) and [D](#)]. Collectively, all the data obtained in this work strongly support a molecular and functional link between RIP140 and *POLK* in CRC.

DISCUSSION

Colorectal cancer is a frequent neoplasm with high genomic instability including MSI due to defects in the MMR system. We previously described that the transcription factor RIP140 was a key factor in the regulation of intestinal homeostasis and tumorigenesis^[24]. We also showed that RIP140 could be involved in microsatellite stability through the regulation of *MSH2/MSH6* gene expression^[26].

In the present study, we demonstrated that RIP140 also strongly regulates *POLK* gene expression, in both mouse and human cells and tissues. Data obtained using luciferase reporter assays demonstrate that this regulation took place at the transcriptional level and implicated the proximal region of the *POLK* gene.

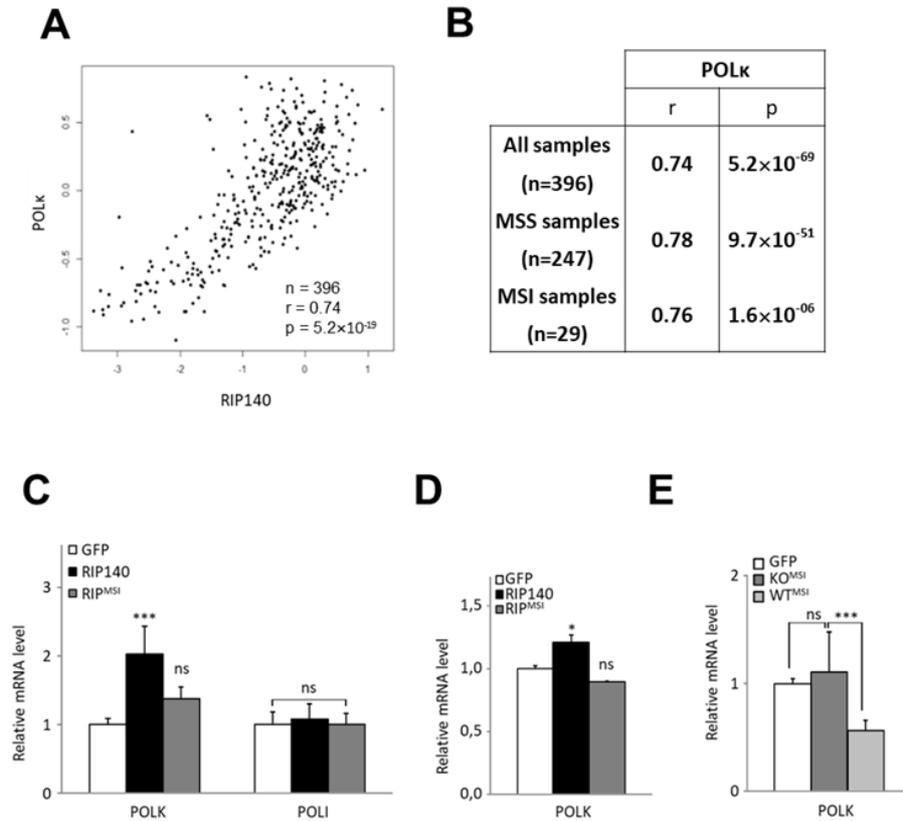

Figure 4. RIP140 and POLK in MSI CRC tumors. (A) Correlation between *RIP140* and *POLK* gene expression in 396 colorectal adenocarcinomas^[34]. (B) Statistical significance was assessed using a Spearman correlation analysis on this cohort, containing 247 microsatellite stable (MSS) and 29 microsatellite instable (MSI) samples. Spearman correlation coefficients between *RIP140* and *POLK* gene expression are indicated for the whole cohort, as well as MSS and MSI samples. (C) mRNA quantification of the *POLK* and *POLI* genes in MEF RIPKO stable cells expressing either the GFP (white box) or the GFP fused wild-type form (black box) or the RIP^{MSI} mutant form (grey box) of RIP140. (D) mRNA quantification of the *POLK* gene in HT29 CRC cells transiently transfected with pEGFP, pEGFP-RIP140, or pEGFP-RIP^{MSI} expression vectors. (E) Analyses of the mRNA expression of the *POLK* gene in MEFs cells stably transfected with the human expression vector of RIP^{MSI} in a RIP140 wild-type background (MEF WT) or knock-out (MEF RIPKO) as compared to the control transfected with a GFP expressing vector in each condition. A Mann-Whitney test was used for statistical analysis (ns = not significant, * $P < 0.05$, ** $P < 0.01$ and *** $P < 0.001$).

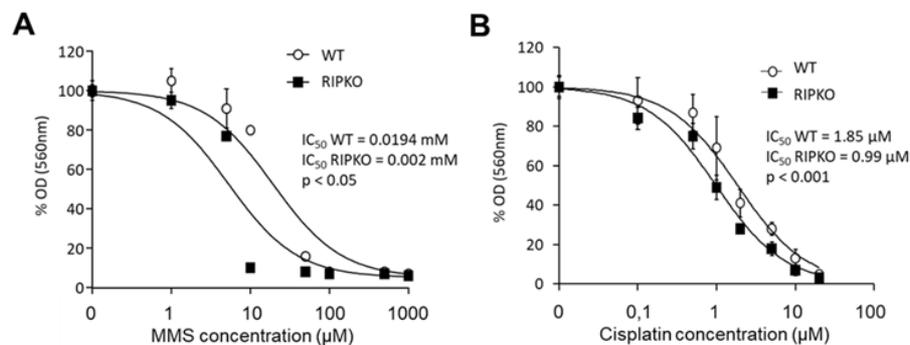

Figure 5. *RIP140* expression affects the response to cytotoxic drugs. (A) MEF WT and RIPKO cells were exposed or not to increasing doses of methyl methane sulfonate (from 0.5 μM to 1 mM). The optical density of diluted formazan crystals was expressed in percentage relative to the control. IC₅₀ values of each cell type are mentioned together with the p-value of the nonlinear regression performed with GraphPad® software, allowing the comparison of IC₅₀ between each cell type dose-response (IC₅₀ ratio WT/RIPKO = 9.7, $P < 0.05$). (B) The same as in (A) with increasing doses of cisplatin (from 0.1 to 20 μM) (IC₅₀ ratio WT/RIPKO = 1.9, $P < 0.001$). Mouse embryonic fibroblasts wild-type.

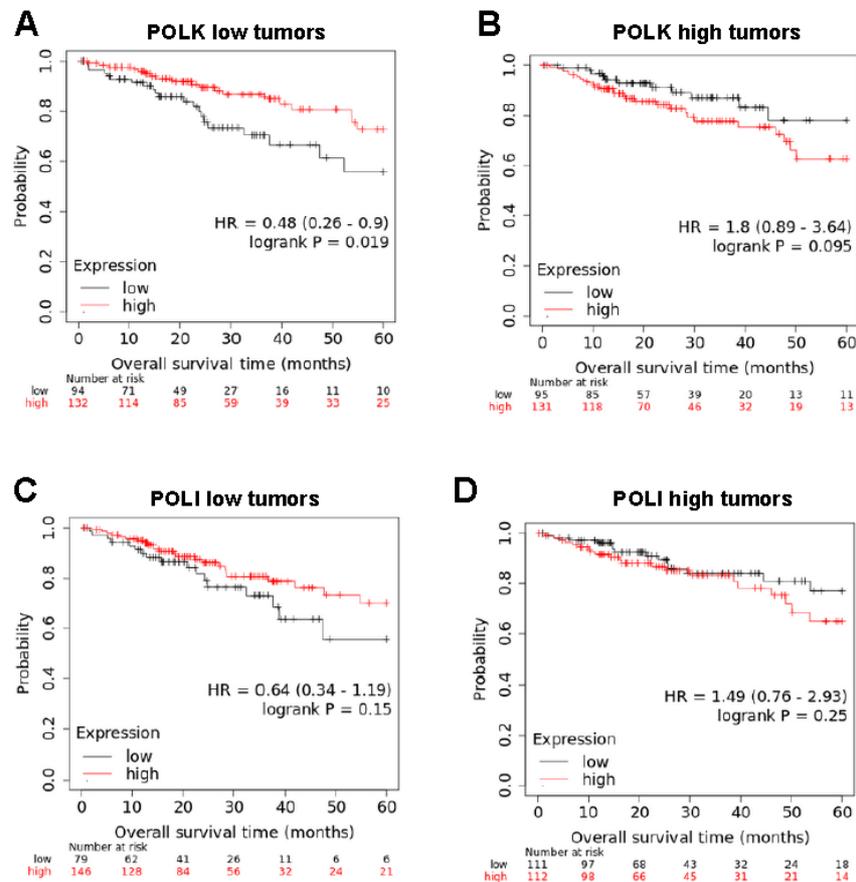

Figure 6. The prognosis value of *RIP140* in CRC tumors is dependent on *POLK* gene expression. (A) Kaplan-Meier analysis of the cumulative OS of patients with low *POLK* gene expression was performed into the groups exhibiting low or high *RIP140* gene expression. A log-rank test was used for statistical analysis. (B) The same analysis as in (A) with tumors expressing high *POLK* gene expression. (C,D) A similar study was performed using *POLI* levels to define the two subcohorts.

Several transcription factors including p53^[40], Sp1, and CREB^[29] or AhR^[42] have been shown to control the expression of the *POLK* gene, and some of them have their activity regulated by *RIP140*^[43]. The data presented herein suggest that p53 is a good candidate to mediate, at least partly, the regulation of *POLK* gene expression since the positive effect of *RIP140* is lost in HCT116 cells no longer expressing the *TP53* gene. Moreover, it has been shown that the HDAC inhibitor Trichostatin A was able to induce *POLK* gene expression^[29]. Since *RIP140* strongly interacts with HDACs^[44], it is possible that HDAC sequestration out of the *POLK* gene promoter also participates in the positive effect exerted by *RIP140* on *POLK* gene transcription as already demonstrated for other transcription factors^[39]. Further work will be necessary to fully decipher the mechanisms used by *RIP140* to transcriptionally control *POLK* gene expression.

Cell survival relies on a subtle equilibrium between accurate genomic DNA replication and less stringent DNA synthesis often linked to DNA damage. *POLK* plays an important and critical role in such equilibrium by contributing to several important DNA transaction pathways. These include translesion synthesis, which allows stalled replication forks to bypass a lesion and restart^[45]; the replication checkpoint^[46], a crucial pathway that regulates the replication stress response to a large array of insults that cause replication arrest; and the synthesis of intrinsic non-B microsatellite DNA^[7]. Consistent with these multiple and complex roles, both overexpression of *POLK* (associated with advanced disease stages and shorter survival in patients with glioma^[47] and non-small cell lung carcinomas^[48]) and under-expression of *POLK* (frequently observed

in colorectal, lung, stomach, and breast cancers^[29,35,49,50]) have been documented to lead to genetic instability. Indeed, excessive Polk can interfere with fork progression and trigger a mutator phenotype and chromosome instability, while downregulation of Polk expression can affect fork progression and induce replicative stress. Since both situations can confer a selective growth advantage during cancer cell evolution, this underlines the importance of tight regulation of *POLK* gene expression at the transcriptional level for the maintenance of genome integrity. Therefore, our discovery here establishing the role of RIP140 in *POLK* gene regulation not only may explain why POLK is abnormally expressed in cancer, notably in CRC, but can also clarify why cancers cells respond differentially to anticancer genotoxic drugs that target DNA replication forks. This last point is illustrated in the present work by cell sensitivity to MMS treatment, which can be modulated by RIP140.

In addition, it is worth mentioning that the regulation of *POLK* gene expression could intensify the phenotypic consequences of the regulation of *MutSa* gene expression by RIP140^[26]. Indeed, this TLS polymerase displays a high accuracy during dinucleotide microsatellite DNA synthesis and has been proposed to play a role in the maintenance of microsatellite stability^[7]. Moreover, Polk interacts with MSH2^[12] and could therefore participate in the control of MutSa activity. Defining the precise involvement of *POLK* gene induction in the effect of RIP140 on the maintenance of genome integrity in colon cancer cells (in particular on the stability of microsatellites) and on their resistance to anticancer drugs will obviously require further work. It would also be interesting to decipher whether, as it is suggested for the MSH2 protein^[51], POLK could be involved in the RIP140-mediated transcriptional regulation of gene expression.

Altogether, the present data suggest that *POLK*-defective cells exhibit an altered DNA replication program, thus explaining the spontaneous genetic alterations observed in *POLK*-deficient mice^[8]. Transcriptional deregulation of *POLK* gene expression may therefore participate in intestinal tumorigenesis and account, at least in part, for the tumor suppressor role of RIP140 that we previously suggested.

DECLARATIONS

Authors' contributions

Substantial contributions to conception and design of the study: Cavailès V, Castet-Nicolas A

Data acquisition, as well as technical and material support: Palassin P, Bonnet S, Lapierre M, Jalaguier S, Teyssier C, Pillaire MJ, Hoffmann JS

Data analysis, statistical analysis and interpretation: Palassin P, Lapierre M, Cavailès V, Castet-Nicolas A

Bioinformatic analysis: Györfy B

Manuscript writing: Palassin P, Lapierre M, Hoffmann JS, Cavailès V, Castet-Nicolas A

The manuscript draft was inserted in the P. Palassin PhD thesis, and not published elsewhere

Manuscript reviewing and editing: Pillaire MJ, Jalaguier S, Teyssier C

Study supervision: Cavailès V, Castet-Nicolas A

Availability of data and materials

Not applicable.

Financial support and sponsorship

This work was supported by INSERM, INCa (Plan Cancer pour la Formation à la Recherche Translationnelle en Cancérologie; ASC14080FSA), CHU Montpellier (Contrat année recherche for PP), the Fondation Val d'Aurelle, Université de Montpellier 1 and the Institut régional du Cancer de Montpellier (ICM). We thank the Réseau d'Histologie Expérimentale de Montpellier (RHEM) for histology facilities.

Conflicts of interest

All authors declared that there are no conflicts of interest.

Ethical approval and consent to participate

In vivo experiments were performed in compliance with the French guidelines for experimental animal studies (agreement B34-172-27 for IRCM and CEEA-LR-12158 for the experiments, obtained from the ethics committee for animal experimentation).

Abstract

In view of the high risk of recurrent disease in stage III and IV ovarian cancer following primary first-line chemotherapy, a variety of maintenance and consolidation treatment strategies have been developed. These have included: radiation, intravenous or intraperitoneal chemotherapy, targeted therapies, and immunotherapy. Popular at this time is the use of Poly-adenosine ribose polymerase (PARP) inhibitors and bevacizumab as maintenance therapy. What effect these maintenance or consolidation therapies have on subsequent response to therapy, specifically platinum-based chemotherapy, is only beginning to be studied. In this manuscript, we review the impact of PARP inhibitors and bevacizumab as well as radiation and maintenance chemotherapy on subsequent response to treatment. Prior use of bevacizumab does not appear to adversely affect subsequent response to platinum-based chemotherapy or platinum-based chemotherapy with bevacizumab. Prior therapy with PARP inhibitors induces platinum resistance to subsequent platinum-based therapy and negates classic predictors of response such as platinum-free interval and breast cancer susceptibility gene (BRCA) mutational status.

Keywords: Maintenance, consolidation, PARP inhibitors, bevacizumab, radiation, chemotherapy

INTRODUCTION

Because of a lack of early detection methodology, most patients with ovarian cancer present with advanced-stage (stage III and IV) disease. Despite high complete response rates to surgery and primary chemotherapy, recurrence occurs in approximately 80% of these patients. Because of this very high recurrence rate, a variety of maintenance/consolidation strategies following completion of first-line chemotherapy have been tested in this patient population. Maintenance/consolidation strategies have included radiation, intravenous or intraperitoneal chemotherapy, targeted therapies, and immunotherapy^[1,2].

Despite maintenance/consolidation strategies, recurrence remains high. Little is known about the interaction of maintenance/consolidation therapies and their impact on subsequent response to treatment. In the era before maintenance therapy, once a patient recurs, a major factor in choosing a second-line therapy is the patient's potential for retreatment with a platinum compound. In 1992, Markman and Hoskins were the first to recognize the importance of defining the recurrent ovarian cancer population and proposed the definition of platinum-sensitive and platinum-resistant disease^[3]. Patients that progressed on therapy had less than a partial response or recurred within 6 months were considered platinum-resistant, while patients who had a previous partial or complete response and did not require chemotherapy for 6 months were considered potentially platinum-sensitive. Subsequent definitions have subdivided patients who recurred within 6 months to those who recur between 0 and 3 months as platinum-refractory vs. 3 to 6 months as platinum-resistant^[4]. Additionally, platinum-sensitive patients have been subdivided into those who recur in 6 to 12 months as partially platinum-sensitive and those who recur more than 12 months as fully platinum sensitive. Other authors feel platinum sensitivity is a continuum without a strict time cut-off^[5]. The duration of time off of platinum defines the platinum-free interval.

Platinum-containing drugs act mainly to induce DNA damage which activates a DNA damage response^[6]. Tumors with deficiencies in homologous recombinant DNA repair are unable to repair platinum-induced DNA damage and undergo apoptosis. Approximately 20% of patients with ovarian cancer have a hereditary germline mutation in the Fanconi Anemia-BRCA pathway, which increases the risk of ovarian cancer and increases their response to chemotherapy^[7]. An additional 30% of the patients with the most common type of ovarian cancer (high-grade serous carcinoma) may also have somatic mutations in the tumor, which increases the likelihood of responding to chemotherapy and are classified as homologous recombinant deficient (HRD)^[8]. In addition to the platinum-free interval, the BRCA mutational and HRD status also is associated with improved response to second-line chemotherapy. Among patients with ovarian cancer patients with BRCA mutations, Tan *et al.*^[9] reported higher response rates (CR/PR) after second-line (70.6 vs. 38.7%; $P = 0.035$) and third-line (64.3 vs. 8.7%; $P = 0.001$) platinum-based chemotherapy compared to non-BRCA mutated patients.

Poly-adenosine ribose polymerase (PARP) enzymes play critical roles in the repair of single-strand DNA breaks (SSB) and maintenance of genomic integrity of a cell^[10]. Like platinum compounds, inhibitors of poly-adenosine ribose polymerase (PARPis) have their greatest oncologic effect on tumors with germline BRCA mutations and HRD. However, even in BRCA mutated patients, response to PARP is closely related to the patient's platinum sensitivity. Fong *et al.*^[11] demonstrated a variable clinical benefit rate across the platinum-sensitive, resistant, and refractory subgroups (69%, 45%, and 23%, respectively). This suggests a common mechanism of drug resistance. Ang *et al.*^[12] made the first report of the clinical outcome of post PARP inhibitor chemotherapy. Among 48 BRCA mutated patients who subsequently received post olaparib platinum-based chemotherapy, a response rate of 40% was noted. The authors suggested non-overlapping mechanisms of drug resistance. More recently, a number of authors have reported decreased response to second- and third-line platinum-based chemotherapy in BRCA mutated patients following PARPi therapy

Table 1. Cecere *et al.*^[13] studied 234 BRCA mutated patients that received olaparib after at least two platinum-based regimens. Eighty-eight percent of these patients received 2-4 platinum-based regimens. Sixty-six of these patients received post olaparib chemotherapy. These patients were stratified by their platinum-free interval. Patients with platinum-free intervals of greater than 12 months predominantly (78%) received a platinum regimen. Fifty-two percent of patients with platinum-free intervals of 6-12 months received a platinum regimen. No patients with platinum-free intervals of < 6 months received a platinum regimen. The response rates were low for all platinum-free intervals. Baert *et al.*^[14] evaluated the rate of disease progression to third-line platinum chemotherapy among 35 BRCA mutated and non-mutated patients. Prior PARP inhibitor treatment significantly increased the frequency of disease progression by 40% vs. 9% in non-PARP inhibitor-treated controls. Frenel *et al.*^[15] evaluated the progression-free survival following third-line platinum-based chemotherapy among BRCA mutated patients enrolled in SOLO-2. The progression-free survival to third-line platinum-based chemotherapy was significantly reduced in the olaparib-treated patients by 7 vs. 14.3 months in the placebo-treated controls. Rose *et al.*^[16] studied BRCA mutated patients who received second- or third-line platinum-based chemotherapy. Patients who received a PARP inhibitor following first- or second-line chemotherapy had a poorer progression-free survival to second- or third-line platinum-based chemotherapy, respectively (8 months vs. 19.1 months). This study also demonstrated that there was no prognostic significance to the platinum-free interval as the progression-free survival among BRCA mutated patients with prior platinum-free intervals of 6 to 12 months, 12 to 24 months, or more than 24 months was the same. Additionally, there was no prognostic significance to BRCA mutational status as the progression-free survival of patients to subsequent platinum-based chemotherapy who were BRCA mutated or non-BRCA mutated following prior PARP inhibitor exposure was the same.

These findings may explain why PARP inhibitors demonstrate significant improvements in progression-free survival but not overall survival. While the mechanisms of platinum and PARP inhibitor resistance have only begun to be determined, Johnson *et al.*^[17] did demonstrate stabilization of mutant BRCA1 protein confer PARP inhibitor and platinum resistance.

Another unresolved issue regarding PARP inhibitor utilization is when PARP inhibition therapy should be instituted. In study 19, which studied olaparib maintenance after second-line platinum-based chemotherapy, a significant improvement in overall survival was only evident when placebo-treated patients who received subsequent PARP inhibitor therapy were excluded from the analysis^[18]. This implies that delayed PARP inhibition may be just as effective as immediate PARP inhibition. The conclusion of the SOLO-2 analysis abstract by Frenel *et al.*^[15] states, “the earlier use of olaparib remains optimal”. The basis for this conclusion is uncertain. The marginal improvement in overall survival in SOLO-2 (upper limit of 95% confidence interval 1.00) is likely due to the fact only 38% of the placebo-treated patients were able to receive a PARP inhibitor^[19]. More recently, the lack of overall survival benefit with niraparib in the Nova trial, which studied niraparib as second-line maintenance in BRCA mutated, HRD positive and HRD negative patients questions the importance of early PARP inhibitor therapy^[20]. Although specific post clinical trial treatment was not collected in this study, it is postulated that many of the placebo-treated control patients subsequently received a PARP inhibitor because of their current greater availability commercially.

This emphasizes the need for a prospective randomized trial to compare the early use of a PARP inhibitor to the delayed use of a PARP inhibitor. In the design of this trial, one would have to think about when early PARP inhibitor therapy should occur. Numerous studies are suggested that 30% of BRCA mutated patients may not recur^[21-23]. Therefore, is it reasonable from a quality of life, toxicity and cost perspectives to treat

Table 1. Studies of chemotherapy following PARP inhibitor therapy

100% of the BRCA mutated patients after first-line chemotherapy when only 70% of the patients may recur? Alternatively, would it be better to delay maintenance therapy once a patient has developed a recurrence?

As reported by Burger *et al.*^[24], “Vascular endothelial growth factor and angiogenesis correlate directly with the extent of disease and inversely with progression-free survival and overall survival.” Several antiangiogenic targeted therapies have been studied in ovarian cancer. The most widely studied antiangiogenic agent is bevacizumab. Two studies conducted in Europe (ICON 7) and in the United States Gynecologic Oncology Group (GOG) 218 demonstrated a benefit of maintenance bevacizumab in stage IV patients^[25,24]. In ICON 7, patients were defined as high risk for progression, which included stage IV disease, inoperable stage III disease, or suboptimally debulked (> 1 cm) stage III disease. The addition of bevacizumab to chemotherapy and as maintenance for 12 cycles resulted in an improvement in overall survival [39.7 months vs. 30.2 months (HR 0.78, P = 0.03)]^[25]. For stage IV patients in GOG 218, the addition of bevacizumab to chemotherapy and maintenance improved the median survival by 10 months (42.8 months vs. 32.6 months, HR 0.75)^[26]. However, no statistical benefit was seen in an exploratory analysis using ICON 7 criteria, suboptimal stage III and IV patients vs. all other stage III patients with survivals of 42.8 months vs. 45.6 months, respectively. The benefit of bevacizumab in the ICON 7 high risk for progression subgroup included inoperable stage III patients treated with neoadjuvant chemotherapy^[25]. GOG 218 did not include patients treated with neoadjuvant chemotherapy and therefore cannot confirm or refute ICON 7 findings in this population.

Whether prior exposure to bevacizumab affects the response to subsequent platinum-based chemotherapy or platinum-based chemotherapy with bevacizumab has been evaluated in three randomized trials. In GO G 213, 10% of patients in each arm had received bevacizumab^[27]. Despite prior bevacizumab, patients who were randomized to retreatment with bevacizumab had an improved progression-free survival, but this was not statistically significant as they comprised only 10% of the study population [HR 0.545 (0.292-1.017)]. In contrast, in the MITO16b/MANGO-OV2/ENGOT-ov17 trial, patients who received platinum-based chemotherapy with bevacizumab as part of first-line therapy were randomized to receive a platinum-based chemotherapy doublet either carboplatin and paclitaxel, carboplatin and gemcitabine or carboplatin and pegylated liposomal doxorubicin, with or without bevacizumab^[28]. The median progression-free survival to

second-line platinum-based chemotherapy doublet was 8.8 months. The response rate for second-line platinum-based chemotherapy was dependent on the platinum-free interval, with different response rates for patients who progress at 6 to 12 months vs. those who progress after 12 months^[4]. Table 2 is a list of platinum-based second-line chemotherapy regimens based on an increasing percentage of patients in the 6- to 12-month interval. GOG 213^[27] and ICON 4^[29] have a more favorable population of patients with a lower frequency of 6- to 12-month platinum-free interval patients 25% and 27%, respectively, compared to MITO16b/MANGO-OV2/ENGOT-ov17 with 35%. The MITO16b/MANGO-OV2/ENGOT-ov17 trial median progression-free survival of 8.8 months compares favorably to other platinum doublets in platinum-sensitive recurrent ovarian cancer. The median progression-free survival to second-line platinum-based chemotherapy doublet was not statistically different at 9.6 and 8.0 months, for patients who had progressed after bevacizumab or progressed on bevacizumab, respectively $P = 0.8$.

The AGO OVAR 2.21/NGOT- ov 18 trial, which compared carboplatin/gemcitabine/bevacizumab with carboplatin/pegylated liposomal doxorubicin/bevacizumab, allowed prior antiangiogenic therapy^[36]. Prior antiangiogenic therapy was received in 47.5% of all patients, most commonly bevacizumab (87.3%). Prior antiangiogenic therapy did statistically decrease the median progression-free survival at 10.1 months (95%CI: 8.5-11.2) vs. 13.6 months (95%CI: 11.7-15.6) for carboplatin/gemcitabine/bevacizumab but not for carboplatin/pegylated liposomal doxorubicin/bevacizumab 11.3 months (95%CI: 10.1-13.8) vs. 14.4 months (95%CI: 12.3-16.8). The median overall survival was decreased more than 5 months with prior antiangiogenic therapy 25.1 months (95%CI: 19.3-27.8) vs. 30.7 months (95%CI: 27.4-36.2) for the carboplatin/gemcitabine/bevacizumab arm and by almost 10 months, 27.7 months (95%CI: 24.0-31.7) vs. 37.3 months (95%CI: 30.9-42.9) for the carboplatin/pegylated liposomal doxorubicin/bevacizumab arm, but these were not statistically significant.

Thirty-one percent of patients in each arm were in the 6-12 months platinum-free interval, so this progression-free survival is consistent with prior studies Table 2 and does not suggest any negative impact of prior antiangiogenic therapy.

RADIATION CONSOLIDATION

Ovarian cancer is radiosensitive, but the potential for metastasis throughout the abdominal cavity requires whole abdominal radiation. While bulky residual disease is difficult to treat, it was believed that patients who had undergone cytoreductive surgery and platinum-based chemotherapy, with the potential for further chemical cytoreduction, consolidation with whole abdominal radiation might be more effective. Lawton *et al.*^[37] from the West Midlands Ovarian Cancer Group randomized patients to whole abdominal radiation therapy using a moving strip technique or one year of chlorambucil. Overall survival at two years was 35%, with no significant difference in survival between the two groups despite the fact that approximately 50% of the patients were optimally debulked prior to consolidation. Toxicity was considerable in both arms, and almost 50% of patients were unable to complete the planned treatment in both arms. A subsequent British trial by the North Thames Group evaluated consolidation platinum-based chemotherapy vs. whole abdominal radiation^[38]. One hundred seventeen patients with residual disease of 2 cm or less at second-look laparotomy or laparoscopy were then randomized to receive consolidation therapy, either five further courses of carboplatin at the same dosage or whole-abdominal RT (24 Gy). The median survival for the whole group from the date of surgery was 25 months. No statistical difference was found in either survival or disease-free survival between those patients who received consolidation chemotherapy and those who were treated with abdominal RT. The Swedish-Norwegian Ovarian Cancer Study Group performed an observation controlled trial comparing receive whole-abdominal irradiation (WAR) or six courses of consolidation chemotherapy (cisplatin 50mg/m² and doxorubicin 50mg/m² or

epirubicin 60mg/m²) vs. no further treatment^[39]. Seven hundred and 42 patients were prospectively studied. Following primary cytoreductive surgery followed by induction chemotherapy (four courses of cisplatin 50mg/m² and doxorubicin 50mg/m² or epirubicin 60mg/m²), patients with no evidence of disease (NED), a complete clinical response (cCR), or partial response (cPR) underwent a second-look laparotomy. At second-look laparotomy, patients were classified as having a pathologic complete response, microscopic residual disease, or macroscopic residual disease. One hundred and seventy-two patients with a pathologic complete response or microscopic residual disease entered into the randomized study. Patients with a pathologic complete response who received radiation therapy had improved progression-free survival compared to patients who received chemotherapy or observation ($P = 0.032$), but overall survival was not improved ($P = 0.084$). Subsequent post-study treatment was not collected or reported in this trial. Preclinical data suggests a possible interaction between radiation resistance and chemotherapy resistance^[40]. Since whole abdominal radiation is not widely utilized clinically, a clinical correlation has not been documented in the literature.

Lastly, although Intraperitoneal P32 was not found to be an effective consolidation therapy for stage III ovarian cancer patients after negative second-look laparotomy, it did not adversely affect overall survival^[41].

MAINTENANCE CHEMOTHERAPY

In 2003, Markman reported the results of the SWOG/GOG 178 trial, which demonstrated that following first-line chemotherapy, patients randomized to 12 cycles of paclitaxel vs. three cycles of paclitaxel had an improved progression-free survival (28 months vs. 21 months $P < 0.005$)^[42]. Once this progression-free survival improvement was reported, patients in the 3 cycle arm were offered additional therapy. Possibly, as a result of this delayed crossover, there was no difference in overall survival. Conte *et al.*^[43] performed a trial of six cycles of paclitaxel vs. observation following primary chemotherapy. No difference in overall survival was noted. The Gynecological Oncology Group performed a larger confirmatory trial (GOG 212) comparing 12 cycles of paclitaxel vs. 12 cycles of polyglutamate paclitaxel (Xyotax) vs. observation^[44]. No difference in overall survival was noted at 51.3 months, 60.0 months, and 54.8 months for paclitaxel, Xyotax, and observation, respectively. Other studies have used topotecan^[45,46] or epirubicin^[47] as maintenance therapy vs. observation, but no difference in

overall survival has been noted. In summary, although multiple chemotherapy agents have been studied as maintenance therapy and ovarian cancer, it is clear that they have not improved overall survival. When non-platinum maintenance chemotherapy was utilized, since patients were off platinum, the platinum-free interval was not affected, and anecdotally subsequent chemotherapy was not adversely affected by non-platinum maintenance chemotherapy.

