(phosphatidylcholines, sphingomyelins, and cholesterol). The cytosolic leaflet consists of electrically neutral phosphatidylethanolamines and anionic phosphatidylserines (for details, see^[36,37]). The cytoplasmic leaflet is approximately twofold more unsaturated than the extracellular leaflet. These structural asymmetries are conserved throughout eukaryotes, suggesting fundamental cellular design principles^[37].

The membrane is well described by its molecular order parameter, S_{mol} , the lateral packing density, π_{M} , the surface potential, Ψ_{m} , and the dielectric constant, ϵ_{m} . Each parameter is briefly explained below.

Molecular order parameter, S_{mol} , of lipid bilayers in the presence of “guest” molecules

Although membranes are highly organized, they are recalcitrant to crystallization because of considerable translational, rotational, and flexing movements of the constituent lipid and protein molecules. The dynamic “structure” of biological membranes is best characterized by deuterium nuclear magnetic resonance (^2H - or D-NMR) spectroscopy^[38,39]. Chemically or biochemically exchanging protons with deuterons, either in the polar head group or in the acyl chains of lipids, provide information on the order and mobility of the molecules without disturbing the system. This is in contrast to most other labels including spin labels or fluorescent labels such as DPH (trimethylamine-diphenylhexatriene). Below, we give a few representative examples of how “guest” molecules (including cholesterol, peptides, membrane proteins, detergents, and drugs) influence the molecular order parameter of phospholipid bilayers.

Cholesterol

The addition of cholesterol to a dipalmitoylphosphatidylcholine (DPPC) bilayer in an equimolar amount doubles the order parameter of the fatty acyl chain region and eliminates the gel-to-liquid crystal phase transition (phase transition temperature for DPPC, $T_{\text{m}} = 41\text{ }^{\circ}\text{C}$), producing a smooth order-temperature profile^[40]. An enhanced order parameter was also reported for bilayers by 1-palmitoyl-2-oleoyl-sn-glycerol-3-phosphocholine (POPC, with $T_{\text{m}} = -2\text{ }^{\circ}\text{C}$)^[41].

Peptides and proteins

The interaction of transmembrane proteins such as cytochrome c oxidase with the surrounding lipids has been investigated extensively by spin-label electron paramagnetic resonance (EPR) and NMR spectroscopy. EPR measurements (monitoring a high frequency range $\sim 10^7$ - 10^8 Hz) revealed two motionally distinct lipid populations. The term “boundary lipids” was coined for the slower component^[42]. However, subsequent ^2H -, ^{31}P -, and ^{14}N -NMR investigations (monitoring a frequency range at least 10-fold lower) did not detect the presence of two lipid populations^[43-45]. All lipids around the reconstituted cytochrome c oxidase exhibited very similar motional behavior and provided no evidence for motionally restricted boundary lipids, neither at the head group region nor at the cis-double bond^[46]. To investigate potential interactions between cytochrome c oxidase and specific lipids, we characterized the few residual lipids attached to cytochrome c oxidase after delipidation using ^{31}P -NMR spectroscopy^[47]. While most previous biochemical studies claimed that cardiolipin was the only lipid remaining after delipidation, the ^{31}P -NMR data show that all three lipids (phosphatidylethanolamine, phosphatidylcholine, and cardiolipin) can be observed, with cardiolipin being the least abundant. Compared with the effect of cholesterol, the effect of proteins and peptides on lipid membranes is thus generally almost negligible, indicating a perfect match between the movement of fluid-like hydrocarbon chains and the movement of the peptide side chains^[48,49]. Natural cells also revealed rapid exchange of lipids around proteins on the NMR timescale (frequency range $\sim 10^6$ Hz)^[50].

Detergents and drugs

Detergents (e.g.,^[51,52]) and drugs (e.g.,^[53]) have been well documented to cause membrane disorder at higher concentrations. Many detergents and drugs are allocrites for ABCB1. Interestingly, ABCB1 exports these

drugs and detergents well below the concentrations that lead to significant disorder of membranes (see below).

Mixing disparate lipids induces domain formation

Mixing bulky disordered lipids, such as the non-physiological DOPC or fluorescent lipids, with highly ordered lipids such as cholesterol and DPPC (e.g.,^[54]) readily induces domain formation or phase separation. Hell and coworkers observed that, unlike phosphoglycerolipids, fluorescently labeled sphingolipids and glycosylphosphatidylinositol-anchored proteins can be transiently trapped (for approximately 10-20 ms) in cholesterol-mediated molecular complexes dwelling within < 20-nm-diameter areas^[55].

Lateral membrane packing density, π_M

Generally, a higher order parameter S_{mol} is associated with higher lateral packing density of the membrane, π_M . A model membrane consisting of POPC, which is the most abundant lipid in mammalian membranes, exhibits a lateral packing density $\pi_M \approx 32$ mN/m at room temperature^[56]. The addition of cholesterol (25 mol %) enhances the lateral packing density to $\pi_M \approx 35$ mN/m^[57]. The lateral packing density, π_M , is relevant because it determines partitioning of compounds into the membrane^[58]. To give an example embryonic cells (e.g., mouse embryo fibroblasts, NIH-3T3 cells^[25]), with a low cholesterol content, exhibit lower lateral packing densities than adult mammalian cells^[59].

Surface potential, Ψ_m

The cytoplasmic membrane leaflet exhibits a negative surface potential, Ψ_m . For mouse embryo fibroblasts (NIH-3T3 cells^[25]), it was estimated as $\Psi_m \approx -30$ to -20 mV under physiological conditions, assuming a cytosolic free magnesium concentration of $C = 0.5$ to 1 mM (with a membrane-binding constant for magnesium, $K = 10$ M⁻¹) and a monovalent cation concentration of $C = 100$ to 150 mM (with a membrane-binding constant for monovalent cations, $K = 0.6$ M⁻¹)^[59]. Under the given conditions, a surface potential of $\Psi_m \approx -30$ mV enhances the lipid-water partition coefficient, K_{lw} , of a strongly cationic drug by a factor of ~ 4 . However, upon titration with cationic drugs, the surface potential decreases (see Ref.^[32], Figure 7 therein).

Owing to the negative surface potential and the high unsaturation, the cytosolic plasma membrane leaflet acts as a drug scavenger for amphiphilic and cationic ABCB1 allocrites. The properties of the cytosolic membrane leaflet may even create a drug concentration gradient within the membrane that is opposed to the concentration gradient in the extracellular vs. intracellular aqueous phase. Notably, model membranes generally lack the asymmetry of natural membranes.

The dielectric constant, ϵ_m

Plasma membranes separate the extracellular and intracellular aqueous phases. Whereas the aqueous phase exhibits a high dielectric constant ($\epsilon_m \approx 80$), the polar lipid head group regions of the membrane exhibit an intermediate one ($\epsilon_m \approx 30-40$) and the hydrophobic core region a very low one ($\epsilon_m \approx 2-4$)^[60,61]. The dielectric constant, ϵ_m , decreases with increasing lateral membrane packing density, π_M , and thus varies somewhat with the lipid chain length, the degree of unsaturation, the cholesterol content, and the phase state of the membrane. The low dielectric constant, ϵ_m , of the membrane strengthens dipolar interactions.

Allocrite recognition

Long before ABCB1 structures were available, hundreds of allocrites had been identified. Allocrites are amphiphilic (or amphipathic)^[1] and often cationic^[62]. To explain the “polyspecificity” of ABCB1, we searched for recurrent elements in the chemical structures of drugs with the ability to interact with the

transporter *within* a lipid environment^[24-27] (see also Ref.^[63]). The analysis of a large number of chemical structures revealed specific patterns formed by π -electron donor groups, that is, hydrogen bond acceptor groups (HBAs) and π -electron systems (i.e., aromatic rings)^[64,65] (see also^[66,67]). The assumption that these patterns interact with the hydrogen bond donor groups (HBDs) and π -electron systems (phenyl and tryptophan residues) in transmembrane helices of ABCB1 through dipolar interactions offers an explanation for the polyspecificity of ABCB1. Figure 1A-E display compounds with possible type I *and/or* type II patterns. Compounds with type II patterns are not only allocrites for ABCB1 but also inducers of ABCB1 expression by interacting with the nuclear pregnane X receptor, for example^[68].

Notably, HBDs in allocrites (e.g., -OH, -NH₂, and > NH) do *not* interact with ABCB1^[64]. However, they significantly reduce the lipid-water partition coefficient (e.g., Refs.^[48,69]) and the rate of passive diffusion across the lipid membrane, which in turn enhances the risk of drugs being caught by ABCB1^[58].

The transporter exposes multiple HBDs

Figure 2 (and Supplementary Figure 1A-D) displays the numerous HBDs in the transmembrane domain of apo-Abcb1a^[20] and the nucleotide-bound ABCB1 (modeled on the high-resolution structure of Sav1866^[18]) from side [Figure 2A and B] and top views [Figure 2C and D]. The amino acids with hydrogen bond donor groups are highlighted in green. Interestingly, many HBDs are oriented towards the lipid phase. The HBDs in transporters most likely play a dual role; on the one hand, they extract compounds with appropriate HBAs (i.e., allocrites) from the lipid membrane, and on the other, they allow allocrite gliding across the membrane^[67]. In this context, phenyl residues that can undergo π - π stacking interactions with unsaturated rings in allocrites may also play a role (see Supplementary Figure 2A-D). The homodimeric Sav1866 from *Staphylococcus aureus*^[18] is the prototypical type IV fold protein and a homolog of the monomeric Abcb1a and ABCB1. These proteins share the cross-over of helices: in the case of the homodimeric Sav1866, helices 4 and 5 from each monomer cross over to the other monomer; in the case of ABCB1, helices 4 and 5 from TMD1 cross over to the C-terminal TMD2 and helices 10 and 11 from TMD2 cross over to the N-terminal TMD1^[6]. Because the X-ray structure of Sav1866 was obtained at a high resolution (3.0 Å)^[18], it provides an ideal basis for modeling other type IV fold proteins.

Transporters with allocrites bound - structural insights

In recent years, several atomic structures of ABC transporters with allocrites bound have been resolved. Most of them are in the apo form. The first crystal structure of ABCB1 (at 4.5-3.8 Å resolution) was obtained with the hydrophobic cyclic peptides QZ59-RRR and QZ59-SSS bound to the transmembrane domain. The peptides and the transporter were assumed to connect via “hydrophobic” interactions^[19]. Because the peptides carry several weak type I patterns formed by nitrogen and selenium, hydrogen bonding with the transporter is possible. The yeast mitochondrial ABC transporter Atm1 (an ortholog of human ABCB7) was crystalized (at 3.06 Å and 3.38 Å resolution) with the substrate glutathione. It revealed hydrogen bond formation between allocrite and transporter^[70]. Locher and colleagues provided several atomic structures (at 4.0-3.2 Å resolution) obtained by cryo-electron microscopy (EM) of human ABCB1 with the three inhibitors elacridar, tariquidar, and zosuquidar, or vincristine bound^[71]. The allocrites are surrounded by ample amino acids with π -electron systems or hydrogen-bonding groups (see, e.g., vincristine^[71] or taxol^[72]). The above inhibitors appear as pairs, arranged either in sequence (one behind the other) or in parallel or antiparallel orientation, respectively (see Ref.^[71], Supplementary Figure 8 therein). Similar observations were made with two molecules of encequidar bound to ABCB1^[73].

Similar to lipid membranes, transmembrane proteins are highly flexible and cannot be crystalized, unless they are stabilized. Molecules that may be favorable in this respect are dodecylmaltoside (DDM) that is an inhibitory detergent, inhibitory allocrites (see below), or the conformation-sensitive antibody UIC2 mAb.

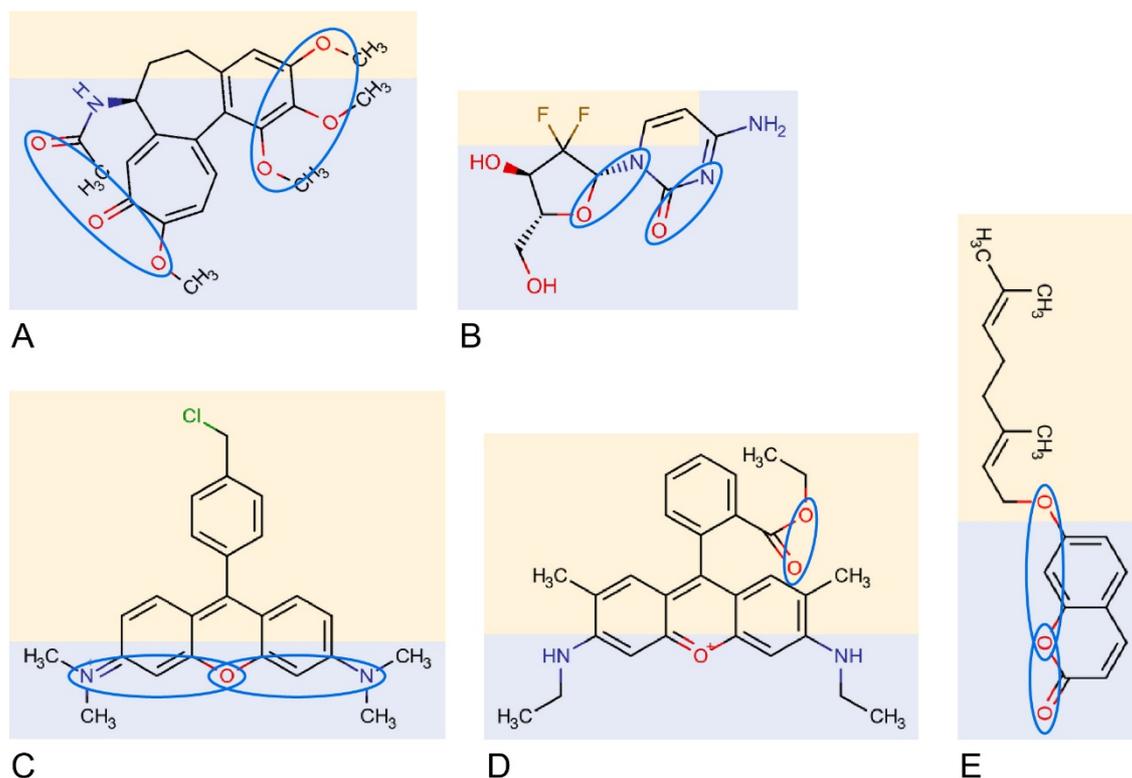

Figure 1. Examples of allocrites. Allocrites for ABCB1 are amphiphilic (polar part in blue, hydrophobic part in yellow) and carry type I or type II π -electron donor patterns (i.e., hydrogen bond acceptor patterns, HBAs) that are attracted by the HBDs in the protein. A type I pattern contains two HBAs separated by $2.5 \pm 0.3 \text{ \AA}$ and a type II pattern contains two or three HBAs, where the outer two are separated by $4.5 \pm 0.6 \text{ \AA}$. Possible type I and type II patterns are encircled in blue: (A) *Colchicine*, two type II patterns. (B) *Gemcitabine* is an anticancer drug, which induces cell death by blocking DNA replication, with either two type I patterns (shown) or one type II pattern (not shown). (C) *Tetramethylrosamine (TMR)*, type II patterns. (D) *Rhodamine 6G (R6G)*, one type I pattern (secondary and primary amino groups are not involved in patterns). (E) *Auraptene*, a citrus phytochemical, one type I or one type II pattern. The orientation of the π -electrons in a pattern does not seem crucial. Unsaturated rings play a role in π - π stacking interactions.

The variation of crystal contacts under different crystallization conditions may also play a role in the wide distribution of conformations observed in ABC transporters^[18,74,75]. Even if atomic structures may not reflect the functionally relevant conformations, they provide relevant aspects, such as the long predicted (i) broad binding areas that can accommodate two allocrites simultaneously^([76,77] see below); and (ii) the allocrite binding mode via weak dipolar interactions^[64,65].

ALLOCRITE BINDING TO ABCB1 - A TWO-STEP PROCESS

Allocrite binding from water to the transporter characterized by the transporter-water binding constant K_{tw} occurs in two steps. The first step is allocrite partitioning from the aqueous phase into the lipid membrane, characterized by the lipid-water partition coefficient, K_{lw} (M^{-1}). The second step is allocrite attraction to the transporter within the membrane, characterized by the transporter-lipid binding constant K_{tl} (dimensionless). The transporter-water binding constant K_{tw} (M^{-1}) can therefore be expressed as the product of the partition coefficient K_{lw} and the binding constant K_{tl} within the membrane [Supplementary Equation 1].

For simplification, we use free energies of binding in the following instead of binding constants. They can be interpreted as affinities and are additive [Supplementary Equations 2-5]. The free energy of allocrite

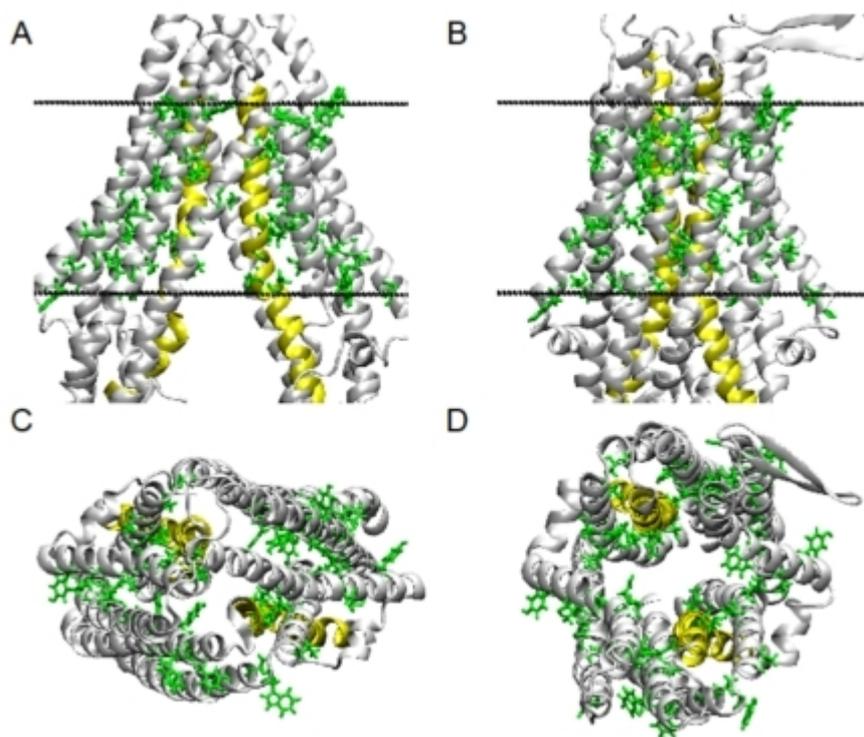

Figure 2. Amino acid residues with HBD side chains of ABCB1 at the level of the membrane (NBDs are truncated). (A) Abcb1a structure of the apo conformation open to the cytosol (PDB entry 4m1m) (side view). (B) Model of the closed conformation, based on the crystal structure of Sav1866 with two nucleotides bound (PDB entry 2hyd) (side view). (C) Apo conformation (top view). (D) Model of the closed conformation (top view). Amino acid side chains with HBDs are shown. TMD6 and TMD12 are colored yellow, whereas other helices are colored light gray. The two dashed lines indicate the position of the membrane (adapted from Ref.^[67], for details see Supplementary Figure 1A and B).

binding from water to the transporter, ΔG_w , is the sum of the free energy of partitioning into the membrane ΔG_m (step I) and the free energy of binding to the transporter within the membrane ΔG_b (step II) [i.e., $\Delta G_w = \Delta G_m + \Delta G_b$, (Supplementary Equation 2)]. Methods for assessing the binding constants and the free energies of binding are detailed in the Supplementary Materials.

Quantification of the individual binding steps ΔG_m , ΔG_b , and ΔG_w

The free energy of binding from water to the activating binding region of the transporter in inside-out plasma membrane vesicles^[78] and live NIH-MDR1-G185 cells was determined as $\Delta G_w = -30$ to -54 kJ mol⁻¹, the free energy of allocrite partitioning from water into the lipid membrane as $\Delta G_m = -23$ to -34 kJ mol⁻¹, and the free energy of allocrite binding from the lipid membrane to the activating binding region of the transporter as the difference between these two free energies [Supplementary Equation 2], $\Delta G_b = -7$ to -27 kJ mol⁻¹. The values given refer to the lowest and highest values for each type of free energy of binding, among the 19 compounds investigated. ΔG_w contributes significantly to the overall binding, but the free energy of allocrite binding to the transporter within the membrane ΔG_b varies more strongly than the free energy of lipid-water partitioning ΔG_m .

Characterization of the driving forces

The partitioning of uncharged amphiphiles such as drugs and detergents into electrically neutral membranes is driven by hydrophobic interactions. The classical hydrophobic effect (i.e., the release of ordered water molecules surrounding the solute in the aqueous phase upon partitioning into the membrane) is essentially entropy-driven (increasing with cooling), as observed for cyclosporine A^[48] and nonionic detergents^[79], for example. Partitioning of electrically charged drugs into an electrically neutral membrane is best described by the “non-classical hydrophobic effect”, which is essentially enthalpy-driven (increasing with warming)^[80]. The same is true for the cationic n-alkyl trimethyl ammonium chlorides (C_m -TACs) (see Ref.^[79], Table 1 therein). Partitioning of amphiphiles decreases exponentially with increasing lateral packing density of the membrane, π_m , and increasing cross-sectional area of the partitioning amphiphile, A_D (Supplementary Equations 6 without and 7 and 8 with a negative surface potential, Ψ_m).

To extract amphiphiles out of the most hydrophobic environment in a cell, that is, the lipid bilayer, hydrophobic interactions are not useful. Amphiphiles such as drugs and detergents can however be extracted by dipolar interactions^[81,82] [Figure 3]. An interesting aspect of the nature of dipolar interactions was revealed from a comparison of studies on allocrite binding to ABCB1 in liquid-crystalline and gel-state membranes^[83,84]. Whereas partitioning of allocrites into the gel-state membrane was lower than into the liquid-crystalline membrane, as expected, because of the enhanced lateral packing density in the gel-state membrane [Supplementary Equation 6^[58]], binding to the transporter within the gel-state membrane increased two to fourfold^[84]. The two to fourfold increase in the binding constant to the transporter K_u within the gel-phase membrane is consistent with a slight decrease of the dielectric constant ϵ_m in the gel phase as compared with that in the liquid-crystalline phase (see e.g., Ref.^[61]) [Supplementary Equations 9-11].

Thus, partitioning into the membrane is driven by hydrophobic interactions and limited by the lateral membrane packing density π_m , whereas allocrite binding to the transporter within the membrane is driven exclusively by dipolar interactions that increase with increasing membrane packing density π_m and concomitantly decreasing dielectric constant ϵ_m .