In summary, patients with advanced-stage ovarian cancer have high responses to primary therapy but have a high recurrence rate. Multiple studies have looked at the use of maintenance or consolidation therapy to prevent recurrence. Currently, both the use of bevacizumab and PARP inhibitors are favored as possible maintenance therapies. Prior use of bevacizumab does not appear to adversely affect subsequent response to platinum-based chemotherapy or platinum-based chemotherapy with bevacizumab. Since the response to PARP inhibitors is related to platinum sensitivity, it suggests a common mechanism of resistance. Prior therapy with PARP inhibitors induces platinum resistance to subsequent platinum-based therapy and negates classic predictors of response such as platinum-free interval and BRCA mutational status. Randomized trials are needed to determine the best time to initiate PARP inhibitor therapy.

Abstract

Definitions of platinum resistance have been questioned and changed over the last five years, even though no predictive biomarker of resistance exists. These have sculpted how we approach platinum retreatment and, consequently, how we devise new treatment strategies for those patients with tumour progression on platinum therapy. Platinum-non-eligible ovarian cancer is treated with single-agent non-platinum drugs. When bevacizumab can be added to chemotherapy, progression-free survival improves significantly. For patients with a BRCA mutation, PARP inhibitor monotherapy is an option compared to chemotherapy. There is currently no clearly identified role for immune-checkpoint inhibition in this patient population. This review describes some of the challenges in treating patients with platinum resistance and suggests refinements in the selection of patients most likely to benefit from targeting a DNA damage response, angiogenesis or immune modulation. It also describes novel agents of interest and possible mechanisms of the synergy of therapeutic combinations.

INTRODUCTION

Background of platinum retreatment

The idea of platinum rechallenge was introduced in the 1980s at a moment in history when few treatments were available for recurrent ovarian cancer. Across several Phase II studies, the treatment-free interval (TFI) was one of the most important variables predicting response to second-line chemotherapy^[1]. Later, Markman and Hoskins proposed that trials of new agents be stratified into primary platinum-resistant, secondary platinum-resistant, potentially platinum-sensitive and those with indeterminate sensitivity^[2]. These definitions underwent further refinement, with variation in the cut-offs of TFI between 4 and 12 months for intermediate platinum-sensitive disease and ultimately 6 months for being considered as platinum-sensitive, with this latter definition being used for the next 3 decades^[3]. It was first rigorously questioned at the 2010 Gynecologic Cancer InterGroup (GCIg) Ovarian Cancer Consensus meeting, during which its use was criticized as the response to platinum gradually increases with TFIp (TFI after platinum) in a non-linear way^[3]. During the fifth GCIg consensus meeting in 2015, the terminology: platinum-sensitive and platinum-resistant in clinical trials was replaced with TFIp considered as a continuous variable among others discussed below.

Current definitions of platinum resistance and clinicopathological predictors of platinum responsiveness

According to ESMO-ESGO consensus meeting guidelines for the management of recurrent ovarian cancer^[4], platinum-non-eligible ovarian cancer (PNEOC) patients are those who progress on or immediately after their last platinum-based chemotherapy or have contraindications to platinum. Platinum-eligible ovarian cancer (PEOC) includes all other cases of relapse. This includes patients without evaluable or no residual disease after primary surgery or who have relapsed following stage I disease.

There is no biomarker of platinum resistance. However, research is ongoing to define predictive biomarkers of resistance as well as prognostic markers that may be used as tools to guide treatment selection in patients with PNEOC.

For example, Lee *et al.*^[5] have developed a nomogram to refine prognostication in this group using six pre-treatment variables [TFIp, performance status, size of the largest tumour, cancer antigen-125 (CA-125), haemoglobin and the number of metastatic organ site]. This nomogram improved overall survival prediction in patients with PEOC compared to models with fewer prognostic factors or TFIp alone. This could have applications for stratification in clinical trials and counselling patients.

An important predictive variable of response to platinum is tumour biology and histology; for example, response rates are lower in patients with clear cell, low-grade serous and mucinous ovarian cancers^[6]. Tumour molecular changes, including the presence of homologous recombination deficiency, increase the likelihood of a response to platinum^[7].

Mechanisms of platinum resistance

DNA damage response detection and repair

The DNA damage response is utilised to detect DNA damage and initiate DNA repair in order to maintain genomic integrity^[8]. It consists of a network of interrelated signalling pathways, which can be broadly divided into homologous recombination (HR) dependent and HR independent repair pathways [Figure 1].

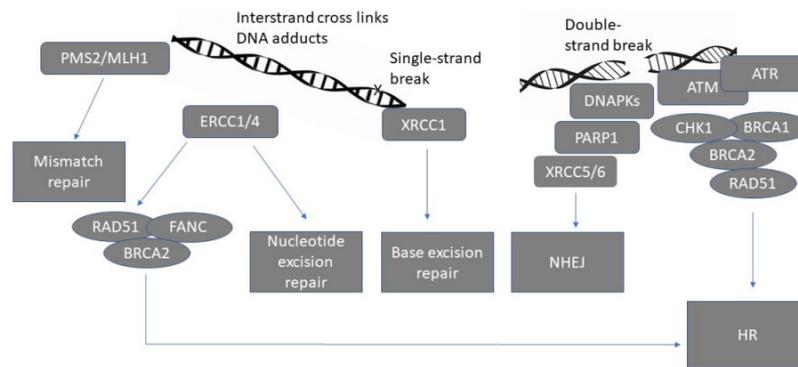

Figure 1. Schematic representation of major DNA repair pathways^[8]. PMS2: postmeiotic segregation increased 2, MLH1: mutL homolog 1, ERCC1/4: Excision repair cross-complementing 1/4, RAD51: RAD51 recombinase, FANCD1: Fanconi anaemia complementation group, BRCA1/2: Breast cancer gene 1/2, DNAPKs: DNA protein kinases, PARP1: Poly (ADP-ribose) polymerase, XRC5/6: X-Ray Repair Cross Complementing 5/6, ATM: ATM Serine/Threonine Kinase, ATR: Ataxia telangiectasia and Rad3-related, CHK1: checkpoint kinase 1, HR: homologous recombination, NHEJ: non-homologous end joining.

HR dependent repair is designed to repair double-strand DNA breaks and interstrand crosslinks and, to a lesser extent, other kinds of DNA damage^[9]. DNA repair, which is not dependent on HR, includes non-homologous end joining (NHEJ) for interstrand, double-strand breaks and intrastrand breaks. Other HR independent pathways that are less error-prone include mismatch repair, base excision repair and nucleotide excision repair (NER). These are typically recruited for the repair of single-strand breaks or damage induced by DNA adducts^[10].

The ERCC1-XPF nuclease enzyme is translated from the mRNAs of the ERCC1 and ERCC4 genes^[11]. This enzyme plays a key role in DNA damage repair chiefly via NER and also that caused by interstrand crosslinks and double-strand breaks by HR and NHEJ^[11]. ERCC1-XPF targeting is a strategy being explored to increase the sensitivity of cancer cells to some DNA-damaging chemotherapeutic agents.

The master sensors (ATM, ATR, and DNA-PKs) are large kinases that sense DNA damage and initiate repair signalling cascades by phosphorylating key proteins, which are primarily involved in HR dependent repairs such as BRCA1, CHK1, CHK2, and RAD51^[12]. The activation of signalling transduction pathways, including PI3K/AKT, promotes the activation of DNA damage response (DDR) cell checkpoints that halt cell cycle progression, allowing more time for DNA repair^[8].

Correlation between platinum sensitivity and PARPi (PARP inhibitor) sensitivity

BRCA-deficient ovarian cancers have increased platinum sensitivity^[13-14]. *In vitro*, reversion of BRCA mutations confers platinum and PARPi resistance^[15-16]. In clinical studies, response to olaparib correlates with TFIp^[17]. There is also a correlation between deficiency in other HR genes, *ex vivo* PARPi sensitivity, and platinum sensitivity in patients^[18]. Multiple resistance mechanisms to platinum and PARPi have been described independently, although, following on from the above, significant mechanistic crossover exists.

Mechanisms of platinum and PARPi resistance

HR-dependent mechanisms of resistance include restoration of BRCA function by secondary or reversion mutations, or restoration of HR by loss of 53BP1, RIF1 or the shieldin complex amongst others [Table 1]. One major limitation of standard HR assays is that they are mostly insensitive to the detection of homologous recombination deficiency (HRD) reversion^[16]. HR functional assays require viable cancer cells to be exposed to DNA damaging agents *ex vivo*, which therefore limits the access to samples and assay

Table 1. Mechanisms of PARP/platinum resistance

Mechanism	Proteins involved
PARP activity alteration	RAS
loss of PARG	PI3K/AKT
increased stabilisation of replication forks	PARP
Altered ion channel drug accumulation	VRAC
upregulation of drug efflux pumps	MRP 2
Intracellular drug inactivation	
Restoration of BRCA function through secondary reversion mutation	BRCA1/2
modification of other HR proteins	53BP1
	RIF1
	shieldin complex

RAS = Rat sarcoma, PI3K phosphor-inositol 3-kinase; AKT: AK strain transforming; PARP: Poly (ADP-ribose) polymerase; PARG: Poly ADP (adenosine diphosphate) Ribose Glycohydrolase; VRAC: volume-regulated anion channel; MRP2: multidrug resistance-associated protein 2; BRCA1/2: Breast cancer gene 1/2; 53BP1: Tumour Protein P53 Binding Protein 1; RIF1: Replication Timing Regulatory Factor 1.

reproducibility.

Mechanisms independent of HR include increased stabilisation of replication forks, upregulation of drug efflux pumps, PARP activity alteration, loss of PARG and RAS/PI3K/AKT pathway activation. Associated overexpression of STAT5B and RELA, two transcription factors associated with platinum resistance, is less well understood^[19].

Platinum resistance may also emerge due to reduced intracellular drug accumulation, for example, through reduced intracellular drug uptake, intracellular drug inactivation, enhanced DNA repair or altered apoptotic signalling pathways^[20].

Refining biomarkers of resistance to platinum and PARPi

HRD is a useful biomarker for predicting the initial response to both platinum chemotherapy and PARPi, though biomarkers of resistance require much refinement.

Standard tests for HRD, including the Myriad genomic instability score and Foundation Medicine loss of heterozygosity test, predict the presence of HRD based on genomic features^[21]. These and other genomic tests vary in terms of the genomic features measured and the threshold definitions for identifying patients considered to have HRD. Clinically, HRD test results and PARPi responses can be discordant. This may be because tumours with reversion mutations that restore HR function still exhibit evidence of HRD on these assays or that alternative HR independent PARPi resistance mechanisms may be playing a predominant role. Functional assays of HR genes may overcome some of these challenges in predicting the presence of HRD^[21]. The measurement of somatic mutations, such as a BRCA reversion mutation in ctDNA, is non-invasive and warrants further development^[22].

Approximately 40% of high-grade serous HR proficient ovarian tumours, demonstrate increased Cyclin E expression by CCNE1 gene amplification, increased copy numbers or enhanced protein expression^[23]. These CCNE1 high tumours are associated with platinum resistance and poor survival^[24].

Other tumour factors contributing to treatment resistance

Tumour microenvironment

Together with genomic alterations in the DNA damage response, the tumour microenvironment is an increasingly recognised contributor to our understanding of resistance mechanisms in ovarian cancer^[19].

The increased infiltration of immunosuppressive regulatory T cells has been correlated with enhanced tumour growth^[25], whereas the presence of CD8+ tumour infiltrating lymphocytes is correlated with enhanced survival^[26]. The most predominant immune cells associated with ovarian cancer are macrophages. Tumour-associated macrophages (TAMs) are easily polarised by tumour-cell-producing colony-stimulating factor-1 into an immunosuppressive M2-like phenotype^[27]. The main pro-tumoural function of M2-like TAMs is the secretion of cytokines and exosomes that induce microRNAs, which directly promote the survival, invasion potential and chemoresistance of ovarian cancer cells^[27]. PD-1, PD-L1 expression and Tumour Mutational Burden have not shown consistent validity as predictive biomarkers for immune checkpoint inhibition in ovarian cancer^[19]. Retinoic acid-inducible gene-I overexpression is correlated with platinum-resistant ovarian and other refractory cancers^[28]. Its overexpression is associated with local immunosuppressive changes and a distinct immune signature. Extensive stromal desmoplasia has also been associated with platinum resistance^[29].

Altered metabolism in cancer tissues

Accumulating evidence suggests that tumour metabolism differs from that of matched normal tissues^[30], and metabolic reprogramming may cause therapy resistance. Of relevance to platinum resistance, in one cisplatin-resistant PDX ovarian cancer model glycolysis, the tricarboxylic acid and urea cycle pathways were deregulated with higher mitochondrial respiration. This may suggest a role for therapies that modulate metabolism, such as metformin. Other drugs used in non-cancer indications and new small molecule inhibitors of mitochondrial complexes are being increasingly utilised to target cancer metabolism^[31].

CURRENT APPROACHES TO THE MANAGEMENT OF PNEOC

Chemotherapy

Highlighting the clinical relevance of the arbitrariness of TFIp to decide on subsequent platinum retreatment, Lindemann *et al.*^[32] compared second-line platinum *vs.* non-platinum regimens in a cohort of patients who would have traditionally been regarded as platinum-resistant, i.e., those with a TFIp < 6 mo. They found a greater CA-125 response rate of 51 *vs.* 21% ($P < 0.001$) in those treated with a platinum-based therapy compared to a non-platinum regimen; and in those patients with TFIp between 3 and 6 months, improved overall survival.

Using the new and modified definition of resistance, patients with PNEOC, i.e., those progressing on platinum, are typically offered non-platinum-based chemotherapy such as weekly paclitaxel, pegylated liposomal doxorubicin (PLD) or topotecan with or without bevacizumab^[3]. There have been comparatively few randomised phase III trials in this setting. [Table 2](#) summarises the key data. In the CORAIL trial, comparing lurbinectedin to PLD or topotecan in patients with a TFI < 6 mo, the PFS was similar across all groups^[33]. In the AURELIA trial, patients who relapsed after 1-2 prior lines of platinum were randomised between topotecan, PLD, or weekly paclitaxel with or without bevacizumab^[34]. The combination of bevacizumab with PLD, weekly paclitaxel or topotecan improved mPFS compared to chemotherapy alone. Alternative non-platinum options include oral etoposide, tamoxifen, gemcitabine and treosulfan^[3].

PARP-inhibitors

There is a role for single-agent PARP inhibitors, particularly in those with BRCA mutations that have become resistant to platinum. This is demonstrated in the single-arm Phase II QUADRA trial, in which patients were treated with niraparib after more than three lines of therapy that did not include a previous PARPi. The clinical benefit rates in patients with a BRCA1 or two mutations and TFIp < 6 months were 38% and 33%, and in the group that was platinum-refractory, 50% and 31%, at 16 and 24 weeks, respectively^[35]. Although this is a single-arm Phase 2 study, the data does suggest an important role for niraparib in

Table 2. Phase III trials in PNEOC

Trial	Treatment Arms	mPFS	Reference
CORAIL	Lurbinectedin vs. control arm (PLD vs. topotecan)	3.5 vs. 3.6 mo HR = 1.057 $P = 0.6294$	Gaillard <i>et al.</i> (2018) ^[33]
ARIEL4	Rucaparib vs. weekly paclitaxel (TFIp 1-6 months)	6.4 vs. 5.7 mo HR = 0.78 (95%CI: 0.54-1.13)	Oza (2021) ^[36]
AURELIA	Bevacizumab plus chemotherapy (PLD or topotecan or weekly paclitaxel) vs. chemotherapy alone	6.7 vs. 3.4 mo HR = 0.48 $P < 0.001$	Pujade-Lauraine <i>et al.</i> (2014) ^[34]
JAVELIN Ovarian 200	Avelumab plus PLD vs. PLD vs. Avelumab	3.7 vs. 3.5 vs. 1.9 mo HR (combination vs. PLD) = 0.78 one-sided $P = 0.03$ HR (avelumab vs. PLD) = 1.68 one sided $P = 0.99$	Pujade-Lauraine <i>et al.</i> (2021) ^[41]

PLD: pegylated liposomal doxorubicin; mPFS: median progression-free survival; mo: months; HR: hazard ratio; TFIp: platinum-free interval; CI: confidence interval.

PNEOC patients with a BRCAm. ARIEL 4 (NCT02855944) is a Phase 3 study evaluating rucaparib vs. standard of care chemotherapy in patients with BRCA-mutated, relapsed ovarian cancer. Approximately half of the patients included in the trial had a TFIp of between 1 and 6 months, and the mPFS in this group was 6.4 months for rucaparib and 5.7 months for chemotherapy (HR 0.78, 95% CI 0.54-1.13)^[36].

VEGF inhibitors

Angiogenesis is a hallmark of cancer^[30], with neo-angiogenesis abundantly present in ovarian cancer. Antiangiogenic therapy plus chemotherapy has shown an improvement in responses and PFS in PEOC compared to chemotherapy alone^[3], and improvements in PFS have also been demonstrated in patients with a TFIp < 6 months in the Phase III AURELIA trial using the VEGF-A monoclonal antibody, bevacizumab, plus chemotherapy^[34], or in smaller randomised Phase II trials of VEGF-R small molecule inhibitors, pazopanib with weekly paclitaxel (MITO-11)^[37] or sorafenib with topotecan (TRIAS)^[38].

In AURELIA, the combination of bevacizumab with PLD, weekly paclitaxel or topotecan improved mPFS compared to chemotherapy alone in patients who relapsed after 1-2 prior lines of platinum^[34] [Table 2]. However, it remains unclear based on these data when it might be appropriate to stop chemotherapy in those continuing to respond to the combination.

Immune checkpoint inhibitors

The results of trials of Immune checkpoint inhibitors (ICPI) monotherapy in ovarian cancer have been disappointing. In two Phase II trials of programmed cell death protein-1/ligand-1 (PD-1/PD-L1) inhibitors, pembrolizumab and avelumab showed little benefit in ovarian cancer cohorts^[39-40]; however, it was hoped that in subgroups of patients including PNEOC patients, they may have a niche role.

Avelumab, either alone or in combination with PLD in platinum-resistant ovarian cancer (JAVELIN Ovarian 200), failed to show a significant OS benefit compared to PLD alone [Table 2]. However, exploratory analyses suggest there may have been a benefit of the combination in those with an initial response to earlier lines of chemotherapy^[41]. As a role for bevacizumab has been demonstrated in AURELIA, the question of whether ICPI enhances this benefit is relevant. NRG-Gy009 study

(NCT02839707), which has completed recruitment, compared the combinations of PLD and bevacizumab vs. PLD and atezolizumab vs. PLD and atezolizumab and bevacizumab; the results are awaited [Table 3].

Combining two ICPIs, such as anti-PD-1 and anti-cytotoxic T lymphocyte-associated-4 antibodies, may increase the activity of immunotherapy with evidence that nivolumab and ipilimumab showed a longer PFS than nivolumab alone (mPFS of 3.9 vs. 2 months), albeit with greater toxicity^[42]. However, these figures are notably comparable to those seen for single-agent non-platinum-based chemotherapies.

Other trials are exploring the use of maintenance immunotherapy after chemotherapy to improve PFS. One such study is the PROMPT Phase II trial, in which patients receive pembrolizumab after 4-6 cycles of weekly paclitaxel (NCT03430700).

NEWER STRATEGIES FOR OVERCOMING PLATINUM RESISTANCE

The above data show that with current regimens, mPFS is short, and tools to select patients likely to benefit most are required.

Refinements in patient selection for bevacizumab

There are currently no predictive biomarkers for bevacizumab response available in the clinic. Angiogenic markers, including micro-vessel density, CD31 expression and tumour VEGF-A levels, may provide prognostic information in recurrent ovarian cancer. These were identified in the Gynecologic Oncology Group (GOG) 218 study as potential predictive biomarkers for the use of bevacizumab^[43]. Another retrospective analytical study showed that a signature comprising alpha-1 acid glycoprotein, mesothelin, FLT4 and CA-125 identified those patients more likely to benefit from bevacizumab^[44]. In a concordance exploratory study of ICON7 samples, plasma concentrations of several angiogenesis-associated factors were determined using multiplex ELISAs, with high Ang1 and low Tie2 levels correlating best with PFS.

Tie1 and 2 are receptor tyrosine kinases that function as key regulators of blood vessel development and pathological processes including angiogenesis^[45]. One observational biomarker study (VALTIVE) is currently recruiting to determine the clinical value of measuring plasma Tie2 concentrations in ovarian cancer patients who are receiving bevacizumab (NCT04523116).

Novel treatments

Targeting Ataxia telangiectasia and Rad3-related

Targeting Ataxia telangiectasia and Rad3-related (ATR) is an important kinase regulating the DDR. It is responsible for sensing replication stress and signalling to cell cycle checkpoints to initiate repair^[46]. ATR inhibitors have been shown to reduce the rate of DNA repair in cells, thereby increasing DNA damage and apoptosis^[47]. Single-agent ATR inhibition appears to show some efficacy in PNEOC^[46].

G-Quadruplex (G4) stabilisation

G4 structures can form at thousands of sequences in the human genome and increase the propensity for DNA damage by impeding DNA polymerase, and thereby DNA damage repair processes^[48]. CX-5461 is a small molecule RNA polymerase transcription inhibitor that selectively kills HR deficient cancer cells by stabilising G4 structures^[49]. Phase 1 studies of CX-5461 are being investigated in solid tumours, including in a platinum/PARP_i resistant ovarian cancer cohort (NCT04890613).

Cell cycle checkpoint inhibition

The cell cycle checkpoint regulators CHK1 and CHK2 halt cell division to allow DNA damage to be

Table 3. Combination trials of interest

PLD: pegylated liposomal doxorubicin; HR: homologous recombination; ATR: Ataxia telangiectasia and Rad3-related; PARP: Poly (ADP-ribose) polymerase; PARPi: PARP inhibitor.

repaired before DNA replication^[50]. Cell cycle checkpoint inhibition may thereby prevent the progression of cancer cells through the cell cycle, halting replication and tumour progression. WEE-1 inhibitors block the activity of WEE-1 kinase, a G2 cell-cycle checkpoint, and enhance cancer cell apoptosis^[51].

Prexasertib is one example of a CHK1 inhibitor, which demonstrated responses in a phase II trial that were most marked in patients with platinum-resistant ovarian cancer^[52]. A phase II study of the combination of AZD1775, a WEE-1 inhibitor and carboplatin in platinum-resistant ovarian cancer, demonstrated an ORR of 43%^[53].

Epigenetic re-sensitisation

Treatment resistance is often associated with the accumulation of epigenetic changes^[54]. It has therefore been hypothesised that epigenetic modulation may re-sensitise tumours to platinum chemotherapy.

The DNA methyltransferase (DNMT) and Histone Deacetylase inhibitors have shown little activity as single agents in platinum-resistant ovarian cancer. However, in combination, they may enhance sensitivity to platinum by altering epigenetic regulation of gene expression. In a randomised phase II study assessing the DNMT inhibitor, guadecitabine in combination with carboplatin vs. investigator's choice of chemotherapy, the PFS rate at 6 months was 37% vs. 11%^[55]. The DNA damage initiated by DNMT inhibitors is repaired by the BER pathway, in which PARP1 plays a key role, and therefore there may also be a rationale to combine DNMT and PARP inhibition.

Combination approaches

Angiogenesis and PARPi

Antiangiogenic therapy has been shown to induce a hypoxic tumour microenvironment associated with the downregulation of HR genes^[56], providing the rationale to enhance the synthetic lethality of PARPi with angiogenesis inhibitors which also separately work to interfere with angiogenesis.

The Phase II AVANOVA2 trial compared the combination of niraparib and bevacizumab vs. single-agent niraparib in patients with PEOC^[57]. Niraparib plus bevacizumab significantly improved mPFS compared with niraparib alone (11.9 mo vs. 5.5 mo; HR 0.35, $P < 0.0001$) and has provided a rationale to test this strategy in PNEOC.

EVOLVE was a phase II trial of cediranib-olaparib in ovarian cancer progressing on PARPi, recruiting a cohort of patients who were also defined as platinum-resistant, with 2/10 patients in this cohort

demonstrating a PR^[58]. The anti-tumour activity of this combination continues to be assessed in the randomised Phase III NRG-Gy005 (NCT02502266) trial currently recruiting patients with platinum-resistant ovarian cancer to receive either olaparib, cediranib, olaparib-cediranib or investigator's choice of chemotherapy (paclitaxel/topotecan/PLD) [Table 3].

DDR response

In a large panel of acquired and *de novo* PARPi- and platinum-resistant CCNE1 amplified *in vitro* and PDX models, ATR and PARPi synergy was demonstrated^[59]. This, amongst other data, has provided the rationale for the combination of ceralasertib and olaparib for recurrent platinum-resistant ovarian cancer in CAPRI^[60]. Although no objective responses were demonstrated, the combination was well tolerated, and in two patients with BRCA1 mutations, a 50% fall in CA-125 was seen.

It will be interesting to see the data from the combination arm of ATARI (NCT04065269) in platinum-resistant ovarian clear cell cancer and carcinosarcomas, which may provide insights into how the combination of these drugs may alter the DDR in those subgroups of patients that do not classically display responsiveness to chemotherapy and PARPi [Table 3].

There is a clear rationale to combine other drugs regulating the DDR described earlier in this review, for example, WEE1 inhibitors, with platinum-based chemotherapy and PARPi.

Immunotherapeutic combinations

An alternative strategy is the combination of an ICPI with a PARPi, chemotherapy or other DDR modifying drugs. One possible mechanism of synergy is the observation that PARPi can activate the STING (stimulator of interferon genes) pathway to increase T-cell tumour infiltration^[61]. TOPACIO was a Phase 1/2 trial testing niraparib plus pembrolizumab in platinum-resistant ovarian and triple-negative breast cancer patients. A subgroup analysis of the ovarian cancer cohort showed that the combination was promising for patients without HR deficiency^[62]. There was a small cohort of patients in this group, and therefore other larger studies will need to focus on immunogenomic profiling to select patients most likely to benefit from this strategy.

CONCLUSION

Although the definition of true resistance to platinum-based chemotherapy has changed over the last four decades, few treatments have significantly changed outcomes in the vast majority of patients in this cohort. Next-generation sequencing has become faster and more affordable due to automation, which is permitting standardisation of techniques for analysing liquid biopsies and immunogenomic profiling. These refinements may lead to an improvement in patient selection for some of the novel strategies and combinations discussed in this review. Biomarker-driven trial designs will accelerate the better selection of and sequencing of treatment lines, including those targeting immune modulation, modification of the DNA damage response and angiogenesis inhibition.

DECLARATIONS

Authors' contributions

Abstract

A dysbiosis in microbial diversity or functionality can promote disease development. Emerging preclinical and clinical evidence emphasizes the interplay between microbiota and both disease evolution and the treatment response of different cancers. One bacterium that has garnered much attention in a few cancer microbiota studies is *Fusobacterium nucleatum* (Fn). To provide updated knowledge of the functional role of Fn in cancer prevention and management, this review summarizes the relationship among Fn, cancer, and chemoimmunotherapy response, with the potential mechanisms of action also intensively discussed, which will benefit the development of strategies to prevent or treat cancer via Fn-based therapeutic interventions.

Keywords: *Fusobacterium nucleatum*, tumor microenvironment, immune evasion, metastasis, chemoresistance

INTRODUCTION

Cancer, as the second leading disease-related cause of death in humans worldwide, affects almost all body regions^[1]. Currently, cancer progression and resistance to therapy remain major challenges in cancer treatment and the main causes of poor prognosis^[2]. Among the factors that contribute to cancer development and chemotherapy response, in addition to host genetic susceptibility and environmental exposures, a new and important player is emerging in regulating the development and drug resistance of cancer: microbiota^[3].

The conventional paradigm proposes that a balanced microbiota is positively health-associated, while damage in microbial diversity or functionality, including dysbiosis or unbalanced microbiota, can promote the development of disease, such as various cancers^[3-5]. Emerging preclinical and clinical evidence links the microbiota and their metabolites with carcinogenesis^[6]. Related studies revealed that cancer formation can be driven by microbial pathogens in 15%-20% of cancer cases^[7]. Bacteria *Prevotella gingivalis*, *Helicobacter pylori*, *Salmonella typhi*, *Prevotella melaninogenica*, *Chlamydia pneumoniae*, *Streptococcus mitis*, *Streptococcus bovis*, and *Capnocytophaga gingivalis* may cause different types of cancers in humans^[8-12]. Importantly, recent insights shed light on the influence of the microbiota on the response to chemotherapy. The interplay between the microbiota and both tumor evolution and the treatment response of different cancers, especially colorectal cancer (CRC), has recently been studied^[13]. One bacterium that has garnered wide interest in a few cancer-related microbiota studies is *Fusobacterium nucleatum* (Fn). Although Fn has been considered as an opportunistic pathogen for infections, its role as a cancer- or chemoresistance-causing member is revealed in various ways, by which Fn contributes to cancer initiation, progression, and the response to chemotherapy.

Based on these findings, we undertook a systematic review of the role of Fn as an oncobacterium. The research included in this review covers a period of 20 years, until the end of November 2021.

THE ROLE OF THE FN IN CARCINOGENESIS

Fn is a Gram-negative anaerobic bacillus that exists, among others, in the human oral cavity and the gastrointestinal tract. It exerts pro- or anti-pathogenic effects in the oral cavity affecting human periodontal health and diseases. The high abundance of Fn has been reported to be associated with head and neck cancer, esophageal cancer, pancreatic cancer, prostatic cancer, cervical carcinoma, and breast cancer [Figure 1]^[14-18]. Some investigators proposed that Fn is a passenger that multiplies under favorable conditions induced by malignant tumors^[19]. However, more research data support Fn as having a mechanistic role in driving carcinogenesis rather than being a microbial passenger, whose effects can be classified into three steps: initiation, promotion, and progression^[20]. In the following section, we review studies on the mechanisms by which Fn initiates and promotes carcinogenesis and enhances disease progression.