ATP HYDROLYSIS IN INSIDE-OUT PLASMA MEMBRANE VESICLES

Early titrations of ABCB1 with drugs yielded bell-shaped activity curves

Monitoring ATP hydrolysis as a function of drug concentration was, and still is, the key experiment for understanding how ABC transporters catalyze allocrite transport or flopping. The first titrations of ABCB1 with drugs were performed with inside-out plasma membrane vesicles. As they expose the NBDs to the extravesicular aqueous phase, the release of inorganic phosphate during ATP hydrolysis can be easily monitored by spectroscopic techniques (see e.g.,^[76]). The plasma membranes used originated from various ABCB1-overexpressing cell lines, including mouse embryo fibroblasts^[85], ovarian carcinoma cells (2780^{AD})^[86], insect cells^[87,88], Chinese hamster ovary cells, CHRC5^[89], CR1R12^[90], CH'B30 cells^[91], and Ehrlich ascites tumor cells^[76]. Most early ABCB1 titrations with drugs show a rise in steady-state ATPase hydrolysis at low concentrations up to a maximum, followed by a decrease at high concentrations, yielding characteristic *bell-shaped* activity (or velocity, V) vs. concentration curves [Figure 4]. ABCB1 titrations in plasma membrane vesicles with verapamil exhibited maximum steady-state ATP hydrolysis rates (V_{max}) around the concentration $C_{verap} \approx 10 \mu\text{M}$, even though the membranes originated from different cell lines. This may be due to the subtle compensation between the reduced allocrite partitioning into membranes of higher lateral packing density and the enhanced dipolar affinity between the allocrite and the transporter within the membrane. The drug-stimulated ATPase activity was directly proportional to the amount of P-glycoprotein, as demonstrated in Ehrlich ascites tumor cell lines^[76], whereas the concentration of half-

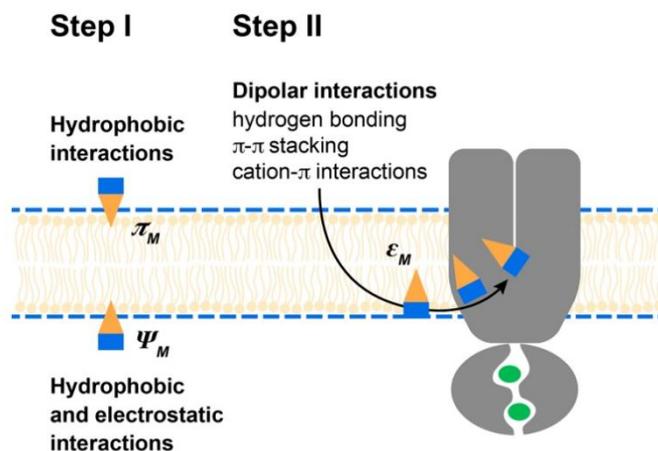

Figure 3. Scheme showing the types of interactions in the two-step process of allocrite binding from the aqueous phase to ABCB1 within the membrane. Step I: Partitioning of an amphiphilic allocrite (with polar part in blue and hydrophobic part in yellow) into the extracellular membrane leaflet depends on the lateral packing density of the membrane, π_m . Moreover, partitioning into the cytosolic leaflet depends in addition on the surface potential ψ_m of the membrane^[59]. Step II: Dipolar interactions between allocrite and transporter (including hydrogen bonding, π - π stacking, and π -cation interactions, given in the order of assumed relevance) are suggested to drive recognition, binding, and "transport" of the polar part to the middle of the membrane. Thereby it is assumed that the hydrophobic part remains in contact with the lipid environment.

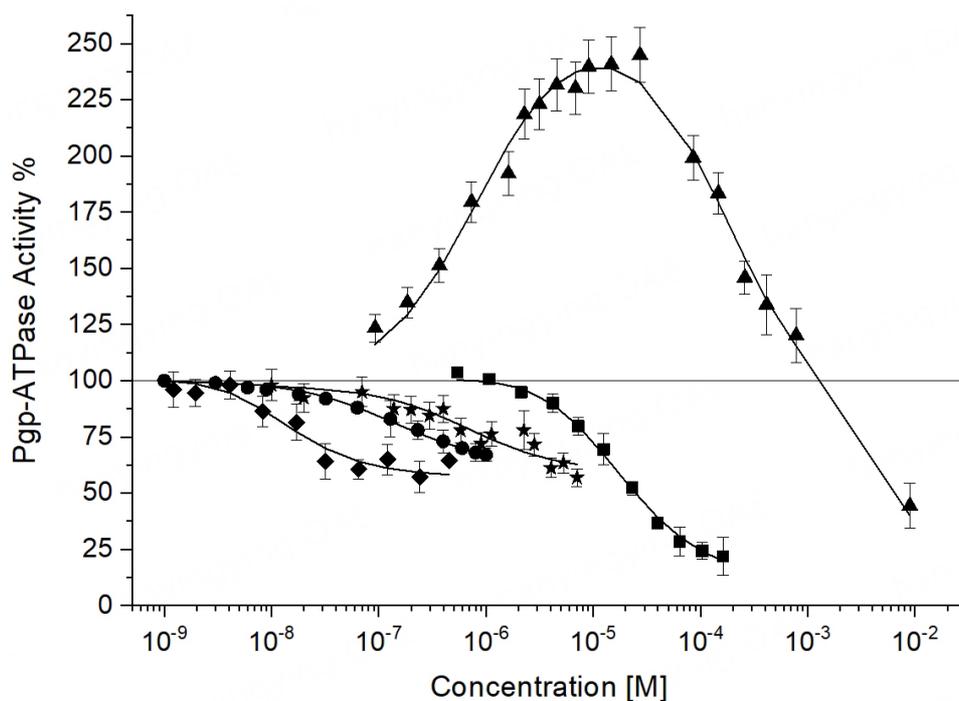

Figure 4. ABCB1 ATPase activity vs. allocrite concentration curves. ATPase activity measured in inside-out plasma membrane vesicles from NIH-MDR1-G185 cells^[25]. Data are fitted to the two-site binding model by Litman et al.^[96]. Tariquidar (diamonds); OC144 093 (circles), cyclosporine A (stars), DDM (squares), verapamil (triangles). Tariquidar, OC144 093, and verapamil inhibit as dimers. DDM^[79] and cyclosporine A (see Ref.^[79], Supplementary Table 3 therein) most likely inhibit as monomers due to their unfavorable $q = \kappa_{d2}/\kappa_{d1}$ values (see below).

maximum activation remained approximately constant. In reconstituted proteoliposomes, the

concentration of maximum activity depends on the type and residual concentration of detergents used for reconstitution, as discussed below.

Bell-shaped ATPase activity curves - artifact or fact?

Around the turn of the millennium, some skepticism arose regarding the inhibitory branch of ABCB1 activity curves and various artifacts were suspected of having influenced the titration curves at high drug concentrations, including membrane disordering, vesicle aggregation, ATP depletion, and a disturbed boundary layer around the protein. To clarify the ABCB1 kinetics, we investigated the potential artifacts.

Membrane disordering?

In 1995, Drori *et al.* observed that the cytotoxicity of anticancer drugs in multidrug-resistant cell lines was potentiated by chemosensitizers (i.e., detergents)^[92]. They hypothesized that chemosensitizer-mediated membrane perturbations could interfere with the ATPase activity of ABCB1 and/or with ABCB1 drug transport capability. We know today that the detergents used by Drori *et al.* are allocrites for ABCB1 and act as ABCB1 inhibitors at higher concentrations^[69,79,81,82,92].

To quantify the disordering effect of detergents and drugs at concentrations relevant for ABCB1 activation and inhibition, we measured the order parameter S_{mol} by D-NMR spectroscopy. The effects were negligibly small at concentrations of half-maximum activation, K_1 , and showed a reduction in the order parameter of only about 5% in the case of detergents at half-maximum inhibition, K_2 ^[79]. Somewhat more disordering was observed in the case of verapamil, owing to its larger cross-sectional area in the folded, membrane-bound conformation^[93] (for quantitative data, see Supplementary Table 1 and references therein). Thus, ABCB1 eliminates allocrites before membrane disordering effects become obvious.

Moreover, a transition state analysis of ABCB1 activity in membrane environments exhibiting different lateral packing densities revealed that the transporter acts in a broad range of environments from densely packed lipids to loosely packed micelles (see Ref.^[94], Figure 6 therein). With decreasing membrane packing density, the activation energy decreased and thus the rate of ATP hydrolysis increased. Whereas the activity was entropy-driven at a high packing density, it was essentially enthalpy-driven at a low packing density^[94]. The activity of ABCB1 is thus robust with respect to its environment and it works perfectly in a much broader range of membrane packing densities than encountered under physiological conditions.

Vesicle aggregation?

In inside-out plasma membrane vesicles, the negatively charged inner membrane surface is exposed and thus these vesicles repel each other. Upon titration with strongly cationic drugs, the negative surface potential is strongly reduced, which may lead to vesicle aggregation at high concentrations. Even under these conditions, a decrease in activity occurs before aggregation takes place. The phenomenon of vesicle aggregation at high drug concentrations is limited to compounds with $\text{p}K_a > 9$. Cationic drugs with lower charge or no charge exhibit no vesicle aggregation, and show bell-shaped curves as well (for details, see^[78]).

ATP depletion?

ATP depletion has been observed with pluronic block copolymers^[95] at an incubation time of 2 h. This is at least twice the incubation time generally used in ATPase activity measurements. The titration of ABCB1 with verapamil under ATP regenerating conditions again yielded practically identical bell-shaped activity vs. concentration curves (see Ref.^[66], Figure 2 therein).

Disturbed boundary lipids?

As mentioned above, boundary lipids or lipid domains were not observed in natural membranes at physiological temperatures upon monitoring different deuterated phospholipids by D-NMR spectroscopy^[50]. Disturbed boundary layers, that is, disordered membranes of lower packing density, would enhance rather than reduce the steady-state ATP hydrolysis rate (for details, see below). We conclude that the decrease in ABCB1 ATPase activity at high drug concentrations is real and highly relevant for understanding transporter inhibition (see below).

Two-site binding models are required

In 1997, Stein and colleagues proposed a model for quantitative evaluation of bell-shaped ABCB1 activity vs. allocrite concentration curves^[76,96]. This model is based on the principle of Michaelis-Menten kinetics and takes into account basal activity, V_0 , in the absence of an exogenous allocrite; enhanced activity, V_1 , with one allocrite molecule bound to the transporter; and reduced activity, V_2 , with two allocrite molecules bound to the transporter [Supplementary Equation 12] (see Figure 4). A related model, however, assuming basal activity, uncoupled from transport, a drug-activated phase, and a drug-inhibited phase, was later proposed by Al-Shawi and colleagues^[77]. The recent advances in atomic transporter structures provide direct evidence for *two* molecules bound to ABCB1 (see e.g., Ref.^[71]) and support the necessity of two-site binding models. We consider the model proposed by Stein and colleagues^[76,96] as more plausible because empty cycling seems unlikely from an energetic point of view.

Allocrites that may contribute to basal activity in plasma membrane vesicles

Basal activity was proposed to be due to an as-yet-unknown allocrite^[10]. Different endogenous allocrites may be considered. The most prevalent among them is POPC. Protonated POPC (POPC⁺) shows the typical characteristics of an ABCB1 allocrite and may be responsible for basal activity. Despite the low intrinsic pK_a value of the phosphate group in the pure phosphatidylcholine (PC) monolayers^[97], a small fraction of PC molecules may be protonated at the phosphate group in the overall negatively charged cytosolic membrane leaflet of cells. As the flipping rate of PC lipids (from the extracellular to intracellular membrane) is low^[98], and ABCB1 may cope approximately by flopping them back to the extracellular membrane leaflet, the concentration of POPC⁺ in the cytosolic membrane leaflet remains low and prevents inhibition of the transporter. ABCB1 may thus contribute to the maintenance of lipid asymmetry in biological membranes, as suggested earlier^[63,99]. The particularly low basal activity in DPPC vesicles^[27] could be due to a very low concentration of the cationic species in the absence of negatively charged lipids, or if the zwitterionic form is also an allocrite, to the an excessive and thus inhibitory concentration of DPPC. Thus, basal ABCB1 activity may arise from flopping POPC⁺, or POPC in general.

The factors influencing the steady-state ATP hydrolysis rate

Correlation between the steady-state ATP hydrolysis rate and allocrite affinity ^{see}

Stein and colleagues studied the correlation between kinetic parameters and the lipid-water partition coefficient as well as the van der Waals surface area of drugs in inside-out plasma membrane vesicles of CR1R12 cells^[96]. With the exception of valinomycin, a good correlation between the surface area of drugs and the compound's affinity to ABCB1 was observed. Similar data were provided by Sharom and colleagues^[99].

A good correlation between size-related parameters and the compound's affinity to the transporter within the lipid phase ^{see}, can be rationalized by assuming that increasing the surface area of the drug requires increasing the number of hydrogen-bonding groups to prevent aggregation. Therefore, increasing the molecular surface area (or molecular weight) roughly correlates with increasing the number of HBAs in

ABCB1 (= O, -O-, -N <), which can interact with HBDs in the transporter. If one considers that valinomycin offers a number of π -electron donor groups for complex formation with potassium, it is no longer an outlier^[96]. The correlation between HBAs and the molecular weight of allocrites is also displayed in [Supplementary Figure 3](#). Thus, the observed decrease in activity with increasing affinity can be explained by weak dipolar interactions between the available HBAs in allocrites and the HBDs in the protein.

A reduced allocrite affinity with a concomitant increase in activity was also obtained by eliminating “anchor points” in the protein binding region, for example, by mutating amino acids able to form π - π stacking or hydrogen bonding interactions with allocrites. Compounds that were “inhibitors” in the native transporter became activators in the mutant^[100,101], supporting the inverse correlation between affinity ΔG_{bind} and the steady-state ATP hydrolysis rate. Thus, the steady-state ATP hydrolysis rate and transport decrease with an increasing number of weak dipolar interactions (see e.g., TMR and R6G in Figure 1 from Ref.^[102]). Using a broader range of tetramethylrosamine (TMR) analogs and their xanthone precursors, Tomblin and colleagues^[102] demonstrated that, in addition to the number of HBAs, the logP (octanol-water partition coefficient, used as a crude estimation of lipid-water partition coefficient) plays an additional role (e.g., Chart 2, compounds 14-16 in Ref.^[102]). A strict correlation between the rate and ΔG_{bind} holds true only if ΔG_{bind} is rather constant. More diverse sets of compounds require the inclusion of ΔG_{bind} (see below).

The steady-state ATP hydrolysis rate ($\ln V_1$) decreases linearly with ΔG_{bind} .

An approximately linear decrease of the steady-state ATP hydrolysis rate, $\ln V_1$ (on a logarithmic scale), with decreasing free energy of binding ΔG_{bind} (or increasing allocrite affinity to the transporter) was observed with various data sets^[78,79,82]. [Figure 5A](#) shows $\ln V_1$ vs. ΔG_{bind} for very diverse types of allocrites, including moderately charged (on the upper diagonal line), highly charged (on the lower diagonal line), and essentially uncharged amphiphiles (between the two diagonal lines). [Figure 5A](#), moreover, includes molecules of low amphiphilicity, such as PSC 833, cyclosporine A, OC144-093, and tariquidar, or molecules of unfavorable amphiphilicity, such as DDM^[79] (below the lower diagonal line). The strict linear dependence of $\ln V_1$ vs. ΔG_{bind} thus exists only within a specific charge group. To understand this phenomenon, we assessed the free energy contribution per single hydrogen bond, ΔG_{HBA} , and per single charge, ΔG_{charge} .

ΔG_{HBA} was assessed by dividing ΔG_{bind} by the number of HBAs in type I and type II patterns of the different compounds ([Figure 5B](#), y-axis). These values were plotted as a function of the number of HBAs per compound ([Figure 5B](#), x-axis). A higher number of HBAs per compound was associated with a lower contribution per single HBA, suggesting that not all HBAs present contribute simultaneously to binding in the case of larger compounds with a higher number of HBAs. The value per single hydrogen bond was estimated by extrapolation [[Figure 5B](#)]. The values given in [Figure 5B](#) were evaluated for mouse embryo fibroblast membranes.

The free energy of binding per charge and HBA - comparison with literature data

To assess the affinity of a full cationic charge to ABCB1, we used the quaternary ammonium ion in C_m -TACs. The free energy of binding per cationic charge to ABCB1 was assessed as $\Delta G_{\text{charge}} = -6.5 \pm 0.7 \text{ kJ mol}^{-1}$ ^[79] (see [Figure 5B](#)). The value is within the range of π -cation interactions^[103].

For electrically neutral detergents with a very peripheral location of the polar head group, and progesterone, which lacks a strong type I pattern, extrapolation to a single HBA yields $\Delta G_{\text{HBA}} \approx -3.5 \text{ kJ mol}^{-1}$ [[Figure 5B](#)]. For

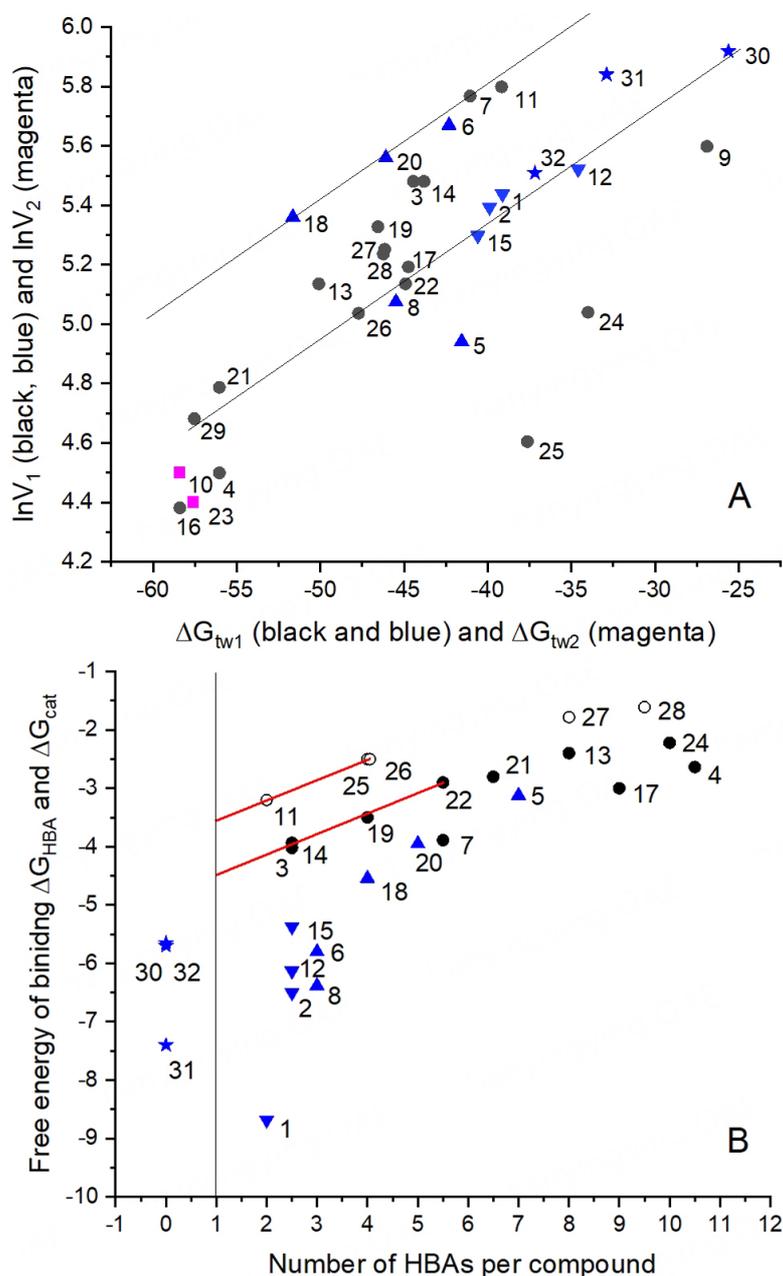

Figure 5. Correlations between maximum steady-state ATP hydrolysis rate and affinity in mouse embryo fibroblast membranes. (A): $\ln(V_1)$ vs. the free energy of binding, ΔG_{tw} . The maximum steady-state ATP hydrolysis rate, V_1 , is expressed as a percentage of the basal steady-state ATP hydrolysis rate taken as 100%. Data were obtained from phosphate release measurements: (1) amitriptyline, (2) chlorpromazine, (3) cis-flupenthixol, (4) cyclosporine A, (5) daunorubicin, (6) dibucaine, (7) diltiazem, (8) glivec, (9) lidocaine, (10) OC144-093, (11) progesterone, (12) promazine, (13) reserpine, (14) trifluoperazine, (15) trifluopromazine, (16) PSC 833, (17) vinblastine (1-17, from Ref. [78]), (18) amlodipine, (19) nimodipine, (20) verapamil (18-20, from Ref. [93]), (21) sirolimus, (22) tacrolimus (21-22 from Simon Lang and A.S., unpublished results), (23) tariquidar (X. Li-Blatter and A.S., unpublished results), (24) etoposide (from Ref. [66]), (25) C₁₂-maltoside, (26) C₁₃-maltoside, (27) C₁₂EO₈, (28) Triton X-100, (29) Tween 80, (30) C₁₀-TAC, (31) C₁₂-TAC, (32) C₁₄-TAC (25-32, from Ref. [79]). Black filled circles: neutral compounds or compounds exhibiting low charge ($pK_a \leq 8$). Blue upward-pointing triangles: cationic compounds with intermediate charge ($pK_a \geq 8$). Blue downward-pointing triangles: strongly charged cationic compounds ($pK_a \geq 9$). (B): The free energy of binding per single cationic full charge, ΔG_{HBA} , and single HBA, ΔG_{cat} , as a function of the number of hydrogen bonds in patterns per compound n_{HBA} . Compound numbers and symbols as in (A), black open circles, uncharged compounds. The free energy per hydrogen bond (y-axis) decreases with the increasing number of hydrogen bonds in patterns per compound (x-axis). We extrapolated to one hydrogen bond in the case of electrically neutral compounds and compounds with low charge (red lines).

electrically neutral drugs likely penetrating more deeply into the membrane, extrapolation to a single hydrogen bond yields $\Delta G_{\text{bind}} \approx -4.5 \text{ kJ mol}^{-1}$. Highly charged compounds such as amitriptyline (pK_a 9.4) exhibit more negative free energy of binding, $\Delta G_{\text{bind}} = -8.7 \text{ kJ mol}^{-1}$ [Figure 5B], owing to a charge contribution. Because most cationic drugs show lower pK_a values than amitriptyline, charge contributions are generally low and hydrogen bonding dominates.

The calculated free energy of hydrogen bond formation is on the order of -20 kJ/mol (see e.g.,^[104]) and is thus much higher than the free energy per HBA assessed for ABCB1. However, our values agree well with the rare *measured* free energies of hydrogen bond formation in large membrane proteins. The H-bond strength of a single $\text{Ca-H}\cdots\text{O}$ H-bond in the transmembrane helical dimer of glycoporphin A, located in the center of the membrane, was assessed as 3.7 kJ mol^{-1} , using vibrational frequency shifts of dimeric and non-dimeric variants of glycoporphin A, containing a deuterium-labeled Gly^[105]. The average contribution of eight interhelical side-chain hydrogen-bonding interactions throughout bacteriorhodopsin, reconstituted in DMPC (1,2-dimyristoyl-sn-glycerol-3-phosphocholine)/CHAPSO {3[(3-cholamidopropyl)dimethylammonio]-2-hydroxy-1-propane-sulfonate}, was determined as 2.5 kJ mol^{-1} ^[106]. The sign of free energy of binding depends on the reference state.

The role of amphiphilicity for the steady-state ATPase rate

Amphiphilicity is a qualitative term used to describe a molecule exhibiting a polar part and a non-polar, hydrophobic part. As shown previously, the steady-state ATP hydrolysis rate of detergents and drugs strongly depends on ratio $q = \Delta G_{\text{bind}}^{\text{mem}} / \Delta G_{\text{bind}}^{\text{wat}}$ (ratio of the free energy of allocrite binding to the hydrophobic membrane and to the more polar transporter)^[79].

The ratio q can be considered as a quantitative description of a compound's amphiphilicity. For ATPase-activating compounds such as the cationic C_m -TACs, the ratio is $q \approx 3$ -4, for cationic drugs, $q \approx 3$, and for electrically neutral detergents, $q \approx 2.7$. Electrically neutral detergents are particularly sensitive to the ratio q . Slight deviations to higher values (e.g., C_{14} -maltoside with $q \approx 3$) lead to a lack of activation/inhibition because the affinity to the membrane is too high. Lower values lead to inhibition [e.g., C_{12} -maltoside (DDM) with $q = 2.5$]. Inhibitory drugs including cyclosporine A show low ratios ($q \approx 1$) (see [Supplementary Information](#) to Ref.^[79]).

Conclusions on the mechanism of transport

Altogether, we demonstrated that the steady-state ATPase hydrolysis rate decreases with increasing affinity of the allocrite from water to the transporter $\Delta G_{\text{bind}}^{\text{mem}}$. However, the rate is particularly sensitive to charge and amphiphilicity. Compounds with two HBAs and a very weak cationic charge or only two HBAs, providing a free energy of binding comparable to that of a single cationic point charge of $\Delta G_{\text{bind}} = -6.5 \pm 0.7 \text{ kJ mol}^{-1}$, induce a higher ATP hydrolysis rate than the latter. Weak dipolar interactions are thus more favorable for transport than a single strong cation- π interaction. Weak interactions thus may allow gliding of the polar part of the allocrite across the transporter binding region towards the center of the transporter in the middle of the membrane (which exhibits the lowest dielectric constant and thus the highest affinity to the transporter) and may facilitate flopping. While the polar part of allocrites forms weak electrostatic interactions with the transporter, the hydrophobic part seems to remain associated with the lipid membrane, as proposed earlier^[81]. The slow-down in the steady-state ATP hydrolysis rate with reduced amphiphilicity is consistent with such an interfacial flopping process. An interfacial transport process has been described for the oligosaccharide transporter PglK with two ATP γ S molecules bound^[107].

ATP HYDROLYSIS IN RECONSTITUTED PROTEOLIPOSOMES AND DETERGENT

MICELLES

Proteoliposomes with residual detergents show higher K_m (K_1) and lower V_{max} (V_1) values

The concentrations of half-maximum activation K_m (Michaelis-Menten constant) or K_1 [Supplementary Equation 12] of specific allocrites in proteoliposomes are often distinctly higher than in natural plasma membrane vesicles. If ABCB1 is reconstituted into lipid vesicles, detergents are used. Even though such detergents are usually removed after reconstitution, residual detergents may remain. Reconstitution of ABCB1 by solubilization in octyl glucoside (OG) in the presence of *Escherichia coli* lipids and subsequent titration with verapamil yielded an almost 10-fold higher concentration of maximum activation (e.g., [108,109]). Still higher concentrations of maximum activation (e.g., [71]) or even a loss of activity [91] were observed when DDM was used. Callaghan and colleagues prevented “inactivation” by a careful reconstitution protocol that included excess crude lipid mixtures and extensive gel filtration to eliminate DDM [91]. The often-observed shift of K_m values to higher concentrations is caused by competitive inhibition of the allocrite (e.g., verapamil) [82]. An increase in K_m , combined with a decrease in V_{max} , is typical for competitive inhibition. The inhibitory power of detergents increases in the order CHAPS < OG < DDM [27] (OG and DDM [79], CHAPS: X.L. and A.S., unpublished results) [Figure 4].

The loss of activity of transporters reconstituted in lipid bilayers is thus caused by residual detergents such as OG and particularly DDM that act as competitive inhibitors. ATPase activity is regained by dilution or squeezing out (see, e.g., effects observed by addition of cholesterol in Ref. [110,111]).

Detergent micelles show higher K_m (K_1) and higher V_{max} (V_1) values

The basal ATPase activity of Sav1866, reconstituted in liposomes, increased two- to threefold upon the addition of detergents above their critical micelle concentration (CMC), which led to the formation of mixed micelles (see Ref. [32], Figure 5 therein).

Ambudkar and colleagues [112] compared the basal ATPase activity of mP-gp (the murine analog of ABCB1) in native High Five insect cell membranes (42 to 54 nmol P_i /min/mg of protein) and in DDM micelles (79 to 83 nmol P_i /min/mg of protein). In DDM micelles, the basal ATPase activity was again about twice as high as in insect cell membranes. Moreover, a 30-150-fold decrease in the apparent affinity for verapamil and cyclic peptide inhibitor QZ59-SSS was observed in detergent micelles compared with that in native or artificial membranes. Consequently, the cyclic peptide “inhibitor” QZ59-SSS and the modulators zosuquidar, tariquidar, and elacridar (inhibitors in lipid vesicles with IC_{50} values in the 10-40 nM range) stimulated the ATPase activity of purified human or mouse P-gp in DDM micelles.

Micelles exhibit higher dielectric constants, ϵ_m , than lipid vesicles, leading to a substantial decrease in allocrite affinity to the transporter (see Supplementary Equations 9-11) and a concomitant increase in ATPase activity and transport, as expected. Thus, ABCB1 remains functional in a micellar environment, although transport becomes Sisyphean because of the low lateral packing density, π_M , of micelles.

Cholesterol enhances the membrane packing density and allocrite affinity

The addition of cholesterol has often enhanced ABCB1 activity (see, e.g., effects observed by addition of cholesterol in Ref. [110,111]). The addition of lipids generally dilutes residual inhibitory detergents such as OG and DDM. Densely packed lipids, including cholesterol, may in addition squeeze detergents out of the lipid bilayer, which leads to enhanced ATPase activity.

However, the specific effect of cholesterol (in the absence of detergents) is to slightly reduce the steady-state ATP hydrolysis rate [84,94]. Cholesterol enhances the lateral membrane packing density, π_M , and reduces the

dielectric constant, ϵ_m , of a lipid bilayer (see above), with the consequence of an enhanced dipolar attraction of the allocrite to the transporter within the membrane.

These predictions are consistent with experiments by Ueda and colleagues^[113], who measured the modulation of drug-stimulated ATPase activity of ABCB1 by cholesterol in the absence of OG or DDM. They reconstituted ABCB1 in membranes with different cholesterol contents ($C_{ch} = 0\%-20\%$ w/w) and used ten allocrites with increasing molecular weights from 345 to 1111 Da (see Ref.^[113], Table 1 therein). For small molecules (molecular mass < 500 Da), K_m decreased (i.e., the affinity to the transporter increased) by about a factor of two with increasing cholesterol content. For larger molecules, K_m remained approximately constant, and for the largest molecule, K_m even increased slightly with increasing cholesterol content. For small compounds, lipid-water partitioning is not limiting and the affinity to the transporter within the membrane increases with decreasing dielectric constant ϵ_m . Conversely, in the case of the largest compounds, the affinity to the transporter slightly decreased because partitioning into the membrane became the limiting factor. With increasing cholesterol content, the activity, V_{max} , clearly decreased for large molecules with many HBAs, whereas it remained approximately constant for small molecules. Although the effects are minor, the data^[113] perfectly agree with the above expectations. Sharom and colleagues obtained related results and also demonstrated that “the cholesterol content of the membrane has only a modest influence on both the basal and the drug-stimulated ATPase activity of P-gp”^[114].

The consequences of using methyl- β -cyclodextrin (m β CD) for cholesterol elimination

Elimination of cholesterol by m β CD often leads to a strong decrease in ABCB1 activity. On the basis of this observation, it was concluded that cholesterol must be strongly ABCB1-enhancing, but this is not the case (see above). Elimination of cholesterol with m β CD is complex. The cyclic polysaccharide has a central hydrophobic cavity that can be occupied by cholesterol, lipids, or any other hydrophobic or amphiphilic molecule. In its empty form, m β CD engulfs cholesterol from the hydrophilic end, thereby partially penetrating into the head group region of the lipid membrane. Sharom and colleagues^[114] found a decrease in ABCB1 activity with increasing concentrations of m β CD in CH^RB30 plasma membrane vesicles, in DMPC proteoliposomes, and in CHAPS micelles, independent of cholesterol and suggested the possibility of a direct interaction between ABCB1 and m β CD^[114]. m β CD carries multiple hydrogen bond acceptor patterns, and therefore direct interaction with ABCB1 is highly likely. It seems to start already at low concentrations (X.L-B and A. S. unpublished results). Because membranes disintegrate at higher m β CD concentrations, obtaining definitive experimental proof of this is difficult.

To inhibit endogenous cholesterol synthesis, lovastatin was used in addition to m β CD^[115]. Lovastatin is also a modulator of ABCB1 directly inhibiting ABCB1 at the concentrations used (A.S. unpublished results). Thus, the strong effects observed upon cholesterol elimination with m β CD are likely caused by direct inhibition of ABCB1 by m β CD at low concentrations and by general delipidation at higher concentrations.

Thus, cholesterol elimination with m β CD strongly reduces ATPase activity, but cholesterol supplementation in a biological membrane would not enhance it.

ATP HYDROLYSIS IN LIVING CELLS

At this point, the altered “*membrane permeability*”^[1] of cells in the presence of ABCB1 becomes relevant. Whereas in inside-out vesicles, active transport and passive diffusion work in the same direction, they work in opposite directions in cells. This phenomenon was described as the “*pump-leak effect*”^[116]. Here, the balance is in favor of export (pump) in the case of large molecules, and in favor of influx (leak) in the case of smaller ones^[58]. The comparison of ATPase activity measurements in inside-out plasma membrane vesicles

and cells is therefore of special interest.

Cells cultured in the presence of glucose generally work under glycolytic conditions^[117]. Under these conditions, the extrusion of one lactate corresponds to one ATP synthesized. As ATP is synthesized according to requirements, ATP hydrolysis can be monitored by measuring the steady-state extracellular acidification rate (ECAR) using a Cytosensor microphysiometer^[117,118]. The drug-stimulated ABCB1 activity was obtained by comparing MDR1-transfected mouse embryo fibroblasts (NIH-MDR1-G185 cells) with the corresponding wild-type cells (NIH-3T3 cells). If the energy requirement is enhanced, cells possess the ability to dynamically switch to oxidative phosphorylation (or respiration)^[119]. To remain under glycolytic conditions and prevent potentially toxic side effects, drugs were applied for short time intervals of 2-3 min^[59,120] and were washed out after each stimulation (see [Supplementary Figure 4](#)).

Small molecules: ABCB1 titration curves in cells and vesicles are similar

Small cationic drugs equilibrate rapidly between the inner and outer plasma membrane leaflets, and thus the concentrations of half-maximum activation K_1 are similar in cells and inside-out vesicles [[Figure 6A](#) and [D](#) or [B](#) and [E](#)]. The slightly lower K_1 values in cells are likely due to the somewhat lower cytosolic free magnesium ion concentration in cells and thus to a somewhat more negative membrane potential compared with that in vesicles^[32,112]. Notably, the ATPase activity induced by small allocrites was more than twofold higher in cells than in plasma membrane vesicles of the same cells, even at the short stimulation times^[69]. Significantly higher steady-state ATP hydrolysis rates in cells than in proteoliposomes [[Figure 6C](#) and [F](#)] were also measured for CFTR (ABCC7)^[14].

Large molecules: titration curves in cells and vesicles differ, revealing transport

For slowly diffusing compounds, such as daunorubicin (MM: 527.5 Da), a known ABCB1 “substrate” [[Figure 6B](#)], the ATPase activity profiles of inside-out vesicles and cells differed distinctly. At identical aqueous concentrations (e.g., $C_{\text{daun}} = 1 \mu\text{M}$), daunorubicin inhibited ABCB1 activity in inside-out vesicles and activated it in living cells. The drug concentration in the cytosolic membrane leaflet of cells was estimated according to the new K_1 value to be approximately one hundredth that in the cytosolic membrane leaflet of inside-out plasma membrane vesicles^[69]. In the case of daunorubicin and other “substrates”, ABCB1 can maintain a concentration gradient (between the inner and outer plasma membrane leaflets) or, in other words, can cope with influx. Transport, reflected by a substantially reduced K_1 value in the cytosolic membrane leaflet of cells, was also observed for Tween (reduced by about one-thousandth)^[69] and vinblastine (reduced by about one-tenth) (see Ref.^[78], [Figure 3A-E](#) therein). Interestingly, even detergents such as Triton X-100 and $C_{12}EO_8$ showed a reduction to approximately one-tenth in the cytosolic membrane leaflet of cells^[69].

ABCB1 efficiently competes with passive influx of large allocrites, that is “substrates” (see Ref.^[35]). Therefore their concentration in the cytosolic plasma membrane leaflet of cells can be significantly lower than in the cytosolic leaflet of inside-out plasma membrane vesicles of the same cells. These measurements provide the first unequivocal insight into the correlation between ATPase activity and transport.

Stoichiometry: one ATP hydrolyzed per allocrite transported

The stoichiometry of ATP-driven ion transporters moving ions from the aqueous phase at one side of the membrane to the aqueous phase at the other side of the membrane has long been determined^[121]. Assessing the stoichiometry of ATP-driven allocrite transport by ABCB1 has proven significantly more challenging. Allocrites are captured in the cytosolic membrane leaflet, and are flopped to the extracellular leaflet^[122]. From the extracellular leaflet, they eventually partition into the aqueous phase according to their lipid-water partition coefficient. Thus, many drugs accumulate within membranes.

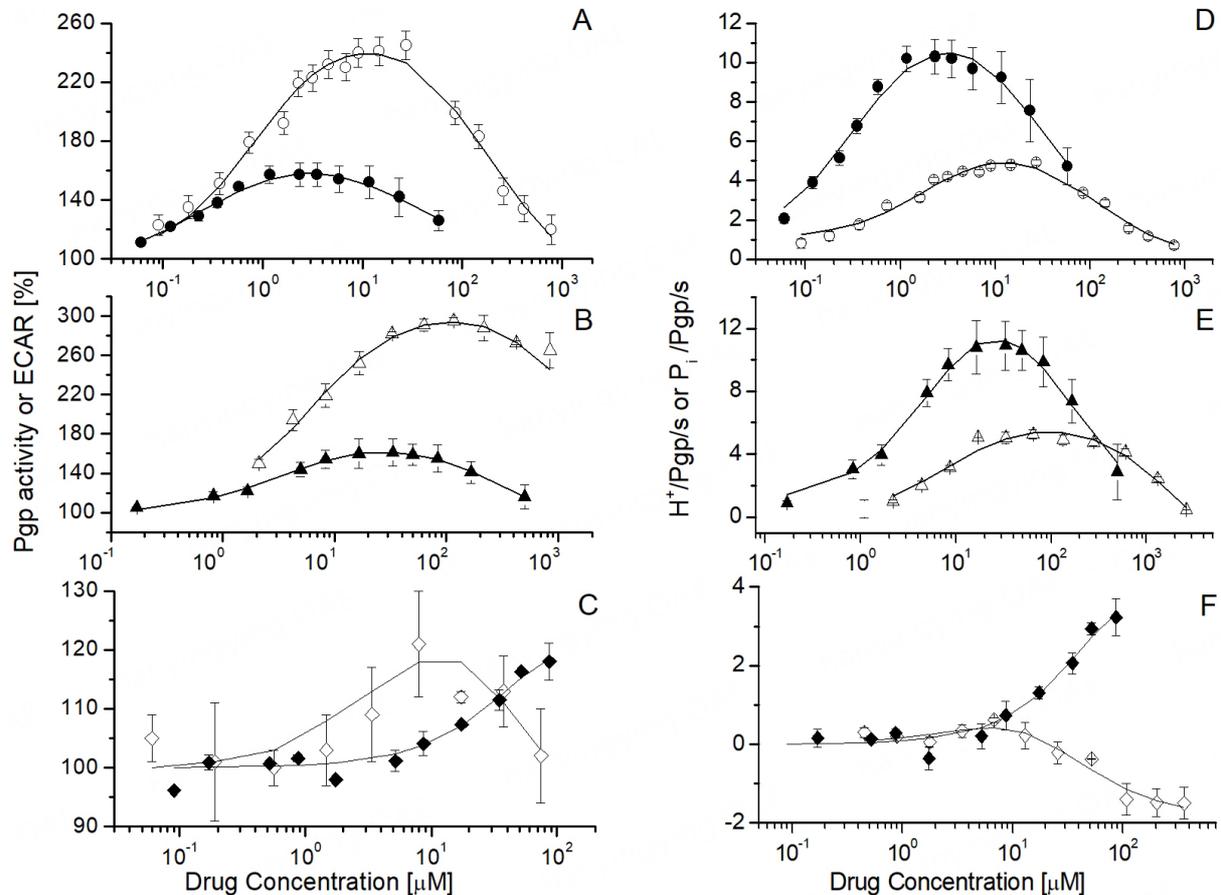

Figure 6. ABCB1 ATPase activity in NIH-MDR1-G185 cells (filled symbols) and inside-out plasma membrane vesicles (open symbols) induced by three drugs. (A-C) ATPase activity expressed as percent of the basal value in the absence of drugs. (D-F) ATPase activity expressed as protons (i.e., lactic acid) or phosphate released per ABCB1 per second. Calculations are based on the expression level of ABCB1 determined for NIH-MDR1-G185 cells^[124]. (A and D) Verapamil (●, ○); (B and E) diltiazem (▲, △), and (C and F) daunorubicin (◆, ◇). Lines are fits to Supplementary Equation 12. Standard deviations are shown (taken from Ref.^[69]). With copyright permission from BBA.

To circumvent the problems caused by allocrite partitioning into the membrane and passive diffusion across the membrane, Eytan *et al.* measured the ATP-dependent uptake of the $^{86}\text{Rb}^+$ -valinomycin complex into proteoliposomes^[123]. They suggested 1.2-2 ATPs hydrolyzed per transported $^{86}\text{Rb}^+$ -valinomycin complex.

Stein and colleagues^[124] used vinblastine, a known “substrate,” as a test molecule. Vinblastine exhibits a comparatively low lipid-water partition coefficient, $K_{\text{lw}} \approx 15 \text{ M}^{-1}$ (in the absence of DMSO) [Table 1] (Li-Blatter X, unpublished results), a relatively large cross-sectional area ($A_{\text{D}} = 140 \text{ \AA}^2$), and accordingly relatively slow diffusion. Maximum outward pumping from NIH-MDR1-G185 mouse embryo fibroblasts loaded with vinblastine was assessed as $2.1 \times 10^6 \text{ molecules s}^{-1} \text{ cell}^{-1}$ with a turnover of $1.1 \text{ molecules s}^{-1}$. Vinblastine uptake in the absence and presence of the inhibitor verapamil (at inhibitory concentration, $c = 50 \text{ \mu M}$) yielded maximum outward pumping of $2.73 \times 10^6 \text{ molecules s}^{-1} \text{ cell}^{-1}$. The turnover was $1.4 \text{ molecules s}^{-1}$ ^[124]. Comparing these values with the steady-state ATP hydrolysis rate in inside-out plasma membrane vesicles ($V_{\text{max}} = 3.5 \text{ ABCB1 molecules}^{-1} \text{ s}^{-1}$) suggested that about two ATPs hydrolyzed per vinblastine transported^[124]. At the low concentrations used for data evaluation ($C_{\text{vin}} \leq 10 \text{ \mu M}$) and the short stimulation times^[124], toxicity was most likely negligible.

Table 1. ABCB1 allocrites used as inhibitors

Allocrites	MW	Log P ⁴⁾	K _{iw}	K _{ii(2)}	K _{tw(2)}	$\Delta G_{tw(1)}$	$\Delta G_{ii(2)}$	$\Delta G_{tw(2)}$
	[Da]		[M ⁻¹]	[M ⁻¹]	[M ⁻¹]	[kJmol ⁻¹]	[kJmol ⁻¹]	[kJmol ⁻¹]
Cyclosporine A ^[48]	1202.6	2.9	5.2*10 ³	1.3*10 ²	6.7*10 ⁵	-32.4	-12.5	-44.9
Taxol ²⁾	853.92	-3						
Vinblastin ²⁾ [78]	811.0	3.7	1.5*10 ¹	1.6*10 ³	2.4*10 ⁴	-17.3	-19.1	-36.4
Encequidar ³⁾	688.7	5.8	-	-	-	-	-	-
Tariquidar ³⁾ [Li-Blatter X, unpubl.]	646.7	6.1	3.8*10 ⁴	2.4*10 ³	9.1*10 ⁷	-37.5	-20.1	-57.6

¹⁾All allocrites listed inhibit as dimers, except cyclosporine A, which may inhibit as a monomer. The free energy of binding of the second, inhibitory molecule $G_{tw(2)}$ is always less negative than the free energy of binding of the first, activating molecule $\Delta G_{tw(1)}$.^[59] ²⁾Taxol and vinblastine are not useful as inhibitors, taxol because of its low solubility^[125] and vinblastine because of its relatively low affinity to the membrane (see Table 1). ³⁾The high affinity of encequidar, tariquidar, elacridar, zosuquidar, and OC144-093 is not due to a particularly high affinity to the transporter, but to a particularly high. ⁴⁾LogP values are from <https://pubchem.ncbi.nlm.nih.gov>

We monitored ATP hydrolysis in the same NIH-MDR-G185 cells and the corresponding wild-type cells as a function of vinblastine concentration using a Cytosensor microphysiometer^[78]. The concentration of half-maximum activation of vinblastine, K_1 , in live cells shifted to an approximately 10-fold higher concentration than that in the inside-out plasma membrane vesicles of the same cells. Although the steady-state ATPase rate was higher in cells than in plasma membrane vesicles, the turnover number at $C_{vin} \leq 10 \mu\text{M}$ was only about 1.4 s^{-1} because of the K_1 shift from $1.6 \mu\text{M}$ in inside-out vesicles to about $16 \mu\text{M}$ in cells. The kinetic data obtained in live cells support a one-to-one stoichiometry. Using rhodamine 123 as a “substrate,” Shapiro and Ling^[126] also proposed a one-to-one stoichiometry. Further arguments supporting a one-to-one stoichiometry are discussed elsewhere^[33]. Under inhibitory conditions, where two allocrites are bound, the hydrolysis of one ATP most likely allows flopping of two allocrites, although at a low rate.

ABCB1 INHIBITION

A broad binding region allows for allosteric or competitive inhibition

In principle, any allocrite that can reach the inhibitory phase of a bell-shaped ATPase activity titration curve can act as an inhibitor (see, e.g., verapamil in Figure 4), provided it is soluble at the concentrations required. Inhibition is moreover obtained by compound combinations. Stein and colleagues^[127] assessed three categories of interactions in the drug binding region of ABCB1: (i) cooperative stimulation between verapamil and amphiphilic molecules smaller in size than verapamil (e.g., progesterone); (ii) allosteric inhibition between verapamil and molecules of similar size (e.g., daunorubicin); and (iii) competitive inhibition between verapamil and molecules larger in size such as cyclosporine A (see Supplementary Figure 3). Competitive inhibition was moreover observed between vinblastine, verapamil, cyclosporine A, and lipids^[99] or between verapamil, cyclosporine A, and the detergents Triton X-100, C₁₂EO₈, and Tween 80^[82]. Depending on the concentration applied, detergents such as polyethylene glycol and Tween that are often used as excipients in drug formulations (see, e.g.,^[128] Figure 5) can also act as inhibitors of ABCB1. The possibility of accommodating a range of compounds in different combinations reveals *broad binding regions*^[127] with multiple anchor points (i.e., HBDs and unsaturated rings). Large ABCB1 binding regions were also observed by cryo-EM (e.g.,^[71]).

If two identical molecules bind, the second inhibitory molecule has a lower affinity to the transporter than the activating first molecule^[59]. Under most circumstances, “inhibition” is therefore a transient slowing-down of the transporter that rapidly fades away by dilution (see [Supplementary Figure 4](#)). This is in contrast to inhibitors of receptors (that work according to the lock-key principle). They generally show higher affinities to the receptor than the activators (see, e.g., the neurokinin-1 receptor. It binds its activator, substance P, an amphiphilic pain transmitter peptide, in the nanomolar concentration range^[129] and inhibitors in the sub-nanomolar concentration range^[130]).