The first step: adhering to and invading human epithelial and endothelial cells

Fn accumulates in distant organ

Adherence and invasion are essential mechanisms for oncobacterium colonization, dissemination, and evasion, subsequently inducing a series of host responses. As one of the most abundant bacteria in the oral cavity, Fn can cause infectious inflammatory conditions at multiple body sites in addition to inflammation of the gingival tissue^[21-24]. It has also been proved that mislocalization of Fn is associated with many cancers. Although it seems possible that Fn directly spreads from the oral cavity to the colon, certain evidence demonstrates that Fn reaches distant sites of inflammation and tumorigenesis via a hematogenous route^[25,26]. However, how can an oral bacterium be implicated in so many infections and cancers within and

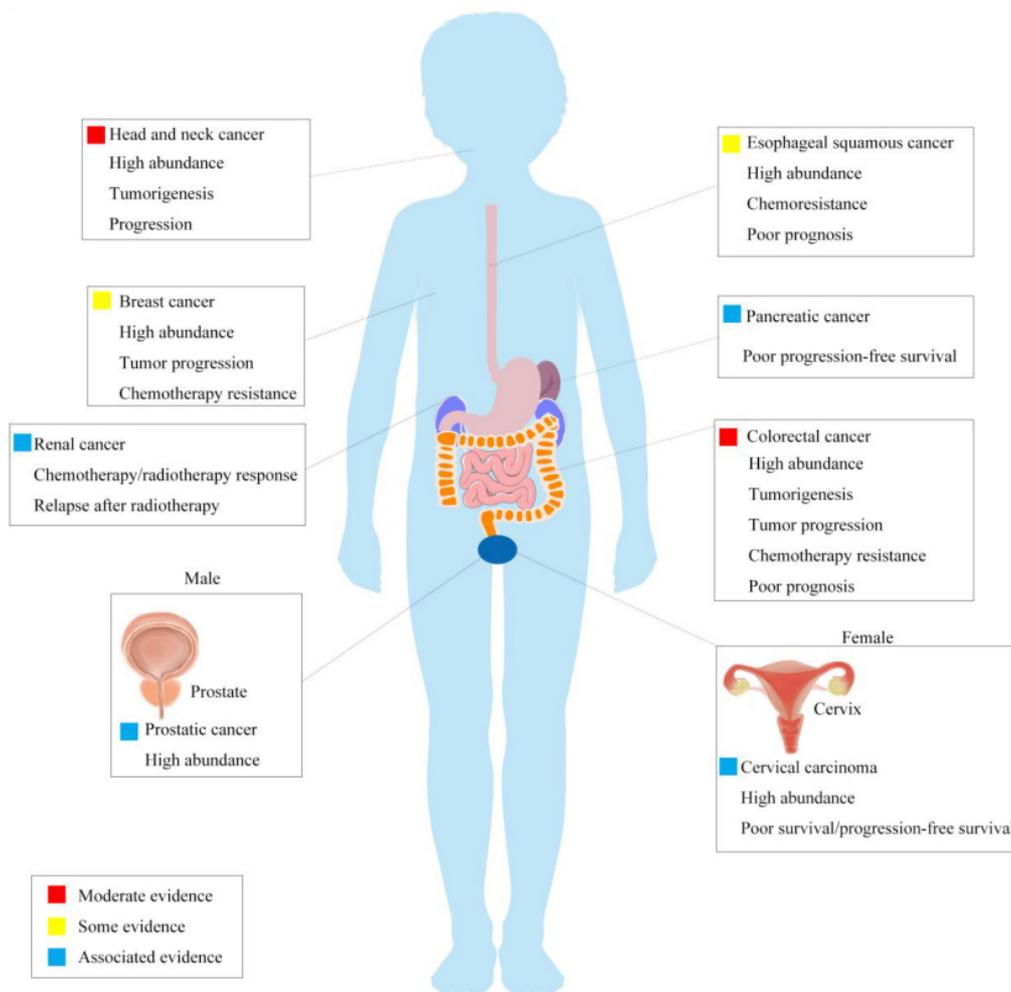

Figure 1. Different cancers associated with Fn. Fn is a Gram-negative anaerobic bacillus that exists, among others, in the human oral cavity and the gastrointestinal tract. For carcinogenesis, the high abundance of Fn is associated with head and neck cancer, esophageal cancer, pancreatic cancer, prostatic cancer, cervical carcinoma, and breast cancer. Relative events reported in each cancer are listed in the rectangles. Fn: *Fusobacterium nucleatum*.

outside the mouth? The main answer lies in two key virulence proteins expressed by Fn, FadA and Fap2, which are responsible for localization and colonization^[27-30].

Mechanisms of the key virulence proteins: FadA and Fap2

FadA of Fn has previously been identified to bind host cells. FadA mainly exists in two forms: the intact pre-FadA anchored to the membrane, comprising 129 amino acids, and the secreted mature FadA (mFadA), consisting of 111 amino acids^[31]. Pre-FadA and mFadA elicit internalization and form an active complex, FadAc, which leads to binding to host cell-junction molecules, cadherins^[31].

Two host receptors, epithelial cadherin (E-cadherin) and vascular endothelial cadherin (VE-cadherin), are found on host epithelial and endothelial cells, respectively^[32,33]. As cadherins are widely expressed in various tissues and cells, the binding of FadA to cadherins likely explains why it can colonize different sites outside oral. Further, the binding of FadAc and VE-cadherin on endothelial cells promotes VE-cadherin to transfer from cell-cell junctions to intracellular compartments, which increases the permeability of the endothelium.

After the activated FadAc binds specifically to the transmembrane domains of E-cadherin or VE-cadherin^[34], the molecules form a FadA-E-cadherin-AnnexinA1 (ANXA1)- β -catenin complex, which is then internalized to induce a series of host responses, such as activation of β -catenin signaling and elevated levels of oncogenic or inflammatory genes, transcription factors, and Wnt-related genes, thereby contributing to cancer initiation and promotion [Figure 2A]^[35].

The other Fn protein, the lectin Fap2, is an autotransporter protein. A transposon screen revealed the significance of Fap2 in mediating bacteria enrichment by binding of microbial and host cells^[36]. An overexpressed D-galactose-b (1-3)-N-acetyl-D-galactosamine (Gal-GalNAc) can be recognized by fusobacterial Fap2. Then, Fap2 directly binds to Gal-GalNAc and functions as a Gal-Gal-NAc lectin to mediate Fn attachment to tumor epithelial cells^[37], which subsequently inhibits immune cell cytotoxicity and activity [Figure 2B]^[38].

The second step: inducing host response for tumor initiation and promotion

DNA damage

DNA damage is broadly acknowledged to facilitate tumor initiation and promotion^[39]. It is recognized that bacteria could directly enhance DNA methyltransferase activity in cell lines and animal models^[40,41]. Fn infection is pervasive and is associated with tumor suppressor gene (TSG) promoter methylation^[40], promoting high microsatellite instability (MSI-H) and a high level of CpG island methylation (CIMP-H)^[42]. Kelly *et al.*^[43], Mima *et al.*^[44,45] and Ito *et al.*^[46] discovered that a high load of Fn was positively correlated with CIMP, MSI-H, and BRAF mutation in CRC tissues by univariate analysis. Tahara *et al.*^[47] also found that Fn-high CRCs were enriched in CIMP, MSI-H, hMLH1 methylation, wild-type p53, and mutant CDH7/8. Mechanistically, first, Fn might trigger TSG promoter hypermethylation by regulating the DNA methyltransferase. Interestingly, Lee *et al.*^[48] also revealed that Fn of high-load patients had higher rates of transition mutation and nucleotide change of C to T (G to A) compared with Fn-low patients regardless of MSI status. Additionally, Fn-high tumors were positively correlated with a higher mutation rate of APC membrane recruitment 1 and Ataxia telangiectasia mutated genes^[48]. Thus, Fn may induce promoter DNA methylation or genic mutation to drive tumorigenesis; however, the mechanism by which Fn affects these epigenetic or genetic alterations is not well understood. One potential interpretation is that Fn, involved in inflammation signals, enhances the production of reactive oxygen species (ROS) and recruits inflammatory cytokines. Although many reports suggest that ROS is associated with DNA hypermethylation, currently, there is no obvious evidence to prove that oxidative DNA damage causes genome-wide hypermethylation of promoter CpG islands and CG sites at other parts of the genome^[42]. One other possible mechanism for gene alteration is the dysregulation of Checkpoint kinase 2 (Chk2), which induces cell cycle arrest and apoptosis upon DNA damage. The data imply that Chk2 is related to DNA damage and progression via Fn-induced E-cadherin/ β -catenin pathway activation^[49].

Once DNA damage occurs, DNA double-strand breaks (DSBs), the most serious type of DNA damage, are repaired by homologous recombination and nonhomologous end joining (NHEJ). However, a deficient repair process results in malignant transformation. Ku70, an NHEJ initiation molecule, participates in DNA damage repair signaling by initiating apoptosis programs and activating cell cycle detection points. Geng *et al.*^[50] reported in 2020 that Fn could cause DNA damage and promote cell proliferation via the Ku70/p53 pathway in oral cancer cells. When suffering from an infection, Nei-like DNA glycosylase 2 (NEIL2), an oxidized base-specific DNA glycosylase, significantly relieves inflammation response and DNA damage. However, the protein level of NEIL2 is reported to be reduced in the progression of several types of cancer^[51]. A recent study demonstrated a suppressed expression of NEIL2 by Fn infection, which consequently increased DSB accumulation and inflammatory responses, contributing to the initiation and progression of CRC^[52].

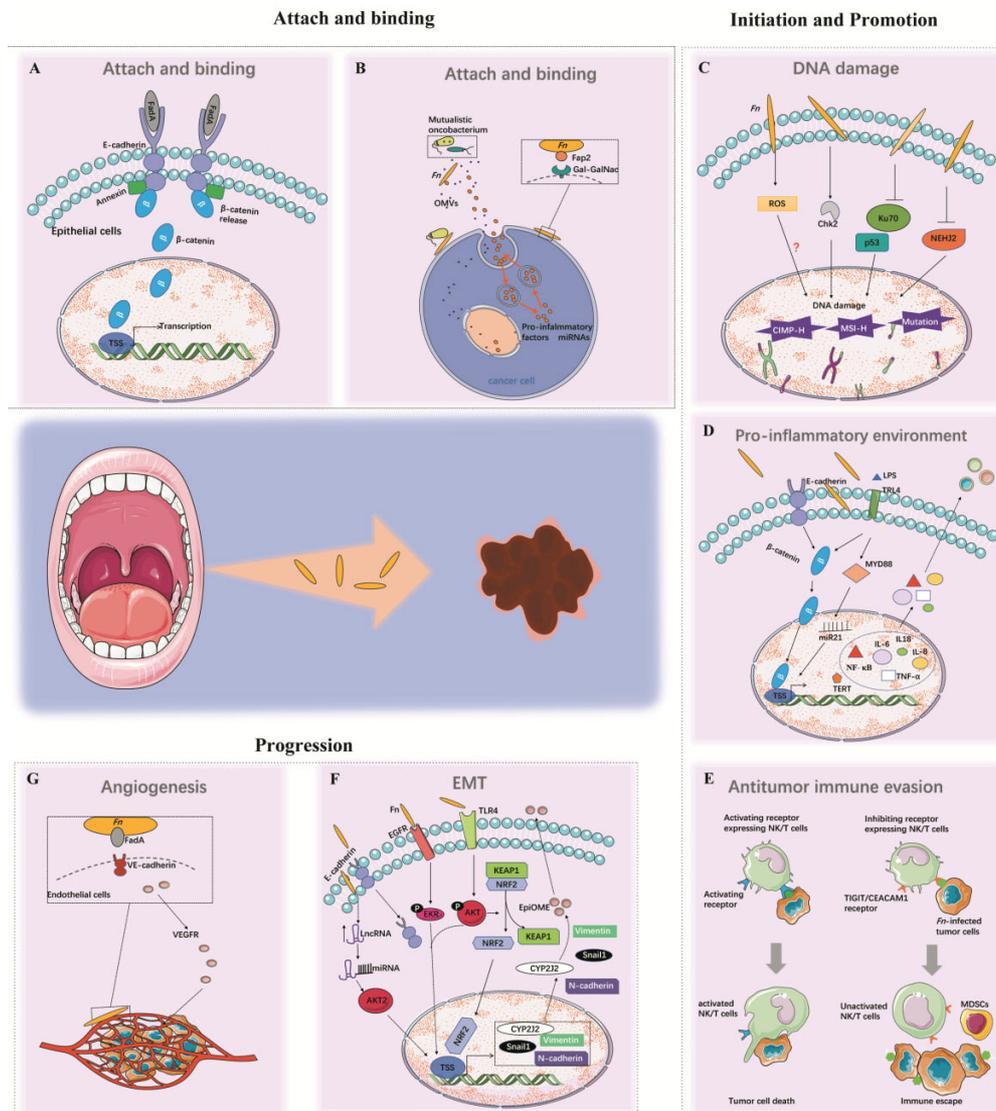

Figure 2. The mechanisms by which Fn initiates and promotes carcinogenesis and enhances disease progression. Fn plays an important role in the whole process of cancer carcinogenesis and progression, supporting the notion that Fn may have a causative role in different states of cancer rather than being a consequence of cancer development. (A,B) Mechanisms of FadA and Fap2 on host cell adherence and invasion. (C-E) Host responses for cancer initiation and promotion including DNA damage, antitumor immune evasion, and pro-inflammatory environment. (F,G) Fn-induced tumor invasion and metastasis for cancer progression. Fn: *Fusobacterium nucleatum*.

In summary, Fn infection induced promoter DNA methylation, genetic mutations, and a deficient DNA damage repair process, and hence it probably plays an essential role in tumor initiation and development [Figure 2C].

Pro-inflammatory microenvironment

Inflammation is well-recognized as a dominant force in cancer initiation. The NF-κB signaling pathway plays a vital role in activating the transcription of many inflammatory genes. Binding of FadAc to the transmembrane domains of E-cadherin induces phosphorylation and internalization of E-cadherin and accumulation of β-catenin, which consequently leads to the activation of β-catenin-regulated transcription (CRT)^[32]. Alternatively, Fn also activates β-catenin signaling through its lipopolysaccharides (LPS) via a TLR4/PAK1/β-catenin S675 cascade in CRC cells^[53]. Then, activated CRT increases the expression of Wnt

signaling genes (such as wnt7a, wnt7b, and wnt9a), NF- κ B (such as NF- κ B2), pro-inflammatory cytokines [including interleukin-6 (IL-6), IL-8 and IL-18], tumor necrosis factor- α (TNF- α), cyclooxygenase-2 (Cox-2), transcription factors (such as the lymphoid enhancer factor), T cell factors (such as TCF1, TCF3, and TCF4), and the oncogenes myc and cyclin D1^[32,54]. In addition, Fn-infected cells could enhance the expression of microRNA-21 (miR21) via activating TLR4 signaling to MYD88, which consequently activates the NF- κ B pathway and elevates telomerase reverse transcriptase expression^[55]. The former is correlated with the inflammatory response, while the latter confers an unlimited replicative potential to initial tumor cells^[56]. Fn further promotes the release of these inflammatory cytokines, particularly IL-8, IL-10, and TNF- α , and inflammasomes to form a pro-inflammatory microenvironment that accelerates cancer progression^[31,54,57]. Inflammasomes contain multiprotein complexes including the apoptosis-associated speck-like protein containing a CARD (ASC), procaspase-1, and a sensor protein, which is either a NOD-like receptor or an absent in melanoma 2 (AIM2)-like receptor^[58]. In oral squamous cell carcinoma (OSCC) cells, Fn infection promotes AIM2 inflammasome expression and potentially upregulates IL-1 β expression^[59]. These collective findings strongly suggest that the Fn-infected tumor microenvironment is highly inflammatory [Figure 2D].

Immunosuppressive microenvironment

NK cell and T cell inhibition

Immune evasion is a fundamental hallmark of cancer. One mechanism by which Fn causes immune evasion of tumor cells is the inhibition of the cytotoxicity and activity of natural killer (NK) cells. As a part of the innate immune system, NK cells directly and indirectly kill viruses, bacteria, cancer cells, and parasites^[60]. Signals from inhibiting and activating NK cell receptors determine NK cell activity. T-cell immunoglobulin and immunodominant tyrosine-based inhibitory motif domain (TIGIT), an inhibitory receptor expressed on NK cells, T cells, and tumor-infiltrating lymphocytes (TILs), inhibit NK cell and T cell activity or mediate human T cell arrest in the G1 phase of the cell cycle^[61]. The direct interaction of Fap2 protein of Fn and TIGIT causes inhibition of NK cell cytotoxicity and cytotoxic T lymphocyte cell death [Figure 2E]^[38]. The amount of Fn is reported to be inversely associated with CD3+ T cell density in CRC tissue^[62]. Another inhibitory receptor, CEACAM1, a member of the carcinoembryonic antigen-related cell adhesion molecules (CEACAMs), is expressed on the surface of T cells and NK cells^[63,64]. Previous studies reported that TILs express high levels of CEACAM1 and produce obviously less IFN- γ compared with T cells derived from para-cancer tissue, suggesting a substantial role of CEACAM1 in mediating T cell exhaustion^[65]. Most recently, Fn was proved to bind to and activate CEACAM1 to inhibit T cell and NK cell activities, which may help tumors evade immune cell attack by an additive mechanism^[65]. However, the functional mechanism of Fn binding to CEACAM1 is unknown and needs further investigation.

MDSC attraction

Another major immunosuppressive cell population is myeloid-derived suppressor cells (MDSCs), a group of CD11b+CD14+CD33+HLADR-immature myeloid cells that express high levels of inducible nitric oxide synthase and arginase-1 and show strong activity in depressing T cell proliferation and inducing T cell apoptosis^[66]. MDSCs and their effectors are key components of the neoplasm to promote tumor progression^[60,67]. Cancer-associated Fn selectively attracts MDSCs and increases the myeloid-lineage infiltrating cells including tumor-associated macrophages (TAMs), tumor-associated neutrophils, CD11b+, M2-like TAMs, conventional myeloid dendritic cells (DCs), and CD103+ regulatory DCs [Figure 2E]. These cells were shown to dampen antitumor immunity and promote tumor progression and angiogenesis^[15,66,68-70].

Additional microenvironmental complexities

Fn has evolved in interaction not only with human cells and tissues but also with the oral microbiota. With its long rod shape, Fn could bind with many other microbial cells, such as *Streptococcus sanguinis* (*S.*

sanguinis)^[71]. When co-cultured with *S. sanguinis*, Fn combined with *S. sanguinis*, and together they assembled into highly corn-cob-like structures; in this way, a single Fn can bind with up to ten *S. sanguinis* cells. This biological behavior of Fn makes it possible to mediate important biofilm-organizing behavior and interactions with host cells [Figure 2B]. In fact, Fn is usually found to be co-existent in tumors with other microorganisms, especially *Leptotrichia spp.* and *Peptostreptococcus spp.*, which mirrors how they are found to be interacting in the oral cavity^[72,73]. Notably, Fn is frequently found co-occurring with *Campylobacter spp.*, another important gastrointestinal pathogen, in the same cancer tissues^[73]. Continual intake of *P. gingivalis* and Fn promote tumor progression in a 4-nitroquinoline-1-oxide (4NQO)-induced mouse tongue cancer model by triggering TLR/STAT3 signaling^[74]. Infection of macrophages by co-culturing with Fn and *P. gingivalis* enhances inflammasome activation more strongly than when infection with Fn alone^[75]. Fn also strengthens the invasive ability of *P. gingivalis*, indicating that these bacteria may act synergistically to develop an inflammatory-permissive and tumor-promoting environment^[76]. Together, these observations suggest that crosstalk between the microbiota may function as a contributor to carcinogenesis.

FINALLY: FN PROMOTE INVASION AND METASTASIS

Relatively little is known about how Fn might impact cancer progression at the later stages of carcinogenesis and metastasis, which determine poor prognosis in patients, despite the detection of Fn in CRC metastases to the liver and lymph nodes.

Epithelial-mesenchymal transition

During cancer progression, activation of the epithelial-mesenchymal transition (EMT) program is another complex hallmark, broadly facilitating local invasion and distant metastasis^[77]. Expression of EMT markers is significantly associated with Fn level in CRC tissues, indicating the potential involvement of Fn in EMT-colitis-associated cancer (CAC) crosstalk during cancer progression^[78]. The role of Fn in CAC progression was further verified in mouse models, as Fn apparently enhances the aggressiveness and EMT alteration of CRC cells that were treated with dextran sodium sulfate compared with untreated ones. This promoting effect of Fn was dependent on activation of the EGFR/AKT/ERK pathway^[79]. Previous studies have found that Cytochrome P450 (CYP) monooxygenases, primarily Cytochrome P450 2J2 (CYP2J2), were involved in tumor progression and cancer drug resistance^[80,81]. 12,13-epoxyoctadecenoic acid (12,13-EpOME), the CYP2J2-mediated metabolite product, was also reported to be associated with various human diseases^[82]. A recent finding demonstrates that CYP2J2 and its oncogenic metabolite 12,13-EpOME are heavily enriched in Fn-abundance CRC patients. Further, overexpression of CYP2J2 or 12,13-EpOME dramatically promoted the invasion and migration of CRC cells and resulted in a mesenchymal phenotype. Mechanically, Fn infection activates TLR4/AKT/Keap1/NRF2 signaling to upregulate cytochrome CYP2J2 expression in CRC cells, which then increases the production of 12,13-EpOME, finally resulting in EMT^[83]. Fn drives cell migration by upregulating mesenchymal markers Vimentin, N-cadherin, and snail1 in human noncancerous immortalized oral epithelial cells (OEC) and OSCC cell lines^[84,85]. In a preliminary study by Fujiwar *et al.*^[86], co-culture with Fn promoted the invasion of OSCC cells by upregulating EMT genes. Another study demonstrated that Fn infection could upregulate the level of lncRNA MIR4435-2HG, which specifically binds with miR-296-5p to weaken the ability of miR-296-5p to silence its target gene Akt2, subsequently activates the expression of snail1, and eventually accelerates EMT in the infected OECs [Figure 2F]^[86].

Extracellular product in tumor microenvironment

Different researchers using a similar *in vitro* method demonstrated that Fn infection enhances migration of human CRC-derived HCT116 cells^[87]. These include inducing secretion of IL-8 and C-X-C motif chemokine ligand 1 (CXCL1), upregulating caspase activation and recruitment domain 3 (CARD3) to activate autophagy, and activating NF- κ B to regulate miR-1322 or enhancer of B cell-dependent Keratin7-

antisense/Keratin7 (KRT7-AS/KRT7), which are associated with increased metastatic potential and poor prognosis^[88-91].

In addition, Fn-infected CRC cells release exosomes carrying metastasis-related miR-1246/92b-3p/27a-3p and CXCL16/IL-8, particularly strongly inducing metastasis. These exosomes are then internalized to induce upregulation of β -catenin, cellular MYC proto-oncogene, cyclin D1, and the mesenchymal markers in CRC cells, implying broad cancer promoting effect of Fn exosomes and driving uninfected recipient cells toward a pro-metastatic phenotype^[92].

As a Gram-negative bacterium, Fn can secrete outer membrane vesicles (OMVs), containing proteins, lipoproteins, phospholipids, and LPS, which act as a delivery system for virulence factors [Figure 2B]^[93]. OMVs interact with host epithelial cells through surface proteins and adhesion molecules^[94]. Intra-OMV proteases of Fn further degrades host E-cadherin, which facilitates bacterial invasion, inflammatory responses, and EMT.

Angiogenesis

Angiogenesis is necessary to provide nutrients and oxygen to tumor cells for further growth and tumor progression. Fn potentially activates the autocrine function of endothelial cells, resulting in a higher release of VEGF, VEGFR1, and VEGFR 2, which is favorable for proliferation and metastasis [Figure 2G]^[95]. In another way, Fn-attracted MDSCs reduce infiltration of T cells into the tumor and increase expression and promote secretion matrix metalloproteinase 9 (MMP-9) and MMP-13 to promote angiogenesis^[79].

ROLE OF FN IN CANCER DRUG RESISTANCE

The development of drug resistance is the major cause of cancer therapy failure, affects cancer progression, and results in a poor prognosis. A growing body of evidence implies that microorganisms could modulate the host response to chemotherapeutic and immunotherapeutic drugs. Increased Fn abundance tracks with tumor stage and is associated with chemotherapy response^[90,96-99]. Inhibiting the growth of Fn significantly augments the first-line chemotherapy efficiency in CRC^[100]. Specific mechanisms of drug resistance may vary with different cancers and drugs. Currently, the research on Fn-mediated drug resistance mainly focuses on 5-fluorouracil (5-FU), oxaliplatin (OXA), and cisplatin (CDDP).

Autophagy pathway

The *in vitro* assay results performed by two research groups provide an insight into Fn-induced chemoresistance via the autophagy pathway in CRC and esophageal squamous cell carcinoma (ESCC) cells. They found that Fn increased the level of multiple autophagy-related genes, such as those encoding ATG7, ULK1, Beclin-1, and LC3-II. One group reported that Fn modulates the endogenous LC3 and ATG7 expression to confer chemoresistance against 5-FU, CDDP, and docetaxel in ESCC [Figure 3A]^[101]. Moreover, the chemoresistance induced by Fn was reversed by inhibiting autophagy through ATG7 knockdown. The results from Yu's study indicate that Fn induces CRC resistance to OXA and 5-FU. Mechanistically, Fn intervention induces a selective loss of miR-4802 and miR-18a*, leading to TLR4/MYD88-dependent autophagy activation and a CRC chemotherapeutic response [Figure 3B]^[102]. These studies provide insight into the role of Fn in the modulation of drug resistance through the regulation of autophagy in host cells.

Apoptosis blocking

Inhibitors of apoptosis proteins (IAPs) are characterized by the presence of baculoviral IAP repeat (BIR) domains, exerting the binding and inhibition of caspases. Baculoviral IAP repeat-containing protein 3

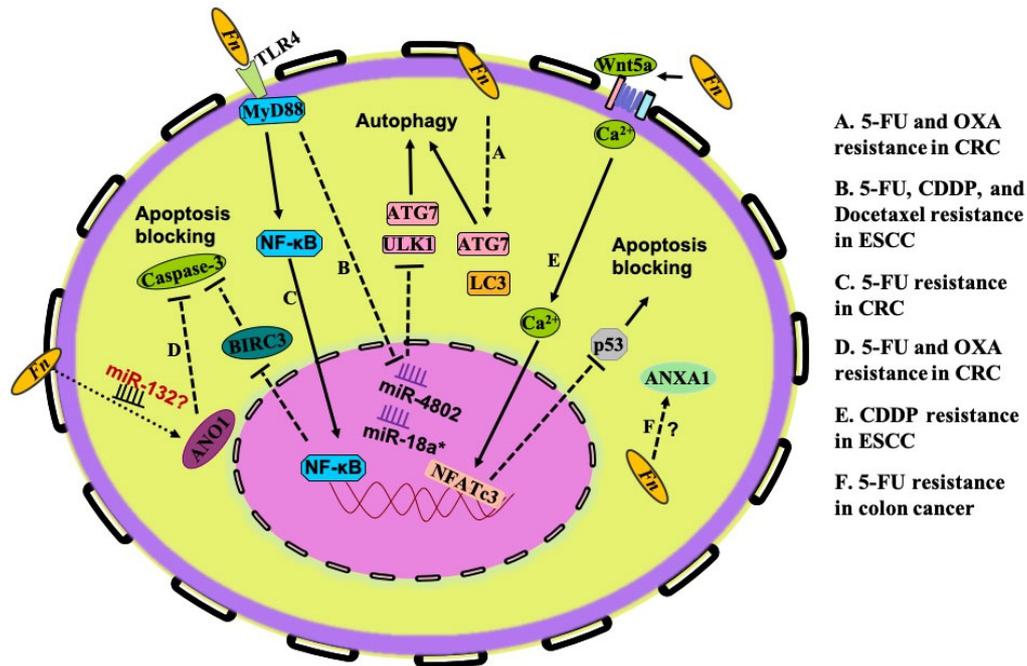

Figure 3. Specific mechanisms of drug resistance induced by Fn. The research on Fn-mediated drug resistance mainly focuses on autophagy activation (A,B) and apoptosis blockade (C-F). (A) Fn modulates endogenous LC3 and ATG7 expression to induce chemoresistance against 5-FU, CDDP, and docetaxel in ESCC. (B) Fn intervention induces a selective loss of miR-4802 and miR-18a*, leading to TLR4/MYD88-dependent autophagy activation and a CRC chemotherapeutic response to OXA and 5-FU. (C) Fn-mediated TLR4/MYD88/NF- κ B pathway activation induces upregulation of BIRC3, which consequently cripples the level of cleaved caspase 3 and cleaved PARP caused by 5-FU. (D) In colon cancer cells, the apoptosis effects induced by OXA and 5-FU could be prevented by Fn-induced ANO1 upregulation. (E) Fn-induced overexpression of ANXA1 confers 5-FU resistance in colon cancer cells, but the specific mechanism needs further investigation. (F) Fn may downregulate p53 expression through the non-canonical Wnt/NFAT pathway to inhibit CDDP-induced apoptosis and migration in OSCC cells. Fn: *Fusobacterium nucleum*; 5-FU: 5-fluorouracil; OXA: oxaliplatin; CRC: colorectal cancer; CDDP: cisplatin; ESCC: esophageal squamous cell carcinoma; BIRC3: baculoviral IAP repeat-containing protein 3; ANO1: Anoctamin-1; ANXA1: Annexin A1; OSCC: oral squamous cell carcinoma; PARP: poly ADP-ribose polymerase.

(BIRC3), a member of the IAP family, can inhibit apoptosis by directly inhibiting the caspase cascade to promote chemoresistance in malignancies^[103-105]. It is reported that Fn infection protects CRCs from 5-FU-mediated apoptosis. The action mechanism is that Fn-mediated TLR4/MYD88/NF- κ B pathway activation induces upregulation of BIRC3, which consequently cripples the level of cleaved caspase 3 and cleaved poly ADP-ribose polymerase (PARP) caused by 5-FU [Figure 3C]^[106]. Anoctamin-1 (ANO1), as one of the human chloride channel proteins, is frequently upregulated in different types of human cancers and is involved in AKT and MAPK signaling activation, which plays a critical role in cancer progression. Research data indicate that Fn promotes ANO1 expression in colon cancer cells and that the OXA- and 5-FU-induced apoptosis could be prevented by ANO1 [Figure 3D]^[103]. Based on the fact that ANO1 is a target of miR-132, which has a crucial role in CRC progression, and the effect of Fn on miRNAs, some authors hypothesized that Fn prevents apoptosis in CRC via the ANO1 pathway involved in modulation of the amounts of miRNA^[107]. Annexin A1 (ANXA1) is a calcium-dependent phospholipid-linked protein that is involved in drug resistance, has anti-inflammatory effects, and regulates cellular differentiation, proliferation, and apoptosis. Onozawa *et al.*^[108] reported that Fn-induced overexpression of ANXA1 confers 5-FU resistance in colon cancer cells, but the specific mechanism needs further investigation [Figure 3E]. The nuclear factor of activated T-cells (NFAT) is a downstream effector of the non-canonical WNT/Ca²⁺ signaling pathway that has been demonstrated to promote the migration of tumor cells and restrain apoptosis^[109]. According to a study in 2021 conducted by Da *et al.*^[110], Fn downregulates p53 expression to

inhibit CDDP-induced apoptosis and migration of OSCC cells. Probing into the mechanism, they found that Fn may downregulate p53 and E-cadherin through the non-canonical Wnt/NFAT pathway and induce drug resistance in Cal-27 and HSC-3 of CDDP [Figure 3F].

PREVENTION STRATEGIES

The above findings not only explain the correlation between Fn abundance and the mechanisms of tumor initiation, promotion, and progression but also raise the question of whether patients with a high abundance of Fn could benefit from an Fn-directed therapy before or concomitant with chemotherapy.