The characteristic features of ABCB1 inhibitors

The principle feature of inhibitors is a very negative $\log K_d$ value. This is achieved with compounds exhibiting either a particularly high affinity to the transporter within the membrane, $\log K_d$ (due to numerous HBAs such as cyclosporine A), or a very negative $\log K_d$ value (high logP or logD values) and an intermediate affinity to the transporter, $\log K_d$ (e.g., encephalid, tariquidar, elacridar, zosuquidar, and OC144-093) [[Table 1](#)]. The sheer length and partial rigidity of some of the newer inhibitors may additionally impede rapid flopping.

A further feature inducing ABCB1 inhibition is the above-discussed inappropriate (e.g., DDM) or low amphiphilicity, which is quite common among inhibitors (e.g., cyclosporine A). A large list of inhibitors is given in a review by Artursson and colleagues^[131]. In addition to many hydrophobic examples, dipyrindole, which is a relatively hydrophilic and non-amphiphilic compound, is listed as an ABCB1 inhibitor^[131].

“Transport substrate or inhibitor”?

Alam and colleagues observed that zosuquidar (“inhibitor”) and taxol (“substrate”) bind to the same pocket and asked about “how ABCB1 distinguishes transport substrates from inhibitors and how these compounds exert opposite effects on the ATPase activity”^[72]. These questions can be answered using the present data [[Table 1](#)]. Zosuquidar is very hydrophobic (high LogP) and has a rather small cross-sectional area perpendicular to the axis of amphiphilicity^[132]. Thus it likely exhibits a very negative $\log K_d$. Owing to the high membrane concentration, two molecules of zosuquidar will bind to the transporter already at low aqueous concentrations. In comparison, taxol and vinblastine exhibit rather large cross-sectional areas. Moreover, they are relatively hydrophilic and exhibit a much less negative $\log K_d$. Thus, they will barely reach the concentration of half-maximum inhibition, $K_{1/2}$. The latter molecules also show a low flux across the membrane and are therefore prone to be exported by ABCB1 in cells (for vinblastine^[78] and taxol^[133]), which further enhances $K_{1/2}$.

Understanding ABCB1 inhibition is fundamental for understanding ABCB1 function. ABCB1 inhibition plays a significant and possibly underestimated role in drug-drug interactions resulting from polypharmacy^[35]. Note, that systemic ABCB1 inhibition to enhance cancer drug absorption was not successful in clinical trials^[134,135].

UNIDIRECTIONAL TRANSPORT CYCLE FOR ABCB1 ALLOCRITES

Combining the physicochemical insights gained in this review with our previous molecular dynamics simulations^[33] yields the transport cycle for ABCB1 schematically summarized in [Figure 7](#): (i) Allocrites partition into the lipid membrane, and accumulate in the cytosolic membrane leaflet with the polar part located in the interfacial membrane region. The polar part of the allocrite, carrying at least one type 1 pattern (with HBAs, see [Figure 1](#)), is attracted by the transporter and likely glides along the numerous HBDs at the protein surface towards the core of the membrane, where the attraction is highest, due to the

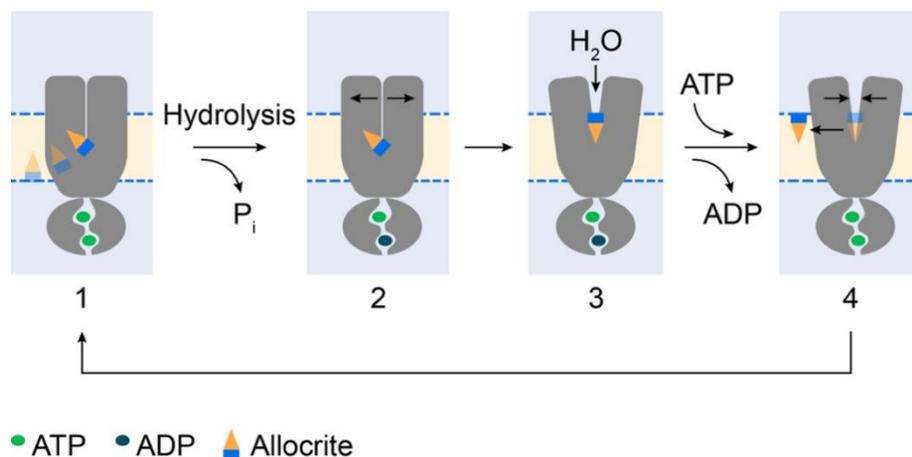

Figure 7. Unidirectional transport cycle in ABC exporters is driven by weak dipolar interactions between the allocrite and the transporter. (1) With two ATPs bound to the NBDs, the TMDs are in the outward closed resting state. The amphiphilic allocrite with HBAs in the polar part (blue) is attracted to the transporter via weak dipolar interactions. The polar groups are then drawn towards the center of the membrane ($\epsilon_m \approx 2$). (2) Hydrolysis of ATP and release of inorganic phosphate (P_i) lead to an asymmetric occupancy state of the NBDs, which initiates the opening of the TMDs. (3) The TMDs adopt an outward open conformation, which allows influx of water molecules. The allocrite flops (i.e., it turns around to expose its polar part towards the aqueous phase). The hydrogen bonds between the allocrite and the transporter are dissolved. The binding of ATP to the empty NBS restores the symmetric occupancy state and favors the outward closed conformation. The allocrites on the extracellular side of the cavity between the TMDs are squeezed out to the membrane (see also Ref. [33]).

lowest dielectric constant. (ii) Allocrite binding likely elicits a strain on the transporter that leads to ATP hydrolysis and opening of the transporter towards the extracellular side. (iii) Inflowing water molecules compete for dipolar interactions with the transporter and the allocrite and induce de-binding of the allocrite, a process described as the solvation exchange mechanism by Omote and Al-Shawi^[136]. As water fills the newly formed cavity, allocrites orient with their polar groups towards the aqueous phase (i.e., they flop). (iv) Upon ATP rebinding, the transporter closes extracellularly. In this way, the potentially remaining allocrite is squeezed out of the transporter into the outer membrane leaflet. It then either diffuses into the aqueous phase or restarts the flip-flop cycle until it is degraded by other enzymes such as CYP3A4^[137], attracting allocrites within the membrane by the same weak dipolar interactions. A more detailed description of the “*unidirectional ABCB1 transport cycle driven by weak dipolar interactions*,” including supporting experimental data, is given in the [Supplementary Materials](#). The rate-limiting step for the overall ATPase activity was previously suggested to be either the de-binding of the ligand or a conformational change of the enzyme, impeded by a bulky substrate^[96]. We observed that the rates of ATPase activity and transport are lower for compounds with a higher affinity to the transporter, for more than one compound bound to the transporter, and for compounds of low amphiphilicity that are not easily oriented at a protein-water interface. Our findings thus suggest that the de-binding and flopping process is rate-limiting, supporting the early suggestions. A more detailed description, including experimental results, is given in the [Supplementary Materials](#).

CONCLUSIONS

Thermodynamics: The *amphiphilicity* of allocrites^[1] implies their accumulation in membranes. In the 1990s, ABCB1 was demonstrated to indeed attract its allocrites within the membrane. An allocrite recognition mechanism based on weak dipolar interactions that works in membranes was proposed. It explains the polyspecificity of ABCB1. With the advent of the first ABCB1 structures, the focus shifted to the protein *only*. In this context, the transporter was often treated conceptually as a receptor, binding its allocrites from the aqueous phase. With this review, we demonstrate that *understanding the nature of allocrite-ABCB1*

interactions requires inclusion of the transporter environment. The binding process starts with partitioning of the amphiphilic allocrite from the aqueous phase into the lipid membrane (step I). Partitioning is driven by classical hydrophobic interactions in the case of electrically neutral amphiphiles and by non-classical hydrophobic interactions in the case of cationic amphiphiles. Once in the membrane, the polar part of the allocrite (with HBAs) is attracted to the transporter (with HBDs and π -electron systems) (step II). Step I and Step II were quantified in terms of the free energies of binding ΔG_{bind} and ΔG_{trans} . The sum of these two free energies yields the overall free energy of allocrite binding from water to the transporter, ΔG_{total} . Whereas partitioning (ΔG_{bind}) decreases with increasing lateral packing density of the membrane, weak electrostatic attraction to the transporter (ΔG_{trans}) was shown to increase with increasing lateral packing density and concomitantly decreasing dielectric constant of the membrane. Owing to these compensatory mechanisms regarding the membrane packing density, the concentration of half-maximum activation, K_1 , changes only moderately in biological membranes.

Kinetics: P-glycoprotein was shown to alter the *membrane permeability*^[1], which suggests the presence of two competing processes, passive diffusion into the cell and active transport out of the cell. Theoretically, these two competing processes can be described rather easily in different ways: Ref.^[116] or Ref.^[58]. Demonstrating these phenomena in a single experiment was more difficult and required ATPase activity measurements with large slowly diffusing allocrites in ABCB1-overexpressing cells as well as large slowly diffusing allocrites. These measurements revealed a significant concentration decrease in the cytosolic membrane leaflet (reflected by higher K_1 values than observed in inside-out plasma membrane vesicles of the same cells), which can be attributed to the flopping activity of ABCB1^[69]. Combining the early drug efflux measurements^[124] with ATPase activity measurements in the same cells, we obtained a stoichiometry of one ATP hydrolyzed per allocrite transported. Moreover, we highlight the importance of bell-shaped ATPase activity curves that account for binding of a second allocrite to the transporter^[96,127]. The concept of two allocrites binding to ABCB1 is indispensable for understanding ABCB1 inhibition as well as drug-drug interactions.

Combining thermodynamics and kinetics yields insights into the nature of allocrite-transporter interactions: Generally, the steady-state ATP hydrolysis rate decreases with increasing allocrite affinity ΔG_{bind} to the transporter [Figure 5A]. However, a detailed inspection of Figure 5A shows that allocrites with identical free energies of binding ΔG_{bind} do not necessarily exhibit identical ATP hydrolysis rates. An allocrite undergoing weak, delocalized interactions with the transporter (e.g., via two HBAs and a weak charge) shows a *higher* steady-state ATP hydrolysis rate than a compound with a single strong point charge. Conversely, allocrites with inappropriate (e.g., DDM) or low amphiphilicity (e.g., cyclosporin A^[79]) and some of the newer inhibitors such as elacridar) show *lower* steady-state ATP hydrolysis rates than expected from their ΔG_{bind} value. A substantial *increase* in the steady-state ATP hydrolysis rate is observed if ABCB1 is reconstituted in detergent micelles. Owing to the higher curvature and lower packing density, micelles exhibit higher dielectric constants than bilayers in lipid vesicles, which in turn significantly reduce dipolar interactions. Micelles, moreover, exhibit a lower “reservoir capacity for amphiphiles” (i.e., a negligible “ ΔG_{bind} ”). Therefore, allocrites that appear as inhibitors in membranes appear as activators in micelles. ABCB1 is thus a robust transporter (or rather a floppase) that perfectly adapts to membranes or micelles exhibiting very different lateral packing densities. The increase in *net permeability* in loosely packed systems is thus not due to a deficient transporter, but to the strongly enhanced passive diffusion. The clear dependence of the steady-state ATP hydrolysis rate on the nature and number of dipolar interactions, as well as on the dielectric constant of the lipid or micellar environment, points to a flopping process that, at least initially, takes place at the interface between the lipid membrane and the protein. The effects observed do not seem possible either

at a protein-water interface (as suggested in alternating access models) or inside a protein channel, which is completely shielded from the lipid membrane.

Combining the physical chemical insights gained in this review with our previous molecular dynamics simulations^[33] suggests that the ABCB1 transport cycle, including allocrite recognition, binding, and transport, is driven by weak dipolar interactions. Allocrite binding induces the hydrolysis of one ATP molecule, which leads to transporter opening towards the extracellular side. Influx of water molecules allows for allocrite flopping. ATP rebinding re-closes the transporter at the extracellular side and expels the potentially remaining allocrites. The individual steps can be quantified when taking into account that the transporter was optimized to operate in a membrane.

DECLARATIONS

Acknowledgments

We are grateful to Dr. Yanyan Xu and Dr. Simon Bernèche for providing Figure 1A-D, Supplementary Figures 1A-D and 2A-D, and to Annette Roulier for drawing Figures 3 and 7.

Authors' contributions

Wrote the manuscript: Seelig A

Abstract

The use of concomitant medications by patients with cancer is observed almost globally; however, little attention has been paid to this topic in the medical literature. Most clinical studies do not describe the type and duration of drugs used at the time of inclusion and during treatment or how these drugs may affect the experimental and/or standard therapy. Even less information has been published on the potential interaction between concomitant medications and tumor biomarkers. However, we do know that concomitant drugs can complicate cancer clinical trials and biomarker development, thus contributing to their interaction, leading to side effects, and resulting in suboptimal adherence to anticancer treatment. On the basis of these premises and moving from the study by Jurisova *et al.*, which reported the effect of commonly used drugs on the prognosis of women with breast cancer and the detection of circulating tumor cells (CTCs), we comment on the role of CTCs as an emerging diagnostic and prognostic tool for breast cancer. We also report the known and hypothesized mechanisms of CTC interplay with other tumor and blood components, possibly modulated by widespread drugs, including over-the-counter compounds, and discuss the possible implications of commonly used concomitant medications on CTC detection and clearance. After considering all these points, it is conceivable that concomitant drugs are not necessarily a problem, but on the contrary, their virtuous mechanisms can be exploited to reduce tumor spread and enhance the effect of anticancer therapies.

Identifying and isolating circulating tumor cells (CTCs) is the most straightforward method to obtain insight into the progression of a neoplastic disease at a systemic level without using invasive methods. However, today, almost three decades after this brilliant consensus was reached, dealing with CTCs remains complicated by technical difficulties and limited clinical utility^[1]. An increasing number of studies have been published on CTCs that address all aspects of this biomarker development (technical validity, clinical validity, and clinical utility). In 2004, the United States Food and Drug Administration (FDA) approved CellSearch™ CTC counting for staging patients with metastatic breast, prostate, and colorectal cancers^[2]. More recently, several cutting-edge studies have reported valuable information obtained from genomic, transcriptomic, and epigenomic analyses on single isolated CTCs^[3]. However, many uncertainties remain in the CTC domain, including the mechanisms underlying their release, clearance, biological significance (i.e., association with the origin, aggressiveness, and metastatic potential of tumors) in addition to response to treatment.

In their study, Jurisova *et al.* addressed an additional neglected aspect: the impact of concomitant medications on the detection of CTC^[4]. Concomitant medications include prescription drugs, over-the-counter drugs, or dietary supplements taken by an individual at the time of diagnosis and/or treatment of a specific disease. Patients with cancer are more likely to take concomitant drugs compared with other patients for two main reasons: first, to minimize disease-related symptoms, and second, as an elective remedy for the disease itself, such as in the case of self-prescribed herbal products^[5]. Concomitant drug use is therefore almost universally observed among patients with cancer, occurring in up to 99% of all cases, whereas it is merely widespread in other types of diseases, ranging between 70% and 83%^[6]. Concomitant drugs may interact with anticancer drugs and have an effect on outcomes, resulting in erroneous conclusions, which is why the rules of Good Clinical Practice require physicians to pay attention to concomitant drugs used before and during a specific treatment^[7].

Because CTCs are used for prognosis as well as for monitoring treatment response, Jurisova *et al.* investigated the possible associations between the use of chronic medications and long-term survival and attempted to avoid the confounding factors caused by the disease itself^[4]. Importantly, they used a CTC-detection approach that can distinguish CTCs with a frankly epithelial phenotype (referred to as CTC_EP) from those undergoing epithelial-mesenchymal (E/M) transition (EMT) and loss of epithelial protein markers and genes expression (referred to as CTC_EMT). Such a distinction would not have been possible using the FDA-approved CellSearch™ approach, which only enumerates the CTC-expressing epithelial markers (EpCAM and CKs). It should be noted that the EMT is not a binary process. Some cells may achieve a hybrid E/M phenotype or migrate as CTC clusters^[8]. The ability to attain a hybrid E/M phenotype rather than a full EMT phenotype confers increased metastatic potential, and CTC clusters are observed more frequently in the early stage rather than during the metastatic stage^[9]. However, long-term treatments, such as anticancer treatments, are known to induce EMT programs, which are often associated with the resistance mechanism, as phenotypic plasticity confers invasiveness and increases the dissemination potential^[10]. In this case, what is actually a resistance pattern driven by EMT could instead be misinterpreted as a reduction or disappearance of epithelial CTC (and thus considered a treatment response). This phenomenon has been described as “drug-related undetectable CTC status”, and it has been ascribed to the hypoxia-driven EMT triggered by the antineoangiogenic drug bevacizumab^[11]. Researchers have also described a similar effect in patients treated with the monoclonal antibody denosumab^[12].

Luckily, Jurisova *et al.* relied on the detection of both CTC_EP and CTC_EMT in a cohort of > 400 women with stage I-III breast cancer who had complete medical history and information on the use of concomitant medications available^[4]. Thus, they dodged the problem of misinterpreting the absence of CTC as a sign of

absence of systemic dissemination and/or of good prognosis simply owing to the technical failure in detecting CTC_EMT. In addition, 10% of patients had primary tumors lacking hormone receptors, which are basal-like in most cases and rarely express CK19, instead showing high expression of CK5 and CK17^[13]. Increased CTC_EMT positivity rates were consistently observed for all classes of drugs tested, although none reached statistical significance. In contrast, the use of angiotensin-converting enzyme (ACE) inhibitors was associated with an almost 50% decrease in CTC_EP positivity. The clinical value of interfering with the angiotensin/renin system has rarely been addressed in the literature and has produced controversial results. Specifically, the landmark LACE study reported in the last decade stated that patients with breast cancer undergoing treatment with ACE inhibitors were more likely to experience recurrence compared with nonusers^[14]. Conversely, another study that investigated the impact of ACE inhibitors in the setting of preoperative treatment reported no immediate effects on tumor response but did find an improvement in relapse-free survival^[15]. More recently, researchers have suggested that ACE inhibitors have no direct cytotoxicity against tumor cells but rather show the potential to inhibit tumor growth owing to the suppression of vascular endothelial growth factor-induced angiogenesis *in vivo*^[16]. Thus, we could hypothesize that ACE inhibitors exert an antiangiogenic activity that hinders the extravasation of CTCs and/or the formation of a metastatic colony in distant organs; alternatively, they could induce tumor mass dormancy or prolong dormancy maintenance. Taken together, these findings suggest that medical oncologists should interpret the results of CTCs on the basis of an individual's use of ACE inhibitors. Furthermore, the findings also have an impact on pooled data collected in clinical studies, suggesting that CTC results should be evaluated separately in users and nonusers of ACE inhibitors.

Drugs other than antihypertensives have been studied with respect to their prognostic effect in cancer, and specifically on the CTCs, which are potential therapeutic targets not only individually but also in aggregated forms with other cell types. For example, in animal models, anti-aggregation therapy can potentially reduce the risk of tumor metastases. Li *et al.* explored genetically modified platelets expressing tumor necrosis factor-related apoptosis-inducing ligand and found that blocking the interactions between platelets and CTCs reduced metastatic potential in a prostate cancer model^[17]. In addition, platelets expressing tumor necrosis factor-related apoptosis inducing ligand could significantly eradicate cancer cells *in vitro*. Thus, agents that are not strictly anticancer could play a virtuous role in CTC interactions. In fact, clinical evidence has shown that aspirin reduced all-cancer mortality after only 5 years^[18]. Those results can hardly be interpreted as aspirin only affecting carcinogenesis or early cancer growth and instead suggest that it may act as an inhibitor of cancer metastasis. Finally, treatment with the salicylate diflunisal induced disease remission (complete and partial) in two patients who refused standard treatment. Notably, both responders showed reduced post-treatment CTC levels^[19]. The most accepted hypothesis is that the downregulation of the platelet-related COX-1 pathway by aspirin may explain the EMT of CTCs and contribute to its antimetastatic effects.

CTCs can also form heteroclusters with neutrophils, and this increases their metastatic potential^[20]. Preclinical studies in mouse models have demonstrated that the anti-inflammatory zileuton, an inhibitor of arachidonate 5-lipoxygenase (5-LOX) and thus of leukotriene production, reduces spontaneous metastasis^[21]; more recently, zileuton-loaded nanoparticles have been shown to reduce breast CTCs^[22]. Interestingly, among 5-LOX inhibitors, there is curcumin, which is often used as a food supplement in general as well as in cancer patient populations^[23]. However, Jurisova *et al.* did not observe any effects of nonsteroidal anti-inflammatory drugs, probably because of the low number of patients reporting the regular use of such medications^[4]. All of these data are limited by the low number of patients and are, in some cases, purely anecdotal. Nevertheless, they offer the opportunity to hypothesize that CTCs not only may be used as a surrogate marker of tumor response but also may themselves become a treatment target with therapies

aimed at decreasing their survival in the circulation and tissue homing.

Similarly to the CTC/platelets and CTC/neutrophils heterogroups, CTC clusters are central to metastatic potential^[24]. Preclinical data showing that the Na⁺/K⁺-ATPase inhibitors digoxin and ouabain used as antiarrhythmic agents are able to disaggregate CTCs clusters^[25] led to the ongoing “Digoxin Induced Dissolution of CTC Clusters” trial (NCT03928210), the results of which are urgently awaited.

Studies such as the one reported by Jurisova *et al.* contribute to the CTC field because even slight effects on CTC enumeration can hide interesting mechanisms exerted by common drugs that can be a premise to their repurposing or off-target use^[4].

Abstract

The clinical treatment of DNA-repair defective tumours has been revolutionised by the use of poly(ADP) ribose polymerase (PARP) inhibitors. However, the efficacy of these compounds is hampered by resistance, which is attributed to numerous mechanisms including rewiring of the DNA damage response to favour pathways that repair PARP inhibitor-mediated damage. Here, we comment on recent findings by our group identifying the lysine methyltransferase SETD1A as a novel factor that conveys PARPi resistance. We discuss the implications, with a particular focus on epigenetic modifications and H3K4 methylation. We also deliberate on the mechanisms responsible, the consequences for the refinement of PARP inhibitor use in the clinic, and future possibilities to circumvent drug resistance in DNA-repair deficient cancers.

Keywords: Double strand break repair, histone methylation, PARP inhibitor, resistance, SETD1A, BOD1L, H3K4

CANCER THERAPY AND DOUBLE STRAND BREAK REPAIR

Many cancer patients will receive radiotherapy as part of their treatment^[1] which relies on ionising radiation (IR) to induce highly toxic lesions in the form of chromosomal DNA double-strand breaks (DSBs). DSBs represent the most lethal type of DNA damage induced by genotoxic therapy, but their programmed repair have important physiological roles in normal metabolism and immune system development. Repair of DSBs

© The Author(s) 2023. **Open Access** This article is licensed under a Creative Commons Attribution 4.0 International License (<https://creativecommons.org/licenses/by/4.0/>), which permits unrestricted use, sharing, adaptation, distribution and reproduction in any medium or format, for any purpose, even commercially, as long as you give appropriate credit to the original author(s) and the source, provide a link to the Creative Commons license, and indicate if changes were made.

is also essential to maintain genome stability and therefore represents a vital anti-tumour barrier^[2].

There are two main pathways used by cells to ensure the efficient repair of DSBs, non-homologous end joining (NHEJ) and homologous recombination (HR). The choice between these two repair pathways is tightly regulated by numerous mechanisms including the cell cycle, post-translational modifications of DNA repair proteins, and interactions between DNA repair proteins and chromatin^[3]. NHEJ is the principal DSB repair pathway and is responsible for repairing 85% of all DSBs induced by IR^[4]. Although NHEJ is active in all phases of the cell cycle, it predominates in G1, and involves direct ligation of the two broken DNA ends. In contrast, HR requires a homologous sister chromatid as a repair template and is therefore restricted to the S and G2 cell cycle phases. HR also requires DNA end resection, which is carried out by a number of cellular nucleases including MRE11, CtIP, EXO1 and DNA2^[5,6]. The actions of these proteins results in formation of a 3' ssDNA tail, which is then coated with the single-stranded DNA binding protein RPA (Replication Protein A) which acts as a substrate for RAD51-mediated homology search and strand invasion. In addition to these two classical DSB repair pathways, alternative mutagenic DSB repair mechanisms have been identified. These include microhomology-mediated end joining (MMEJ; also known as alternative end-joining) and single strand annealing (SSA)^[7]. As with HR, these alternative pathways rely on extensive end resection. However, lack of a repair template results in significant loss of genetic information in these pathways, therefore MMEJ and SSA are considered error-prone and highly mutagenic.

BRCA1 AND 53BP1: BALANCING DSB REPAIR

The choice between HR and NHEJ is controlled by multiple factors, of which 53BP1 and BRCA1 are two of the most important. The antagonistic relationship between 53BP1 and BRCA1 controls DNA-end resection and thus dictates repair pathway choice. 53BP1 is one of the first proteins recruited to DSBs, which is mediated by the interaction between 53BP1 and two histone modifications: H4K20me2 and H2AK15Ub. Localisation of 53BP1 at DSBs protects DNA from resection via a series of downstream effectors including PTIP^[8], RIF1^[9-12], REV7^[13,14], and the Shieldin -CST- pol α complex^[15-18]. This pathway inhibits the localisation and activity of BRCA1 and the endonuclease CtIP to DSBs, promoting NHEJ, and maintains DSBs via fill-in of ssDNA.

In contrast, the tumour suppressor BRCA1 promotes end-resection in S and G2 and counteracts 53BP1. In part, this is mediated by post-replicative dilution of H4K20me2 on “parental” histones, promoting the recruitment of BRCA1 and its partner BARD1 to DSBs where it displaces 53BP1 from DNA ends^[19,20]. BRCA1 also facilitates end-resection and therefore HR by promoting the actions of phosphorylated CtIP and MRE11^[21]. In addition, BRCA1 has further roles in HR, promoting recruitment of the RAD51 recombinase to ssDNA. BRCA1 also interacts via PALB2 with BRCA2, with this tripartite complex assisting RAD51 loading and recombination^[22]. Finally, BRCA1 and BARD1 enhance the recombinase activity of RAD51, promoting successful HR repair.

HISTONE METHYLATION AND DNA REPAIR

Histone lysine methylation is a critical post-translational modification essential for numerous cellular processes. This modification is carried out on lysine residues within histone tails by a family of enzymes known as lysine methyltransferases (KMTs). In terms of DNA repair, several lysine methylation events are known to be required for the proper repair of DSBs^[23]. For example, the localisation of 53BP1 to damaged chromatin requires binding of its tandem Tudor domains to di-methylated lysine 20 of histone 4 (H4K20me2)^[24-26]. Furthermore, the binding of BARD1 to di-methylated H3K9 (H3K9me2) is required to retain BRCA1 at DSB sites to promote repair by HR^[27]. These examples illustrate the importance of histone methylation events in the regulation and recruitment of proteins critical for DSB repair.

Methylation of lysine 4 of histone H3 (H3K4me) is most well-known as a marker for genomic regions undergoing active transcription. In yeast, H3K4me is carried out by a single methyltransferase, Set1, but in higher eukaryotes this modification is principally catalysed by the KMT2 family of enzymes^[28]. Studies have shown that transcription is required for DSB repair and suggested that without active transcription DNA damage response (DDR) proteins are unable to efficiently localise to repair foci^[29-31]. However, transcription can also be largely suppressed at sites of DSBs despite the presence of H3K4me^[32], suggesting that this histone modification could also have an important transcription-independent role in DNA repair.

Several studies have examined levels of H3K4me at DSBs, yielding conflicting results. Globally, there appears to be no change in the levels of H3K4me3 following DNA damage when examined by immunoblotting^[33,34]. However, more sensitive methods have demonstrated differences in the prevalence of this modification at DSBs. Several studies suggest that H3K4 di- and tri-methylation levels decrease following UV laser micro irradiation or in GFP-based DSB repair reporter assays. This is attributed to increased activity of various lysine demethylases (KDMs) that act on H3K4, including KDM1A, KDM5A and KDM5B^[35-37]. In contrast, other studies demonstrate an increase in H3K4me3 at DSBs, the removal of which by KDM5B is required to allow recruitment of DNA repair factors^[38]. We recently used chromatin immunoprecipitation (ChIP) to measure levels of histone methylation surrounding newly-formed DSBs induced on a Lac-operator by mCherry-lacI-FokI. These studies revealed an increase in H3K4me3 following DSB induction^[39]. Collectively these data all indicate an important role for H3K4me in DSB repair, however their conflicting findings suggest that results could be dependent upon type of DNA damage induced and the methods used to detect this modification. Interestingly, H3K4 methylation is also important for other types of DNA repair, as loss of H3K4me at replication forks during replication stress induces genome instability by allowing degradation of DNA^[40].

H3K4 METHYLATION AND HR/NHEJ

Analysis of DSBs undergoing repair by NHEJ or HR (classified by the proteins bound to these breaks) first identified that HR-competent chromatin is enriched in H3K4me2^[41]. In support of this, favouring HR-mediated repair by treating cells with an inhibitor of DNA-PKcs increases levels of H3K4me at DSBs induced by the yeast rare-cutting endonuclease IScel^[42]. These studies on regions of “open” chromatin initially suggested that H3K4me may promote HR-mediated repair.

Recently, we have significantly revised the former findings by identifying an important role for H3K4 methylation in facilitating RIF1-dependent NHEJ^[39]. We showed that loss of SETD1A, a member of the KMT2 family of methyltransferases, or its cofactor BOD1L, significantly impairs RIF1 localisation to DSBs and their subsequent repair by NHEJ. Loss of SETD1A/BOD1L function induced uncontrolled DNA end resection, impaired end-joining of dysfunctional telomeres, and reduced immunoglobulin class switching, all of which are characteristic of 53BP1-RIF1 deficiency^[10]. This is dependent upon lysine methylation by SETD1A, as these phenotypes were also apparent in cells deficient in SETD1A activity, in H3K4 methylation or overexpressing the H3K4 demethylase KDM5A. Furthermore, RIF1 and H3K4me3 overlap at a genome wide level, which seems independent of external factors including origin firing or transcription start sites. Therefore, H3K4 methylation seems to directly stimulate DSB repair by NHEJ. Interestingly, our data suggests that the mechanism by which H3K4me controls DSB repair is direct, as *in vitro* binding assays showed that RIF1 binds directly to methylated H3K4, an interaction mediated by the HEAT repeats present in the N-terminal of RIF1^[39]. This is particularly intriguing given that similar experiments demonstrate that BRCA1 binds with a higher affinity to unmethylated H3 peptides compared to H3K4me3 peptides^[36], suggesting that H3K4me at DSBs might directly influence DSB pathway choice by regulating both BRCA1 and RIF1. Despite these

advances, it is unclear exactly how H3K4me determines if a DSB undergoes repair by HR or NHEJ, and much work remains to identify the specific mechanism(s).

TARGETING HR DEFICIENCY WITH POLY (ADP-RIBOSE) POLYMERASE INHIBITORS

Inherited mutations in either BRCA1 or BRCA2 are associated with susceptibility to multiple cancer types including a higher risk for breast and ovarian cancer. Since BRCA1 and BRCA2 regulate multiple stages of HR, cells with compromised BRCA1/BRCA2 activity are deficient in HR activity^[43]. Targeting DSB repair deficiency represents an important paradigm in cancer therapy, exemplified by the use of poly (ADP-ribose) polymerase inhibitors (PARPi) to treat HR-deficient tumours^[44]. PARPi work by trapping PARP enzymes on DNA, preventing the repair of single strand breaks (SSBs) via a PARP-reliant pathway known as base excision repair. As a consequence, unrepaired SSBs are converted into DSBs when encountered by replication forks. Since the resulting DSBs require repair via HR, in cells lacking sufficient levels of BRCA activity these DSBs cannot be repaired, resulting in NHEJ-dependent toxic chromosome fusions which drive cell death^[44,45]. To date, four PARP inhibitors have received clinical approval in multiple BRCA1- and BRCA2-deficient settings: olaparib, rucaparib, talazoparib and niraparib.

Although treatment with PARPi induces a significant increase in patient survival, many patients develop resistance, and their prognosis is poor. Indeed, 40% of metastatic breast cancer patients harbouring germline BRCA1/2 mutations failed to respond to olaparib^[46]. This resistance seems to arise from 4 main biological mechanisms^[47]: restoration or reactivation of BRCA1 or BRCA2 activity (e.g., by reversion mutations or promoter demethylation); loss of PARP1 or PARG expression; upregulation of PARPi efflux; and rewiring of the DDR, including restoration of HR and replication fork protection. In particular, loss of members of the 53BP1-dependent NHEJ pathway (e.g., RIF1, REV7, 53BP1, Shieldin) renders BRCA1-deficient cells resistant to PARPi^[9,13,17,21]. This is thought to be mediated via the absence of the Shieldin complex on DNA ends, leaving them unprotected and subject to resection by nucleases to initiate repair by HR^[48]. Therefore, the balance between HR and NHEJ is key in determining the response to these targeted inhibitors. Interestingly, this mechanism of resistance has not been observed in BRCA2-deficient cells to date, which is likely due to differing roles between BRCA1 and BRCA2 in promoting HR^[49].

SETD1A AND H3K4ME IN PARP INHIBITOR RESISTANCE

Our recent findings impact substantially on these mechanisms of drug resistance. We demonstrated that, like loss of RIF1^[10], loss of SETD1A also induces PARPi resistance in BRCA1-deficient cells^[39]. Our data also demonstrate that this resistance can be linked to a partial restoration of HR in these cells, as we observed cells deficient in both BRCA1 and SETD1A were able to recruit RAD51 to chromatin following treatment with PARPi, and that functional HR was at least partially restored in cells lacking both BRCA1 and SETD1A. Therefore, loss of SETD1A allows reactivation of HR in BRCA1-deficient cells [Figure 1]. Strikingly, many of these phenotypes (increased end-resection, defective RIF1 recruitment, PARPi resistance) were also observed in cells expressing SETD1A but in which H3K4 methylation had been perturbed by either mutation or over-expression of a lysine demethylase^[39], suggesting that PARPi resistance in BRCA1-defective cells is driven by epigenetic modifications, at least in part. Indeed, given that RIF1 interacts with H3K4me3 *in vitro*, this suggests that SETD1A-mediated histone methylation is responsible for promoting NHEJ and therefore sensitivity to PARPi [Figure 1].

Interestingly, SETD1A, H3K4me and RIF1 dysfunction is linked with a second mechanism known to control PARPi resistance, the protection of nascent DNA^[40,50]. Newly replicated DNA is protected from degradation by several factors, including BRCA1, BRCA2, RIF1, 53BP1, SETD1A, BOD1L and H3K4me^[51], all of which also have roles in DSB repair. At stalled replication forks, these factors act to suppress the

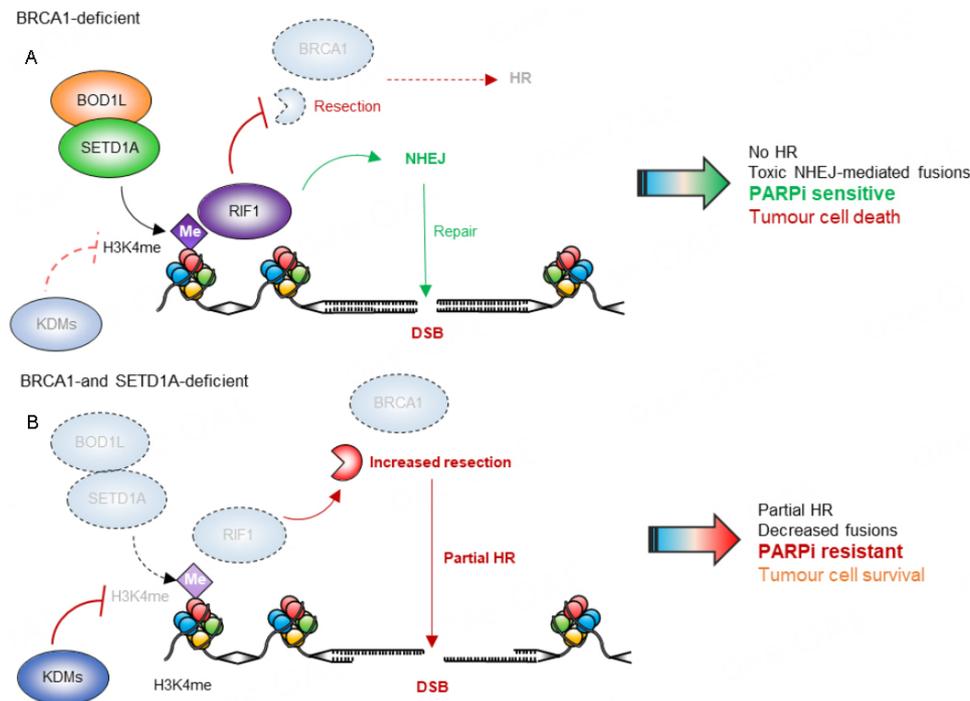

Figure 1. Effects of BOD1L/SETD1A loss on PARP inhibitor sensitivity in BRCA1-deficient cells. (A) H3K4me mediated by the BOD1L/SETD1A complex promotes RIF1 localisation at DNA double-strand breaks (DSBs) and stimulates NHEJ. In BRCA1-deficient cells, DNA-end resection and RAD51 loading are inhibited and lesions cannot be repaired by homologous recombination (HR), resulting in sensitivity to PARP inhibition and cell death. (B) Depletion of the BOD1L/SETD1A complex results in loss of H3K4me and decreased RIF1 localisation to DSBs. This allows DNA end-resection and RAD51 loading, partially restoring HR. This mediates resistance to PARP inhibition and allows cells to survive. Me: Methylation; PARP: poly(ADP) ribose polymerase; NHEJ: non-homologous end joining; KDMs: lysine demethylases.

actions of nucleases including DNA2, EXO1 and MRE11. In their absence, excessive nucleolytic degradation leads to genomic instability and drives sensitivity to PARPi. Therefore, loss of fork degradation (or restoration of protection) leads to PARPi resistance^[52,53]. However, this only seems to be applicable in certain genetic backgrounds: whilst loss of BRCA1/2 and thus loss of fork protection sensitises cells to PARPi, cells deficient of SETD1A, RIF1 or 53BP1 are also deficient in this pathway, but are not sensitive to PARPi. Furthermore, co-depletion of SETD1A and BRCA1, or RIF1 and BRCA1, does not restore fork protection^[39], suggesting a complex interplay between roles for these proteins at DSBs vs. replication forks. Nevertheless, our findings that PARPi sensitivity can be driven by epigenetic changes are in broad agreement with other studies demonstrating that such modifications can also regulate the response to PARPi^[53,54]. Clearly, much more work remains to be done to comprehend the different mechanisms of DDR rewiring and how these impact on PARPi resistance in various genetic backgrounds and tumour types.

THERAPEUTIC IMPLICATIONS AND FUTURE PERSPECTIVES

Identifying resistance: In terms of clinical implication, predicting which patients may develop resistance to PARPi is an important area of investigation. Previous work has shown that significant changes in the expression and activity of methyltransferase and demethylase enzymes occurs during cancer development, suggesting that disruption to their function is important in disease pathogenesis^[55]. Furthermore, analysis of publicly available datasets suggests that SETD1A expression correlates with chemotherapeutic sensitivity and overall survival in multiple tumour types^[56,57]. This provides further evidence that SETD1A expression might be a useful prognostic indicator to be considered when choosing a patient’s treatment regime

[Figure 1]. Furthermore, monitoring SETD1A expression during the onset of resistance, and linking BRCA1 mutation status with SETD1A expression, would be invaluable in evaluating its utility as a potential biomarker. Taken together, profiling of SETD1A expression may well be a valuable prognostic tool to identify patients who are more likely to develop resistance to PARPi allowing them to be placed on alternative therapies including KDM inhibitors or in combination other genotoxins, in the hope that this would kill resistant cancer cells.

Therapeutic approaches: Investigating novel ways of manipulating DSB repair is crucial for the development of new and more effective treatments for patients treated with PARPi [Figure 2]. Several potential strategies could be envisaged to prevent HR reactivation upon PARPi-resistance, ultimately increasing the efficacy of these therapies. Firstly, increasing H3K4me could represent a direct approach to facilitate RIF1 recruitment to DSBs, promoting NHEJ and driving toxic chromosomal fusions and cell death. This could be achieved via manipulating SETD1A expression/activity, or the inhibition of KDM enzymes to prevent the removal of specific methylation marks. KDM1A/LSD1 is a prominent demethylase which counteracts the activities of SETD1A, and inhibitors to this protein have already been developed^[58,59] and are currently being assessed for their use in cancer therapy. This raises the possibility that alleviating PARPi by manipulating the balance between H3K4 methylation and demethylation using these inhibitors could offer potential treatment benefit. Further pre-clinical work leading to their exploration in BRCA1-deficient patients would be an exciting avenue of future research.

A second approach to prevent reactivation of HR would be to inhibit the cellular nucleases responsible for DNA resection [Figure 2]. Loss of the 53BP1 pathway and/or SETD1A in BRCA-deficient cells allows uncontrolled end-resection by nucleases such as MRE11, CtIP, EXO1 and DNA2^[39]. Combining PARPi treatment with inhibitors of these nucleases could be a promising way of preventing HR reactivation. Indeed, there is already evidence from pre-clinical studies that MRE11 inhibitors sensitise cancer cells to other agents such as IR^[60]. Furthermore, MRE11 activity determines the sensitivity of cells to PARPi treatment in colorectal cancer^[61]. However, given the diverse roles of MRE11 it would be important to monitor effects of its inhibition to ensure functions aside from its role in DNA end-resection are not compromised. CtIP depletion has also been shown to sensitise breast^[62] and ovarian^[63] cancer cells to treatment with PARPi, however this appears independent of BRCA-deficiency. As above, this opens novel areas of exploration, and could provide benefit to treat tumours without the traditional “BRCA-deficient” definitions.

Thirdly, deficiencies in pro-NHEJ components drive PARPi resistance in BRCA1-deficient cells, but also induces collateral vulnerabilities to other DNA-damaging agents including IR and cisplatin^[17]. Exploring how loss of SETD1A/H3K4me affects the response to other genotoxic agents may help to identify other therapies that could be used to bypass PARPi resistance [Figure 2]. Notably, loss of SETD1A or its cofactor BOD1L sensitise cells to inter-strand crosslink (ICL)-inducing agents similar to cisplatin^[40]. Furthermore, combinations of PARPi with pharmacological inhibitors to histone deacetylases, apical DNA repair kinases ATM and ATR, PI3K and mTOR, and immune checkpoint proteins have all been studied extensively^[64], and may provide worthwhile avenues of investigation in cells lacking SETD1A, BOD1L or H3K4me. Finally, exploring the link between SETD1A and H3K4me with MMEJ may offer an alternative therapeutic vulnerability^[65].

Beyond BRCA: There is growing evidence that the efficacy of PARPi as an anti-cancer therapy extends beyond BRCA1/BRCA2-deficiency to a range of other factors involved in HR. For example, loss of other key HR pathway proteins such as RAD51 and PALB2, as well as the apical DNA repair kinase ATM, gives

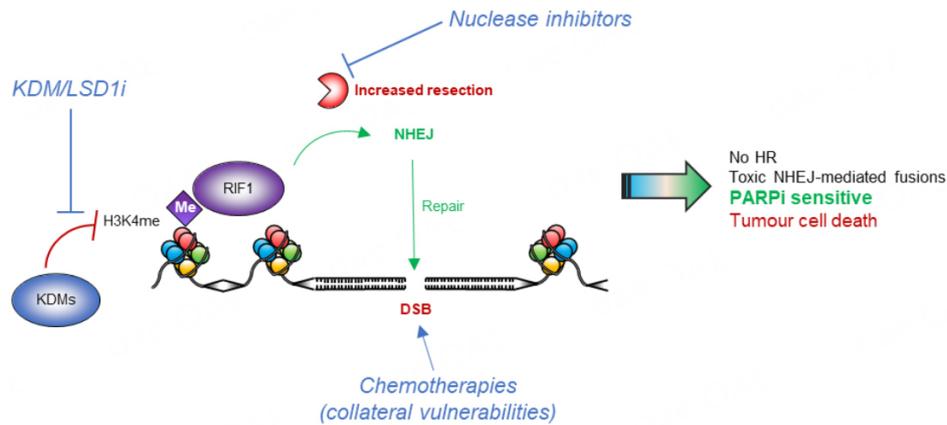

Figure 2. Future strategies to restore PARP inhibitor efficacy in BRCA1-deficient cells upon loss of SETD1A function. Sensitivity to PARP inhibition following loss of the BOD1L/SETD1A complex or H3K4me perturbation could potentially be restored via 3 mechanisms including: (1) inhibition of the lysine demethylases (KMD5 and LSD1) responsible for removing H3K4me; (2) inhibiting nucleases such as MRE11 to prevent DNA-end resection which facilitates HR; and (3) exploiting collateral vulnerabilities using chemotherapeutics, e.g., cisplatin. Me: Methylation; PARP: poly(ADP) ribose polymerase; HR: homologous recombination; NHEJ: non-homologous end joining; DSB: double-strand break; KDMs: lysine demethylases.

rise to synthetic lethality with PARP inhibition^[66]. However, the mechanisms of resistance applicable to these contexts have not been widely explored. Previous studies have indicated that DDR rewiring is unable to restore HR in BRCA2-deficient cells. For example, depletion of 53BP1 cannot rescue HR in BRCA2-deficient mouse embryonic fibroblasts^[49]. To date, known PARPi resistance mechanisms in BRCA2-deficient cells include loss of the PARG glycosylase^[67] and restoration of functional BRCA2 activity via the acquisition of secondary reversion mutations^[68]. This suggests that the resistance mechanisms acting in BRCA2-deficient cells differ significantly to those in other HR-deficient contexts. A key area for future investigation is therefore to establish whether PARPi resistance induced by loss of SETD1A provides a general mechanism of resistance that can be applied to wider HR-deficient contexts including RAD51, ATM and possibly BRCA2 deficiency. Combined with the above developments, this will increase the efficacy of DDR inhibitors in the clinic and help develop novel biomarkers and treatment strategies to overcome resistance.

CONCLUSION

The induction of DSBs by chemo- and radio-therapy has been used for many years in order to successfully treat a range of different cancers. However, the one major disadvantage of this approach is its lack of specificity. More recent developments involving the use of targeted inhibitors of DSB repair pathways such as PARPi have enabled more selective targeting of cancer cells, exploiting their intrinsic vulnerabilities such as HR deficiencies in BRCA-mutated cancers. However, these approaches are hampered by resistance. Our recent findings^[39] have added to this field by identifying the potential clinical usefulness of regulating RIF1-dependent NHEJ through manipulation of SETD1A-dependent H3K4me. This is of particular relevance in BRCA1-deficient patients who develop PARPi resistance in the clinic, as maintaining H3K4 methylation/SETD1A activity and therefore the recruitment of RIF1 to DSBs could be a key strategy to prevent treatment resistance in these patients. Despite these advances, there is still much work to be done in the fields of SETD1A, NHEJ and histone methylation to enable the development of more tailored treatments to eradicate human cancers.