Most clinical isolates of Fn are sensitive to a number of antibiotics, including metronidazole and clindamycin and some β -lactam antibiotics. In patient-derived xenograft models of CRC with Fn enrichment, treatment with metronidazole reduced Fn load and impaired cancer cell proliferation and overall tumor growth, suggesting that Fn-abundant tumors may benefit from anti-fusobacterial therapy^[72]. However, owing to the diversity of microbiota, implementing such an antibiotic intervention would be problematic in many ways. This is because antibiotics non-selectively kill both pro- and anti-tumoral bacteria. To avoid such a problem, a gut microbiota-modulatory therapy based on phage-guided biotic-abiotic hybrid nanomaterials was described by Zheng *et al.*^[100]. In brief, they first isolated a phage strain from human saliva that could specifically lyse Fn. Then, they encapsulated irinotecan (IRT), a first-line drug against CRC, within dextran nanoparticles (DNPs) to form IRT-loaded DNPs (IDNPs). Finally, using a bioorthogonal reaction, they covalently linked IDNPs to azide-modified phages (A-phages) to construct a phage-guided biotic-abiotic hybrid nanosystem^[100]. *In vivo* experiments were then carried out to demonstrate that A-phages accumulated in CRC tumors and that the oral administration of the nanosystem eliminated intra-tumor Fn, which inspires future treatment strategies for tumors with Fn abundance. Alternatively, an Fn-specific narrow-spectrum antibiotic might be beneficial, but due to concerns about antibiotic resistance for both broad- and narrow-spectrum antibiotics, strategies targeting virulence or interaction receptors between Fn and host cells may be more promising^[15]. The Fn adhesin Fap2 and TIGIT/TLR4 may be attractive targets as they promote Fn enrichment, compromise antitumor immunity, and confer chemoresistance. An Fn-directed vaccine target at FomA (an outer membrane protein expressed by Fn that functions in bacterial co-aggregation and biofilm formation) that elicits immune response has already been tested^[111]. However, data concerning the incidence of CRC after receiving the vaccine are still lacking. Further, Brennan *et al.*^[15] argued that, even if the vaccination can elicit certain types of immune responses (such as human versus T cell responses), some Fn strains still escape from the immune killing effect in their intracellular phase^[112]. Alternatively, T cell-inducing vaccines, similar to those vaccines targeting malaria and tuberculosis, might produce a preferable strategy for Fn. Microbial ecosystem replacement, using consortia of designed microorganisms or designed cocktails of human-derived isolates, may be another option to change the tumoral microbiota that potentially harbors Fn enrichment. This approach is clinically on trial with *Clostridium difficile* and might be tested in the future to exclude Fn.

CONCLUSION

Fn is a multidimensional bacterium that engages in interactions ranging from beneficial to detrimental in nature with other microorganisms and humans. Some researchers suggested that Fn is a passenger rather than a driver in disease states^[113]. However, from the above review, we can conclude that Fn plays an important role in the whole process of cancer initiation, disease progression, and chemotherapy resistance, supporting the notion that Fn may have a causative role in different states of cancer rather than being a consequence of cancer development and chemoresistance. Nevertheless, it is still unknown how Fn transforms from a beneficial bacterium to a harmful one. Before we consider Fn-targeted treatments, we must obtain more knowledge about the basic biology of Fn. Two important challenges within this issue are:

(i) investigating how Fn strains and levels in different organs affect cancer; and (ii) understanding the mechanistic complex interactions of Fn-microbe-host within the tumor microenvironment^[6]. Only by continuous investigation of the mutualistic and pathogenic characters of Fn will we reveal the divergent ways that can be used for diagnostic, preventive, and therapeutic purposes.

DECLARATIONS

Abstract

PolyADP ribose polymerase inhibitors (PARPi) have transformed the treatment of ovarian cancer. Particularly in high-grade serous ovarian cancer (HGSOC), a disease characterized by homologous recombination deficiency (HRD), PARPi have had a rapid and profound impact on the disease course, as well as biologic and biomarker definitions of HGSOC, thereby creating a paradigm shift in the approach to treatment. In this review, we discuss the role of PARPi in the maintenance treatment of HGSOC, its effect on platinum sensitivity, and cross-resistance between platinum and PARP inhibitors.

Keywords: PARP inhibitors, olaparib, niraparib, ovarian cancer, maintenance therapy

INTRODUCTION

Ovarian cancer is a chemosensitive disease with chemosensitivity to platinum-based chemotherapy being at least in part due to defects in homologous recombination (see below). However, the majority of the patients recur after platinum-based chemotherapy, typically within 18-24 months of the treatment completion. One

of the most reliable predictors of response to subsequent chemotherapy is the duration of progression-free interval (PFI), defined as the interval between completion of the last cycle of platinum-based chemotherapy and the time of disease recurrence (progression)^[1]. According to Markman's original observation, the disease that recurs within 6 months of completion of the last platinum-based chemotherapy is considered platinum resistant, whereas recurrence after a PFI of 6 months is considered platinum-sensitive [Table 1]^[1]. More recently, another category has been introduced - platinum refractory - for the disease that progresses during the platinum-based regimen or within 4 weeks of the last cycle [Table 1]^[2]. In addition, the partially platinum-sensitive disease was designated as a subgroup of the originally defined platinum-sensitive disease, and it applies to recurrences between 6-12 months from the completion of platinum-based chemotherapy [Table 1]. Initially, the definition of platinum sensitivity applied only to the first recurrence; however, subsequently, the term has been used even beyond 2nd line chemotherapy^[3]. Platinum sensitivity is based on retrospective clinical observations and some clinicians consider it as a continuum. It is important to know that platinum response remains one of the most critical determinants of clinical management of patients with ovarian cancer, and it is a very important parameter in the design of clinical trials, although there has been some variability in the way the disease categories have been used in trials^[4]. In general, most patients with ovarian cancer will have a platinum-sensitive disease; this group has a predictable response rate of over 60% to subsequent 2nd line chemotherapy and an expected duration of response of 9-13 months. Patients with partially platinum-sensitive disease, when treated with platinum-based chemotherapy at the time of recurrence, typically achieve a response rate of 39% and median progression-free survival (PFS) of 9.4 months^[5]. In platinum-resistant disease, 16% (\pm 12%) of patients can be expected to demonstrate benefit, albeit in most cases with a shorter interval before disease progression^[6]. Finally, primary platinum-refractory ovarian cancer is uncommon, frequently of non-high grade serous subtype, and has an unfavorable prognosis.

PARP INHIBITORS: OVERVIEW

PolyADP ribose polymerase inhibitors (PARPi) have changed the treatment landscape of ovarian cancer in a relatively short time. PARPi initially entered the clinic based on the ability to block base excision repair resulting in the accumulation of double-strand DNA breaks that were synthetically lethal with defects in homologous recombination mediated by mutations in *BRCA1/2*. High-grade serous ovarian cancer has subsequently been demonstrated to have defects in genes involved in homologous recombination DNA repair in at least 50% of cases. Based on these observations, PARPi moved quickly from the laboratory to clinic in the span of 2005 to 2009^[7,8]. PARPi are approved in ovarian cancer both for treatment of recurrent disease and for maintenance of response to platin agents. Three PARPi have been approved as single-agent therapy for patients who have progressed after multiple prior lines of chemotherapy, showing remarkable activity even late in the disease course. In 2014, olaparib was approved for the 4th line treatment for patients with germline *BRCA* mutations based on the results of Study 42, a single-arm phase 2 study^[9]. This was followed by the approval of rucaparib as 3rd line treatment for patients with germline and somatic *BRCA* mutations (Ariel 2 and Study 10)^[10,11]. Finally, in 2019, niraparib was approved in HRD platinum-sensitive late recurrence treatment, with a remarkable response rate of 24% compared with an average 6% response rate in the late recurrent setting (Quadra trial)^[12]. Subsequent studies have demonstrated activity in earlier stages of therapy and have further demonstrated combination activity with multiple different agents in ovarian cancer. While optimal activity is observed in patients with defects in homologous recombination pathway, there remains a limited activity in patients without HRD as detected by current assays. Whether this represents a failure of current assays to identify all patients with HRD or activity of PARPi outside of HRD remains to be fully elicited.

Table 1. Platinum sensitivity/resistance classification

Platinum sensitivity classification	Refractory	Resistant	Partially sensitive	Sensitive
Timing of initial progression	Chemotherapy	0-6 months→	6-12 months→	> 12 months→
Probability of 2nd line platinum response (%)	0	< 10	39	> 60

The success of the PARPi therapy studies in patients with germline and somatic *BRCA* mutated ovarian cancer opened the door to the utilization of PARPi for maintenance in the setting of recurrent platinum-sensitive ovarian cancer. In each of the subsequent 2nd line maintenance studies, PFS was extended for patients with platinum-sensitive disease, with a degree of benefit relative to genetic biomarker status [Table 2]. In SOLO2, a phase 3 study of olaparib maintenance in platinum-sensitive recurrence, there was a PFS difference of 19 vs. 5 months in patients with germline *BRCA* mutations receiving olaparib vs. placebo^[13]. In Ariel 3, the PFS doubled from 5.5 to 10.8 months with a hazard ratio (HR) of 0.36 in intention to treat patients with somatic *BRCA* mutation on rucaparib maintenance^[14]. The Nova trial showed remarkable efficacy of niraparib, but the degree of benefit was relative to biomarker status. Trial participants who received niraparib had a significantly longer median PFS than those in the placebo group in all three pre-specified groups: 21 vs. 5.5 months (HR: 0.27) for the germline *BRCA* group; 12.9 vs. 3.8 months (HR: 0.38) in the HRD subgroup of the non-germline *BRCA* cohort; 9.3 months vs. 3.9 months (HR: 0.45; 95%CI: 0.34 to 0.61) in the overall non-germline *BRCA* mutation cohort^[15].

After significant success with the use of PARPi in the recurrent setting, and with 80% of patients initially platinum sensitive, PARPi were then explored as first-line maintenance in clinical trials with the hope not only for prolonged PFS, but also the extension of overall survival (OS). Of note, prior clinical trials utilizing chemotherapy with taxol and topotecan as initial maintenance therapy^[16-18] showed 8 months PFS advantage, but no impact on OS^[16]. Bevacizumab maintenance in the up-front setting (GOG 218) has also failed to improve OS^[19]. Irreversible toxicities of taxanes and bevacizumab include neuropathy, fistula, and stroke. Therefore, prior to moving PARPi to first-line maintenance, most patients with a major response to a platinum analog were in a “watch and wait” period following completion of primary treatment.

SOLO1 changed the landscape of primary maintenance in ovarian cancer^[20]. In the trial, approximately 400 patients with *BRCA* mutations (germline > somatic) were randomized to receive olaparib or a placebo. After nearly 41 months of follow-up, the treated group had a 70% lower risk of disease progression or death than the placebo group (HR: 0.30). Sensitivity analysis showed absolute longer PFS/PFI with olaparib. The median time to the first subsequent therapy or death was 51.8 months in the olaparib group vs. 15.1 months in the placebo group (HR: 0.30; 95%CI: 0.22 to 0.40) [Table 2]. Two other phase 3 trials in frontline maintenance were completed. Olaparib alone was compared to bevacizumab plus olaparib in the Paola-I study, which showed impressive benefit in the intent to treat a population with HR of 0.58^[21]. In the Prima study within HRD population, the median duration of PFS was 22.1 months in the niraparib group and 10.9 months in the placebo group (HR: 0.40; 95%CI: 0.27 to 0.62) in the subgroup with *BRCA* mutations; in the HRD+ group with no *BRCA* mutation, median PFS was 19.6 months vs. 8.2 months in niraparib and placebo groups, respectively (HR: 0.50). In the subgroup of patients with homologous-recombination proficiency, the median duration of PFS was 8.1 months in the niraparib group and 5.4 months in the placebo group (HR: 0.68), leading to FDA approval of niraparib for all patients in the first-line maintenance [Table 2]^[22].

PLATINUM AND PARP INHIBITOR RESISTANCE

As noted above, HRD contributes in part to platinum sensitivity in high-grade serous ovarian cancer. Perhaps the most cogent evidence supporting this contention is the “healing” of defects in *BRCA1/2* in patients treated with platinum analogs. This “healing” reconstitutes HR and contributes to platinum resistance. Given that resistance to PARPi is frequently due to reconstitution of HRD including “healing” of defects in *BRCA1/2*, it is reasonable to assume that PARPi treatment could contribute to resistance to platinum analogs. Furthermore, since patients can receive PARPi maintenance therapy for prolonged periods of time (> 1 year), there is a potential for PARPi to alter the response to retreatment with platinum analogs. In an alternative concept, could the prolonged period of PARPi therapy actually increase the response to platinum retreatment due to the long intervening period? At a minimum, however, the intervening treatment with PARPi requires that we redefine the concept of what period of time from prior platinum treatment would warrant retreatment with a platinum analog rather than moving to a different therapeutic alternative.

In the case of PARPi, the most important issue to address is the question of how sensitive recurrences after maintenance PARPi are to subsequent platinum-based chemotherapy due to the overlap in sensitivity and resistance mechanisms. The initial studies suggest possible cross-resistance between PARPi and platinum^[23]. MITO, a retrospective study of 234 patients with *BRCA1/2*-mutations, found that patients with progression on olaparib had lower than expected response rates to subsequent platinum therapy, with a response rate of 22% in patients with a PFI > 12 months at the time of recurrence^[24]. Similarly, Frenel *et al.* reported a secondary analysis of SOLO2 to show that recurrences after olaparib were less sensitive to subsequent platinum treatment compared to patients who received placebo as maintenance, with time to second progression being 14 months vs. 7 months in favor of the placebo group^[25]. Lheureux *et al.* studied 34 patients who had progressed on a prior PARPi and were treated with olaparib and cediranib^[26]. The study identified mechanisms of resistance among 19 patients: *BRCA1/2* reversion, *BRCA1/2* over-expression, multi-drug resistance protein overexpression, and *CCNE1* amplification/overexpression^[26].

Moreover, from ARIEL studies of rucaparib where pretreatment biopsies were required, data showed that patients with BRCA mutation reversions had a shorter PFS with rucaparib than those with no BRCA mutation reversion^[27]. Other cross-resistance mechanisms to PARPi include (i) *BRCA1* alternative splicing^[28]; (ii) *53BP1* loss^[29]; (iii) *ABCB1* gene fusions^[30]; and (iv) loss of BRCA1 methylation^[27].

In patients who progress after olaparib as first-line maintenance, the time to recurrence is crucial to the definition of platinum sensitivity in the context of response to further chemotherapy. This is currently being investigated in the OREO clinical study. Although the initial results suggest that recurrences after a period of at least 24 months may respond favorably to subsequent platinum, additional analyses are needed to precisely discern the degree of platinum sensitivity and particularly the duration of response after PARPi treatment. For example, the reported median PFS in the placebo group of only 2.8 months raises the question of whether a platinum regimen has a very low activity even in responders previously treated with PARPi, or whether the high number of previous lines of therapy in the OREO trial explains the short PFS in a group of patients responding to platinum. Furthermore, one should have a clearer understanding of the degree of benefit from retreatment with a PARPi for patients with *BRCA*-associated tumors whose disease did not progress during PARPi as frontline maintenance compared to patients who were treated with PARPi with subsequent progression. A small study of 22 patients previously treated with PARPi showed that both groups experienced the benefit of retreatment with PARPi, suggesting that the development of resistance is not necessarily universal with prior exposure and progression on PARPi^[31].

The complexity of biologic responses to chemotherapy after PARPi maintenance-and to some extent following bevacizumab maintenance as well-has led experts to recommend the use of treatment-free interval (TFI), as opposed to platinum sensitivity status, to more broadly assess whether intervening maintenance agents impact disease response to subsequent treatment^[32]. It was proposed that TFI be defined as the period from the last disease-directed therapy, including PARPi, platinum-based, and biologic agent treatments (typically bevacizumab)^[32]. The TFI concept gives us the opportunity to address unanswered questions regarding the length of maintenance treatment with PARPi as first-line maintenance. The current studies have recommended olaparib for 2 years and niraparib for 3 years in frontline maintenance. The time of recurrence and whether the recurrence occurs on treatment vs. after completion of prescribed maintenance is associated with the duration of platinum sensitivity. In that sense, it would be important to have a uniform established duration of the first-line maintenance treatment. Finally, there is also a need to determine whether patients who progress on PARPi after an initial response to platinum agents will benefit from retreatment with a platinum analog and to what degree compared to alternative treatment approaches.

As platinum sensitivity may be considered as a continuum, and with maintenance treatment having moved to first-line platinum responders, there is an opportunity to better understand the biological effects of PARPi on the disease response to subsequent therapies. With the response to subsequent therapy being closely related to platinum sensitivity (which is also a marker of PARPi sensitivity), this question merits further investigation via molecular analytics of serial biopsies pre- and post- first line treatment, first-line maintenance and subsequent treatment. The long-term responses in first-line PARPi maintenance treatment may indicate that a group of women will eventually be cured, which would decisively change ovarian cancer treatment and prognosis. However, patients who recur after PARPi or while on PARPi and are retreated with platinum represent the group in which we must obtain additional insight. Given the concept of retreatment with platinum analogs in patients with a prolonged PFI, a number of trials of "PARPi after PARPi" are underway. Even if "PARPi after PARPi" trials yield positive results, combination treatment with PARPi such as PARPi/Wee-i or ATRi/PARPi or PD-1/PD-L1/PARPi approaches have the potential to reverse PARPi resistance and, if toxicity allows them to be moved earlier in the treatment

spectrum, may prevent or delay the emergence of PARPi (and potentially platinum) resistance. In this manuscript, we have treated PARPi as a single modality, with this being supported by similar responses in trials across PARPi. However, different PARPi have different trapping abilities and specificity for different members of the PARP family. Further, new PARPi with greater specificity and abilities to cross the blood-brain barrier are being explored. Whether all of the PARPi will have similar effects on platinum sensitivity remains to be determined. We expect that ongoing precise and rigorously designed translational studies will, in the near future, bring more clarity to the best therapy sequence for ovarian cancer patients, and particularly identify populations of patients who are likely to benefit (or not) from platinum analogs following PARPi therapy either therapeutic or maintenance.

CONCLUSION

Today platinum remains the cornerstone of chemotherapy for ovarian cancer and PARPi are critical as a maintenance treatment. Resistance to platinum and PARPi has important clinical and prognostic significance, and the mechanisms of resistance are being rapidly investigated. A more precise understanding of the genomic markers of HRD, platinum sensitivity, and cross-resistance between PARPi and platinum will require serial biopsies (pre-, on-treatment) to be able to improve patient stratification and identify therapeutic strategies based on molecular vulnerabilities.

Abstract

Androgen deprivation therapy (ADT) is the standard of care treatment for advanced stage prostate cancer. Treatment with ADT develops resistance in multiple ways leading to the development of castration-resistant prostate cancer (CRPC). Present research establishes that prostate cancer stem-like cells (CSCs) play a central role in the development of treatment resistance followed by disease progression. Prostate CSCs are capable of self-renewal, differentiation, and regenerating tumor heterogeneity. The stemness properties in prostate CSCs arise due to various factors such as androgen receptor mutation and variants, epigenetic and genetic modifications leading to alteration in the tumor microenvironment, changes in ATP-binding cassette (ABC) transporters, and adaptations in molecular signaling pathways. ADT reprograms prostate tumor cellular machinery leading to the expression of various stem cell markers such as Aldehyde Dehydrogenase 1 Family Member A1 (ALDH1A1), Prominin 1 (PROM1/CD133), Indian blood group (CD44), SRY-Box Transcription Factor 2 (Sox2), POU Class 5 Homeobox 1 (POU5F1/Oct4), Nanog and ABC transporters. These markers indicate enhanced self-renewal and stemness stimulating CRPC evolution, metastatic colonization, and resistance to antiandrogens. In this review, we discuss the role of ADT in prostate CSCs differentiation and acquisition of CRPC, their isolation, identification and characterization, as well as the factors and pathways contributing to CSCs expansion and therapeutic

Keywords: Prostate cancer, second-generation antiandrogens, cancer stem cells, castration resistance prostate cancer, androgen deprivation therapy

INTRODUCTION

Prostate cancer is the most commonly diagnosed cancer in the United States, and approximately 50% of the men diagnosed with advance stage prostate cancer undergo androgen deprivation therapy (ADT)^[1]. US Food and Drug Administration approved ADT to treat metastatic prostate cancer as a neo-adjuvant in post-radiation therapy^[2]. ADT has also been accepted as the first-line treatment for prostate tumors that have extended to the lymph nodes, and biochemical recurrence followed by prostate-specific antigen (PSA) resurgence, asymptomatic metastatic and locally advanced disease^[3]. Since androgen receptor (AR) is essential for the function, survival, and differentiation of prostatic tissue, ADT reduces androgens necessary to block cancer progression^[4]. Accumulating data suggests that androgens are important players in the human body in maintaining physiological functions^[5-6]. Androgen receptor holds a key function in prostatic epithelial cells' growth and proliferation in response to testosterone^[7]. ADT comprises the use of the first-generation antiandrogens such as bicalutamide, nilutamide or flutamide that solely targets AR translocation to the nucleus and prevent downstream signaling. The second-generation antiandrogens *viz.* enzalutamide, apalutamide and darolutamide, as well as inhibitors of androgen biosynthesis such as abiraterone acetate, improve upon this mechanism^[8]. Changes in the function of AR signaling result in tumor suppression to tumor promotion, where the disease eventually progresses to the emergence of castration-resistant prostate cancer (CRPC)^[9]. Accumulated evidence suggests that ADT has a significant role in the management of metastatic prostate cancer; it reduces complications and enhances overall survival^[2,10-11]. In a study based on Cochrane meta-analysis, the neo-adjuvant ADT with radical prostatectomy significantly improves adverse histopathologic parameters such as surgical margin or pathologic tumor stage^[12]. Studies reported that prostate cancer patients undergoing radiotherapy together with ADT treatment further increases the probability of disease-free survival^[12-13]. This combinatorial treatment is well accepted and highlighted in the guidelines of the American Urological Association and European Association of Urology^[14-15]. However, numerous studies indicate that ADT is associated with a multitude of side effects that can impact the quality of life^[16-18]. These include fatigue, loss of libido, arterial stiffness, erectile dysfunction, hot flushes, new-onset diabetes mellitus, altered body composition, osteoporosis and induced skeletal complications, and cognitive decline^[16-18]. Some recent findings also demonstrated that ADT treatment might increase cardiovascular-mediated morbidity and mortality^[19-20].

Prostate cancer resistance during ADT treatment is reported in *in vitro* models of recurrence and CRPC patients^[21]. CRPC development is linked with genes associated with AR signaling, both at transcription and translation levels^[21]. A study including multiple isogenic tumor xenograft models demonstrated increased AR expression in recurrent tumor samples compared to paired androgen-sensitive samples^[22]. AR stabilization alters the rate of post-translational modifications and interaction with heat shock proteins which ultimately modulates normal cellular physiology^[23]. Studies also reported that stabilization of AR is positively associated with ADT resistance, which may be linked with CRPC^[4, 24]. Phosphorylation at particular sites and enrichment of growth factors reactivate AR, which further increases prostate cancer proliferation under low androgen levels^[25]. Apart from AR stabilization and phosphorylation, the mutation in *AR* gene is also associated with resistance development^[26]. A point mutation was reported in the lymph node of a patient with metastatic prostate cancer and causes amino acid substitution at position 878, threonine to alanine^[27]. This amino acid substitution results in response to non-androgen hormones that enhance resistance to ADT treatment. Some other reported mutations are W742C, H875Y/T, F877L and

L702H in response to resistance development against enzalutamide, nilutamide, flutamide and bicalutamide^[28-29]. Other factors such as different AR splice variant expression, aberrant glucocorticoids and glucocorticoid receptor expression, impairment of DNA repair pathway, miRNAs, cellular metabolism, and alterations in enzymatic and signaling pathways tightly support resistance development in response to ADT^[30-31].

Emerging research implicates that cancer stem cells (CSCs) are key to the development of therapeutic resistance, and studies have also established a link to ADT relapse tumors^[32]. Subsequent work has shown that ADT increases the enrichment of CSCs populations which are inherently treatment-resistant having the ability to promote CRPC^[33]. The CSC hypothesis is an emerging model that describes several molecular characteristics of cancer. CSCs facilitate the development of a cellular hierarchy, maintain a CSC rich-pool, differentiate into a proliferating progeny, and assist the formation of a heterogeneous tumor^[34]. As a result, there is a strong consensus that CSCs are the cells of origin in cancer and have the propensity of cancers to relapse, metastasize, and develop resistance to conventional therapies^[34]. In this review, we describe the role of ADT in CSC differentiation during CRPC acquisition, their isolation, identification and characterization. Outlining the underlying mechanisms triggered by ADT and highlighting potential CSCs targets could aid in the development of future therapeutic strategies in prostate cancer patients leading to improved outcomes.

PROSTATE CANCER STEM-LIKE CELLS

Stem cell markers in prostate cancer

Normal stem cells possess the intrinsic capacity for unlimited replicative potential as well as differentiation into all lineages of mature cells required for tissue and/or organ maintenance^[35]. In general, cancer cells possess cellular heterogeneity and inherent genetic instability, which makes them immortal in characteristics. CSCs are commonly defined as cells that demonstrate characteristics similar to a normal stem cell, including lack of senescence, self-renewal capacity and pluripotency^[36]. This type of cancer cell possesses the ability to develop a cellular hierarchy, facilitating the maintenance of a CSC pool while differentiating into a proliferating progeny, enabling the formation and growth of a heterogeneous tumor.

The prostate gland consists of basal (undifferentiated), differentiated and neuroendocrine cells^[37]. The basal cells are androgen-independent and express cytokeratin 5, cytokeratin 14, Tumor Protein P63, and Cell Surface Glycoprotein (CD44) markers^[38-40]. They also express much less AR, PSA and prostatic acid phosphatase (PAP)^[38-40]. Differentiated cells include glandular epithelial and secretory luminal cells, which express AR, PSA, PAP, cytokeratin 8 and cytokeratin 18^[41]. The neuroendocrine cells are androgen-independent and do not secrete PSA^[42]. Prostate cancer stem cells are androgen-independent cells that give rise to androgen-sensitive progenitor cells^[38]. These progenitor cells in the presence of androgens differentiate into androgen-dependent cells. A number of research studies indicate that CSCs are considered as the cells of origin in cancer and have been linked to tumorigenesis, treatment resistance and cancer relapse^[41].

Several research studies identified prostate CSCs genes that are important for self-renewal, pluripotency, resistance and serve as markers for identification^[43]. Stem cell antigen-1, aldehyde dehydrogenases (ALDH), CD133 (PROM1), trophoblast cell surface antigen 2 and CD44 are markers to identify prostate CSCs in the basal compartment^[44]. The other common markers include CD44, CD24, and CD49 Antigen-Like Family Member D (also known as Integrin Subunit Alpha 4), which have been tightly associated with prostate CSCs^[45]. Another study identified a rare prostate cancer stem cell maker, KIT Proto-Oncogene, Receptor Tyrosine Kinase (KIT) in adult mouse prostatic stem cell population, which possess cancer stem cell-like

features such as differentiation and self-renewal^[46]. The prostate CSCs enriched in CD133⁺ cells isolated from established primary human prostate cancer cell lines and in alpha(2)beta(1)-integrin subunit phenotype identified as genetically unstable with clonogenic formation and invasive potential^[47]. Yu *et al.*^[48] have identified high ALDH1 activity in LNCaP and PC-3 prostate cancer cells associated with CSC-like properties; in particular, ALDH^{hi}/CD44⁺ cells possess a high clonogenic function and tumorigenic potential. A study conducted on prostate cancer tissue specimens indicated *Oct4*, *Sox2* and *Nanog* genes as prostate CSC markers^[49]. Collins *et al.*^[50] further demonstrate in the mouse xenograft model that elevated levels of ALDH support stemness in cells; indeed, ALDH^{hi}/CD44⁺/α2β1⁺ cells are enhanced during castration and were critical in the development of antiandrogen resistance. Further, cells possessing similar phenotypes were isolated from clinical specimens and analyzed for self-renewal and spheroid formation. The outcome showed that ALDH^{hi}/CD44⁺/α2β1⁺ cells significantly support cell proliferation and colony formation^[51]. A study performed on patient biopsies samples (Gleason score range 5-6) suggested that CD133⁺/CD44⁺/ATP-binding cassette sub-family G member 2 (ABCG2)⁺/CD24⁻ cells actively participate in spheroid formation^[52]. In addition, primary tumor cells containing Enhancer of Zeste 2 Polycomb Repressive Complex 2 Subunit (EZH2⁺)/E-cadherin⁻ markers are highly associated with tumor recurrence [Table 1]^[53].

Molecular pathways in the generation of prostate cancer stem-like cells post ADT

AR is a key transcription factor involved in androgen-dependent prostate cancer growth. Targeting AR with the first-generation antiandrogens does not inhibit inter or intramolecular N-C interactions required for the nuclear localization^[57]. At the diagnosis of metastatic CRPC, the common genomic alteration event found in AR is amplification and AR mutation^[58]. These AR genomic alterations dysregulate the signaling pathway in patients and demonstrate a compensatory resistance mechanism *via* increasing AR expression in response to the potent AR inhibition by enzalutamide, which results in diminished efficacy of treatment overtime^[59]. In a systemic study, exome sequencing of 150 metastatic CRPC biopsy specimens demonstrated 63% of AR mutation and amplification in comparison to 440 primary prostate cancer tissues^[60]. Apart from AR mutation, AR variants such as ARV7 were also reported for resistance development and support androgen-independent growth of prostate cancer cells^[61]. Prostate cancer patients who underwent ADT showed hematopoiesis from pluripotent stem cells, PI3K/AKT signaling, ERK/MAPK signaling, and Wnt/β-catenin signaling, and the role of Nanog in mammalian embryonic stem cell pluripotency signaling pathways were overrepresented [Figure 1]. This information revealed that the genomic alteration in AR either by amplification or mutation tends to increase the expression of associated stem cell markers.

With reference to hematopoiesis, pluripotent stem cells, the expression of transmembrane receptors genes, which includes *CD4*, *CD247*, *CD3E*, *CD8A*, *CSF3*, *CXCL8*, and family members of immunoglobulin heavy constant gamma proteins (IGHA1, IGHD, IGHG1, IGHG2, IGHG3, IGHM) and the expression of cytokines such as IL6 and IL10 were increased in patients undergoing ADT [Table 2].