Abstract

HER2-positive breast cancer is an aggressive disease. As a result of the development of specific HER2-targeted therapies, such as trastuzumab, more than 20 years ago, the prognosis of these patients has improved. Metastatic HER2-positive breast cancer patients are achieving better survival rates upon treatment with anti-HER2 therapies than patients with HER2-negative disease. Double HER2 blockade with trastuzumab and pertuzumab combined with a taxane achieved an unprecedented survival of over 57 months in first-line patients. Trastuzumab emtansine, the first antibody-drug conjugate approved for patients in second-line treatment was a potent cytotoxic agent bound to trastuzumab and is currently a standard therapeutic strategy. Despite the progress in treatment development, most patients develop resistance and eventually relapse. Advances in the design of antibody-drug conjugates have led to the development of new generation drugs with enhanced properties, such as trastuzumab deruxtecan and trastuzumab duocarmazine, which are significantly changing the paradigm in the treatment of HER2-positive metastatic breast cancer.

INTRODUCTION

The development of anti-HER2 therapies: from antibodies to antibody-drug conjugates

Human epidermal growth factor receptor 2 protein (HER2)-positive breast cancer is an aggressive disease that accounts for approximately 15%-20% of the total breast cancer cases worldwide^[1]. Most of these cases are diagnosed at the early stage. The HER2 pathway drives the growth and expansion of tumor cells. Research into the development of anti-breast cancer therapies has been focused on blocking the HER2 receptor with different strategies.

Trastuzumab

Trastuzumab is an anti-HER2 humanized monoclonal antibody directed against the extracellular portion of HER2. Trastuzumab was the first therapy approved by the FDA in 1998 for metastatic breast cancer patients with tumors with HER2 overexpression and it was approved in 2006 for use in the adjuvant setting after demonstrating a significant benefit in progression-free survival (PFS) and overall survival (OS) in both early and advanced disease^[2,3]. The mechanisms of action of trastuzumab are the inhibition of HER2 shedding and inhibition of the PI3K-AKT pathway, resulting in an attenuation of cell signaling and promotion of antibody-dependent cell-mediated cytotoxicity (ADCC). Trastuzumab has significantly changed the landscape for HER2-positive patients^[4]. However, some tumors acquire resistance to trastuzumab through mechanisms including increased cell signaling, PTEN loss, PIK3CA mutations, increased AKT activity, alternative cell signaling mediated by EGFR pathways, TGF- α overexpression, and expression of extracellular domain-truncated HER2 (p95 HER2)^[5].

Pertuzumab

To overcome trastuzumab resistance and improve treatment efficacy, a strategy was developed of combining trastuzumab with pertuzumab, another antibody that binds a different epitope of HER2, preventing the formation of HER2-HER3 heterodimers, the most active forms in signaling^[6]. The combination of this double anti-HER2 blockade with a taxane was approved by the FDA in 2012 for first-line treatment for HER2-positive advanced disease on the basis of results of the CLEOPATRA trial, which demonstrated an improvement in PFS and OS with this strategy^[7].

Trastuzumab-emtansine (T-DM1): the first anti-HER2 ADC

Through continued research, another strategy was developed using a novel drug design technology for antibody-drug conjugates (ADCs), in which a potent cytotoxic agent is conjugated to an antibody with a linker to selectively deliver the payload to cells expressing a specific antigen, theoretically sparing normal cells from toxicity [Figure 1]. HER2-positive disease was an attractive target for ADC development. T-DM1, the first ADC, was designed to act against the HER2 receptor [Table 1]. The clinical benefit of T-DM1 in terms of both efficacy and toxicity was demonstrated in the EMILIA trial, which compared T-DM1 with the combination of capecitabine and the tyrosine kinase inhibitor (TKI) lapatinib. The results showed a significant improvement in PFS and OS with T-DM1, leading to the approval of T-DM1 by the FDA in 2013^[8,9]. Later attempts to position T-DM1 in advanced first-line treatment or even in the neoadjuvant setting were not so successful, as there was no significant benefit in first-line treatment with T-DM1 compared with trastuzumab and a taxane or in the neoadjuvant early setting comparing TM-1 combined with pertuzumab and TCHP (docetaxel, carboplatin, trastuzumab, pertuzumab)^[10,11]. However, in the KATHERINE trial, T-DM1 significantly decreased the risk of relapse in patients who had remaining residual disease after anti-HER2 neoadjuvant treatment^[12].

A better understanding of the mechanisms of action of T-DM1 will help elucidate how primary and acquired resistance develop *in vivo*, and thus these mechanisms have been a subject of intense investigation^[13]. The antitumor effects of T-DM1 reflect the activities of its components. Trastuzumab not

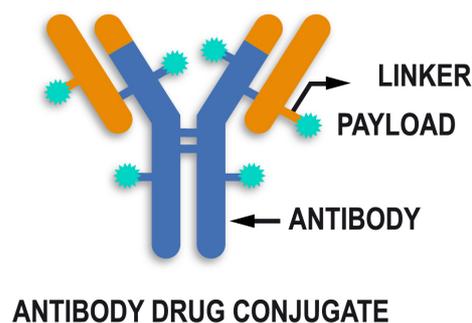

Figure 1. General structure of an antibody drug conjugate. The antibody drug conjugate contains three key components: antibody, linker, and payload.

only enables binding to tumor cells, but also inhibits HER2 signaling, HER2 extracellular domain shedding and ADCC. DM1 is a potent derivative of the maytansinoid toxin with a cytotoxic effect that is mediated through the inhibition of tubulin polymerization, which leads to the death of proliferating cells. Another key component is the non-cleavable thioether linker that conjugates trastuzumab and its payload, which allows the release of DM1 through liposomal degradation after the receptor-ADC complex has been internalized in the cell [Figure 2]. The drug-to-antibody ratio (DAR) for T-DM1 is 3.5:1 which defines the number of cytotoxic payloads held by each antibody. This is an important characteristic of an ADC that may be related to its potency^[14]. Once the active payload lysine-MCC-DM1 complexes are released from the lysosome, cytotoxic effects are induced in the tumor cell but not in neighboring cells because of the membrane impermeability of the complexes^[15]. Hence, there is no bystander effect from the killing of nearby tumor cells that do not present the antigen. Notably, loss or reduction of HER2 expression disables the internalization of ADC and thus represents the main mechanism of resistance^[16,17]. Intratumor heterogeneity of HER2 expression leads to reduced access of T-DMI to non-HER2-expressing cells and

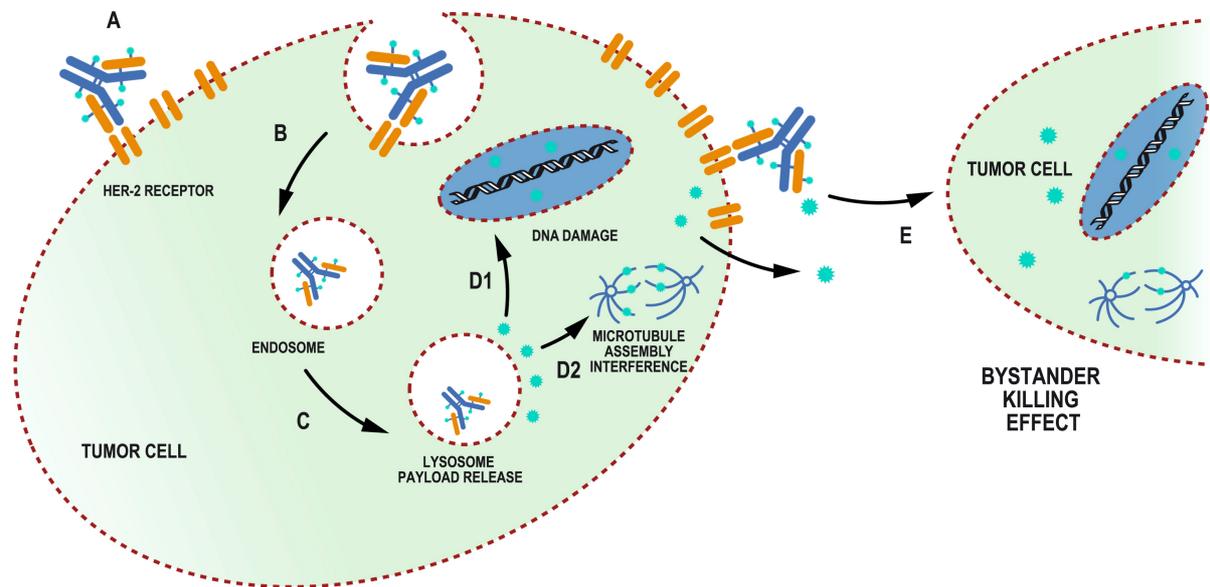

Figure 2. General mechanism of action of an antibody drug conjugate (ADC). A: The antibody binds to the HER2 receptor (RT) in the tumor cell and initiates the internalization process. B: The ADC-RT complex forms an endosome. C: Lysosomal degradation of the endosome releases the payload to the cytoplasm. D: The payload produces various cytotoxic effects, such as the following: D1, DNA damage, as with the topoisomerase I inhibitor in trastuzumab deruxtecan; D2, microtubule assembly interference, as with DM1 in trastuzumab emtansine; and E, bystander killing effect in neighbor tumor cells not expressing the antigen. After payload liberation in the tumor microenvironment by proteases, the payload, with cell membrane permeability, exhibits cytotoxic effects in neighboring tumor cells.

might influence primary resistance to T-DM1, as has been suggested in clinical trials^[18,19]. Alterations in the internalization of the receptor-T-DM1, formation of endosomes and the lysosome pathway required for release of the DM1 payload have also been described in T-DM1 resistant cell lines in preclinical studies^[13]. The upregulation of drug efflux transporters of which T-DM1 and other maytansinoids are substrates may also lead to resistance^[20]. Other *in vitro* studies suggest that resistance to DM1-mediated cytotoxicity may result from the reduction of cyclins needed to promote cell progression to the mitotic phase, causing attenuation of mitotic catastrophe and apoptosis^[21].

One of the strategies proposed to overcome or delay resistance to T-DM1 is the combination of T-DM1 with other drugs. The combination of T-DM1 with the anti-PD-L1 antibody atezolizumab was evaluated in the phase II trial KATE2 and showed improved PFS for the PD-L1-positive population but negative results for the intention-to-treat population^[22]. The subsequent clinical trial, KATE3, is recruiting HER2+/PD-L1-positive patients with advanced breast cancer and will explore the efficacy of the combination. Furthermore, the Astefania study is examining the efficacy of the combination of T-DM1 and atezolizumab in patients with high-risk (N+) residual disease after neo-adjuvant chemo/trastuzumab/pertuzumab^[23].

The combination of T-DM1 with anti-HER2 TKIs is another potential treatment strategy to improve efficacy and takes advantage of different anti-HER2 mechanisms of action as well as increasing activity in the brain since TKIs are able to cross the brain-blood-barrier. The HER2CLIMB 02 trial phase III is exploring the combination of T-DM1 with the reversible anti-HER2 TKI tucatinib^[24].

NEW GENERATION OF ADCS

As another potential strategy to overcome resistance, a new generation of anti-HER2 ADCs, such as trastuzumab deruxtecan (T-DXd) and trastuzumab duocarmazine (SYD985), with an enhanced design that confers improved efficacy, is a current focus of research. There are new generation ADCs that are similar to T-DM1, as they use antibodies with the same sequence as trastuzumab, thus targeting the same antigen [Tables 2 and 3]. This is the case for trastuzumab deruxtecan and trastuzumab duocarmazine. Others, like ARX-788, use a different anti-HER2 antibody to bind to tumor cells. These ADCs also show differences in the linker technology design that permits them to be cleavable under specific conditions and do not require lysosomal degradation, as in T-DM1. The cytotoxic payloads have different mechanisms of action and properties, such as membrane permeability, which allows for killing of neighbor cells not presenting the antigen, enhancing the efficacy of these agents [Figure 2]. These properties also result in activity in tumors expressing lower levels of HER2 (defined as HER2-low tumors) and enable the treatment of HER2-negative patients that might also obtain clinical activity from these ADCs^[25].

All these potential improvements are already being translated into a significant clinical benefit in HER2-positive metastatic breast cancer patients, as some of these new ADCs such as T-DXd and trastuzumab duocarmazine are already in an advanced phase of clinical development.

These promising therapies have raised interest in the scientific community, and several recent reviews describing the most updated data in this field have been published^[26-28].

Trastuzumab-Deruxtecan

T-DXd is composed of trastuzumab linked by an enzymatically cleavable peptide-linker to DXd, which is an exatecan derivative, a potent topoisomerase I inhibitor that induces double-strand DNA breaks and apoptosis. The DAR of T-DXd is 7.7:1, which is higher than that of T-DM1 (3.5:1), allowing more delivery of payload by each ADC in target tumor cells. Preclinical results have shown promising antitumor effects in T-DM1-resistant cells and low HER2-expressing cells^[29]. From these results, the initial clinical development plan targeted HER2-positive patients who had become resistant to T-DM1 or whose tumors were expressing low HER2 [defined as HER2 1+ and 2+ by immunohistochemistry with in situ hybridization (ISH) negative]. The phase I trial included 115 HER2-positive patients treated with the doses recommended for expansion that had received previous therapy (a median of seven lines); the overall response rate (ORR) was 60% in this heavily pretreated population. The toxicity profile showed more frequently gastrointestinal and hematological adverse events and 20 patients developed interstitial lung disease (ILD), including two treatment-related deaths from pneumonitis^[30]. The phase 2 trial DESTINY-breast01 confirmed the clinical activity of T-DXd in HER2-positive patients resistant to T-DM1 and confirmed 5.4 mg/kg as the recommended dose for further development in phase III trials. A total of 184 patients received T-DXd at the recommended dose with a median of six previous lines of therapy in the metastatic setting. The primary endpoint was objective response following independent central review with other efficacy and safety secondary endpoints^[31]. Updated results with a 20.5 median follow-up confirmed a 61.4% ORR and 19.4 months PFS with a median duration of response of 20.8 months. The most common G3 or higher adverse events were neutrophil count decrease, anemia, and nausea. Approximately 15.2% of cases had ILD, and 2.7% (5 patients) died^[32]. As a result of the clinical activity demonstrated in this phase 2 trial for patients who had developed resistance to previous therapies including T-DM1, T-DXd was approved by the FDA and EMA for use in HER2-positive metastatic patients that had received at least two previous lines of treatment. The most relevant data on the clinical activity of T-DXd reported thus far is the head-to-head comparison with T-DM1 in the phase III DESTINY-breast03 trial. Patients with HER2-positive advanced breast cancer that had been previously treated with a taxane and trastuzumab were randomized at 1:1 to

ARX788	Payload: dolastatin monomethyl auristatin F Linker: non-cleavable AS269 DAR: 1.9 Bystander effect: no	ACE-Pan Tumor 01 ^[43] Phase 1: advanced solid tumors with HER2 expression NCT03255070	ARX788	Breast cohort: PFS 17 m
RC48-ADC	Payload: monomethyl auristatin E DAR: 4 Linker: cleavable valine-citrulline Bystander effect: no	Phase 1 ^[45] : advanced breast cancer with HER2+ or HER2 low expression NCT03052634	RC48-ADC	Pooled results in HER2+ MBC: PFS: 4 to 6.3 m
ZW49	Payload: N-acyl sulfonamide auristatin DAR: 2 Linker: cleavable Bystander effect: NA	Phase 11 ^[51] : HER2 expressing cancers NCT03821233	ZW49	Results in HER2+ MBC: ORR: 13% PFS: NA

ADC: Antibody-drug conjugate; DAR: drug-to-antibody ratio; MBC: metastatic breast cancer; NA: non available; ORR: objective response rate; m: month; HR: hazard ratio; PFS: progression-free survival; OS: overall survival; TPC: treatment of physician's choice.

receive T-DXd or T-DM1. The primary endpoint was PFS and OS was a key secondary endpoint. The median follow-up for T-DXd was 16.2 months; the median PFS was 6.8 months for the T-DM1 groups, while the median PFS had not been reached for the T-DXd group, with a highly significant difference (HR of 0.28, 0.22-0.37, $P = 7.8 \times 10^{-22}$). The median OS had not been reached for both treatment arms, with a 12-month OS rate of 94.1% for the T-DXd group and 85.9% for the T-DM1 group, with no significant difference in this first analysis. The difference in ORR between the groups, with 79.7% for the T-DXd group compared with 34.2% for the T-DM1 group, was remarkable. The most common toxicity was hematological and gastrointestinal toxicity, with nausea as the most frequent event. Among the 524 randomized patients, 27 patients (10.5%) had ILD and 2 cases had G3 events with no cases of fatal pneumonitis for T-DXd compared with 5 cases of G1-2 for T-DM1^[33]. These data currently position T-DXd as a standard second-line treatment in the metastatic setting, moving T-DM1 to later lines^[34]. Another ongoing clinical trial is exploring the role of T-DXd in first-line treatment; this trial is comparing T-DXd combined with pertuzumab/placebo to the standard treatment of a taxane plus double blockade with trastuzumab and pertuzumab^[35]. This ADC is likely to make its way to the early setting, because ongoing clinical trials are comparing it to adjuvant T-DM1 in post-neoadjuvant residual disease and another trial is exploring it as

initial neoadjuvant treatment alone or in sequence with paclitaxel, trastuzumab and pertuzumab (THP) compared with the sequential standard scheme of anthracycline-cyclophosphamide followed by THP^[36,37]. Special attention and monitoring of potential T-DX-related ILD is being applied in these early disease trials, with clinical awareness and periodical imaging testing to rule out this potential severe toxicity.

Trastuzumab duocarmazine

Trastuzumab duocarmazine (SYD985) is another second-generation ADC that is composed of an antibody backbone with the same amino acidic sequence as trastuzumab with a cleavable linker to the vc-seco-DUBA payload, a potent duocarmycin analog with a DAR of 2.8:1. The cytotoxic payload is an alkylant agent that

binds to the minor groove of DNA and exhibits activity in both dividing and non-dividing cells. The linker is cleaved by proteases of the lysosome after endocytosis and by proteases such as cathepsin B that are found extracellularly; thus, there is a bystander killer effect^[38]. Preclinical studies that compared SYD985 with T-DM1 demonstrated encouraging activity of SYD985 in HER2-positive and HER2 low expression models, prompting exploration of SYD985 in a phase I trial in breast cancer and other HER2-expressing histologies^[39]. In breast cancer dose-expansion cohorts, 33% of patients with HER2-positive breast cancer achieved objective partial responses; additionally, 28% of patients with HER2-low, hormone receptor-positive breast cancer and 40% with HER2-low, hormone receptor-negative breast cancer also showed objective partial response. The most common treatment-related adverse events were fatigue, conjunctivitis, and dry eye; most patients had at least one ocular adverse event^[40]. The drug went directly into the TULIP trial, a phase III trial in a HER2-positive metastatic patient population that compared 2:1 SYD985 with the treatment of physician's choice (TPC) based on predefined standard options of a combination of chemotherapy and trastuzumab or lapatinib. Patients with two or more previous lines in the metastatic setting or with previous T-DM1 were included; patients had a median of four prior therapies. The primary endpoint of the study was centrally reviewed median PFS, which was 7.0 months for the SYD985 group and 4.9 months for the TPC group, with a statistically significant HR of 0.64 and no benefit in terms of OS in the first analysis. No significant differences were observed in ORR or health-related quality of life (HRQoL). The most frequently reported adverse events for SYD985 were conjunctivitis (38.2%), keratitis (38.2%) and fatigue (33.3%). Approximately 7.6% of patients treated with SYD985 showed ILD/pneumonitis, including two fatal events^[41]. Ocular toxicity from this ADC may potentially be permanent, so it is crucial to treat it and find strategies to mitigate it.

ARX788

In addition to the two anti-HER2 ADCs described above, other ADCs are in the earlier phase of development, such as ARX788. This new generation ADC has a site-specific anti-HER2 antibody with an amino acid sequence different from that of trastuzumab; it uses a nonnatural amino acid-enabled conjugation technology and a non-cleavable Amberstatin (AS269) drug-linker, a highly potent tubulin inhibitor with a DAR of 1.9:1. Preclinical data demonstrated activity in HER2-high and HER2-low expression cell lines and xenograft and patient-derived xenograft models of breast and gastric cancer, motivating clinical development in these patient populations^[42]. The phase I trial ACE-Breast-01 examined the use of ARX788 in HER2-positive metastatic breast cancer patients whose disease was resistant or refractory to HER2-targeted agents. The results showed a disease control of 100% and a median PFS of 17 months in the 29 patients treated at therapeutic doses who had been heavily pretreated in the advanced setting. However, there was some uncertainty about the anti-HER2 therapies to which this population would have been previously exposed. The safety profile was also favorable, with most adverse events being G1-G2; no dose-limiting toxicities were found and no drug-related deaths were reported. Since the cytotoxic payload of ARX788 is not a substrate of common efflux transporters, this is probably not a mechanism of resistance^[43]. The phase 2 trial ACE-Breast-03 is ongoing and includes patients whose disease is resistant or refractory to T-DM1 and/or T-DXd and/or tucatinib-containing regimens^[44].

RC48-ADC

RC48-ADC is a HER2-targeting ADC with a cleavable linker and a potent microtubule inhibitor payload MMAE with bystander killing effect in tumor cells. The DAR for this ADC is 4:1. Pooled results from two phase I studies in HER2-positive and HER2-low patients showed that among 70 HER2-positive patients, the ORR ranged from 22.2%-42.9% and the median PFS was 4-6.3 months for the different dosing levels. The most frequent G3 and above adverse events were decreased neutrophil count, increased GGT and fatigue^[45]. This ADC is currently in various clinical trials including a phase II/III for HER2-positive patients that is comparing RC48-ADC with capecitabine and lapatinib^[46]. As the field is moving forward, there are new

generation TKIs that are improving the results obtained with lapatinib, hence capecitabine and lapatinib might no longer be considered an optimal control arm in future clinical trials^[47,48].

ZW49 and MEDI4276

Other new generation ADCs include zanidatamab zovodotin (ZW49), which contains a biparatopic antibody to optimize binding to target tumor cells. This ADC consists of the antibody ZW25 (zanidatamab) that binds to the same epitopes of the HER2 receptor as trastuzumab and pertuzumab and a cleavable linker to an aurastatine payload, with a DAR of 2:1. Preclinical data demonstrated antitumor activity in low and high HER2-expressing breast cancer cell lines and PDX models^[49]. A phase I trial is currently ongoing in patients with locally advanced or metastatic HER2-expressing cancers; additional cohorts are being recruited^[50]. Preliminary results have suggested promising efficacy in various types of HER2-positive tumors. In eight breast cancer patients with a median of six prior therapies treated at the cohort expansion recommended dose, the ORR was 13%. Toxicity analysis revealed two cases of G2 keratitis lasting more than 14 days; approximately 43% of patients exhibited keratitis, but all events decreased to G1 or eventually resolved. There were no ILD events or deaths related to treatment^[51].

Another new generation ADC is MEDI4276, a biparatopic tetravalent antibody targeting two epitopes of the HER2 ecto-domain that has site-specific conjugation to a tubulysin-based microtubule inhibitor payload. Results from a phase I trial in advanced breast and gastric cancer demonstrated clinical activity, but also alteration of liver function tests and gastrointestinal toxicity^[52].

ZW49 and MEDI4276 are representative examples of ADCs currently in clinical development for HER2-positive and HER2-low expressing populations, but there are many other ADCs. In the following years, new ADCs targeting HER2 will be developed. While ADCs are demonstrating unprecedented response rates and improvements in PFS that will likely translate in a clinically significant increase in OS, there is an important need to discover the mechanisms underlying the resistance that eventually develop as patients progress. A better understanding of the mechanisms underlying primary and acquired resistance will help inform the development of treatment strategies for patients. Knowledge of the presence of cross-resistance to payloads in different ADCs would help predict the absence of clinical benefit in a patient, thus avoiding unnecessary toxicity.

Combining ADCs

The combination of ADCs with other agents is a potential strategy to overcome or delay resistance and is being explored in clinical trials. The combination of ADCs with targeted agents is the most widely used approach, especially with TKIs and immune checkpoint inhibitors. Theoretically, these agents could enhance antitumor activity by targeting the intracellular domain of the HER2 receptor and trespassing the blood-brain-barrier (in the case of TKIs) or triggering innate and adaptive immunity (in the case of anti-PDL1 agents). Determining whether this combination strategy leads to improvement in efficacy without significantly increasing toxicity is critical.

Activity beyond HER2-positive: How low can we go

Research has demonstrated that a higher expression of HER2 corresponds with a greater clinical benefit. HER2 positivity has generally been defined by immunohistochemistry (IHC) and in situ hybridization (ISH) and used to predict the clinical benefit of anti-HER2 therapies. Notably, the new generation ADCs are also demonstrating significant activity *in vitro* and clinical benefit in patients considered HER2-negative, redefining a so-called HER2-low population that would include tumors with IHC HER2 1+ and HER2 2+ with ISH negative. The threshold of HER2 expression from which a patient might benefit from these agents has not yet been clearly determined. Recent results from the phase II DAISY trial demonstrated activity of

T-DXd in heavily pretreated patients with different levels of HER2 expression. Notably, clinical activity was observed in the cohort that included patients with HER2-null tumors (IHC0+)^[53]. These results suggest that the levels of HER2 expression needed for ADC to exert clinical activity might vary depending on the properties of the different linkers and payloads. The DAISY trial was designed to address the mechanisms of action and resistance to T-DXd. The results indicated that HER2 levels were significantly associated with efficacy, with a median PFS of 11 months for HER2-positive patients compared with 4 months for HER2-null patients. A high percentage and spatial distribution of HER2 IHC0+ cells was associated with a non-response to T-DXd. Approximately 65% of patients progressing to T-DXd had a decrease in HER2 expression compared with baseline levels^[54]. There was a difference in the transcriptomic response to T-DXd depending on HER2 levels. No recurrent baseline driver mutations were identified as predictors of primary resistance, but 6% of patients presented an ERBB2 hemizygous deletion that might be associated with upfront resistance. SLX4 gene mutations were found in 20% of biopsies tested at progression, suggesting that SLX4 may be involved in a potential mechanism of acquired resistance^[55].

Results from the phase 3 randomized study DESTINY-breast04 were reported in ASCO 2022 for the HER2-low population that accounts approximately for at least 50% of all metastatic breast cancer cases^[25]. Patients with HR-positive tumors with one or two previous lines of therapy were included and randomized at 2:1 to receive T-DXd or TPC. There was a significant difference in PFS (the primary endpoint) of 10.1 months *vs.* 5.4 months, in favor of T-DXd, with a HR of 0.51. Furthermore, there was also a significant advantage in OS (23.9 months *vs.* 17.5 months) with a HR of 0.64. There was a similar benefit for the smaller exploratory subgroup of HR-negative patients included in the trial. These results led to FDA approval of T-DXd as the first ADC for treatment for a HER2-low population.

Brain metastases

As the survival of HER2-positive advanced cancer patients increases, the risk of the development of brain metastasis also increases. The activity of ADCs for patients with locally treated brain metastasis has been demonstrated in clinical trials for anti-HER2 ADCs, but there is not a wide representation of this population because of the restrictive inclusion criteria. Exploring how these agents perform in patients with non-treated or active brain disease is critical to design the best therapeutic sequence. Data from the phase IIIb single-arm KAMILLA clinical trial demonstrated the activity of T-DM1 in patients with brain metastases even in the absence of previous local treatment, challenging the hypothesis that larger molecules such as ADCs might not be capable of crossing a non-disrupted blood-brain barrier^[56]. Preliminary data from DEBBRAH and TUXEDO trials with T-DXd were designed to address this question and demonstrated responses in patients with active brain metastases, both untreated patients and those progressing after previous local treatment^[57,58]. The ongoing DESTINY-Breast12 trial is enrolling up to 250 patients with either active or stable brain metastases and should shed further light on the role of T-DXd in patients with CNS disease^[59].

Mitigating toxicity

While current data on the potential effects of ADCs are encouraging, there is still room for improvement in terms of efficacy and toxicity. The toxicity profiles are different among ADCs depending on the payload used and the properties of the linkers that are cleavable under specific conditions. A better understanding of the toxicity profile of these agents is required to develop strategies to mitigate the most frequent adverse events along with adverse effects that are rare but might be severe. Identifying the mechanisms and risk factors that favor the occurrence of ILD is important to prevent ILD. A very strong research effort is ongoing, but so far, the most efficacious approach is an early diagnosis through radiological imaging and the identification of respiratory symptoms to enable treatment and initiate ILD management following available guidelines. There is also a need to understand the underlying causes of the eye toxicity that can be

found with these agents. In the case of SYD985, activation of the payload in the conjunctive tissue initially produces xerophthalmia, which may evolve into different ocular alterations including keratitis. One possible strategy for avoiding these ocular side effects is already under investigation in a clinical trial that is investigating SYD985 and eye drops specifically developed to inactivate the payload in the eye^[60].

CONCLUSIONS

The new ADCs are rapidly changing the paradigm of treatment of HER2-positive advanced breast cancer patients and expanding the population that can benefit from them even in patients previously considered HER2-negative that have been defined as HER2-low. The results demonstrating the level of PFS achieved even in heavily pretreated populations indicate that these agents will improve survival. The proportion of HER2-positive metastatic patients that remain in a long-term response that could be considered potentially cured increases as new therapies are being developed, especially with the availability of these new generation ADCs. However, because a considerable number of patients will still eventually show disease progression, there is a need to continue developing more effective therapeutic options. A better understanding of the mechanisms of resistance to these agents is required to develop new strategies to overcome resistance as well as to define the best therapeutic sequence for each patient. Toxicity is still an issue and there is a need for better comprehension of the mechanisms and factors contributing to toxicity to develop mitigating strategies, especially with the implementation of these ADCs in the early stage disease as neo/adjuvant therapies.

Abstract

Aim: Efficient and readily available anticancer drugs are sought as treatment options. For this reason, chromene derivatives were prepared using the one-pot reaction and tested for their anticancer and anti-angiogenic properties.

Methods: 2-Amino-3-cyano-4-(aryl)-7-methoxy-4H-chromene compounds (2A-R) were repurposed or newly synthesized via a three-component reaction of 3-methoxyphenol, various aryl aldehydes, and malononitrile. We performed assays to study the inhibition of tumor cell growth [3-(4, 5-dimethylthiazol-2-yl)-2, 5-diphenyl tetrazolium bromid (MTT) assay], effects on microtubules (immunofluorescence), cell cycle (flow-activated cell sorting analysis), angiogenesis (zebrafish model), and MYB activity (luciferase reporter assay). Fluorescence microscopy was applied for localization studies via copper-catalyzed azide-alkyne click reaction of an alkyne-tagged drug derivative.

Results: Compounds 2A-C and 2F exhibited robust antiproliferative activities against several human cancer cell lines (50% inhibitory concentrations in the low nanomolar range) and showed potent MYB inhibition. The alkyne derivative 3 was localized in the cytoplasm after only 10 min of incubation. Substantial microtubule disruption and

G2/M cell-cycle arrest were observed, where compound 2F stood out as a promising microtubule-disrupting agent. The study of anti-angiogenic properties showed that 2A was the only candidate with a high potential to inhibit blood vessel formation *in vivo*.

Conclusion: The close interplay of various mechanisms, including cell-cycle arrest, MYB inhibition, and anti-angiogenic activity, led to identifying promising multimodal anticancer drug candidates.

Keywords: Chromene, pyran, anticancer drugs, microtubule, angiogenesis, MYB inhibition

INTRODUCTION

Multi-component reactions such as the Biginelli reaction, Van Leusen reaction, and the Ugi reaction, and their modifications are helpful for the design of biologically active compounds^[1-4]. An efficient three-component synthesis of biologically active pyrans was reported using naphthol, phenol, and hydroxyquinoline derivatives, which led to several new anticancer compounds^[5-8]. For instance, the naphthopyran LY290181 or 2-amino-4-(3-nitrophenyl)-4*H*-naphtho(1, 2-*b*)pyran-3-carbonitrile (1A) was identified as an active anticancer MDA (microtubule-binding/destabilizing agent)^[9,10]. The close analog 1B was initially described as an apoptosis inducer in breast cancer and non-small-cell lung cancer cells^[6]. It was also recently determined to be a highly potent inhibitor of the transcription factor MYB^[11]. MYB is encoded by the proto-oncogene MYB and is involved in the development of malignancies, making it a potential therapeutic target^[12]. The structurally optimized 7-methoxy-4*H*-chromene 2B is an even more potent apoptosis-inducing agent than 1B and showed high antiproliferative activities^[5]. The 2-amino-4-aryl-5-oxo-4, 5-dihydropyrano[3,2-*c*]chromene-3-carbonitrile 1C inhibited centrosome clustering in melanoma cells, leading to the formation of multiple mitotic spindles, chromosome segregation defects, and cell death [Figure 1]^[13].

Based on these active anticancer pyran heterocycles, several 2-amino-3-cyano-4-aryl-7-methoxy-4*H*-chromenes were prepared for testing their antiproliferative and MYB-inhibitory activities. Experiments on cell death induction, microtubule destabilization, drug localization, and anti-angiogenic effects were performed to investigate the underlying mechanisms of action of the most active compounds.

METHODS

Chemistry

General

Starting compounds and reagents were obtained from Aldrich, TCI, and Alfa Aesar. The already published compounds 1A, 1B, 2B, 2O, and 2R were prepared as described^[5,6,9,14]. For compound analysis, the following instruments were used: Gallenkamp for melting points (uncorrected); Perkin-Elmer Spectrum One FT-IR spectrophotometer (ATR) for IR spectra; BRUKER Avance 300 spectrometer for nuclear magnetic resonance spectra; chemical shifts were expressed as ppm (parts per million, δ) downfield from TMS (tetramethylsilane) as the internal standard; Varian MAT 311A (EI) and UPLC/Orbitrap (ESI-HRMS) for mass spectra; Perkin-Elmer 2400 CHN elemental analyzer for elemental analyses (microanalyses), and compounds were > 95% pure as to elemental analysis.

Synthesis

2-Amino-3-cyano-4-(3'-chloro-4', 5'-dimethoxyphenyl)-7-methoxy-4*H*-chromene (2A)

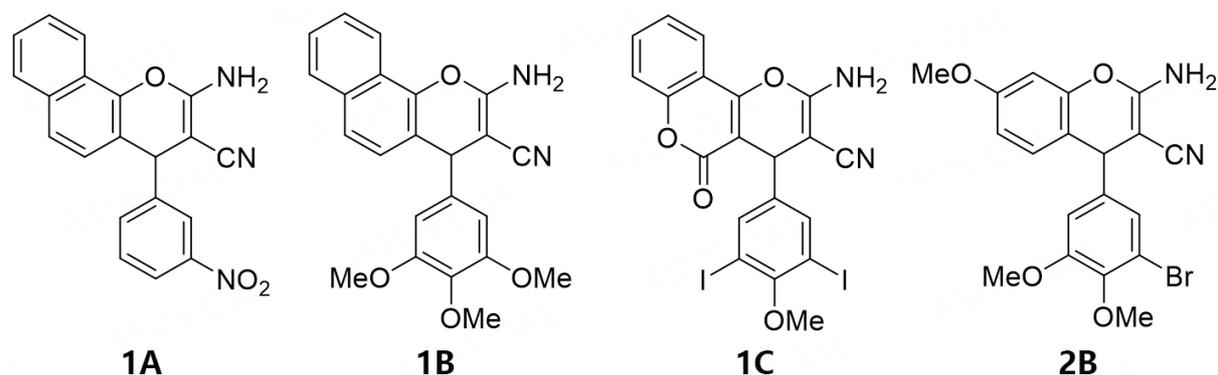

Figure 1. Structures of LY290181 (1A); MYB inhibitor Bcr-TMP (1B); chromosomal de-clustering agent 1C; and antiproliferative compound 2B.

3-Chloro-4, 5-dimethoxybenzaldehyde (200 mg, 1.0 mmol) and malononitrile (70 mg, 1.0 mmol) were dissolved in MeCN (5 mL), and three drops of Et₃N were added. The reaction mixture was stirred at room temperature for 30 min. 3-Methoxyphenol (109 μ L, 1.0 mmol) was added, and the reaction mixture was heated with a heat gun and stirred at room temperature for 2 h. The precipitate was collected, washed with MeCN and *n*-hexane, and dried in a vacuum. Yield: 80 mg (0.22 mmol, 22%); colorless solid of mp = 224-225 $^{\circ}$ C; ν_{\max} (ATR)/cm⁻¹ 3397, 3332, 3220, 2943, 2846, 2186, 1651, 1619, 1572, 1509, 1465, 1430, 1415, 1399, 1313, 1281, 1258, 1231, 1207, 1193, 1178, 1148, 1137, 1124, 1051, 998, 928, 856, 834, 813, 801, 780, 753, 714, 690, 659; ¹H NMR (300 MHz, CDCl₃) 3.77 (3 H, s, OMe), 3.82 (6 H, s, 2 x OMe), 4.5-4.6 (3 H, m, 4-H, NH₂), 6.53 (1 H, d, J = 2.5 Hz, 8-H), 6.6-6.7 (3 H, m, 6'-H, 6-H), 6.71 (1 H, s, 2'-H), 6.85 (1 H, d, J = 8.7 Hz, 5-H); ¹³C NMR (75.5 MHz, CDCl₃) 40.2 (4-C), 55.5 (OMe), 56.2 (OMe), 60.7 (OMe), 101.4 (8-C), 110.6 (6-C), 111.8 (6'-C), 113.9 (4a-C_q), 119.6 (CN), 121.2 (2'-C), 128.5 (3'-C), 130.1 (1'-C), 141.3 (4'-C), 149.1 (5'-C), 153.9 (8a-C_q), 159.1 (7-C), 159.6 (2-C); HRMS for C₁₉H₁₈O₄N₂Cl [M⁺ + H] calcd. 373.09496, found 373.09355.

2-Amino-3-cyano-4-(3'-iodo-4', 5'-dimethoxyphenyl)-7-methoxy-4H-chromene (2C)

Analogously to the synthesis of 2B, compound 2C (150 mg, 0.32 mmol, 32%) was obtained from 3-iodo-4, 5-dimethoxybenzaldehyde (292 mg, 1.0 mmol), malononitrile (70 mg, 1.0 mmol), three drops of Et₃N, and 3-methoxyphenol (109 μ L, 1.0 mmol) in MeCN (5 mL). Colorless solid of m.p. 223-224 $^{\circ}$ C; ν_{\max} (ATR)/cm⁻¹ 3403, 3334, 3220, 2937, 2841, 2186, 1651, 1619, 1582, 1563, 1508, 1479, 1464, 1411, 1397, 1308, 1272, 1253, 1231, 1200, 1178, 1136, 1124, 1044, 999, 875, 855, 812, 801, 777, 750, 688, 655, 611; ¹H NMR (300 MHz, dimethyl sulfoxide [DMSO]-d₆) 3.67 (3 H, s, OMe), 3.74 (3 H, s, OMe), 3.78 (3 H, s, OMe), 4.68 (1 H, s, 4-H), 6.56 (1 H, d, J = 2.5 Hz, 8-H), 6.68 (1 H, dd, J = 8.7 Hz, 2.5 Hz, 6-H), 6.9-7.1 (5 H, m, 6'-H, 6-H, 5-H, NH₂); ¹³C NMR (75.5 MHz, DMSO-d₆) 39.1 (4-C), 55.4 (OMe), 55.6 (OMe), 55.9 (OMe), 93.0 (3'-C), 100.9 (8-C), 111.4 (6-C), 112.7 (6'-C), 114.8 (4a-C_q), 120.4 (CN), 128.2 (5-C), 129.9 (2'-C), 144.4 (1'-C), 146.9 (4'-C), 148.7 (5'-C), 152.2 (8a-C_q), 159.0 (7-C), 160.3 (2-C); *m/z* (%) 464 (43) [M⁺], 201 (100); Anal. calcd. for C₁₉H₁₇IN₂O₄ (%), C, 49.16, H, 3.69, N, 6.03; found: C, 49.24, H, 3.77, N, 5.98.

2-Amino-3-cyano-4-(3', 5'-dichloro-4'-methoxyphenyl)-7-methoxy-4H-chromene (2D)

Analogously to the synthesis of 2B, compound 2D (115 mg, 0.31 mmol, 31%) was obtained from 3,5-dichloro-4-methoxybenzaldehyde (205 mg, 1.0 mmol), malononitrile (70 mg, 1.0 mmol), three drops of Et₃N, and 3-methoxyphenol (109 μ L, 1.0 mmol) in MeCN (5 mL). Colorless solid of m.p. 229 $^{\circ}$ C;

ν_{\max} (ATR)/ cm^{-1} 3395, 3331, 3219, 3004, 2973, 2938, 2841, 2192, 1652, 1619, 1583, 1557, 1509, 1478, 1448, 1404, 1395, 1318, 1301, 1282, 1265, 1254, 1195, 1150, 1127, 1082, 1043, 1029, 996, 949, 914, 888, 857, 848, 807, 795, 775, 751, 741, 687, 667, 653; ^1H NMR (300 MHz, $\text{CDCl}_3/\text{DMSO-d}_6$) 3.62 (3 H, s, OMe), 3.70 (3 H, s, OMe), 4.44 (1 H, s, 4-H), 5.58 (2 H, s, NH_2), 6.4-6.5 (2 H, m, 6-H, 8-H), 6.6-6.7 (1 H, m, 5-H), 6.96 (2 H, s, 2'-H, 6'-H); ^{13}C NMR (75.5 MHz, $\text{CDCl}_3/\text{DMSO-d}_6$) 39.7 (4-C), 55.4 (OMe), 57.7 (3-C), 60.5 (OMe), 101.4 (8-C), 111.5 (6-C), 113.5 (4a- C_q), 120.2 (CN), 128.0 (2'-C, 6'-C), 129.3 (3'-C, 5'-C), 129.9 (5-C), 142.9 (1'-C), 149.0 (4'-C), 150.9 (8a- C_q), 159.5 (7-C), 160.0 (2-C); m/z (EI) 378 (16) [M^+], 376 (23) [M^+], 201 (100); Anal. calcd. for $\text{C}_{18}\text{H}_{14}\text{Cl}_2\text{N}_2\text{O}_3$ (%), C, 57.31, H, 3.74, N, 7.43; found: C, 57.40, H, 3.70, N, 7.36.

2-Amino-3-cyano-4-(3', 5'-dibromo-4'-methoxyphenyl)-7-methoxy-4H-chromene (2E)

Analogously to the synthesis of 2B, compound 2E (125 mg, 0.27 mmol, 31%) was obtained from 3, 5-dibromo-4-methoxybenzaldehyde (259 mg, 0.88 mmol), malononitrile (70 mg, 1.0 mmol), three drops of Et_3N , and 3-methoxyphenol (109 μL , 1.0 mmol) in MeCN (5 mL). Colorless solid of m.p. 247 °C; ν_{\max} (ATR)/ cm^{-1} 3396, 3331, 3218, 2943, 2190, 1652, 1619, 1582, 1547, 1508, 1471, 1420, 1407, 1394, 1317, 1296, 1282, 1253, 1194, 1150, 1125, 1064, 1045, 1028, 999, 990, 947, 888, 857, 847, 811, 800, 779, 750, 733, 704, 686, 663; ^1H NMR (300 MHz, $\text{CDCl}_3/\text{DMSO-d}_6$) 3.70 (3 H, s, OMe), 3.76 (3 H, s, OMe), 4.52 (1 H, s, 4-H), 5.90 (2 H, s, NH_2), 6.47 (1 H, d, $J = 2.5$ Hz, 8-H), 6.55 (1 H, dd, $J = 8.6$ Hz, 2.5 Hz, 6-H), 6.77 (1 H, d, $J = 8.6$ Hz, 5-H), 7.23 (2 H, s, 2'-H, 6'-H); ^{13}C NMR (75.5 MHz, $\text{CDCl}_3/\text{DMSO-d}_6$) 39.1 (4-C), 54.9 (OMe), 56.9 (3-C), 59.9 (OMe), 101.0 (8-H), 111.0 (6-C), 113.1 (4a- C_q), 117.6 (3'-C, 5'-C), 119.7 (CN), 129.4 (5-C), 131.3 (2'-C, 6'-C), 143.7 (1'-C), 148.6 (4'-C), 152.2 (8a- C_q), 159.0 (7-C), 159.7 (2-C); m/z (EI) 468 (8) [M^+], 466 (16) [M^+], 464 (8) [M^+], 201 (100); Anal. calcd. for $\text{C}_{18}\text{H}_{14}\text{Br}_2\text{N}_2\text{O}_3$ (%), C, 46.38, H, 3.03, N, 6.01; found: C, 46.29, H, 2.98, N, 6.06.

2-Amino-3-cyano-4-(3, 5-diiodo-4-methoxyphenyl)-7-methoxy-4H-chromene (2F)

Analogously to the synthesis of 2B, compound 2F (165 mg, 0.30 mmol, 30%) was obtained from 3, 5-diiodo-4-methoxybenzaldehyde (388 mg, 1.0 mmol), malononitrile (70 mg, 1.0 mmol), three drops of Et_3N , and 3-methoxyphenol (109 μL , 1.0 mmol) in MeCN (5 mL). Colorless solid of m.p. 228 °C; ν_{\max} (ATR)/ cm^{-1} 3400, 3332, 3219, 2936, 2841, 2187, 1652, 1619, 1580, 1534, 1506, 1460, 1405, 1387, 1316, 1293, 1281, 1247, 1198, 1150, 1124, 1048, 1028, 993, 945, 897, 885, 854, 808, 798, 778, 749, 737, 711, 708, 700, 685; ^1H NMR (300 MHz, $\text{CDCl}_3/\text{DMSO-d}_6$) 3.70 (3 H, s, OMe), 3.72 (3 H, s, OMe), 4.49 (1 H, s, 4-H), 6.07 (2 H, s, NH_2), 6.47 (1 H, d, $J = 2.6$ Hz, 8-H), 6.54 (1 H, dd, $J = 8.6$ Hz, 2.6 Hz, 6-H), 6.77 (1 H, d, $J = 8.6$ Hz, 5-H), 7.47 (2 H, s, 2'-H, 6'-H); ^{13}C NMR (75.5 MHz, $\text{CDCl}_3/\text{DMSO-d}_6$) 54.9 (OMe), 56.6 (3-C), 59.9 (OMe), 90.3 (2'-C, 6'-C), 100.9 (8-C), 111.0 (6-C), 113.3 (4a- C_q), 119.8 (CN), 129.4 (5-C), 138.4 (2'-C, 6'-C), 144.9 (1'-C), 148.6 (8a- C_q), 156.9 (4'-C), 158.9 (7-C), 159.7 (2-C); m/z (EI) 560 (52) [M^+], 201 (100); Anal. calcd. for $\text{C}_{18}\text{H}_{14}\text{I}_2\text{N}_2\text{O}_3$ (%), C, 38.60, H, 2.52, N, 5.00; found: C, 38.69, H, 2.45, N, 4.97.