Isolation, identification and characterization of prostate cancer stem cells

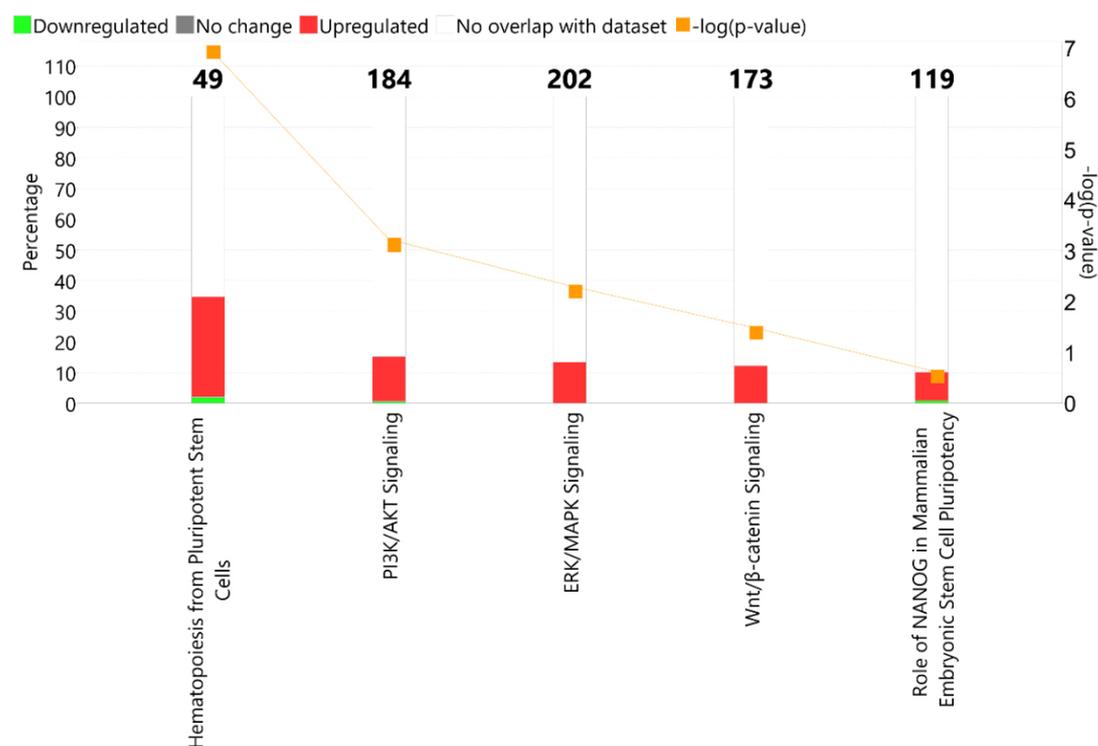

Extensive work has shown that CSCs from primary prostate tumors or established cancer cell lines can be isolated from a heterogeneous population using cell surface markers, such as CD44 and CD133, aldehyde dehydrogenase (ALDH) activity using the ALDEFLUOR assay, and Hoechst dye to identify the side population^[62-63]. Isolation of prostate CSCs has been performed by several groups. The first CSC isolation was performed from patients undergoing radical prostatectomy^[64]. These CSCs exhibited a significant capacity for self-renewal and the ability to regenerate the phenotypically mixed populations of non-clonogenic cells. The prostate CSCs were isolated using the CD44/α2β1^{high}/CD133⁺ phenotype and demonstrated high clonogenic and invasive capacity of basal cell origin with high levels of genetic instability^[64-65]. A study by Rajasekhar *et al.*^[66] observed that CSCs expressing human pluripotent stem cell marker TRA-60-1⁺ /CD151⁺ /CD166⁺ possess high self-renewal and differentiation ability, and were able to

Table 1. Prostate cancer stem cells markers

Pathways	Markers names	Gene symbol	Ref.		
Tumor progression	KIT proto-oncogene, receptor tyrosine kinase	<i>CD117/c-kit</i>	[43,54-56]		
	Prominin 1	<i>CD133</i>			
	Indian blood group	<i>CD44</i>			
	$\alpha 2\beta 1$ integrin	<i>ITGB1</i>			
	Integrin Subunit Alpha 6	<i>$\alpha 6$ integrin</i>			
	C-X-C motif chemokine receptor 4	<i>CXCR4</i>			
	Epithelial cell adhesion molecule	<i>EPCAM</i>			
	Cytokeratin 5	<i>KRT5</i>			
	Kallikrein related peptidase 3	<i>KLK3/PSA</i>			
	Tumor-associated calcium signal transducer 2	<i>Trop2</i>			
	Activated leukocyte cell adhesion molecule	<i>ALCAM</i>			
	Aldehyde dehydrogenase 1 family member A1	<i>ALDH1</i>			
	Transglutaminase 2	<i>TG2</i>			
	Enhancer of zeste 2 polycomb repressive complex 2 subunit	<i>EZH2</i>			
Metastatic colonization and growth	KIT proto-oncogene, receptor tyrosine kinase	<i>CD117/c</i>	[43,56]		
	C-X-C motif chemokine receptor	<i>CXCR4</i>			
	Epithelial cell adhesion molecule	<i>EPCAM</i>			
	E-cadherin/ cadherin 1	<i>CDH1</i>			
	Indian blood group	<i>CD44</i>			
	Enhancer of zeste 2 polycomb repressive complex 2 subunit	<i>EZH2</i>			
Recurrence and therapeutic resistance	KIT proto-oncogene, receptor tyrosine kinase	<i>CD117/c-kit</i>	[43,54-56]		
	$\alpha 2\beta 1$ integrin	<i>ITGB1</i>			
	Integrin subunit alpha 6	<i>ITGA6</i>

	Aldehyde dehydrogenase 1 family member A1	<i>ALDH1</i>			
	Enhancer of zeste 2 polycomb repressive complex 2 subunit	<i>EZH2</i>			

Table 2. List of genes, location, types, along with fold changes value associated with hematopoiesis pluripotent stem cells

Gene symbol	Gene name	Fold change in ADT	Location	Type(s)
CD4	CD4 molecule	1.829	Plasma membrane	transmembrane receptor
CD247	CD247 molecule	1.437	Plasma membrane	transmembrane receptor
CD3E	CD3e molecule	1.597	Plasma membrane	transmembrane receptor
CD8A	CD8a molecule	1.469	Plasma membrane	other
CSF3	colony stimulating factor 3	5.074	Extracellular space	cytokine
CXCL8	C-X-C motif chemokine ligand 8	3.395	Extracellular space	cytokine
FCER1G	Fc fragment of IgE receptor Ig	1.815	Plasma membrane	transmembrane receptor
IGHA1	immunoglobulin heavy constant alpha 1	3.2	Extracellular space	other
IGHD	immunoglobulin heavy constant delta	2.58	Extracellular space	other
IGHG1	immunoglobulin heavy constant gamma 1 (G1m marker)	2.139	Extracellular space	other
IGHG2	immunoglobulin heavy constant gamma 2 (G2m marker)	3.362	Plasma membrane	other
IGHG3	immunoglobulin heavy constant gamma 3 (G3m marker)	2.922	Extracellular space	other
IGHM	immunoglobulin heavy constant mu	2.946	Plasma membrane	transmembrane receptor
IL6	interleukin 6	6.333	Extracellular space	cytokine
IL10	interleukin 10	1.764	Extracellular space	cytokine
LIF	LIF interleukin 6 family cytokine	2.636	Extracellular space	cytokine

Figure 1. Canonical signaling pathway overrepresented in prostate cancer patients under ADT. These pathways play a critical role in driving cancer stem-like cell phenotype. The red bar represents the genes upregulated and green is downregulated and overlaid with IPA database. The X-axis in the graph represents the signaling pathways while the Y-axis showed $-\log(P\text{-value})$ and percentage (%). ADT: Androgen deprivation therapy

reiterate tumor heterogeneity in serial *in vivo* transplantations. More recent studies have identified that a majority of prostate tumors harbor prostate-specific *TMPRSS2* gene and the *ERG* oncogene (*TMPRSS2*:

ERG) gene fusion which could be used as a stem cell marker with high specificity providing *ERG*-driven survival advantages^[67]. Moreover, *ALDH1*^{high} prostate cancer cells have been shown to exhibit several CSC characteristics such as clonogenicity, migration, tumorigenicity, and propensity to form metastases *in vivo*^[68]. Another method to enrich the CSC population is developing tumorspheres in cell culture with a higher *in vivo* tumor incidence rate^[69].

Our group and others have demonstrated fluorescence-activated cell sorting and magnetic-activated cell sorting utilizing various human prostate cancer cell lines^[70-71]. Other studies showed that *CD44* and *CD133* were associated with high *Nanog* expression in prostate carcinoma cell lines^[71]. *Nanog* has shown to be predominantly expressed from the *NanogP8* pseudogene in a panel of prostate carcinoma cells including DU145, LNCaP, and PC-3 and primary prostate carcinoma cells. *NanogP8* expression was enriched several folds in *CD133*⁺ and *CD133*⁺/*CD44*⁺ CSCs compared to non-CSCs^[71]. Human prostate cancer PC-3 cells displayed high *CD44*⁺/*CD133*⁺ CSC-like features including enhanced tumor sphere formation and elevated *Nanog* levels. Similarly, *CD117*⁺/*ABCG2*⁺ cells isolated from 22Rv1 prostate cancer cells overexpress the core stem cell transcription factors, *Nanog*, *Oct3/4*, and *Sox2*, and the CSC marker *CD133*^[72]. A recent study from our group has demonstrated high expression of *ALDH1*^{high}, *Oct4* and *Sox2* in clinical prostate cancer specimens undergoing ADT, compared to grade-matched controls^[73].

Most standard therapies for prostate cancer primarily affect cancer cells, but CSCs undergo G0/G1 phase cell cycle arrest and remain static, thus evading cell death from chemotherapeutic drugs^[74]. Experimental data also suggest that CSCs are resistant to conventional chemotherapy and radiation and may be the cells responsible for disease recurrence and/or progression^[75]. A study showed that *CD133*⁺ had a high capacity to proliferate *in vitro* and have AR⁺ phenotype^[76]. These *CD133*⁺ cells form branched spheroids structure in a 3D culture system and generate prostatic-like acini *in vivo*^[76]. Hence, the drug-resistant characteristic of CSCs is useful to isolate and identify CSCs. Previous studies have shown that radiotherapy combined with hypoxic culture can also be used to enrich CSCs population^[77].

Therapeutic opportunities for prostate cancer stem-like cells

Prostate cancer patients undergo treatment therapy such as radiotherapy or chemotherapy, resulting in shrinkage of tumors^[78]. However, after therapy, some cells accumulate genetic/epigenetic changes that result in loss of control on self-renewal potential. These cells, referred to as prostate CSCs, reprogram the tumor environment to their benefit, supporting increased survival, self-renewal, and tumor recurrence^[64]. Research showed that cellular immunotherapy has some beneficial role in the treatment of prostate cancer^[79]. The T cell-based immunotherapy showed a positive response to prostate cancer patients with metastatic CRPC and increased the overall survival^[79]. A research group prepared an immunogenic peptide derived from dendritic cells sensitized to *CD44* and *EpCAM* followed by co-culture with the expanded peripheral blood lymphocyte (PBL)-derived cytokine-induced killer cell^[80]. This study showed that dendritic cells- cytokine-induced killer cells exhibit remarkable cytotoxicity against prostate cancer stem-like cells-enriched prostate spheroids both *in vitro* and *in vivo*^[80]. In addition to these findings, several other cellular events impart growth advantages to CSCs. In this context, various signaling pathways such as Wnt/ β -catenin, hedgehog, NF- κ B and Notch; ABC transporters and tumor microenvironment could be the putative target(s) for prostate CSCs^[81] [Figure 2].

Wnt signaling pathway is involved in various cellular processes and is crucial for cell fate determination, cell polarity, cell migration, neural patterning and organogenesis during embryonic development. Wnt pathway is also associated with the maintenance of stem cells in a self-renewing state^[82]. A study demonstrated that Wnt signaling activation is oncogenic in the prostate and supports CRPC growth *in vivo*^[83]. This study also

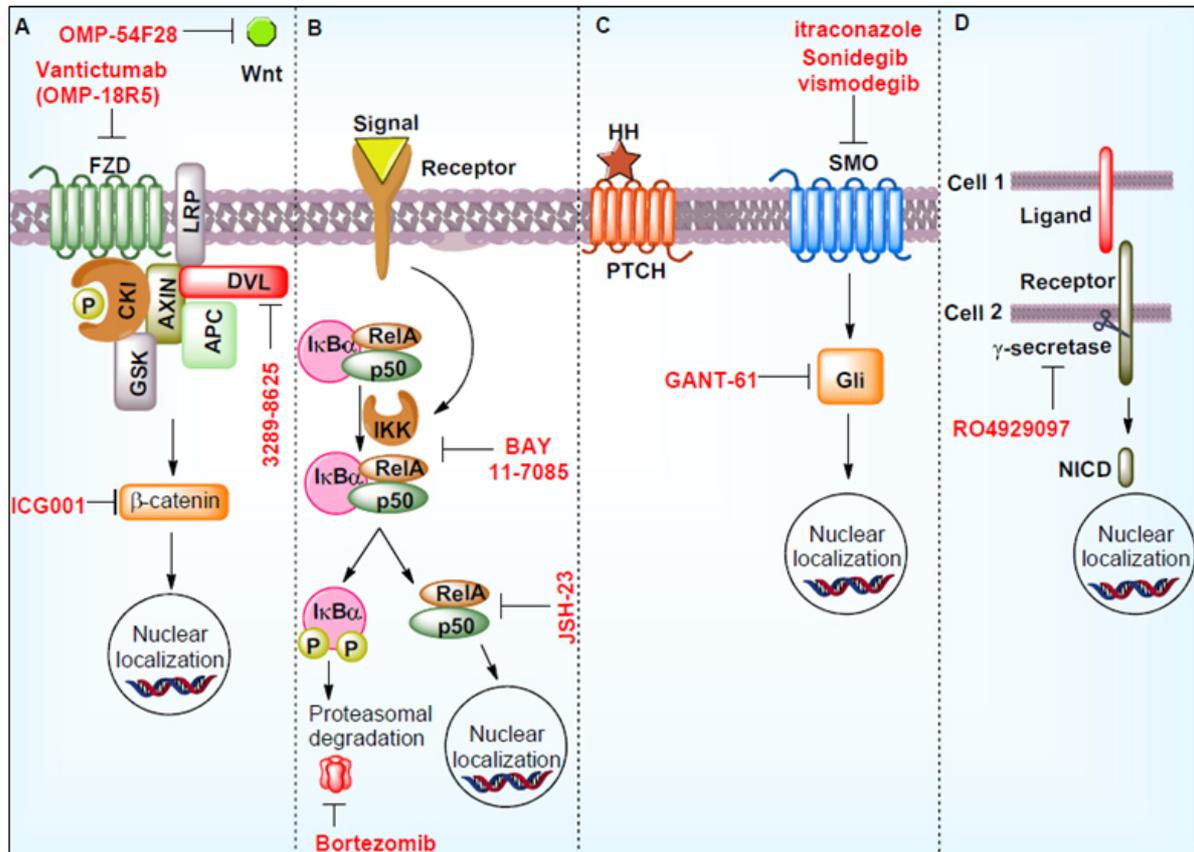

Figure 2. Signaling pathways regulating CSCs and the use of inhibitors in suppressing these pathways. These molecules thereof could be developed as potential therapeutics. The denotes in the figure are: Hedgehog signaling pathway (HH), notch intracellular domain (NICD), phosphorylation (P), smoothened (SMO), Wnt signaling pathways (Wnt), nuclear factor of kappa light polypeptide gene enhancer in B-cells inhibitor, alpha (I κ B α), RELA Proto-Oncogene (RelA), Frizzled (FZD), casein kinase I (CKI), Axin (AXIN), APC Regulator of WNT Signaling Pathway (APC), Dishevelled (Dvl), Glycogen Synthase Kinase (GSK), I κ B Kinase (IKK).

showed that increased Wnt signaling induces neuroendocrine differentiation, epithelial-mesenchymal transition and drives stem cell-like features to prostate cancer cells. A number of small molecule inhibitors and monoclonal antibodies have been tested to inhibit the Wnt signaling pathway. Wnt signaling inhibitors such as 3289-8625, Foxy-5, and OMP-54F28 have been reported to inhibit prostate cancer cell growth^[84-86]. A porcupine (palmitoylation of Wnt ligands) inhibitor LGK974 combined with docetaxel and paclitaxel also showed remarkable effectiveness on solid tumors^[64]. A monoclonal antibody vantictumab (OMP-18R5) blocks canonical Wnt signaling pathways and inhibits prostate cancer progression^[87].

Hedgehog signaling pathways play an important role in the development of prostate cancer. Hedgehog signaling targets genes involved in prostate CSCs survival, proliferation, and metastasis^[88]. This signaling also enhanced the overexpression of ABC transporters in prostate cancer cells^[88]. Hedgehog signaling inhibitor sonidegib (LDE-225) suppresses the key genes including *Oct4*, *Nanog*, *c-Myc*, and *Sox2* involved in self-renewal and stemness potential^[89]. Gli transcription factor inhibitor GANT-61 inhibits PTCH1 expression and tumor growth *in vivo*^[90]. Other Hedgehog signaling inhibitors such as vismodegib, itraconazole and orteronel either alone or in combination and/or surgery inhibit prostate cancer growth^[64].

Upregulation of the NF- κ B pathway has been observed in cancer stem cells^[91]. Various studies also demonstrated that NF- κ B signaling was upregulated in prostate cancer cells and associated with increased progression, chemotherapy resistance, metastasis and recurrence^[92]. Several clinical trials have been performed by targeting the NF- κ B signaling pathway. Clinical trial NCT01695473 used PI3K inhibitor BKM120, which acts downstream of NF- κ B in high-risk localized prostate cancer patients^[93]. NCT00118092 clinical trial was performed using heat shock protein 90 inhibitor 17-(allylamino)-17-demethoxygeldanamycin to treat metastatic prostate cancer patients^[94]. Aspirin, a reported drug for inflammation-regulated cancer, was utilized in clinical trial NCT02757365^[95]. This trial demonstrated that aspirin suppresses CRPC progression.

Notch signaling pathways are well known for their contribution to self-renewal, differentiation, resistance and stemness development^[96]. Interaction of Notch receptor and ligand facilitates NICD production through gamma-secretase, which translocates to the nucleus and initiates transcription of self-renewal, stemness, and other CSC development associated genes^[97]. In this context, a number of gamma-secretase inhibitory agents were identified. A clinical trial (NCT01200810) was performed in prostate cancer patients using gamma-secretase inhibitor RO4929097 with bicalutamide^[98]. This trial compares PSA expression with time after surgery/radiation and combined treatment^[98].

Alteration in ABC transporter genes and tumor microenvironment tightly regulates cellular physiology and transcriptomic machinery in prostate CSCs^[99]. The tumor microenvironment plays a decisive role in regulating CSCs progression^[100]. It also facilitates abnormal cancer signaling pathways, epithelial-mesenchymal transition, invasion, *etc.* Overexpression of ABC transporters exports therapeutic drugs outside the cells, which makes them resistant to the drug^[101]. Several lines of research have been performed to target the ABC transporters. An ABC transporter efflux inhibitor verapamil inhibits prostate cancer proliferation by inhibiting the potassium ion channel^[102]. Cyclosporin A, another ABC transporter inhibitor, inactivates NFATc1 (nuclear factor of activated T-cells) in biochemical recurrence and CRPC^[103].

CONCLUSION

Despite thorough research for mechanisms leading to CRPC as a result of resistance to antiandrogens in the past few decades, our understanding remains limited. ADT causes complex alterations within tumors in terms of factors and pathways as well as its epigenetics and genetics affecting the tumor microenvironment. Several research studies showed that aberrant cellular signaling, generation of AR variants, and AR mutation support the development of drug resistance. The accumulative effects of these factors also contribute to the generation of prostate cancer stem-like cells. CSCs are the reservoir of cancer cells that exhibit surface markers such as ALDH, CD133 and CD44, possessing properties of self-renewal and the ability to reestablish the heterogeneous tumor cell population promoting metastatic colonization, self-renewal, and recurrence. Research showed that targeting prostate CSCs could be a better strategy for the treatment of CRPC. In this direction, various small molecule inhibitors, antibodies and other combinatorial treatments have been evaluated in various clinical trials. The outcome demonstrated that these therapies increased overall survival in prostate cancer patients. However, the lifespan increment of prostate cancer patients is still challenging for clinicians as all these drug therapies become resistant after a certain time of treatment.

DECLARATIONS

Authors' contributions

Made substantial contributions to conception and writing of the manuscript: Kushwaha PP, Verma S, Kumar S, Gupta S

Developed the figures and tables: Kushwaha PP, Verma S

Made substantial contributions to conception and design of the manuscript and performed data analysis and interpretation: Kushwaha PP, Verma S

Provided administrative, technical, and material support: Gupta S

Availability of data and materials

Not applicable.

Financial support and sponsorship

Abstract

Breast cancer (BC) is the second most common cause of cancer-related deaths and the most frequently diagnosed cancer in females. Among breast cancer types, HER2-positive breast cancer occurs in nearly 20% of human breast cancers and is associated with increased aggressiveness, poor prognosis, and shortened overall survival. HER2+ breast cancer is currently managed with multidisciplinary treatment strategies including surgery, radiation, chemotherapy, and targeted therapy. Drug resistance remains a continuing challenge, especially to targeted therapy utilizing monoclonal antibodies and tyrosine kinase inhibitors. This review discusses some of the recent molecular mechanisms that are involved in the development of resistance to Her2-targeted therapies including the PI3K/Akt/mTOR pathway, IGF-IR, Src, c-MET, the PP2A family, CD36, p27^{kip1}, and miRNAs.

Keywords: HER2+, Targeted therapy resistance, IGF-IR, Src, c-MET, PP2A, CD36, miRNA

INTRODUCTION

Breast cancer (BC) is the most frequently diagnosed cancer in females and the second most common cause of cancer-related deaths, accounting for 30% of malignancies in women^[1]. In the U.S, it is estimated that approximately 40,000 women die from breast cancer each year^[2]. Moreover, in 2020, 2.3 million women

were diagnosed with BC worldwide, with the number of deaths reaching 685,000. Near the end of 2020, 7.8 million women diagnosed with BC in the previous five years were alive, making it the most prevalent cancer globally^[3].

Breast cancers prognosis and classification rely not only on tumor morphology but also on the expression levels of three proteins, specifically the estrogen receptor, progesterone receptor, and human epidermal growth factor receptor 2 (HER2). Tumors that do not express any of these proteins are classified as triple-negative breast cancers, a form of the disease that is particularly difficult to treat^[4].

HER2 (ERBB2) belongs to the ERBB family, which includes epidermal growth factor receptor 1 (EGFR) (ERBB1/HER1), HER3 (ERBB3), and HER4 (ERBB4)^[5]. HER2 shares structural and sequence similarities with the other family members consisting of three regions: an extracellular N-terminal domain, a single transmembrane α -helix domain, and a tyrosine kinase intracellular domain^[6,7].

Extracellular ligands have a conserved EGF motif bind with ERBB receptors, causing homo- and heterodimeric interactions between the ERBB receptors in various combinations^[7]. HER2 lacks a ligand binding domain and does not require a ligand for activation and may be found in an activated state via homo-dimerization or hetero-dimerization with other members of the ERBB family. Homo- or hetero-dimerization causes autophosphorylation of the tyrosine kinase domains, resulting in the subsequent activation of different signaling pathways, primarily the phosphoinositide 3-kinase/protein kinase B/mammalian target of rapamycin (PI3K/Akt/mTOR) and Ras/Raf/mitogen-activated protein kinase (MAPK) pathways, promoting cell survival, proliferation, differentiation, angiogenesis, and invasion^[8-11]. Although ERBB receptors are vital regulators for different cellular processes, their dysregulation, as a result of mutations, could lead to the development of cancers^[7].

Amplification or overexpression of the human epidermal growth factor receptor-2 occurs in nearly 20% of human breast cancers and is associated with increased aggressiveness, poor prognosis, and short overall survival^[11].

HER2+ breast cancer is currently managed with multidisciplinary treatments that include surgery, radiation, chemotherapy, and targeted therapy^[12]. Targeted therapy includes monoclonal antibodies such as trastuzumab and tyrosine kinase inhibitors. Although these drugs markedly improve the prognosis of HER2+ breast cancer patients^[13,14], a substantial fraction of these patients still suffer from relapse due to intrinsic or acquired resistance to the treatment, particularly in the case of trastuzumab. The majority of patients who achieve an initial response to trastuzumab-based therapy develop resistance within one year^[15-17]. In fact, 70% of patients with HER2+ BC show intrinsic or acquired resistance to trastuzumab^[18].

In this review, we will shed light on some of the molecular mechanisms that are involved in resistance to anti-HER2 therapies, which significantly hinder their efficacy.

SPECIFIC MECHANISMS OF RESISTANCE

Dysregulation of the PI3K/Akt/mTOR pathway

Targeted therapy resistance may occur as a result of the sustained activation of signaling pathways such as the PI3K/Akt/mTOR pathway, despite HER2 blockage, priming a drug escape mechanism^[19-21].

PI3K/Akt signaling dysregulation results in mTOR pathway upregulation and increased mRNA translation leading to enhanced cellular proliferation^[22,23], which is mediated by the overexpression of growth factor receptors and loss of the phosphatase and tensin homolog (PTEN) [Figure 1]^[24]. Breast cancer models of hyperactive PI3K/Akt/mTOR pathway have shown resistance to targeted therapy^[25].

The persistent activation of this pathway may result from mutations in genes such as PIK3CA, AKT1, AKT2 amplification, and PTEN loss^[26]. PTEN loss or PIK3CA mutations are common oncogenic events in HER2+ breast cancer, occurring in approximately 19% and 42% of patients, respectively^[27].

PTEN, an mTOR negative regulator, is a tumor suppressor gene whose suppression leads to trastuzumab resistance and shorter survival^[20,28]. Nagata *et al.*^[29] provided compelling evidence supporting the role of PTEN loss in trastuzumab resistance. They showed that PI3K/Akt signaling increased via PTEN downregulation [Figure 1], which resulted in blockage of the growth arrest mediated by trastuzumab. Furthermore, they demonstrated that the absence of PTEN expression was associated with a significantly poorer response to trastuzumab-based therapy in HER2+ BC patients than in those with normal PTEN expression. Moreover, in PTEN-deficient cells, PI3K inhibitors decrease trastuzumab resistance both *in vitro* and *in vivo*^[29].

PIK3CA is a gene that encodes the PI3K catalytic subunit. PIK3CA mutations acquired during disease progression are suggested to reflect increased activation of the PI3K pathway [Figure 1]^[19]. *In vitro* data show that PI3KCA gene mutations and HER2 gene amplification are accompanied by resistance to HER2-targeted therapy^[21,30,31]. In addition, biomarker analysis from the CLEOPATRA trial showed that PIK3CA mutations were associated with worse survival outcomes in patients with advanced HER2+ breast cancer^[32]. Moreover, in the EMILIA trial, PTEN loss or PIK3CA mutations were associated with shorter survival and lower overall response rates in patients receiving capecitabine and lapatinib^[33].

These data support a role of the dysregulated PI3K/Akt/mTOR signaling pathway in the development of resistance to HER2 targeted agents.

c-MET

c-MET (mesenchymal-epithelial transition factor) is a tyrosine kinase receptor encoded by the proto-oncogene MET. Along with RON, c-MET belongs to the MET family, which is widely expressed in epithelial and endothelial cells^[34-36]. c-MET controls a number of different cellular processes, including replication, survival, and motility^[37].

c-MET becomes activated upon binding with its ligand, the hepatocyte growth factor (HGF), triggering a variety of downstream signaling pathways, including PI3K/AKT, Ras/MAPK [Figure 1], Src, signal transducer, and transcription activator^[38-41].

Aberrant c-MET activation can contribute to both tumor growth and metastasis^[37]. For example, c-MET was reported to be highly expressed in HER2+ BC cell lines and in 25% of HER2+ BC patients' tissues^[42,43]. Poorly differentiated and invasive cell lines also showed an elevated level of c-MET^[44]. Clinically, a number of trials demonstrated that c-MET hyperactivity in breast tumors is associated with a lower survival rate^[43,45].

Several experimental findings suggest a role for c-MET in targeted-therapy resistance. Engelman *et al.* showed that c-MET amplification causes HER3-mediated activation of PI3K, and results in gefitinib resistance in lung cancer^[46]. In addition, c-MET hyperactivity has been reported as a potential contributor to

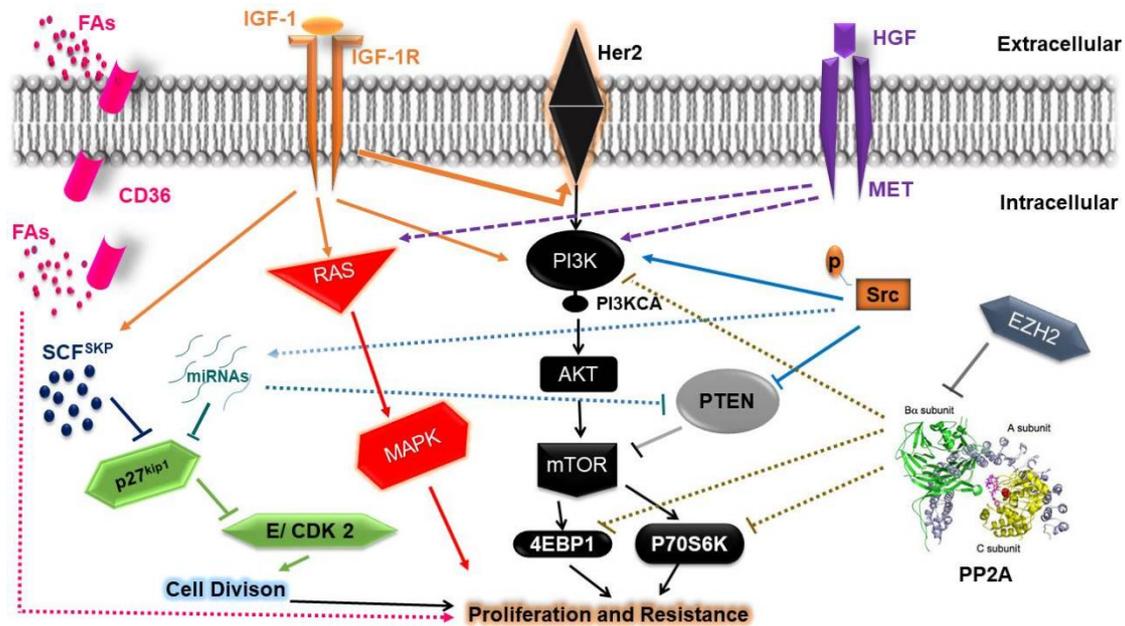

Figure 1. Signaling pathways involved in the development of resistance to Human epidermal growth factor receptor 2 (Her2)-targeted therapy. A central element of resistance appears to be PI3K/AKT/mTOR signaling, which may demonstrate persistent activation through c-MET, IGF-1, p-Src, or interference with PTEN and PP2A mediated suppression of mTOR and downstream signaling at the level of p70S6K and 4EBP1. PP2A activity could also be inhibited by EZH2-mediated slicing of the PP2A regulatory B-subunit. miRNAs and p-Src can also promote the loss of PTEN activity. Resistance could also be mediated through c-MET or IGF1 activation of the RAS/MAPK signaling pathway well as IGF-1; IGF1 can also induce Her2 receptor phosphorylation. p27^{Kip1} expression is reduced via SCF^{SKP} E3 ubiquitin-mediated degradation, which can be augmented by IGF-1 or via miRNAs which are overexpressed through p-Src, causing loss of cyclin E/CDK2 control and promoting cell cycle progression. CD36 contributed to tumor growth and resistance to Her 2 targeted therapies by providing FAs as a critical energy source for tumorigenesis. PTEN: Phosphatase and tensin homolog; IGF: insulin-like growth factor; MAPK: mitogen-activated protein kinase; FAs: fatty acids.

trastuzumab resistance that may be mediated through sustained Akt activation [Figure 1]^[42,43]. Additionally, c-MET/HGF axis amplification was reported in a cohort of HER2+ BC patients who failed to respond to trastuzumab-based therapies^[42].

Upon treatment with trastuzumab, HER2-overexpressing BC cells may upregulate c-MET, which then protects cells against trastuzumab^[42]. Moreover, loss of c-MET function is reported to improve the response of these cell lines to trastuzumab^[47].

In studies to demonstrate the significance of c-Met inhibition, Yue *et al.*^[48] reported that miR-182 directly targets the c-MET gene in BC cells and that miR-182 downregulation is associated with trastuzumab resistance in BC cells. They utilized miR-182 to reverse the trastuzumab resistance of BC cells in part via targeting c-MET and its downstream PI3K/AKT/mTOR pathway. Their studies showed that c-MET downregulation restored sensitivity to trastuzumab *in vitro* using SKBR3 and BT474 BC cell lines, as well as in xenografted models^[48].

Cell lines that have upregulated the c-MET/HGF axis have also demonstrated reduced lapatinib sensitivity, indicating that c-MET activation may decrease the effectiveness of the EGFR/HER2 inhibitors. Conversely, lapatinib or erlotinib combined with foretinib, a c-MET inhibitor, suppressed the growth of these cell lines^[49,50].

Many selective c-MET inhibitors are currently under clinical development. Cabozantinib, for example, an inhibitor of c-MET and VEGFR2, is being evaluated, in combination with trastuzumab, in HER2 positive BC patients who suffer from brain metastasis^[50] [Table 1].

Insulin-like growth factor 1 receptor signaling

Another pathway involved in targeted therapy resistance is mediated via the Insulin-like growth factor-I receptor (IGF-IR)^[51]. IGF-IR is a tyrosine kinase receptor that plays a critical role in tumor progression. Upon ligand binding, IGF-IR initiates signaling through the Ras/MAPK and PI3K/ AKT pathways [Figure 1], resulting in cell proliferation and the inhibition of apoptosis^[52].

A number of studies support a role of IGF-IR in the development of HER2+ breast cancer resistance. One study demonstrated that IGF1R interacts with and induces phosphorylation of HER2 in trastuzumab-resistant cells [Figure 1], but not in the sensitive parental cells. Moreover, the resistant cells showed more-rapid IGF1 stimulation of PI3K/Akt and Ras/MAPK pathways compared with the parental cells^[53]. Furthermore, in the *in vitro* model of resistance, IGF1R signaling inhibition either by IGF1R tyrosine kinase suppression or antibody blockade restored sensitivity to trastuzumab^[53].

In a study by Lu *et al.*^[51], the link between trastuzumab resistance and IGF1R signaling was confirmed. These investigators demonstrated that the growth inhibition mediated by trastuzumab was lost in breast cancer cells having high HER2 and IGF1R levels. Moreover, growth arrest was restored when IGF1-mediated activation of IGF1R was inhibited by IGF-binding protein 3 (IGFBP3)^[51]. IGF1 signaling was also demonstrated to elevate the expression of the p27^{Kip1} ubiquitin ligase, SKP2, resulting in degradation of the cyclin-dependent kinase inhibitor p27^{Kip1} and loss of growth arrest [Figure 1]^[54]. p27^{Kip1} belongs to the family of cyclin-dependent kinase inhibitors (CDKIs), which have inhibitory activity towards different CDKs and may function as a tumor suppressor gene by inducing cell cycle arrest^[55].

In another study, cyclin-dependent kinase 2 activity was found to be increased in trastuzumab-resistant HER2+ BC cells, accompanied by a reduction in p27^{Kip1} levels. The addition of exogenous p27^{Kip1} increased sensitivity to trastuzumab. Thus, these data suggest that p27^{Kip1} reduction is associated with trastuzumab resistance, which may be mediated by HER2 and IGF-IR heterodimerization^[56,57].

p27^{Kip1}

p27^{Kip1} (p27) is a member of the CDKI family^[58] that functions as an inhibitor of cell cycle transition from the G1 to S phase by suppressing cyclin E/CDK 2 [Figure 1]^[59]. The p27^{Kip1} expression level serves as a prognostic marker for BC patients^[60]. p27^{Kip1} level can be decreased at post-transcriptional levels during G1/S phase progression via ubiquitination and proteasomal degradation after its phosphorylation^[61].

Several studies have investigated the role of p27 in targeted-therapy resistance, particularly to trastuzumab and lapatinib in Her2-positive breast cancer.

Trastuzumab-mediated growth arrest appears to depend, in large part, on p27 activity. Trastuzumab causes G1 cell-cycle arrest through increasing the formation of p27-CDK2 complexes^[62]. Moreover, trastuzumab increases p27 half-life via decreasing its phosphorylation by cyclin E/CDK2, as well as by suppressing the subsequent ubiquitin-mediated degradation^[63].

Yakes *et al.* and Le *et al.* demonstrated that the reduction of p27 levels in SKBR3 HER2+ BC cells by antisense oligonucleotides^[64] or by small interfering RNA^[63] blocked the growth arrest mediated by

Table 1. A summary of different targets that promote the development of Human epidermal growth factor receptor 2 (Her2)-targeted therapy resistance and drugs to potentially overcome resistance

Factors	Mechanism	Drugs	Ref.
PTEN loss	PTEN loss causes loss of PI3K/Akt/mTOR pathway control and its sustained activation	BEZ235	[29,127]
PIK3CA mutations	PIK3CA mutations increase activation of the PI3K/Akt/mTOR pathway	BEZ235	[19,127]
c-MET	Upon activation with its ligand HGF, c-MET triggers a variety of downstream signaling pathways, including PI3K/AKT, Ras/MAPK, and Src	Cabozantinib	[38-41,50]
IGF-IR	Upon ligand binding, IGF-IR initiates signaling through the Ras/MAPK and PI3K/ AKT pathways. IGF1 signaling also elevates the expression of the p27 ^{Kip1} ubiquitin ligase, SKP2, resulting in the degradation of p27 ^{Kip1}	BMS-754807	[52,53,54,127]
p27 ^{Kip1}	IGF1 signaling induces the phosphorylation of the HER2 receptor Alteration in its cellular localization or reduced expression is permissive for the activation of cyclin E/ CDK 2, causing cell cycle progression	MG132	[63,64,65,56]
Src	pSrc promotes activation of the PI3K/Akt/mTOR pathway, EGFR, HER2, and HER3 receptors. Src has been found to inhibit PTEN activity and interfere with its membrane localization	Dasatinib Saracatinib	[29,78,80,81,82]
PPP2R2B	PPP2R2B downregulation or its silencing by EZH2 causes persistent PI3K/Akt/mTOR pathway activation	EPZ-6438	[94,95,96-101,102]
CD36	The CD36-mediated pathway is activated and becomes the major source of FAs uptake rather than FASN-mediated FAs de novo biosynthesis, and provides the cell with needed energy sources, promoting tumor growth and survival	-----	[111]
MicroRNAs	MicroRNAs upregulation targets cell cycle regulators such as p57 and p27. miR-221 directly inhibits PTEN	-----	[69-71,72,118]

PTEN: phosphatase and tensin homolog; MAPK: mitogen-activated protein kinase; PIK3CA: PIK3 catalytic subunit; HGF: hepatocyte growth factor; IGF-IR: insulin-like growth factor-I receptor; PPP2R2B: regulatory B-subunit of PP2A; pSrc: phosphorylated Src; FAs: fatty acids.

trastuzumab. Nahta *et al.* also reported that the trastuzumab-resistant SKBR3 cells showed reduced p27 levels and increased CDK2 activity^[56].

Furthermore, Nahta *et al.* showed that transfection-mediated expression of p27 in the resistant cells increased trastuzumab sensitivity^[56,57]. This is consistent with the findings of Kute *et al.*^[65] in which p27 induction by MG132 (a proteasome inhibitor) [Table 1] restored trastuzumab sensitivity, suggesting that downregulation of p27 is likely to result from increased protein degradation. They also reported that the p27 cellular localization might be important for the response to trastuzumab, as trastuzumab-resistant BT474 HER2+ BC cells showed a loss in the nuclear expression of p27^[65].

These data are consistent with earlier results in which trastuzumab exposure caused an elevation in p27 levels and nuclear localization in the sensitive cells^[64].

In addition, studies by Kute *et al.*^[65], Shattuck *et al.*^[42], and Lu *et al.*^[51,54] suggested that the IGF1R and MET signaling could contribute to p27 downregulation and the development of trastuzumab-resistance, indicating that p27 appears to be a common endpoint for various resistance pathways^[42,51,53,54].

Several studies also showed that Src overexpression activated the proteolysis of p27, which may confer lapatinib-resistance in Her2 + breast cancer^[66]. It was reported that Src phosphorylates p27 at Tyr74 and Tyr88 to reduce its stability and reduce p27-cyclin E-CDK2 complex formation during G1 phase^[67]. Moreover, p27 phosphorylation by Src further promotes the phosphorylation of p27 by cyclin E/ CDK 2, resulting in p27 degradation by SCF^{SKP} E3 ubiquitin^[68].

miR-221 upregulation has been reported in different tumors and may be involved in tumor progression by affecting expression levels of the cell cycle regulators such as p57 and p27 [Figure 1]^[69-71]. Interestingly,

Huynh *et al.*^[72] reported that Src-activated NF- κ B may result in miR-221 upregulation in lapatinib-resistant cells [Figure 1]. In addition, the findings of Huynh *et al.* indicated miR-221 involvement, and not the ubiquitination-proteasomal degradation pathway, in p27 downregulation in the lapatinib - resistant cells^[72].

These data demonstrated the crosstalk of p27 with the different signaling pathways as well as its role in the development of targeted therapy resistance.

Src

The cellular proto-oncogene Src is a non-receptor tyrosine kinase that regulates varied biological processes such as cellular replication, differentiation, and survival^[73,74]. Aberrant Src activation is considered to be a marked oncogenic event^[75]. Src is normally found inactivated by the intramolecular binding of its phosphotyrosine (Tyr530) with the Src homology 2 domain^[73]. The involvement of receptor tyrosine kinases (RTKs) with growth factors such as EGF and PDGF causes Y530 dephosphorylation and consequent Src activation^[76,77]. The activated Src then autophosphorylates tyrosine 416 residue (Tyr416) in its kinase domain, enabling it to interact with a variety of targets^[73].

In terms of the relationship between Src activation and the response to targeted therapy, one study which involved 57 BC patients showed that tumors with a high level of phosphorylated Src (pSrc) had a poor clinical response and more aggressive disease after trastuzumab therapy. As might have been anticipated, the overall survival was significantly lower than for patients with pSrc-low tumors^[78].

Peiró *et al.*^[79] demonstrated that Src activation resulted in trastuzumab resistance and poor prognosis in HER2+ breast cancer patients. Moreover, the *in vitro* inhibition of Src restored trastuzumab sensitivity in the resistant cells, with the ability to suppress tumor growth in several preclinical models of resistance. These data are consistent with findings by Zhang *et al.*^[78], where expression of the activated SRC in a trastuzumab-sensitive BC cell line, BT474, caused trastuzumab resistance both *in vitro* and in xenografted mouse models. Conversely, sensitivity was restored by Src inhibition^[78]. In a related finding, in a phase 2 trial of 23 patients with metastatic HER2+ BC, the combination of paclitaxel, trastuzumab, and dasatinib (Src inhibitor) showed high efficacy and success rate^[80] [Table 1].

Lapatinib resistance has also been reported in cell lines showing a high level of the activated Src. Lapatinib combined with Saracatinib (Src inhibitor) significantly prolonged the xenografted-mice survival^[81] [Table 1].

In efforts to understand the mechanistic relationships between the HER family, IGF-1R, PTEN, and Src, the work of Zhang *et al.*^[78] showed that overexpression of EGFR or IGF-1R or PTEN loss caused Src hyperactivation that is monitored by Tyr416 phosphorylation. The activated Src then promoted trastuzumab resistance in BC cell lines via a PI3K/Akt-dependent [Figure 1] or via independent manner^[78]. These cell lines also showed sensitivity to Src inhibitors^[78]. Moreover, Src inhibition led to a reduction in EGFR, HER2, and HER3 activation, suggesting that the Src hyperactivity in trastuzumab-resistant cells induces a feedback loop where the active Src causes receptor activation, which, then activate Src.

Studies by Nagata *et al.*^[29] and Lu *et al.*^[82] also suggest a linkage between Src and PTEN, wherein PTEN can use its protein phosphatase activity to regulate Src phosphorylation. Src has been found to inhibit PTEN activity through tyrosine phosphorylation as well as by blocking the membrane localization of PTEN^[29,82] [Figure 1], indicating that Src and PTEN may regulate each other to produce trastuzumab resistance.

These results suggest that Src activation is a common event during the development of targeted therapy resistance and that Src inhibition may be a novel therapeutic strategy.

The Protein Phosphatase 2A (PP2A) Family

PP2A is a serine/threonine phosphatase family that regulates a variety of cellular processes including growth, metabolism, and apoptosis^[83]. PP2A family members are also well known for their role as tumor suppressors^[84,85], suppressing several oncogenic pathways in carcinogenesis including Wnt, Myc, and PI3K/AKT/mTOR^[86-88].

Structurally, the PP2A family is found as a heterotrimeric complex that consists of scaffolding A-subunit (PPP2R1A), regulatory B-subunit (PPP2R2B), and catalytic C-subunit (PPP2R2C)^[89]. The PPP2R1A subunit often carries inactivating mutations^[90,91], while the PPP2R2C and PPP2R2B subunits may be subjected to epigenetic repression or deletions^[88,92,93]. These mutations suppress the PP2A tumor suppressor activity, leading to cancer development.

One critical pathway that PP2A controls is the PI3K/AKT/mTOR pathway. The ribosomal protein S6 kinase beta-1 (p70S6K) and eukaryotic translation initiation factor 4E binding protein 1 (4EBP1) regulate two downstream pathways of AKT and mTOR that are vital for cellular proliferation and tumorigenesis^[94,95]. PP2A can directly dephosphorylate p70S6K and 4EBP1 to maintain the PI3K/AKT/mTOR pathway equilibrium [Figure 1]^[96-101]. Consequently, PP2A may be linked to targeted-therapy sensitivity in cancer, including monoclonal antibodies and tyrosine kinase inhibitors^[88,90].

In a study by Tan *et al.*^[88], the silencing of PPP2R2B by DNA hypermethylation was found to be accompanied by mTOR inhibitor resistance, while Bao *et al.*^[102] demonstrated that PPP2R2B downregulation is associated with poor prognosis in HER2+ BC and resistance to HER2-targeted therapy, including both lapatinib and trastuzumab. Additionally, these authors suggest that the persistent activation of both p70S6K and 4EBP1 following HER2-targeted therapy in low PPP2R2B-expressing tumor cells might result in therapy failure.

EZH2 is the catalytic subunit of the polycomb repressive complex 2, which suppresses gene expression via mediating the lysine 27 methylation of histone 3^[103]. In this study by Tan *et al.*^[103], PPP2R2B silencing mediated by EZH2 was shown to be required for both drug tolerance and HER2-targeted therapy resistance [Figure 1]. Moreover, HER2-targeted therapies combined with EZH2 inhibitors in anti-HER2 resistant cell lines and mouse models engrafted with trastuzumab-resistant cells showed significant tumor growth arrest in both cases. These studies suggest that the combination of EPZ-6438 (EZH2 inhibitor) with HER2-targeted therapy might prevent tumor recurrence and metastasis^[102].

Taken together, these data indicate the involvement of the PP2A family in the development of HER2-targeted therapy resistance with the potential use of the PPP2R2B expression levels as a predictive marker for the response.

CD36

Fatty acids (FAs) play a vital role in various biological processes, including cellular signaling, membrane phospholipids synthesis, and energy production^[104,105]. Generally, two FAs sources are available for cells to meet their energy requirements: exogenously via specialized transporters and/or endogenously via FA synthase (FASN)-mediated de novo biosynthesis^[106]. In contrast to normal cells (except liver and adipose tissues), which preferentially acquire FAs from exogenous sources, more than 90% of FAs in cancer cells are

normally derived from de novo FAs synthesis^[105]. Tumor cells depend on these two sources not only to sustain their proliferative capacity but also to secure a critical energy source under stress conditions^[107].

In terms of exogenous FAs uptake, specific transporters are needed to facilitate FAs movement across the plasma membrane. The most commonly identified transporter is CD36^[108], an 88-kDa glycosylated membrane protein that is well-known as a member of the type B scavenger receptor family. CD36 binds several ligands including anionic phospholipids, thrombospondin, and fatty acids^[109].

Vazquez-Martin *et al.*^[110] reported that the FASN-mediated FAs de novo biosynthesis is inhibited in response to HER2 inhibition and cancer cells undergo apoptosis, indicating crosstalk between FASN and HER2. However, a recent study found that lapatinib-resistant cells are unresponsive to (-)-C75, which is well-established to suppress FASN^[111]. Furthermore, the lapatinib-resistant cells showed a significantly higher level of CD36 with an enhanced rate of FAs uptake, as well as an increase in the presence of lipid droplets compared to their sensitive counterparts^[112]. CD36 expression has also been reported to be increased after anti-HER2 therapy, including lapatinib and trastuzumab, which significantly correlates with a poor prognosis in HER2+ BC patients^[111]. These data suggest that there is a shift in the metabolic dependence toward CD36-mediated FAs uptake in these cells for maintaining the cellular FAs requirements^[111].

CD36 knockdown via siRNA or the small molecule inhibitor, sulfosuccinimidyl oleate (SSO), re-sensitizes lapatinib-resistant cells and induces apoptotic cell death^[111]. The role of CD36 in lapatinib resistance was also supported by a tumor xenograft study in mice, in which an anti-CD36 antibody markedly sensitized the resistant tumors to lapatinib. Moreover, CD36 knockdown repressed the tumor growth and extended the survival in a HER2+ BC model^[111].

Illustrating the mechanistic aspects of how FAs source alteration in response to targeted therapy ultimately leads to resistance, Feng *et al.*^[111] suggested that HER2 activates FASN via phosphorylation, as well as via transcriptional induction. Therefore, HER2 inhibition mediated by trastuzumab or lapatinib causes the suppression of FASN activity. The CD36-mediated pathway is then activated to become the major source of FAs uptake, promoting tumor growth and survival [Figure 1]^[111].

These reports indicated the possible role of CD36 in resistance to anti-Her2 targeted therapy.

MicroRNAs

MicroRNAs (miRNAs) are a class of 22-25 nucleotide RNA molecules that downregulate gene expression^[113]. miRNAs also play a vital role in the post-transcriptional regulation of mRNA stability and translation efficiency through base-pairing with the complementary locations in the 3'untranslated region of the mRNA^[113,114].

miRNAs have been shown to be significantly deregulated in many types of cancer, especially breast cancer, in which deregulated miRNAs are associated with breast cancer metastasis and poor prognosis in some cases, highlighting their critical roles in carcinogenesis, tumor growth, and metastasis^[114-116].

The oncogenic miRNA, miR-221, is one of the few miRNAs that are persistently elevated in malignancies of different tissue including breast cancer^[117], and has been suggested to accelerate cancer progression by targeting cell cycle regulators such as p57 and p27 [Figure 1]^[69-71].

Several studies suggest the role of miRNA in the development of targeted therapy resistance. Xingming *et al.*^[118] reported that miR-221 is upregulated in breast cancer cells resistant to trastuzumab. In addition, miR-221 directly inhibits PTEN [Figure 1], causing an elevation in motility and invasiveness of HER2+ BC cells. Moreover, miR-221 suppression or the restoration of PTEN expression reversed the malignant phenotypes of HER2+ BC, indicating the critical role of miRNAs in regulating the progression of HER2+ breast cancer^[118].

Huynh *et al.*^[72] discovered that miR-221 upregulation by the Src/NF- κ B pathway contributed to the development of lapatinib resistance by targeting p27 [Figure 1]. Furthermore, miR-221 inhibition by Src inhibitors may serve as a novel therapeutic strategy to overcome targeted-therapy resistance^[72]. Interestingly, miR-16 has been reported to be involved in regulation of the NF- κ B pathway^[119]. In addition, miR-630 and miR-16 have been shown to play a role in HER2+ BC sensitivity to lapatinib^[120-121]. The interplay among miR-16, miR-630, and miR-221 in regulating the cellular response to targeted-therapy needs to be further investigated.

CONCLUSIONS

Her2-targeted therapies are safe and effective drugs for Her2-positive breast cancer; however, de novo or acquired resistance to these agents has limited their clinical efficacy, which ultimately leads to disease relapse and tumor progression. Many molecular mechanisms are incorporated in targeted-therapy resistance including signaling through alternative RTKs^[122,123], altered immune response^[122], altered antibody-receptor interaction^[123], Her2 TK domain mutations^[124], HER3 or HER4 overexpression^[125,126] and p95HER2 overexpression^[50]. In this review, we have focused on recent mechanisms that play a role in resistance development and the crosstalk between different signaling pathways that contribute to disease progression and resistance. Current and future strategies for overcoming resistance include switching or combining different Her2-targeted agents and the development of small molecule inhibitors such as BEZ235 (Dual PI3K/mTOR inhibitor)^[127] [Table 1], BMS-754807 (IGF1R inhibitor)^[127] [Table 1], and EPZ-6438 (EZH2 inhibitor)^[102] [Table 1]. These strategies show promise towards improving survival in Her2 positive BC patients.

DECLARATIONS

Authors' contributions

Made substantial contributions in terms of the organization, presentation, writing and editing of this article: Elshazly AM, Gewirtz DA

Availability of data and materials

Not applicable.

Financial support and sponsorship

Work in Dr. Gewirtz's laboratory relating to breast cancer is supported by NIH/NCI Grant # CA260819 and Grant #W81XWH19-1-0490 from the Department of Defense Breast Cancer Research Program. The funding agencies had no role in the development of this article.

Conflicts of interest

All authors declared that there are no conflicts of interest.

Abstract

Over the past two decades, high sensitivity to HER2-amplified primary breast cancers has been achieved with HER2-targeted therapies. CDK4/6 inhibitors have long been identified as a potential treatment option for advanced breast cancer patients. However, acquired HER2 heterogeneity leading to resistance during the treatment has been identified as a bottleneck. This review focuses on the recent resistance mechanisms identified and potential therapeutic targets for conventional and combination endocrine therapies with CDK4/6 inhibitors by various breast cancer clinical trials and research groups in HER amplified and/or mutated breast cancer tumour. Activating *HER2* alterations, JNK pathway, hyperactivated TORC1, co-mutations in *HER2* and *HER3*, phenotypic changes of HER2, and few other advanced findings are identified as potential therapeutic targets in treating current HER2 endocrine therapy-resistant tumour. Along with the HER2-focused resistance mechanisms, we also describe how the microbiome may play a role in breast cancer therapy and its potential for new therapeutic strategies to overcome drug resistance in breast cancers.

Keywords: HER2, CDK4/6, MONALESSA-2 trial, JNK pathway, HER2 and HER3 co-mutations, microbiome, hot and cold tumour, drug resistance

INTRODUCTION

Human epidermal growth factor receptor 2 (*HER2*), a gene frequently implicated in breast cancers and a variety of other tumour types, results in a growth factor receptor, which, when upregulated, promotes tumour growth by inducing cell division. There has been a concerted effort to design cancer drugs that can inhibit the mutant *HER2* protein, thereby successfully controlling the cell division and tumour growth. MONALESSA-2 trial^[1] is the first report of median overall survival exceeding five years in phase 3 postmenopausal hormone receptor positive (HR+)/human epidermal growth factor receptor 2 negative (*HER2*-) metastatic breast cancer (MBC) when treated with cyclin-dependent kinase (CDK) CDK4/6 inhibitor with an aromatase inhibitor. Whether this is a one-off successful trial or can be replicated in other breast cancer patients will be interesting to observe. CDK4/6 inhibitors have long been identified as a potential treatment option for advanced breast cancer patients. For nearly two decades, CDK4/6 inhibitors have become the standard of care for HR+/*HER2*- breast cancer. A recent study analysed the association of *HER2* low expression determined by immunohistochemistry score in HR positive and *HER2* negative metastatic breast cancer subjects treated with CDK4/6 inhibitors. They found that the low expression of *HER2* is associated with inferior progression-free survival^[2]. However, not all patients achieve the expected survival outcome and become resistant to treatment regimens. Further research is needed to understand how tumour cells escape the known resistance CDK4/6 mechanisms involving E2F transcriptional activity, tumour suppressor protein RB dependent cell division arrest and senescence stage, cyclin D dependent apoptosis, and others. Hence, it is important to identify novel underlying biological mechanisms leading to resistance and cancer metastasis. Some known mechanisms leading to resistance involve the role of different coregulators (e.g., AP-1, SP-1, and AIB1), kinases (e.g., *EGFR*, *HER2*, *IGF1-R*, *PI3K*, *AKT*, and *MAPK*), and loss or modification of oestrogen receptor- α (*ESR1*) while regulating the ER signalling pathway. Since *HER2* amplification alone can act as a driver in promoting carcinogenesis, targeting both *HER2* activity and interacting proteins/pathways may provide a more precise and synergistic effect on tumour regression in a combination therapy setup. The use of advanced genomic technologies and computational modelling resulted in the recent reporting of potential molecular vulnerabilities and mechanisms leading to biological breakthroughs that help advance clinical trial designs and treatment of breast cancer relatively for improved response and survival rates. Many excellent reviews have covered various breast cancer molecular vulnerabilities and resistance mechanisms^[3-8]. In this review, we focus on explaining the most recent studies that proposed resistance mechanisms in *HER2* mutated breast cancers, along with the potential use of microbiome in combinatorial immunotherapies to treat breast cancer tumour for effective response.

HER2 DEPENDENT BREAST CANCER RESISTANCE MECHANISMS

Activated *HER2* alterations

Oestrogen receptor (ER), the major driver in breast cancer causation, is a known target to treat breast cancer. ER's expression not only depends on the patient's age and grade of the tumour but also on *HER2* expression and loss of the *TP53* gene. CREATE-X study^[9] reported that after standard neoadjuvant chemotherapy with anthracycline, taxane, or both, the addition of adjuvant capecitabine is safe and effective in improving the disease-free survival and overall survival among patients with *HER2*- breast cancer and residual invasive disease. To understand the benefits of adjuvant therapy in primary breast cancer patients, multigene tests (e.g., OncotypeDx, MammaPrint, PAM50, and others) are being performed^[10-12]. These multigene tests also assist in distinguishing patients who may benefit from endocrine therapy in combination with chemotherapy. These tests stratify the tumour based on the tumour grade, risk of recurrence, and likelihood of treatment response. Endocrine therapy has been shown to be effective mostly in ER+ metastatic breast cancer patients. It is known that CDK inhibitors with endocrine therapy improve outcomes in patients with metastatic ER+ breast cancer. However, its value in early-stage patients is still unclear, and research is still limited on how varying clonal events between primary and metastatic biopsies

could result in developing resistance to endocrine therapies in combination with CDK inhibitors. With 25%-30% achieving response to endocrine therapy and others developing resistance, it becomes apparent that resistance to endocrine therapy develops during the treatment resulting in cancer metastasis. Beyond the historically known resistance mechanisms, few recent studies have shed light on how activating *HER2* mutations in ER+ metastatic breast cancer tumour had developed resistance to aromatase inhibitors, tamoxifen or fulvestrant^[13]. Whole exome sequencing analysis of the primary tumour biopsies before endocrine therapy and 12 hotspot *HER2/ERBB2* mutations covering kinase, extracellular, transmembrane, and cytoplasmic domains resulted in detecting the *HER2* alterations only in the metastatic biopsies but not the primary, suggesting that these alterations were acquired during the course of therapy [Figure 1].

Clonal evolution analysis to evaluate the clonal expansion structure and dynamics also concluded similar origins of the alterations. Examination of the functional role of these alterations in T47D and MCF7 cell lines through lentiviral transduction showed strong resistance to oestrogen deprivation resistance to tamoxifen and fulvestrant. Hyperphosphorylation of both ERK and AKT under conditions of oestrogen deprivation or inhibition was also associated with the *HER2* alterations. Based on the cell viability analysis, they showed that the combined inhibition of *HER2* mutants restored sensitivity to fulvestrant. Activating *HER2* alterations are shown to offer a distinct mechanism of acquired resistance to varying ER-directed combination therapies in MBC and are postulated to be overcome by an irreversible *HER2* inhibitor.

Resistance via JNK activated pathway

While the novel clonal mutations can improve understanding of the underlying resistance mechanisms and alternative therapy options, identifying the certain common characteristics or pathway alterations leading to resistance can also help offer alternative treatments. From the FELINE clinical trial^[14], using exome and single-cell RNA sequencing of serially collected biopsies from ER+ breast cancer patients treated with letrozole mono endocrine therapy or in combination with different doses of CDK4/6 inhibitor ribociclib, researchers tried to understand the early-stage breast cancer evolution and develop resistance. Also, the researchers examined how disruption of CDK6, Cyclin E2 and interaction of MAPK8-10, MAPK11-14, and JNK103 could result in resistance to endocrine therapy. The study^[15] identified JNK activation as offering an alternative mechanism to oestrogen-independent proliferation under combined therapy. Tumour cells with diminished endocrine signalling can bypass CDK4/6 inhibition through upregulation of the JNK pathway and showed that in cancer cells with high oestrogen signalling, potentiation of CDK4/6 activation can occur through ERBB4 and ERK upregulation and activation. In tumour without CDK6 amplification, the resistant cancer cell state was deemed to reflect a phenotypic shift from ERK to JNK MAPK signalling and reduced oestrogen signalling. When combination therapy was used in tumour without CDK6 amplification, JNK activation provided an alternative pathway to oestrogen-independent cell proliferation. Also, such showed less ERBB4 upregulation, indicating that JNK activation is a mechanism of resistance to endocrine but not CDK inhibition. Along with the activation of JNK signalling in tumour without CDK6 amplification with combination therapy, the absence of ERK signal further reflects the transition to an endocrine independent resistance state, with reduced reliance on the interaction of ESR1/ERK [Figure 2].

Both JNK and ERK pathways, which are major components of the MAPK network, showed differing activity patterns following combination therapy but not endocrine therapy alone. Along with the cell cycle, *TGF-β* and *TP53* pathway-related genes with frequent mutations, the majority of patients in the study maintained persistent polyclonal populations. Earlier reports demonstrated the stress kinase pathway via p38 and JNK to modulate ER function by phosphorylation of ER and its coregulators^[16-17]. Identifying the phenotypic changes and common resistance phenotypes in the clones that survived using both exome and single-cell RNA sequencing offered an efficient method to detect resistance mechanisms. Researchers suggested that increased ERBB4 signalling, oestrogen signalling loss, responsive states, JNK pathway

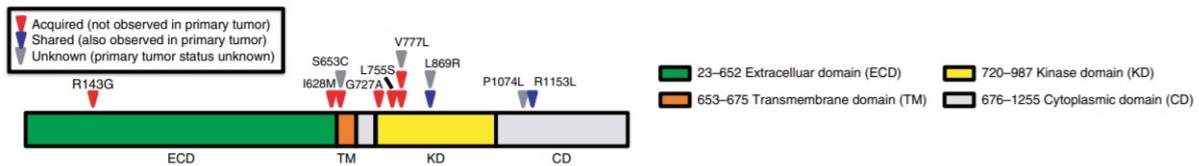

Figure 1. Acquired *HER2* alterations in patients with endocrine resistance. The location of *HER2* alterations identified by sequencing metastatic biopsies is depicted along the length of the protein. Protein domains are indicated by colour coding. Evolutionary classification for alterations: red triangles, acquired alterations; blue triangles, alterations shared with primary tumour; grey triangles, indeterminate or unknown. Figure 1 and legend used from Nayar *et al.*^[13].

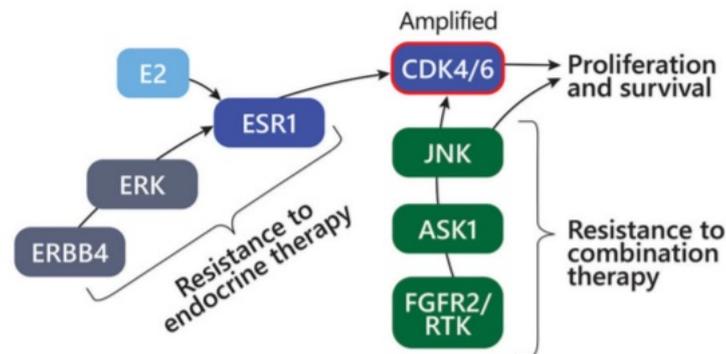

Figure 2. A schematic diagram showing resistance mechanisms driven by upregulation of ERBB4 and CDK6 amplification (red circle signifies amplification) or alternative signalling via FGFR2/RTK's and JNK signal transduction. Figure used from Griffiths *et al.*^[15].

activation, and increase in basal-like tumour attribute as underlying features for developing endocrine therapy resistance and can be potential biomarkers while selecting and treating early-stage breast cancer patients^[15].

Hyperactivated TORC1 driven acquired resistance

Neratinib, an irreversible pan-HER tyrosine kinase inhibitor, inhibits the growth of *HER2*-mutant tumour. It has been shown to be effective in preclinical studies in different tumour, including breast^[18], colorectal, and non-small cell lung cancers with *HER2* mutations. Following that, two clinical trials MutHER^[19] and SUMMIT^[20] explored the efficacy of neratinib in metastatic breast cancer patients with *HER2* mutations. Initial findings reported by the SUMMIT trial indicated that neratinib plus fulvestrant combination has been shown to be clinically active in heavily pre-treated *HER2*-mutant HR+ MBC patients, including in those who had received prior fulvestrant and CDK4/6i therapy with clinical benefit rate of 47% among the trial participants^[20]. Based on the varying degrees of efficacy and clinical benefits of neratinib in *HER2* mutant cancers, Sudhan *et al.*^[21] postulated the role of different genomic modifiers towards the response and in developing resistance. They went on to identify clinically actionable mechanisms leading to resistance to neratinib in *HER2*-mutant cancers. Using bladder & ovarian cancer cells, they demonstrated that neratinib resistant cells showed enrichment of cell cycle promoting E2F targets, along with nuclear factor kappa B (*NF-KB*), epithelial-to-mesenchymal transition, KRAS, TORC1, inflammation, and immunological signatures. While TORC1 substrates such as p70 S6 kinase (S6K) and S6 have increased phosphorylation in drug resistance cells, EGFR, *HER2*, and *HER3* phosphorylation were reported to be suppressed upon neratinib treatment, indicating sustained drug target inhibition. Similar activity of TORC1 was shown in neratinib-resistant breast cancer patient-derived xenografts. To confirm the role of TORC1 and to evaluate the involvement of other PI3K isoforms in neratinib's resistance, the researchers further tested the efficacy

of combining neratinib with PI3Ka (alpelisib), TORC1 (everolimus), MEK1/2 (selumetinib), AKT (MK-2206), and with the pan-PI3K inhibitor buparlisib. Pharmacological suppression testing of TORC1 resulted in identifying PI3K or MAPK inhibitors to partially suppress TORC1 activation and, hence, are less effective at reversing neratinib resistance. Further investigation revealed that both PI3K and MAPK pathways work collectively to promote TORC1 activity. Based on how RAS modulates mTOR activity through simultaneous activation of both PI3K and MAPK pathways, researchers examined RAS pathway activation status [Figure 3].

Interestingly, unlike in bladder and ovarian cancer cells, TORC1 activation in breast cancer cells was not associated with an upregulation in RAS function. This suggests that different *HER2*-mutant cancer types may develop distinct resistance mechanisms involving TORC1 signalling. The study identified hyperactivation of TORC1 as a potentially actionable mechanism driving primary and secondary resistance to neratinib in *HER2*-mutant cancers and concluded that the combination of TORC1 inhibitors with neratinib should be tested in *HER2*-mutant cancers with *de novo* or acquired mTOR pathway mutations^[21].

Co-mutations in *HER2* and *HER3* and resistance

SUMMIT trial^[22] demonstrated an effective way of probing the underlying biology among *HER2* and *HER3* mutated cancers through pharmacological HER kinase inhibition in patients. It showed an effective application of next-generation sequencing technologies in precision clinical trials while advancing our understanding of the biological impact and consequences of *HER2* and *HER3* mutations in human cancers. Although the study did not identify co-mutation of *HER2* and *HER3* in any of the study participants, concurrent aberrations in cell cycle checkpoints and activation of RTK/RAS/RAF pathway were associated with worse outcomes. While the SUMMIT trial did not report any patients with *HER2-HER3* co-mutations, another study^[23] reported that co-expression of mutant *HER2/HER3* enhances *HER2/HER3* co-immunoprecipitation and ligand-independent activation of *HER2/HER3* and PI3K/AKT, resulting in enhanced growth, invasiveness, and resistance to *HER2*-targeted therapies. Computational modelling and *in vitro* studies of *HER2-HER3* co-mutations showed strong binding affinity and co-mutated cells grew spikes that assisted matrix invasion, a sign of metastasis [Figure 4].

The authors suggested that patients carrying *HER2-HER3* co-mutations may not be good candidates for *HER2* inhibitors alone and need a new therapeutic approach in combination with TKI and PI3Ka inhibitors to suppress the *HER3* activity^[23]. Although *HER3* lacks an active tyrosine kinase binding domain, it has several docking sites to bind with PI3K and form heterodimers to activate PI3K pathway and improve response to PI3K inhibitors in combination with *HER2* and TKI inhibitors^[23].

HER2 low positive tumour and resistance mechanisms

To further understand the use of anti-*HER2* agents, Denkert *et al.*^[24] conducted a deep clinical and molecular analysis among 2310 patients with *HER2*-non-amplified primary breast cancer from four prospective, neoadjuvant trials. Based on the standardised immunohistochemistry technique, the authors reported that *HER2*-low-positive tumour can be identified as a new subgroup of breast cancer with distinct biology and show differences in hormone receptor status, tumour proliferation, grading, and response to neoadjuvant therapy. Significant differences in the presence of *BRCA1/2* germline variants and other breast cancer predisposition genes were observed between *HER2*-0 and *HER2*-low-positive tumour. Likewise, varying frequencies of *TP53* and *PIK3CA* mutations in the two subgroups indicate different genetic and mutational backgrounds. Thus, providing enough evidence for further characterisation of the two groups to identify the mechanisms leading to sensitivity and/or resistance to treatment. A more recent study at ESMO 2021, for the first time, presented a study in which they reported a change of *HER2* negative (*HER2*-0) to *HER2* low negative tumour^[25]. Among 547 primary breast tumour, they reported a 30% shift from *HER2*-0

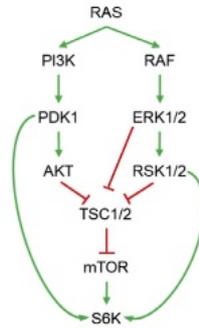

Figure 3. Schematic representation of RAS-mediated TORC1 activation by both PI3K and MAPK pathways. Figure used from Sudhan et al.^[21].

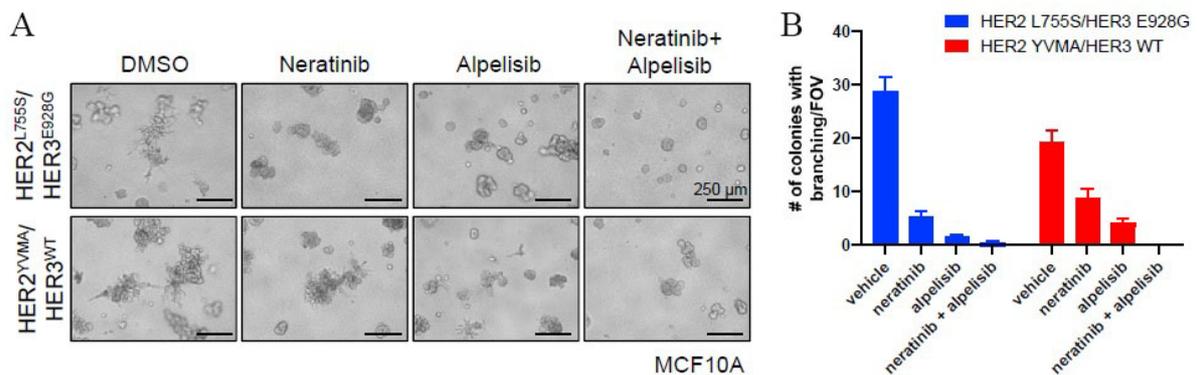

Figure 4. A: Shows MCF10A cells stably expressing the indicated genes were grown in 3D Matrigel in EGF/insulin-free medium + 1% charcoal/dextran-stripped serum (CSS) treated with vehicle [dimethyl sulfoxide (DMSO)], 20 nM neratinib, 1 mM alpelisib, or the combination. Scale bars, 250 μ m. B: Shows the number of colonies with invasive branching per field of view (FOV) from (B) was quantified. Data represent the average \pm SD ($n = 3$). Figure and legend used from Hanker et al.^[23].

to Her2 low expression on recurrence. This switch in HER2 expression status offers more therapeutic alternatives in HER2- and also for triple-negative breast cancer patients, in which 14% tumour reportedly had the HER2 expression change. It also shows the necessity to re-test HER2 expression at relapse for improved care.

Beyond HER2 mutations and resistance mechanisms in hormone-receptor positive breast tumour

The past decade has shown the power of combining genomic sequencing and clinical information while elucidating the role of molecular vulnerabilities in targeted therapies. One such study analysed 1,918 advanced breast cancers, of which 692 tumour were previously treated with hormonal therapy. Using Memorial Sloan Kettering integrated mutation profiling of actionable cancer targets (MSK-IMPACT) platform, identified increased frequency of alterations in MAPK and oestrogen receptor transcriptional regulators and their exclusive occurrence with ESR1 mutations. The study identified *HER2* activating mutations, NF1 loss and EGFR amplification as potential therapeutic targets while treating the resistant tumour.^[26] Along with understanding the role of clinically actionable mutations, it is also important to know if other variants contribute to cancer resistance. The known association of *MAP3K1*, *PIK3CA*, and *TP53* mutations with poor prognosis in luminal A and luminal B subtypes of breast cancer, using targeted sequencing, Griffith et al.^[27] reported the significant association of frameshift nonsense (FS/NS) mutations in *NF1* and variants of unknown significance in *PIK3R1* and *DDR1* as a marker for poor prognosis and

resistance in oestrogen receptor-positive breast cancer cohort^[27-28].

Transcriptomic heterogeneity and breast cancer resistance

Transcriptional heterogeneity and KDM5i therapeutic resistance

Understanding the intra- and inter- tumour heterogeneity of breast tumour has helped advance our understanding of how cancers evolve and develop resistance. The role of cancer-associated genetic alterations on transcriptomes has been very well covered in earlier reviews^[29-32] and most recently in a study by pan-cancer analysis of a whole-genome consortium^[33]. With growing emphasis on oncogene addiction^[34] and transcriptional addiction^[35], it becomes natural that more studies will focus on investigating various mechanisms leading to transcriptional addiction and resistance. Earlier, the generation of genome-wide maps of DNA-associated proteins to understand the dysregulated transcription and transcriptional heterogeneity was limited due to the number of cells that were needed^[35]. However, precise measurement of transcriptional heterogeneity for effective treatment alternatives has been made possible with advances in single-cell sequencing technologies. An association of KDM5B/JARID1B, which encodes a histone H3 lysine 4 (H3K4) demethylase, with shorter disease-free survival^[36] was reported in breast cancer patients treated with endocrine therapy. To understand the mechanistic contribution of the KDM5 family of histone demethylases (HDMs) to tumourigenesis and therapy resistance, Hinohara *et al.*^[37] carried out functional studies using breast cancer cell lines. They hypothesised that modulating KDM5 activity will affect intra-cellular heterogeneity, subsequently resulting in therapeutic resistance. Using single-cell RNA sequencing and Mass spectrometry, they confirmed higher KDM5B expression levels in luminal subtypes compared with basal-like breast cancer cells. ER+ primary tumour with higher KDM5B expression levels was more likely to develop local and distant metastatic recurrence in tamoxifen-treated breast cancer patients. They also confirmed heterogeneous expression of both *KDM5B* and *KDM5A* genes. KDM5 inhibitor (KDM5i) treatment decreased cellular transcriptomic heterogeneity in luminal ER+ breast cancer cells^[37]. **Table 1** summarises the different resistance mechanisms through which breast tumour develop resistance to endocrine and combinatorial therapies. Less cellular heterogeneity could lead to more responses, thus providing evidence of an association between heterogeneity and KDM5-driven resistance.

Dormant cells, HER2 status and resistance to endocrine therapy

Another line of thought among clinicians and researchers is whether endocrine therapy works by inhibiting cell division and/or by shifting the cancer cells to dormant cells. A study using single-cell and imaging analysis by Hong *et al.*^[38] investigated the contribution of clonal genetic diversity and transcriptional plasticity in both early and late phase tumour with endocrine therapy. Interestingly, they assigned therapy resistance to pre-adapted or dormant cells which had undergone transcriptomic reprogramming and copy number alterations. Earlier studies have reported that thrombospondin 1^[39] and integrin^[40] induce breast cancer cell proliferation and chemoresistance by the interaction between the cells and secreted molecules. Studies in mice have shown that some cancer cells with E-cadherin expression have activated HER2 and WNT-dependent migration^[41] to distant organs and progesterone-induced migration of HER2+ cancer cells resulting in distant metastasis^[42]. This suggests that the disseminated cancer cells remain dormant for a period of adaptation and attains positive clonal selection^[43] before they proliferate^[44]. The use of stage-specific pre-adapted biomarkers to characterise the pre-adapted cells could assist in detecting resistance. A recent *in vitro* study also demonstrated that activating the MET/FAK signalling axis leads to CDK4/6-independent CDK2 activation and could thus become a target to improve the response of cancers to CDK4/6-targeted therapies^[45].

Tumour microenvironment, microbiome, and therapeutic resistance

The tumour microenvironment surrounding tumour cells is extremely important for their growth. The tumour microenvironment is characterized by stroma, fibroblasts, inflammatory cells, immune cells,

Table 1. Summary of breast cancer resistance mechanisms and molecular vulnerabilities identified as potential therapeutic targets

Resistance mechanism	Molecular vulnerability/potential biomarker	Study in...	Reference
Activated <i>HER2</i> alterations	Hyperphosphorylation of both ERK and AKT	Metastatic breast cancer	[13]
Activated JNK activated	Increased ERBB4 signalling, oestrogen signalling loss, and responsive states	Early breast cancers	[14]
Hyperactivated TORC1	PI3K and MAPK pathways	<i>HER2</i> -mutant tumour	[21]
Co-mutations in <i>HER2</i> and <i>HER3</i>	Activation of <i>HER2/HER3</i> and PI3K/AKT	<i>HER2-HER3</i> co-mutated tumour	[23]
<i>HER2</i> low positive	Varying frequencies of <i>TP53</i> and <i>PIK3CA</i> mutations	<i>HER2</i> negative tumour	[24,25]
<i>HER2</i> activating mutations, NF1 loss and EGFR amplification	<i>HER2</i> activating mutations, copy number aberrations in NF1 and EGFR	Advanced tumour with hormonal therapy	[26]
Variants of unknown significance driven resistance	Frameshift nonsense (FS/NS) mutations in <i>NF1</i> , <i>PIK3R1</i> , and <i>DDR1</i>	Oestrogen receptor-positive breast cancer	[27,28]
KDM5 driven resistance	Higher KDM5B expression	Breast cancer cell lines	[37]

vascular system, and connective tissue. As each tumour is unique, the microenvironment surrounding the tumour is also extremely diverse. The interrelationship between tumour cells and the tumour microenvironment is deeply involved in tumour growth, invasion, metastasis, and antitumour drug sensitivity and resistance. Antitumour drug resistance is acquired through diverse mechanisms, such as blocking the immune clearance of tumour cells, preventing drug absorption, and stimulating paracrine growth factors to promote tumour cell growth^[46]. Changes in the tumour microenvironment can also be attributed to the microbiome^[47]. Microbiome can alter the tumour microenvironment by regulating circulating inflammatory and immunocompetent cells, even in a distant tumour. In treatment, the antitumour effect of cytotoxic agents is influenced by the activation of immune cells and the microbiome^[48]. Differences in the microbiome have been found to affect antitumour efficacy. A report showed that certain types of microbiome act to enhance antitumour immunity and help immune checkpoint inhibitors. *Bifidobacterium* induces immune-related genes in dendritic cells and enhances the antitumour effect of immune check inhibitors by inducing the activity of CD8-positive cells^[49]. The *Bacteroides* species, *Bacteroides thetaiotaomicron*, and *Bacteroides fragilis* enhance the effect of anti-CTLA-4 antibodies^[50]. There is growing clinical evidence that the microbiome influences the effectiveness of tumour immunotherapy. The patients who showed drug resistance or low drug efficacy had a lower microbiome diversity^[51] and abundant *Ruminococcus obeum* and *Roseburia intestinalis*^[52-53]. These studies suggest that if the antitumour immune activity is weak due to the insufficient microbiome, immune checkpoint inhibitors will not be sufficiently effective. The role of the microbiome in the efficacy of immunotherapy has been increasingly evaluated at the cellular level. Activation of macrophages and dendritic cells has been reported to be under the control of the microbiome^[54]. The suppression of drug resistance in breast cancer could be solved by inducing the immunosuppressive “cold” tumour microenvironment, which inhibits the antitumour effect, to an immunologically active state, “hot” tumour immune microenvironment, by the microbiome. Prediction of drug efficacy and drug resistance by analysis of the intestinal microbiota and elimination of drug resistance by alteration of the intestinal microbiota may become a new therapeutic strategy in the future.

CONCLUSION

The use of advanced tumour and single-cell technologies has resulted in redefining the *HER2* expression status, thus helping in identifying more accurate treatment alternatives for increased sensitivity. Reproducing similar clinical outcomes like in MONALEESA-2 trial would be more encouraging for both clinicians and patients. For researchers, such trials provide a unique opportunity to understand and elucidate specific molecular vulnerabilities and potential therapeutic targets among non-responders and

responders.

Abstract

Breast cancer is one of the most common cancer and leading causes of death in women in the United States and Worldwide. About 90% of breast cancers belong to ER+ or HER2+ subtypes and are driven by key breast cancer genes Estrogen Receptor and HER2, respectively. Despite the advances in anti-estrogen (endocrine) and anti-HER2 therapies for the treatment of these breast cancer subtypes, unwanted side effects, frequent recurrence and resistance to these treatments remain major clinical challenges. Recent studies have identified ER coactivator MED1 as a key mediator of ER functions and anti-estrogen treatment resistance. Interestingly, MED1 is also coamplified with HER2 and activated by the HER2 signaling cascade, and plays critical roles in HER2-mediated tumorigenesis and response to anti-HER2 treatment as well. Thus, MED1 represents a novel crosstalk point of the HER2 and ER pathways and a highly promising new therapeutic target for ER+ and HER2+ breast cancer treatment. In this review, we will discuss the recent progress on the role of this key ER/HER2 downstream effector MED1 in breast cancer therapy resistance and our development of an innovative RNA nanotechnology-based approach to target MED1 for potential future breast cancer therapy to overcome treatment resistance.

Keywords: MED1, transcription cofactor, estrogen receptor, HER2, therapy resistance, RNA nanotechnology

INTRODUCTION

Breast cancer remains one of the most common malignancies in women and is responsible for over 287,000 new diagnoses and 43,000 deaths annually in the US despite advances in treatment and detection. Based on the presence of key breast cancer biomarkers and global gene expression analyses, breast cancers can be generally subdivided into five subtypes, Estrogen Receptor (ER)+ Luminal A, Luminal B, HER2-enriched, Basal-like and the more recently identified Claudin Low subtype^[1,2]. ER is the first and most prevalent breast cancer biomarker that is expressed at various levels in about 70%-75% of breast cancers, while the transmembrane receptor tyrosine kinase HER2 (Neu, ERBB2) is highly expressed, typically as a result of amplification of the genomic DNA containing *HER2* and several other genes, in around 15%-20% of human breast cancer^[3-5]. ER+ and HER2+ breast cancer subtypes thus form the vast majority of breast cancer, and anti-estrogen and anti-HER2 targeted therapies have been developed and widely used in clinics for their treatment, respectively^[6-8]. Although the development of these ER and HER2-targeted therapies has greatly improved the patient outcome and survival, unfortunately, unwanted side effects, frequent recurrence and resistance to these treatments remain significant clinical issues and severely hinder their effectiveness^[3,9-11]. Thus, further understanding of molecular mechanisms underlying anti-estrogen and anti-HER2 treatment resistance and the development of new targeted therapies for better and safer patient care are urgently needed.

CURRENT ANTI-ESTROGEN AND ANTI-HER2 TREATMENT AND RESISTANCE MECHANISMS

Anti-estrogen (endocrine) therapies include the following types based on their mechanism of action: Selective Estrogen Receptor Modifiers (SERMs), Aromatase Inhibitors (AIs), and Selective Estrogen Receptor Degraders (SERDs)^[12-14]. SERMs, such as tamoxifen and raloxifene, compete with endogenous estrogen for the hormone binding site on the estrogen receptor and preferentially recruit co-repressors to inhibit the transcription of ER target genes^[8,15]. AIs, such as letrozole, anastrozole, and exemestane, function by inhibiting the aromatase enzyme essential for estrogen production in the body, thus depleting the hormone required for cancer cell growth^[9,16]. SERDs, most notably fulvestrant and several others currently in clinical trials, provide some additional benefits by targeting ER for degradation upon binding to the ER^[14,17]. While these drugs have greatly benefited and improved the outcome for many patients, the unwanted side effects, including increased risk for osteoporosis, arthralgia, rheumatoid arthritis, and endometrial cancer, hindered their usage and effectiveness. Furthermore, the de novo (intrinsic) or acquired resistance to these treatments is highly frequent and estimated to occur in about 50% of ER+ breast cancer patients.

It is now recognized that the resistance mechanisms for anti-estrogen therapies are complex and include genetic and epigenetic alterations of growth signaling pathways, ER itself and its coregulators and pioneer factors, intracellular heterogeneity, and interactions with the tumor microenvironment and immune system, *etc.*^[18]. The expression of ER in most endocrine-resistant tumors suggests a continued but altered role of ER, commonly through crosstalk with aberrant upregulation and activation of growth factor receptor tyrosine kinases (RTKs) and intracellular cascades such as EGFR, HER2, Insulin-like Growth Factor 1 (IGF-1), FGFR, PI3K/AKT/mTOR, RAS/RAF/MEK/ERK, CDK4/6, *etc.*^[19-25]. Indeed, several therapies have recently been developed and approved to target these pathways (e.g., PI3K inhibitor Alpelisib, mTOR inhibitor Everolimus, CDK4/6 inhibitors Palbociclib, Ribociclib, and Abemaciclib) for breast cancer patients^[26-30]. However, these treatments only showed limited benefit in certain patient populations and are again met with treatment discontinuation due to side effects and quick development of treatment resistance^[26,31-33]. Thus, additional mechanistic and clinical investigations into the causes and molecular mechanisms of endocrine resistance and the development of new, safer and more effective treatment

strategies are still in great need despite the success and progress of anti-estrogen treatments^[18].

HER2 (Neu) is a member of the EGFR family of receptor tyrosine kinases that activate and potentiate pro-growth signaling cascades. Current anti-HER2 therapies primarily include small molecules targeting the intracellular kinase domain and monoclonal antibodies targeting the extracellular domains^[4,34,35]. The small molecule HER2 tyrosine kinase inhibitors include lapatinib, neratinib, and tucatinib, which have been shown to inhibit cell proliferation, amplify the response to chemotherapy and anti-estrogen therapy, and potentially help limit brain metastases^[36-38]. Despite these benefits, adverse events such as diarrhea, nausea, vomiting, and hand-foot syndrome have been documented, which may lead to treatment discontinuation^[36]. Monoclonal antibodies against HER2 include trastuzumab, pertuzumab, and more recently antibody-drug conjugates such as T-DM1 or T-DXd, which have trastuzumab antibodies conjugated to either the microtubule inhibitor emtansine or the topoisomerase inhibitor deruxtecan, respectively^[39-41]. Unfortunately, targeted HER2 therapies come with their own side effect profile, too, including diarrhea, skin rash, and problematic levels of cardiotoxicity^[42-44]. The overall response to anti-HER2 antibody therapies is limited as well, with only around one-third of HER2+ breast cancer patients ultimately benefiting from anti-HER2 antibody therapies^[36]. Again, anti-HER2 therapy resistance and recurrence are also common, especially for patients with advanced and metastatic cancers, through point mutations affecting the ATP-catalytic site, alternate splicing/cleavage, and upregulation of other RTKs (e.g., HER3, IGF-1R, PI3K/Akt, and MET), *etc.*^[10,45-48].

ESTROGEN RECEPTOR COACTIVATOR MED1 AND BREAST CANCER

Estrogen receptor is a member of the nuclear receptor transcription factor family that drives breast cancer through the transcription activation of its target genes. Upon binding to hormonal estrogen, ER binds to estrogen responsive elements and promotes gene transcription through stepwise and cyclic recruitment of diverse transcriptional coactivators^[49]. These coactivators play a variety of roles in the transcription process, such as remodeling chromatin structure (e.g., SWI/SNF), modifying histones (p300, SRCs, PRMT1, CARM1), and recruiting additional proteins or RNAs to create a permissive environment for the assembly of transcription machinery^[50-54]. However, to initiate transcription, it still needs another coactivator complex to bridge ER and transcription machinery that is known as the Mediator [Figure 1, adapted from Ref.^[55]]. The Mediator complex is a complex of 25-30 subunits, and mediator subunit 1 (MED1) was found to be essential for estrogen-dependent interactions between mediator complex and estrogen receptor^[56,57]. In addition to bridging ER with RNA polymerase II and transcription machinery, recent studies also support that MED1 could participate in ER-mediated gene transcription through additional mechanisms including chromosome looping, enhancer RNA transcription, liquid-liquid phase separation and formation of transcription condensates and super-enhancers, *etc.*^[58-66]. Recent structural studies using crystallography, cryoelectron-microscopy and cross-linking mass spectrometry have revealed detailed Mediator interactions with transcription factors and general transcription machinery in transcription initiation and Pol II phosphorylation, *etc.*^[67-70]. Future further super-resolution structural analyses of human MED1/Mediator complex with ER, other transcriptional coregulators, and even chromatin and RNAs using these and more advanced technologies will likely provide new deep insights into the regulation and diverse functions of MED1 and Mediator in these processes.

In breast cancer, it was found that MED1 is overexpressed in approximately 50% of breast cancers^[71,72]. Further, MED1 is located in the genomic region containing HER2, commonly called the HER2 amplicon^[73,74]. As such, MED1 coamplifies with HER2, and its expression is strongly correlated with HER2 amplification and expression in breast cancers. Interestingly, MED1 only exists in a subpopulation of mediator complex with a distinct subunit composition and enrichment of RNA polymerase II^[75].

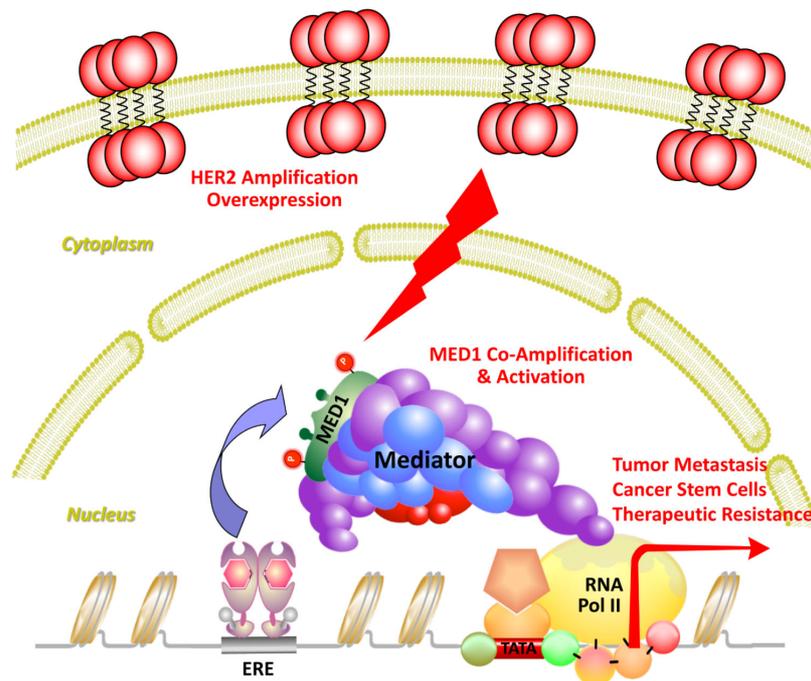

Figure 1. Transcription coactivator MED1 as a central crosstalk point of ER and HER2 pathways. Transcriptional activator MED1 directly interacts with ER to bridge it with RNA polymerase II and transcriptional machinery to initiate gene transcription and mediate ER functions in breast cancer. MED1 also coamplifies with HER2 and is activated by HER2 signaling cascades through phosphorylation to promote breast cancer growth, metastasis, stem cell expansion, and therapeutic resistance. Adapted from Yang et al.^[55] Cell Reports.

Furthermore, the MED1/Mediator complex is selectively recruited to ER target gene promoter by estrogen induction but not to other transcription factor regulated target genes (e.g., UV activation of p53), indicating some specificity of MED1 for ER-mediated transcription function. Importantly, loss of MED1 resulted in a severe abrogation of ER target gene expression in *in vitro* transcription assays, and estrogen-dependent endogenous gene transcription and growth of breast cancer cells^[56,75]. More recently, our studies further support the key *in vivo* role of MED1 in mediating selective ER functions in pubertal mammary gland development, tumor growth, metastasis, cancer stem cell formation and therapy resistance during mammary tumorigenesis as detailed in the next few sections.

TISSUE-SPECIFIC ROLE OF MED1 AND ITS LXXLL MOTIFS *IN VIVO*

Estrogen receptor interacts with a variety of transcription cofactors including MED1, SRC1, and SRC3 *etc.*, via a domain on these proteins called the LxxLL motifs or NR-boxes^[76-78]. MED1 contains two closely associated LxxLL motifs, which, when mutated to LxxAA, prevent MED1 from binding to ER in a ligand-dependent manner^[79]. To better understand the physiological role the MED1/ER plays, a knock-in mutant mouse model was generated in which the two LxxLL motifs of MED1 were both mutated to LxxAA to inhibit MED1's interaction with ER^[80]. Interestingly, when the LxxLL motifs of MED1 were mutated, mice were born at appropriate Mendelian ratios, and both the heterozygous and homozygous mutants were generally healthy and fertile. The primary phenotype was in the mammary glands of homozygous MED1-LxxAA mutant knockin mice during the pubertal development. These mice showed a significant delay in mammary gland development as measured by the mammary ductal branch morphogenesis in both ductal length and number of branches^[80]. On a cellular level, it was found that MED1 was primarily expressed in the luminal but not basal cells of the mammary gland. Significantly, it was found that the luminal progenitor cells were significantly decreased in MED1 mutant knockin mice despite MED1 being expressed at equal

levels. Importantly, while total estrogen levels and estrogen-dependent uterine growth were unaffected by the MED1 mutations, the mammary gland ductal growth in response to estrogen was greatly blocked as measured by growth and ER target gene expression.

When these MED1-LxxLL mutant knockin mice were further crossed with a HER2-driven mammary tumor model (MMTV-HER2), it was found that MED1 LxxLL mutations were able to significantly delay the tumor onset, growth and metastasis^[81]. When compared to WT tumors, tumors from MED1 mutant knockin mice crossed with MMTV-HER2 mice showed impaired estrogen responsiveness and had much lower growth rates and metastasis. It was found that MED1 LxxLL motifs mutations significantly decreased cell proliferation, angiogenesis and cancer stem cell formation of MMTV-HER2 tumors. Consistent with these findings, the expression of a number of key ER/HER2 downstream genes involved in these processes (e.g., IGF-1, Cyclin-D1, LIF, ACP6, Twist, MMP9, VEGFA) were significantly inhibited by the MED1 mutations. Interestingly, we found that MED1 acts by directly regulating the ER downstream IGF-1 but not amphiregulin signaling pathway in our rescue experiments. This was further supported by several other findings including marked reductions in phosphorylation of IGF-1 signaling pathway proteins including the IGF-1 receptor, AKT, and mTOR in MED1 mutant tumors, phenocopying of IGF-1R inhibition and MED1 mutations in both mouse and human cancer cells, and correlation of MED1 and IGF-1 protein levels in human clinical samples. Overall, these studies support that MED1 and its LxxLL motifs play a central role in mammary tumorigenesis and suggest that MED1 could potentially serve as a tissue-specific target in breast cancer therapy.

ROLE OF MED1 IN ANTI-ESTROGEN TREATMENT RESISTANCE

As discussed above, MED1 overexpression is a frequent occurrence in approximately 50% of all breast cancers. Interestingly, the MED1 gene is located in the HER2 amplicon and coamplifies with HER2 in almost all instances. We have further confirmed that MED1 protein levels highly correlate with HER2 status of human breast cancer by using a human breast cancer tissue microarray^[82]. Given HER2 amplification and overexpression is a common mechanism of endocrine resistance, Cui *et al.*^[82] carried out to investigate whether HER2 and MED1 cooperate in driving endocrine resistance. Interestingly, it was found that MED1 levels and especially the phosphorylated form of MED1 are increased in tamoxifen-resistant BT474, MCF-7/TAM, MCF-7/HER2 cells compared to MCF-7 controls, in a manner dependent on HER2 and MAPK activation. Importantly, knockdown of MED1 in these cells was found to increase the sensitivity of these otherwise resistant cells to tamoxifen treatment. In addition to reduced expression of traditional ER target genes (e.g., TFF1, Cyclin D1) by MED1 knockdown in these cells, it was found that MED1 is also required for the expression of another class of newly defined HER2 activated ER-target genes like *LIF* and *ACP6*^[82,83].

Mechanistically, it is known that when tamoxifen binds to ER, the conformational change forces ER into a repressive state, and rather than recruiting coactivators, ER preferentially recruits co-repressors such as NCoR and SMRT to inhibit transcription of downstream target genes^[15]. However, in these tamoxifen-resistant cells with MED1 overexpression and activation, it was found that tamoxifen treatment still resulted in the recruitment of MED1 and phospho-MED1 but not co-repressors to the ER target gene promoters [Figure 2]. Importantly, this was completely reversed with MED1 knockdown in these cells and restored the recruitment of the co-repressors under tamoxifen treatment. Furthermore, it was found that only wild-type but not phospho-defective mutant of MED1 (T -> A) was able to displace the co-repressors after tamoxifen treatment in these MED1 knockdown cells, supporting the importance of MED1 phosphorylation by HER2 in mediating tamoxifen resistance.

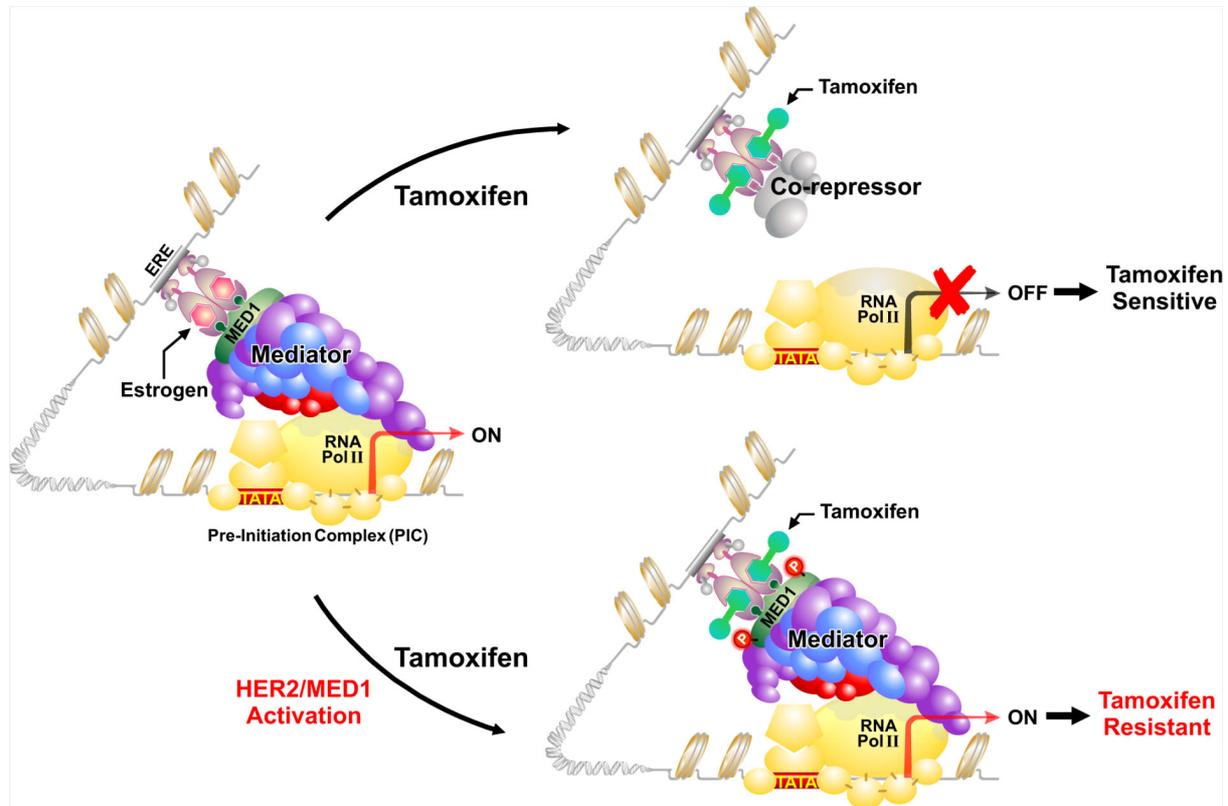

Figure 2. Molecular mechanisms of HER2 and MED1 in anti-estrogen treatment resistance. In endocrine-sensitive breast cancer cells, treatment with anti-estrogen tamoxifen results in the recruitment of co-repressors to suppress gene transcription. However, when MED1 is overexpressed and phosphorylated by growth factor cascades such as HER2, the MED1/Mediator complex rather than ER co-repressors is recruited to activate gene transcription and render endocrine resistance. Adapted from Leonard et al.^[72], JZUS-B.

Consistent with our studies above, other laboratories have also reported clinical evidence indicating MED1 as a gene associated with poor endocrine treatment outcome, and that high MED1 expression correlates with poor survival of breast cancer patients that have undergone anti-estrogen therapy^[84,85]. In addition, another genome-wide study identified an increased frequency of MED1 mutations in circulating plasma DNA in breast cancer patients following anti-estrogen and anti-HER2 treatments^[86]. These studies suggest a broad role of MED1 in anti-estrogen treatment resistance to other anti-estrogen therapies besides tamoxifen. Indeed, we found that MED1 depletion sensitized the MCF-7 cell derived fulvestrant resistant cell line (MCF-7-F) and HER2/MED1 overexpressing BT-474 and ZR-75.1 cells to fulvestrant treatment as well *in vitro* and *in vivo*^[87]. Together, these data support that MED1 overexpression and activation by growth factor signaling pathways like HER2 can drive broad resistance to anti-estrogen treatments, and that MED1 could serve as a potential therapeutic target to overcome such treatment resistance.

TARGETING MED1 IN ANTI-ESTROGEN RESISTANCE BREAST CANCER BY RNA NANOTECHNOLOGY

Based on these findings, Zhang's laboratory has developed a targeted approach to block MED1 specifically in anti-estrogen resistant breast cancers using an innovative RNA nanotechnology approach^[88]. The reason we selected this approach is due to many advantages of the RNA nanotechnology: multifunctional capabilities with simultaneous targeting and therapy, high stability and nanoscale size allows slower body clearance and better tissue penetration, retention, and cellular uptake, low toxicity and immunogenicity,

controlled synthesis and self-assembly for great manufacturing and scale-up compatibility, *etc.*^[88-93]. Furthermore, this technology also allows for the development of ways to target the transcriptional coactivators like MED1 that are difficult to target with traditional small molecules or antibody-based approaches. By using a phi29 3-way junction pRNA nanodelivery system, we have created RNA nanoparticles that are composed of two MED1-targeting siRNAs to silence MED1 and an aptamer that specifically binds to membrane receptor HER2 to allow for targeted delivery into breast cancer cells [Figure 3]. These pRNA-HER2apt-siMED1 RNA nanoparticles can be generated uniformly with high reproducibility as measured by dynamic light scattering and atomic force microscopy. By using 2'Fluoro modified nucleotides, these RNA nanoparticles exhibited high stability, even in conditions that mimic or are more extreme than physiological conditions, including treatment with RNase A, Serum, Urea or heat up to 70 degrees Celsius. Importantly, we have shown that treatment with recombinant Dicer enzyme can easily release the siRNA arms from the nanoparticle, an essential step in the RNAi pathway.

These highly stable multifunctional RNA nanoparticles have been successfully tested in both *in vitro* and *in vivo* preclinical models and exhibited highly desirable tumor-specific targeting and treatment efficacy with no apparent toxicity^[88]. It was found that the pRNA-HER2apt-siMED1 nanoparticles can silence MED1 expression in both de novo tamoxifen-resistant BT-474 cells that have HER2 amplification and acquired tamoxifen-resistant MCF-7/TAM cells with elevated HER2 expression but no amplification. These knockdown effects are specific and dependent on both siMED1 sequences and intact HER2 binding aptamer. Furthermore, triple-negative breast cancer MDA-MB-231 cells were not able to take up these RNA nanoparticles or knockdown MED1. In addition to growth inhibition, we found that these MED1 targeting RNA nanoparticles significantly reduce cell migration, stem cell formation, and MED1 target gene expression compared to control scramble RNA nanoparticles or tamoxifen alone. When we cotreated these cells with tamoxifen, we found further decreased cell growth, motility, and cancer stem cell formation compared to either treatment alone.

The distribution and the efficacy of pRNA-HER2apt-siMED1 nanoparticles were further examined *in vivo* using a human breast cancer orthotopic xenograft mouse model. It was found that pRNA-HER2apt-siMED1 but not the HER2apt mutant nanoparticles were able to significantly accumulate and enrich in the tumors while both showed only residual levels in the liver and kidneys, and were undetectable in other organs such as lung, spleen and heart. Remarkably, we found that once a week systemic injection of the RNA nanoparticles through tail vein achieved greater tumor growth inhibition *in vivo* than regular 5 days per week tamoxifen treatment. Immunohistochemistry staining and western blot analyses confirmed that the expression of MED1 was significantly depleted in the pRNA-HER2apt-siMED1-treated groups along with a great reduction of Ki-67 expression, tumor growth, lung metastasis and stem cell formation compared to those of control treatments. Importantly, we did not observe apparent toxicity, and there was no body weight change or histological abnormalities in major organs during the course of treatment including liver and kidney. This lack of toxicity in these organs could be due to one or a combination of the rapid tissue clearance of the RNA nanoparticle, our tumor-specific HER2 aptamer ligand design and the inability of RNA nanoparticles to enter the cells in these organs, as well as the tissue-specific roles of MED1 and its lack of key biological functions in these organs, *etc.* Together, these findings support that our biosafe pRNA-HER2apt-siMED1 nanoparticle represents a highly promising new therapeutic regimen for potential future breast cancer treatment to overcome resistance.

MED1 IN HER2-MEDIATED TUMORIGENESIS AND ANTI-HER2 THERAPY RESPONSE

We have discussed above that MED1 is frequently overexpressed and coamplified in breast cancers with HER2 and crosstalk with HER2 in mediating anti-estrogen treatment resistance. However, it was still not

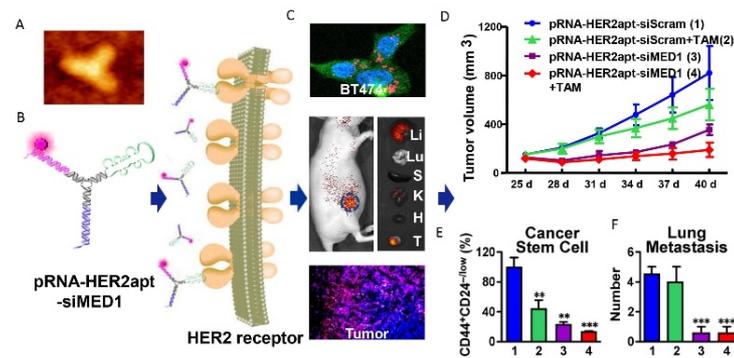

Figure 3. Overcoming breast cancer therapeutic resistance by MED1 targeting multifunctional RNA nanoparticles. The figure shows the atomic force microscopy (A) and schematic (B) of the pRNA-HER2apt-MED1siRNA nanoparticle, its tumor-specific uptake *in vitro* and *in vivo* (C), and therapeutic effect to inhibit endocrine-resistant tumor growth (D), cancer stem cell formation (E), and lung metastasis (F) *in vivo* in an orthotopic xenograft mouse model. ** $P < 0.01$, *** $P < 0.001$. Adapted from Zhang *et al.*^[88], ACS Nano.

known whether MED1 plays a role in mediating HER2-mediated tumorigenesis and the response to anti-HER2 treatment. To achieve that, we have generated a MED1 mammary specific overexpression mouse model MMTV-MED1^[55]. We found that over-expression of MED1 in mammary glands resulted in a slightly increased number of mammary stem and progenitor cells, but no other phenotypical abnormalities or increase in cancer incidence. However, when we crossed these MMTV-MED1 mice with the MMTV-HER2 mammary tumor-prone mouse model, we found a strong increase in mammary tumor formation marked both by the earlier onset of an initial tumor and an increase in the number of individual tumors formed per mouse. Furthermore, these MMTV-HER2/MMTV-MED1 tumors grew much faster and formed more lung metastases compared to MMTV-HER2 tumors. These *in vivo* findings were further validated by *in vitro* assays showing that isolated MMTV-HER2/MMTV-MED1 tumor cells had higher tumor mammosphere forming ability and metastatic capabilities. Flow cytometric analysis using stem cell markers and limiting dilution assays further indicated a higher stem-like cell content in MMTV-HER2/MMTV-MED1 tumors compared to that of MMTV-HER2 tumors.

Interestingly, MED1 was found to play a role in the tumor response to anti-HER2 treatment as well. It was found that MMTV-HER2/MMTV-MED1 tumors were highly resistant to anti-HER2 lapatinib treatment, as these tumors, despite treatment with lapatinib, still grew at the same rate as vehicle-treated HER2+ tumors and significantly faster than lapatinib treated HER2+ tumors^[55]. Furthermore, MMTV-HER2/MMTV-MED1 tumors could still readily metastasize to the lung after lapatinib treatment, while the same treatment eliminated lung metastasis of MMTV-HER2 tumors. This is consistent with high Ki67 staining and the number of tumor-initiating cells by limiting dilution assays observed in MMTV-HER2/MMTV-MED1 tumors compared to that of MMTV-HER2 tumors after the treatment. Similar phenomena were also observed using human breast cancer cells and further supported the role of MED1 in HER2-treatment responses. Additional work is ongoing to test the role of MED1 in resistance to other anti-HER2 small molecule and antibody therapies discussed above. Mechanistically, it was found that MED1 overexpression results in increased expression of a variety of downstream genes, including JAB1, which regulates protein ubiquitination. Interestingly, MED1 was found to be a target of JAB1 directed ubiquitination as well, which was found to be essential for MED1's cyclic recruitment to its target genes' promoters and the expression of these target genes. Importantly, it was found that MED1 and JAB1 protein levels were closely correlated, particularly in HER2 positive breast cancer clinical samples^[55]. Together, these data indicate that MED1 plays critical roles in HER2-mediated tumorigenesis and therapy response, and MED1 therapy could be

potentially utilized in the treatment of HER2+ breast cancers as well.

CONCLUSIONS AND FUTURE PERSPECTIVES

Despite the development and advancement in targeted therapies for ER+ and HER2+ breast cancers, severe unwanted side effects, frequent resistance, and relapse remain the greatest clinical challenges. In this review, we have provided experimental and clinical evidence from our laboratory and others that support the key roles of MED1 in both anti-estrogen and anti-HER2 treatment resistance and the potential use of MED1 therapy to overcome treatment resistance. It will be important in the future to further understand the molecular mechanisms underlying MED1 functions and its upstream and downstream regulators in mediating treatment resistance, as these will not only help us better understand the basic cancer biology of these tumor subtypes but also provide potential new therapeutic targets. In ER+ breast cancers, it will be important to understand what drives MED1 overexpression, the further fundamental molecular details on how MED1 regulates ER target gene expression, and whether targeting MED1 could delay the development of anti-estrogen treatment resistance, *etc.* It will also be interesting to know further the role and molecular mechanisms of MED1 in the treatment resistance of HER2+ tumors to both anti-HER2 small molecules and antibodies, whether it plays a role in mediating the poor response of ER+ tumors in HER2+ heterogeneous tumors, and what role it might play in HER2+ER- tumors and the mechanisms, among others.

Many of these questions should be addressed in appropriate breast cancer cell lines, organoids, orthotopic xenograft, and PDX models, and most importantly, tested in clinics. Significantly, we have developed an innovative patented RNA-nanotechnology-based approach to target MED1 specifically in breast cancer cells and successfully tested it in both *in vitro* and *in vivo* preclinical models. Given the many advantages of RNA nanotechnology described above and our highly stable multifunctional RNA nanoparticles designed with specific tumor targeting and dual MED1 siRNA therapeutic modules, we expect our MED1 RNA therapeutics to be less toxic, more effective, and less prone to develop treatment resistance. Since MED1 functions far downstream in the ER and HER2 pathways at the last step before transcription initiation, targeting MED1 will not only help gain better treatment outcomes but will likely be less prone to the development of resistances commonly occurring through aberrant activation of upstream signaling kinases or mutations in ER itself. Finally, the better safety profile and long-lasting effects with fewer treatments needed for our RNA nanoparticles could also mean better patient treatment compliance as well which is also a major issue with current treatment. With increasing FDA approval, large-scale production and broad use of RNA-based vaccines and medicines, we are very excited about the opportunities and fully anticipate that our RNA nanotherapeutics could represent a highly promising next-generation therapy to ultimately benefit patient care through better efficacy, fewer side effects, and improved patient quality of life and treatment compliance.

Abstract

Aim: This study aimed to translate a known drug-resistance mechanism of long-term CSF1R inhibition into multicellular biomarkers that can serve as potential therapeutic targets as well as predictive markers for the survival of glioma patients.

Methods: Using existing data from a published mouse study of drug resistance in immunotherapy for glioma, we identified multicellular differentially expressed genes (DEGs) between drug-sensitive and drug-resistant mice and translated the DEGs in mouse genome to human homolog. We constructed correlation gene networks for drug resistance in mice and glioma patients and selected candidate genes via concordance analysis of human with mouse gene networks. Markers of drug resistance and an associated predictive signature for patient survival were developed using regularized Cox models with data of glioma patients from The Cancer Genome Atlas (TCGA) database. Predictive performance of the identified predictive signature was evaluated using an independent human dataset from the Chinese Glioma Genome Atlas (CGGA) database.

Results: Fourteen genes (*CCL22*, *ADCY2*, *PDK1*, *ZFP36*, *CP*, *CD2*, *PLAUR*, *ACAP1*, *COL5A1*, *FAM83D*, *PBK*, *FANCA*, *ANXA7*, and *TACC3*) were identified as genetic biomarkers that were all associated with pathways in glioma progression and drug resistance. Five of the 14 genes (*CCL22*, *ADCY2*, *PDK1*, *CD2*, and *COL5A1*) were used to construct a signature that is predictive of patient survival in the proneural subtype GBM patients with an AUC under the time-dependent receiver operating characteristic (ROC) of 2-year survival equal to 0.89. This signature also shows promising predic-

tive accuracy for the survival of LGG patients but not for non-proneural type GBMs.

Conclusion: Our translational approach can utilize gene correlation networks from multiple types of cells in the tumor microenvironment of animals. The identified biomarkers of drug resistance have good power to predict patient survival in some major subtypes of gliomas (the proneural subtype of GBM and LGG). The expression levels of the biomarkers of drug resistance may be modified for the development of personalized immunotherapies to prolong survival for a large portion of glioma patients.

Keywords: Drug resistance, tumor microenvironment, translational research strategy, multicellular gene correlation network, glioma, precision medicine

INTRODUCTION

Glioma is an aggressive and malignant brain tumor with a poor prognosis. The traditional standard-of-care therapies (surgical removal, radiotherapy, chemotherapy, *etc.*) only slightly extend the survival of glioma patients^[1]. Despite the recent advances in cancer immunotherapies and targeted therapies in treating many types of cancer, only a fraction of patients developed durable responses, which indicates the common existence of intrinsic/acquired resistance to existing immunotherapies. To date, the effect of immunotherapies in treating glioma has been even more disappointing, partly due to prevalent drug resistance^[2-4]. To improve patient survival, it is critical to discover potential therapeutic targets and prognostic biomarkers for novel biological interventions to overcome drug resistance.

The tumor microenvironment (TME) plays a crucial role in the progression and responses to therapies^[5]. In addition to tumor cells (TCs), the TME also includes T cells, tumor-associated macrophages (TAMs), epithelial cells, *etc.*^[6,7] The immunosuppressive action of TAMs based on the release of anti-inflammatory cytokines within the TME could promote the proliferation of tumor cells and the subsequent drug resistance^[5,6,8,9]. Immunotherapies are often designed to enhance antitumor capacity of the immune cells such as TAMs, and, in turn, the enhanced TAMs could attack and kill TCs. In particular, inhibition of CSF1R (by the small-molecule BLZ945 treatment) in TAMs has been a promising intervention for glioblastoma (GBM) in mice; however, persistent usage of CSF1R inhibition can lead to drug resistance in mice^[1]. Importantly, a well-designed mouse study published by Quail *et al.*^[1] discovered and characterized the mechanism of the drug resistance to CSF1R inhibition in mice. Specifically, long-term inhibition of CSF1R in TAMs resulted in the increased secretion of IGF1 to TME and the alternative activation of TAM, which was reflected by the elevated expression level of M2-like genes. The combination of IGF1 in TME and its receptor in TCs, IGF1R, activated the downstream PI3K signaling pathways to support tumor regrowth and led to drug resistance. Based on this drug-resistant mechanism, they further identified multiple interventions, including blockage of IGF1R (by OSI906) and inhibition of PI3K pathway (by BKM120), that resulted in substantial improvement in survival in mouse studies when combined with CSF1R inhibition. However, the important findings from this mouse study of drug resistance have not been translated to human gliomas to prolong patient survival. Thus far, it is unclear whether the findings of the mice study can be successfully translated to some subtypes or all types of gliomas in humans.

Given the importance of the multiple types of cells in TME for drug resistance, it is desired to have cell-specific (immune cell and tumor cell) gene-expression data to investigate cell-specific effects and interactions between different types of cells in TME when studying drug resistance in humans. However, due to the extensive labor cost and technical challenges in obtaining cell-specific data in humans, discovering the multicellular mechanism of drug resistance directly in human trials is currently challenging. In contrast, as cell-type-specific gene expression data from mouse studies are more affordable^[1], we suggest a translational study strategy that projects the multicellular results of the animal experiment to human genome to investigate drug resistance. In

particular, borrowing strength from the mouse study published by Quail *et al.*^[1], we can combine cell-specific mouse gene expression data with gene expression data from human bulk tissue to identify biomarkers of drug resistance and patient survival. Furthermore, as Quail *et al.*^[1] also identified interventions to overcome the drug resistance in mice, any genetic biomarkers we identify would likely to be actionable targets for therapeutic intervention in human precision medicine, too.

For the purpose of developing novel treatment targets that are feasible for biomedical intervention, for convenience, we would like to select a small set of genes that can adequately account for drug resistance as well as patients' survival. However, response and resistance to an intervention typically involve a great number of genes and pathways in addition to population heterogeneity. In practice, it is hard to decide which genes are biologically more important than others, given the vast number of genes involved, and it is generally challenging to distinguish driver genes from passenger genes based on cross-sectional gene expression data. To the best of our knowledge, there is no known method that can efficiently identify biomarkers of drug resistance with high predictive accuracy for patient survival. Given that biological pathways involve the cooperation of clusters of highly correlated genes, we used gene correlation network analysis and gene-set enrichment analysis to detect biologically important gene clusters. Focusing on gene clusters in important pathways can borrow strength from existing biological knowledge based on independent studies; thus, it should be more likely to determine genes with driver effects and avoid the abundance of false positives, compared to the common approach of focusing on the analysis of individual genes with top *P*-values. Moreover, important and well-connected genes in gene networks are generally sparse^[10,11]; thus, constructing weighted gene networks reflecting such sparsity would be desirable. Moreover, regularized Cox regression models that account for the sparsity of important genes in correlation networks can be used to further shrink the number of candidate genes in order to form a compact gene set predictive of patients' survival.

In cancer research, the “one treatment for all patients” approach is generally impractical given various heterogeneities associated with cancers. For precision medicine, it is desired and more practical to find an effective and suitable treatment strategy for each particular subtype of cancer and subgroup of patients. Furthermore, it is important to identify treatment targets and biomarkers that have high prognostic accuracy for each specified subgroup of patients in order to develop novel personalized treatments including overcoming drug resistance in existing therapies. Indeed, complex diseases are often classified into subtypes characterized by the difference in histology and pathology. In particular, gliomas are usually classified into two major categories according to the World Health organization (WHO) grading: lower-grade gliomas (LGG; WHO grade II and III gliomas) and glioblastoma multiforme (GBM; WHO grade IV gliomas). GBM can be further divided into four subtypes based on their gene expression profile: classical, mesenchymal, proneural, and neural^[12]. Due to the heterogeneity in histology and gene expression, drug resistance for different types of patients can be due to many different biological mechanisms involving many different pathways. Given the poor overall survival of GBM and gliomas currently, it is very valuable if we can identify a particular subgroup of patients that may benefit from interventions based on the identified drug-resistant targets or pathways.

In this study, we used a translational research strategy to identify biomarkers of drug resistance as targets for precision medicines for gliomas in humans. Beginning with results and data from an existing mouse study^[1], we compared the gene expression levels between drug-sensitive and drug-resistant mice to obtain differentially expressed genes (*DEGs*) in TAMs and TCs, respectively, which were then translated to human homolog. Because the mouse study was conducted on mice initiated with the proneural subtype of GBM tumor, we hope the findings of the mouse study can be translated to the proneural type GBMs in humans. Thus, our subsequent analysis will first be conducted on the proneural type GBM subjects. Next, weighted gene correlation networks of drug resistance were constructed in TAMs and TCs, using the expression data of humans and mice, respectively. Then, we performed concordance analysis to compare human networks to mouse networks within each cell type and performed enrichment analysis to get the biologically important gene clusters

(indicating pathways), from which candidate genes were selected according to their importance and individual predictive capacity for patient survival. Lastly, integrating the findings of M2-like genes and PI3K pathways identified in the drug-resistance mouse study, we applied regularized Cox regression models to get a small set of genetic biomarkers. For precision medicine, it is important to identify some major subgroups or subtypes of gliomas such that expression levels of the identified molecular biomarkers of drug resistance can predict population survival rates of human glioma patients, and ideally, the expression levels of the biomarkers can be modified to prolong survival of a large portion of patients. Towards this end, time-dependent ROC curves, corresponding AUCs, and Kaplan-Meier (KM) curves were generated to demonstrate the predictive performance of the identified genetic biomarkers in the proneural subtype of GBM, non-proneural type of GBM, and LGG patients, respectively. The identified genetic biomarkers showed high AUCs at two years in the proneural subtype of GBM, indicating good predictive performance of the identified signature. Importantly, the signature developed using the proneural type mouse study had poor predictive power of survival in non-proneural subtypes of GBM, suggesting that different mechanisms and therapeutic targets should be considered for different subtypes of glioma. We also discuss the identified biomarkers as potential treatment targets to overcome drug resistance.

METHODS

A translational strategy to identify predictive biomarkers of drug resistance and patient survival

Since obtaining cell-specific gene expression data in human brains is a challenge and such cell-specific mouse data are available from the study by Quail *et al.*^[1], we introduced a translational study design that borrows strength from the mouse cell-specific data to identify biomarkers of drug resistance in humans. First, we identified and translated DEGs between drug-resistant (Reb) and drug-sensitive (Ep) mice to humans in TAMs and TCs, respectively. Then, weighted gene correlation networks were constructed, and gene clusters were detected for TAMs and TCs in mice and human patients, respectively. By comparing mouse networks to human networks via concordance analysis, biologically important gene clusters were selected from the highly concordant gene clusters, integrating the result from enrichment analysis. Next, to discover therapeutic targets of gliomas that may be actionable in future intervention, we reduced the number of candidate genes using principal component analysis (PCA) and K-index based on the biologically important gene clusters. In addition, since M2-like genes and PI3K pathway-related DEGs were indicated to be associated with drug resistance in mice^[1], they were combined with genes selected from the biologically important gene clusters to construct predictive signatures using regularized Cox regression models. Finally, the performance of the identified predictive signature was examined by KM analysis and time-dependent ROC curves. The entire workflow is shown in Figure 1. More details are described in the following subsections.

An existing randomized mouse study for drug resistance in gliomas

To investigate the biological mechanism of drug resistance to the CSF1R inhibition of TAMs, a randomized study of mice with gliomas was conducted and reported by Quail *et al.*^[1]. The CSF1R inhibition treatment is aimed at enhancing immune capacity of the tumor-associated macrophage (TAM) so that the treated TAMs can more effectively kill glioma cells or inhibit tumor growth. There were two randomized groups of mice in the study conducted by Quail *et al.*^[1]: the treatment naïve or vehicle group (Veh) and the treatment group or CSF1R inhibition group. The treatment group was divided into two subgroups: the group of treated mice that had durable treatment response, called the drug-sensitive or endpoint (Ep) group, and the group of treated mice that had tumor regrowth after short-term treatment response, called the drug-resistant or rebound (Reb) group. There were five Veh samples, six Ep samples, and four Reb samples with available gene expression data (RNA-seq data) for both TCs and macrophages (TAMs). The RNA-seq data of the 15 samples were selected for subsequent analyses, and the data could be downloaded from the Gene Expression Omnibus (GEO) website (<https://www.ncbi.nlm.nih.gov/geo/>) under the accession number GSE69104. By comparing gene expressions in TAMs of the treated and untreated (Veh) groups, we could identify differentially expressed genes (DEGs)