2-Amino-3-cyano-4-(2'-fluorophenyl)-7-methoxy-4H-chromene (2G)

Analogously to the synthesis of 2B, compound 2G (73 mg, 0.25 mmol, 25%) was obtained from 2-fluorobenzaldehyde (124 mg, 1.0 mmol), malononitrile (70 mg, 1.0 mmol), three drops of Et_3N , and 3-methoxyphenol (109 μL , 1.0 mmol) in MeCN (5 mL). Yield: 73 mg (0.25 mmol, 25%); colorless solid of m.p. 198 °C; ν_{\max} (ATR)/ cm^{-1} 3405, 3336, 3214, 2194, 1652, 1619, 1582, 1509, 1486, 1453, 1435, 1405, 1317, 1292, 1255, 1240, 1224, 1193, 1152, 1124, 1103, 1092, 1045, 1031, 937, 871, 857, 817, 803, 787, 753, 721, 705, 679; ^1H NMR (300 MHz, CDCl_3) 3.75 (3 H, s, OMe), 4.65 (2 H, s, NH_2), 5.04 (1 H, s, 4-H), 6.51 (1 H, d, $J = 2.6$ Hz, 8-H), 6.59 (1 H, dd, $J = 8.6$ Hz, 2.6 Hz, 6-H), 6.92 (1 H, d, $J = 8.6$ Hz, 5-H), 7.0-7.2 (4 H, m, 3'-H, 4'-H, 5'-H,

6'-H); ^{13}C NMR (75.5 MHz, CDCl_3) 33.8 (4-C), 55.5 (OMe), 59.2 (3-C), 101.3 (8-C), 111.7 (6-C), 114.1 (4a- C_q), 115.8 (d, $J = 22.0$ Hz, 3'-C), 119.6 (CN), 124.6 (5'-C), 128.9 (d = 8.3 Hz, 4'-C), 129.7 (5-C), 131.5 (d = 12.7 Hz, 6'-C), 149.2 (8a- C_q), 159.4 (7-C), 159.8 (2-C), 160.0 (d = 195.9 Hz, 2'-C); m/z (EI) 296 (42) [M^+], 201 (100); Anal. calcd. for $\text{C}_{17}\text{H}_{13}\text{FN}_2\text{O}_2$ (%), C, 68.91, H, 4.42, N, 9.45; found: C, 68.99, H, 4.36, N, 9.39.

2-Amino-3-cyano-4-(2'-chlorophenyl)-7-methoxy-4H-chromene (2H)

Analogously to the synthesis of 2B, compound 2H (500 mg, 1.6 mmol, 40%) was obtained from 2-chlorobenzaldehyde (562 mg, 4.0 mmol), malononitrile (280 mg, 4.0 mmol), six drops of Et_3N , and 3-methoxyphenol (436 μL , 4.0 mmol) in MeCN (5 mL). Colorless solid of m.p. 184 °C; ν_{max} (ATR)/ cm^{-1} 3435, 3343, 3216, 2937, 2840, 2186, 1639, 1618, 1580, 1506, 1466, 1441, 1402, 1311, 1291, 1278, 1253, 1198, 1154, 1123, 1033, 956, 935, 874, 854, 817, 782, 758, 724, 708, 694, 675; ^1H NMR (300 MHz, CDCl_3) 3.75 (3 H, s, OMe), 4.62 (2 H, s, NH_2), 5.31 (1 H, s, 4-H), 6.51 (1 H, d, $J = 2.6$ Hz, 8-H), 6.57 (1 H, dd, $J = 8.6$ Hz, 2.6 Hz, 6-H), 6.89 (1 H, d, $J = 8.6$ Hz, 5-H), 7.2-7.3 (3 H, m, 4'-H, 5'-H, 6'-H), 7.3-7.4 (1 H, m, 3'-H); ^{13}C NMR (75.5 MHz, CDCl_3) 36.8 (3-C), 55.5 (OMe), 59.7 (4-C), 101.3 (8-H), 111.6 (6-C), 114.2 (4a- C_q), 119.5 (CN), 127.5 (6'-C), 128.4 (5'-C), 129.7 (4'-C), 129.9 (3'-C), 130.7 (5-C), 133.0 (2'-C), 141.8 (1'-C), 149.1 (8a- C_q), 159.5 (7-C), 159.6 (2-C); m/z (EI) 314 (6) [M^+], 312 (24) [M^+], 201 (100); Anal. calcd. for $\text{C}_{17}\text{H}_{13}\text{ClN}_2\text{O}_2$ (%), C, 65.29, H, 4.19, N, 8.96; found: C, 65.36, H, 4.12, N, 9.02.

2-Amino-3-cyano-4-(3', 4'-difluorophenyl)-7-methoxy-4H-chromene (2I)

Analogously to the synthesis of 2B, compound 2I (98 mg, 0.31 mmol, 31%) was obtained from 3, 4-difluorobenzaldehyde (142 mg, 1.0 mmol), malononitrile (70 mg, 1.0 mmol) three drops of Et_3N , and 3-methoxyphenol (109 μL , 1.0 mmol) in MeCN (5 mL). Yield: 98 mg (0.31 mmol, 31%); colorless solid of m.p. 193 °C; ν_{max} (ATR)/ cm^{-1} 3433, 3349, 3220, 2842, 2186, 1663, 1616, 1580, 1507, 1464, 1436, 1408, 1311, 1289, 1255, 1202, 1191, 1156, 1123, 1109, 1046, 959, 928, 889, 856, 828, 816, 802, 775, 746, 697, 673; ^1H NMR (300 MHz, CDCl_3) 3.77 (3 H, s, OMe), 4.61 (2 H, s, NH_2), 4.64 (1 H, s, 4-H), 6.53 (1 H, d, $J = 2.6$ Hz, 8-H), 6.62 (1 H, dd, $J = 8.6$ Hz, 2.6 Hz, 6-H), 6.81 (1 H, d, $J = 8.6$ Hz, 5-H), 6.9-7.0 (2 H, m, 5'-H, 6'-H), 7.0-7.1 (1 H, m, 2'-H); ^{13}C NMR (75.5 MHz, CDCl_3) 39.8 (4-C), 55.5 (OMe), 60.5 (3-C), 101.5 (8-C), 111.9 (6-C), 113.8 (4a- C_q), 116.7 (d, $J = 17.6$ Hz, 2'-C), 117.4 (d, $J = 17.4$ Hz, 5'-C), 119.4 (CN), 123.7 (d, $J = 9.8$ Hz, 6'-C), 130.1 (5-C), 141.8 (1'-C), 147.1 (d, $J = 156.0$ Hz), 149.1 (8a- C_q), 151.2 (d, $J = 156.0$ Hz, 3'-C), 159.1 (7-C), 159.7 (2-C); m/z (EI) 314 (33) [M^+], 201 (100); Anal. calcd. for $\text{C}_{17}\text{H}_{12}\text{F}_2\text{N}_2\text{O}_2$ (%), C, 64.97, H, 3.85, N, 8.91; found: C, 65.08, H, 3.79, N, 8.96.

2-Amino-3-cyano-4-(3'-chloro-4'-fluorophenyl)-7-methoxy-4H-chromene (2J)

Analogously to the synthesis of 2B, compound 2J (100 mg, 0.30 mmol, 30%) was obtained from 3-chloro-4-fluorobenzaldehyde (159 mg, 1.0 mmol), malononitrile (70 mg, 1.0 mmol), three drops of Et_3N , and 3-methoxyphenol (109 μL , 1.0 mmol) in MeCN (5 mL). Colorless solid of m.p. 192-193 °C. ν_{max} (ATR)/ cm^{-1} 3432, 3350, 3285, 3219, 3087, 2972, 2842, 2186, 1659, 1615, 1579, 1505, 1495, 1464, 1435, 1412, 1401, 1320, 1306, 1291, 1254, 1221, 1201, 1153, 1122, 1058, 1044, 948, 897, 855, 828, 815, 801, 774, 755, 711, 702, 693; ^1H NMR (300 MHz, CDCl_3) 3.77 (3 H, s, OMe), 4.61 (2 H, s, NH_2), 4.64 (1 H, s, 4-H), 6.54 (1 H, d, $J = 2.6$ Hz, 8-H), 6.61 (1 H, dd, $J = 8.6$ Hz, 2.6 Hz, 6-H), 6.80 (1 H, d, $J = 8.6$ Hz, 5-H), 7.0-7.1 (2 H, m, 5'-H, 6'-H), 7.1-7.2 (1 H, m, 2'-H); ^{13}C NMR (75.5 MHz, CDCl_3) 39.7 (4-C), 55.6 (OMe), 60.5 (3-C), 101.5 (8-C), 112.0 (6-C), 113.8 (4a- C_q), 116.8 (d, $J = 21.3$ Hz, 5'-C), 119.4 (CN), 121.4 (d, $J = 18.0$ Hz, 3'-C), 127.6 (6'-C), 130.0 (2'-C), 131.1 (5-C), 141.9 (1'-C), 149.1 (8a- C_q), 157.3 (d, $J = 248.9$ Hz, 4'-C), 159.1 (7-C), 159.7 (2-C); m/z (%) 330 (47) [M^+], 201 (100), 186 (43), 158 (43). Anal. calcd. for $\text{C}_{17}\text{H}_{12}\text{ClFN}_2\text{O}_2$ (%), C, 61.74, H, 3.66, N, 8.47; found: C, 61.84, H, 3.71, N, 8.50.

2-Amino-3-cyano-4-(3', 4'-dichlorophenyl)-7-methoxy-4H-chromene (2K)

Analogously to the synthesis of 2B, compound 2K (105 mg, 0.30 mmol, 30%) was obtained from 3, 4-dichlorobenzaldehyde (175 mg, 1.0 mmol), malononitrile (70 mg, 1.0 mmol), three drops of Et₃N, and 3-methoxyphenol (109 µL, 1.0 mmol) in MeCN (5 mL). Colorless solid of m.p. 192 °C; ν_{\max} (ATR)/cm⁻¹ 3433, 3349, 3220, 2186, 1661, 1616, 1579, 1506, 1463, 1434, 1412, 1320, 1290, 1251, 1199, 1180, 1157, 1123, 1046, 1029, 948, 911, 895, 885, 856, 825, 809, 786, 753, 732, 703, 692, 665; ¹H NMR (300 MHz, CDCl₃) 3.77 (3 H, s, OMe), 4.63 (1 H, s, 4-H), 4.66 (2 H, s, NH₂), 6.53 (1 H, d, J = 2.6 Hz, 8-H), 6.61 (1 H, dd, J = 8.6 Hz, 2.6 Hz, 6-H), 6.80 (1 H, d, J = 8.6 Hz, 5-H), 7.03 (1 H, dd, J = 8.2 Hz, 2.1 Hz, 6'-H), 7.22 (1 H, d, J = 2.1 Hz, 2'-H), 7.37 (1 H, d, J = 8.2 Hz, 5'-H); ¹³C NMR (75.5 MHz, CDCl₃) 39.8 (4-C), 55.5 (OMe), 60.0 (3-C), 101.5 (8-C), 111.9 (6-C), 113.5 (4a-C_q), 119.4 (CN), 127.3 (6'-C), 129.8 (2'-C), 130.1 (5-C), 130.8 (5'-C), 131.4 (4'-C), 132.9 (3'-C), 145.0 (1'-C), 149.0 (8a-C_q), 159.2 (7-C), 159.7 (2-C); *m/z* (EI) 348 (7) [M⁺], 346 (13) [M⁺], 201 (100); Anal. calcd. for C₁₇H₁₂Cl₂N₂O₂ (%), C, 58.81, H, 3.48, N, 8.07; found: C, 58.94, H, 3.55, N, 8.09.

2-Amino-3-cyano-4-(2', 4'-difluorophenyl)-7-methoxy-4H-chromene (2L)

Analogously to the synthesis of 2B, compound 2L (100 mg, 0.32 mmol, 32%) was obtained from 2, 4-difluorobenzaldehyde (142 mg, 1.0 mmol), malononitrile (70 mg, 1.0 mmol), three drops of Et₃N, and 3-methoxyphenol (109 µL, 1.0 mmol) in MeCN (5 mL). Colorless solid of m.p. 169-170 °C. ν_{\max} (ATR)/cm⁻¹ 3432, 3349, 3220, 3084, 3015, 2969, 2936, 2840, 2186, 1660, 1615, 1602, 1581, 1497, 1463, 1409, 1316, 1280, 1262, 1241, 1220, 1202, 1190, 1155, 1138, 1124, 1086, 1039, 960, 852, 827, 808, 781, 751, 730, 683; ¹H NMR (300 MHz, CDCl₃) 3.76 (3 H, s, OMe), 4.63 (2 H, s, NH₂), 5.01 (1 H, s, 4-H), 6.52 (1 H, d, J = 2.6 Hz, 8-H), 6.60 (1 H, dd, J = 8.6 Hz, 2.6 Hz, 6-H), 6.7-6.8 (2 H, m, 3'-H, 5'-H), 6.88 (1 H, d, J = 8.6 Hz, 5-H), 7.0-7.1 (1 H, m, 6'-H); ¹³C NMR (75.5 MHz, CDCl₃) 33.5 (4-C), 55.5 (OMe), 59.2 (3-C), 101.4 (8-C), 103.8-104.5 (m, 3'-C), 111.6-112.0 (m, 5'-C, 6-C), 113.8 (4a-C_q), 119.4 (CN), 127.5 (d, J = 12.9 Hz), 129.7 (5-C), 130.5-130.7 (m, 6'-C), 139.0 (1'-C), 149.2 (8a-C_q), 159.6 (7-C), 159.8 (2-C), 160.3 (d, J = 247.5 Hz, 4'-C), 162.0 (d, J = 248.8 Hz, 2'-C); *m/z* (%) 314 (43) [M⁺], 201 (100); Anal. calcd. for C₁₇H₁₂F₂N₂O₂ (%), C, 64.97, H, 3.85, N, 8.91; found: C, 64.90, H, 3.78, N, 8.88.

2-Amino-3-cyano-4-(2', 3'-difluorophenyl)-7-methoxy-4H-chromene (2M)

Analogously to the synthesis of 2B, compound 2M (100 mg, 0.32 mmol, 32%) was obtained from 2, 3-difluorobenzaldehyde (142 mg, 1.0 mmol), malononitrile (70 mg, 1.0 mmol), three drops of Et₃N, and 3-methoxyphenol (109 µL, 1.0 mmol) in MeCN (5 mL). Colorless solid of m.p. 183-184 °C. ν_{\max} (ATR)/cm⁻¹ 3429, 3331, 3213, 2975, 2935, 2840, 2193, 1652, 1627, 1614, 1576, 1508, 1478, 1416, 1310, 1287, 1266, 1249, 1231, 1190, 1150, 1123, 1043, 1030, 969, 929, 895, 857, 824, 792, 782, 758, 740, 718, 697, 683; ¹H NMR (300 MHz, CDCl₃) 3.76 (3 H, s, OMe), 4.64 (2 H, s, NH₂), 5.05 (1 H, s, 4-H), 6.52 (1 H, d, J = 2.6 Hz, 8-H), 6.60 (1 H, dd, J = 8.6 Hz, 2.6 Hz, 6-H), 6.9-7.1 (4 H, m, 5-H, 4'-H, 5'-H, 6'-H); ¹³C NMR (75.5 MHz, CDCl₃) 34.1 (4-C), 55.5 (OMe), 58.9 (3-C), 101.5 (8-C), 111.8 (6-C), 113.5 (4a-C_q), 116.1 (d, J = 17.2 Hz, 4'-C), 119.3 (CN), 124.3-124.5 (m, 6'-C), 129.7 (5-C), 133.9 (d, J = 9.8 Hz, 5'-C), 148.1 (d, J = 151.0 Hz, (2'-C), 149.2 (8a-C_q), 151.4 (d, J = 156.0 Hz, 3'-C), 159.7 (7-C), 159.9 (2-C); *m/z* (%) 314 (27) [M⁺], 201 (100); Anal. calcd. for C₁₇H₁₂F₂N₂O₂ (%), C, 64.97, H, 3.85, N, 8.91; found: C, 64.88, H, 3.80, N, 8.94.

2-Amino-3-cyano-4-(2', 5'-difluorophenyl)-7-methoxy-4H-chromene (2N)

Analogously to the synthesis of 2B, compound 2N (95 mg, 0.30 mmol, 30%) was obtained from 2, 5-difluorobenzaldehyde (142 mg, 1.0 mmol), malononitrile (70 mg, 1.0 mmol), three drops of Et₃N, and 3-methoxyphenol (109 μL, 1.0 mmol) in MeCN (5 mL). Colorless solid of m.p. 179-180°C. v_{\max} (ATR)/cm⁻¹ 3629, 3458, 3408, 3333, 3213, 3080, 2983, 2938, 2843, 2192, 1651, 1618, 1579, 1508, 1490, 1452, 1436, 1404, 1317, 1290, 1252, 1240, 1190, 1176, 1150, 1122, 1082, 1044, 1028, 961, 942, 883, 855, 849, 817, 806, 794, 777, 752, 739, 731, 716, 700; ¹H NMR (300 MHz, CDCl₃) 3.76 (3 H, s, OMe), 4.67 (2 H, s, NH₂), 5.04 (1 H, s, 4-H), 6.52 (1 H, d, J = 2.6 Hz, 8-H), 6.61 (1 H, dd, J = 8.6 Hz, 2.6 Hz, 6-H), 6.8-7.0 (4 H, m, 5-H, 3'-H, 4'-H, 6'-H); ¹³C NMR (75.5 MHz, CDCl₃) 33.8 (4-C), 55.5 (OMe), 58.8 (3-C), 101.5 (8-C), 111.9 (6-C), 113.4 (4a-C_q), 115.2-116.2 (m, 4'-C), 116.7-117.2 (m, 3'-C, 6'-C), 119.3 (CN), 129.7 (5-C), 133.1-133.4 (m, 1'-C), 149.2 (8a-C_q), 156.2 (d, J = 239.8 Hz, 2'-C), 159.0 (d, J = 243.3 Hz, 5'-C), 159.7 (7-C), 159.9 (2-C); *m/z* (%) 314 (60) [M⁺], 201 (100), 186 (37), 158 (33); Anal. calcd. for C₁₇H₁₂F₂N₂O₂ (%), C, 64.97, H, 3.85, N, 8.91; found: C, 65.04, H, 3.90, N, 8.98.

2-Amino-3-cyano-4-(3', 4', 5'-trifluorophenyl)-7-methoxy-4H-chromene (2P)

Analogously to the synthesis of 2B, compound 2P (105 mg, 0.32 mmol, 32%) was obtained from 3, 4, 5-trifluorobenzaldehyde (160 mg, 1.0 mmol), malononitrile (70 mg, 1.0 mmol) three drops of Et₃N, and 3-methoxyphenol (109 μL, 1.0 mmol) in MeCN (5 mL). Colorless solid of m.p. 237-238 °C; v_{\max} (ATR)/cm⁻¹ 3428, 3346, 3221, 3053, 3014, 2945, 2848, 2187, 1662, 1616, 1579, 1524, 1506, 1465, 1446, 1409, 1342, 1310, 1292, 1232, 1203, 1182, 1156, 1131, 1116, 1035, 985, 897, 879, 855, 834, 822, 803, 785, 756, 716, 709, 688; ¹H NMR (300 MHz, DMSO-d₆) 3.79 (3 H, s, OMe), 4.81 (1 H, s, 4-H), 6.57 (1 H, d, J = 2.5 Hz, 8-H), 6.69 (1 H, dd, J = 8.7 Hz, 2.5 Hz, 6-H), 6.98 (1 H, d, J = 8.7 Hz, 5-H), 7.07 (2 H, s, NH₂), 7.1-7.2 (2 H, m, 2'-H, 6'-H); ¹³C NMR (75.5 MHz, CDCl₃/DMSO-d₆) 54.8 (3-C), 55.4 (OMe), 101.1 (8-C), 111.5-112.0 (m, 2'-C, 6'-C, 6-C), 113.8 (4a-C_q), 120.2 (CN), 129.9 (5-C), 136.0 (1'-C), 143.3 (4'-C), 148.8 (8a-C_q), 150.2 (dd, J = 248.7 Hz, 9.8 Hz, 3'-C, 5'-C), 159.2 (7-C), 160.4 (2-C); HR-MS (ESI, *m/z*) for C₁₇H₁₂O₂N₂F₃ [M⁺ + H] calcd. 333.08454, found 333.08436.

2-Amino-3-cyano-4-(3'-pentafluorothiophenyl)-7-methoxy-4H-chromene (2Q)

Analogously to the synthesis of 2B, compound 2Q (130 mg, 0.32 mmol, 32%) was obtained from 3-pentafluorothiobenzaldehyde (232 mg, 1.0 mmol), malononitrile (70 mg, 1.0 mmol) three drops of Et₃N, and 3-methoxyphenol (109 μL, 1.0 mmol) in MeCN (5 mL). Colorless solid of m.p. 226-227 °C; v_{\max} (ATR)/cm⁻¹ 3472, 3321, 3281, 3233, 3205, 3071, 2936, 2841, 2192, 1652, 1626, 1612, 1577, 1508, 1464, 1434, 1402, 1293, 1252, 1191, 1155, 1125, 1111, 1097, 1036, 938, 911, 884, 833, 810, 794, 780, 747, 717, 697, 688; ¹H NMR (300 MHz, CDCl₃) 3.77 (3 H, s, OMe), 4.64 (2 H, s, NH₂), 4.75 (1 H, s, 4-H), 6.55 (1 H, d, J = 2.6 Hz, 8-H), 6.62 (1 H, dd, J = 8.6 Hz, 2.6 Hz, 6-H), 6.80 (1 H, d, J = 8.6 Hz, 5-H), 7.3-7.4 (2 H, m, 5'-H, 6'-H), 7.53 (1 H, s, 2'-H), 7.6-7.7 (1 H, m, 4'-H); ¹³C NMR (75.5 MHz, CDCl₃) 40.5 (4-C), 55.5 (OMe), 60.2 (3-C), 101.6 (8-C), 112.0 (6-C), 113.5 (4a-C_q), 119.3 (CN), 124.9 (2'-C), 125.3 (4'-C), 129.3 (5'-C), 130.1 (5-C), 131.1 (6'-C), 145.9 (1'-C), 149.2 (8a-C_q), 154.3-155.0 (m, 3'-C), 159.3 (7-C), 159.8 (2-C); *m/z* (%) 404 (31) [M⁺], 201 (100), 186 (38), 158 (33); Anal. calcd. for C₁₇H₁₂F₅N₂O₂S (%), C, 50.50, H, 3.24, N, 6.93; found: C, 50.59, H, 3.20, N, 6.88.

2-Amino-3-cyano-4-(3'-bromo-4', 5'-dimethoxyphenyl)-7-propargyloxy-4H-chromene (3)

A mixture of malononitrile (70 mg, 1.0 mmol) and 3-bromo-4, 5-dimethoxybenzaldehyde (245 mg, 1.0 mmol) in ethanol (EtOH) (5 mL) was treated with three drops of piperidine, and the reaction mixture was stirred for 30 min at room temperature. 3-Propargyloxyphenol (148 mg, 1.0 mmol) was added, and the

reaction mixture was stirred under reflux for 4 h. The solvent was evaporated, and the residue was taken up in ethyl acetate, washed with water, and dried over Na_2SO_4 . The solvent was evaporated, and the residue was purified by column chromatography (silica gel 60). Yield: 50 mg (0.11 mmol, 11%); off-white solid of m.p. 206-207 °C; $R_f = 0.47$ (ethyl acetate / *n*-hexane, 1:1); ν_{max} (ATR)/ cm^{-1} 3442, 3331, 3294, 3240, 3202, 3009, 2971, 2939, 2834, 2192, 1651, 1629, 1608, 1570, 1508, 1488, 1459, 1431, 1401, 1312, 1284, 1230, 1183, 1157, 1124, 1044, 1028, 995, 880, 850, 840, 823, 801, 780, 762, 684, 654; ^1H NMR (300 MHz, DMSO-d_6) 3.59 (1 H, s, CCH), 3.70 (3 H, s, OMe), 3.81 (3 H, s, OMe), 4.72 (1 H, s, 4-H), 4.80 (2 H, s, CH_2), 6.65 (1 H, d, $J = 2.6$ Hz, 8-H), 6.73 (1 H, dd, $J = 8.6$ Hz, 2.6 Hz, 6-H), 6.88 (1 H, s, 6'-H), 7.0-7.1 (4 H, m, 5-H, 2'-H, NH_2); ^{13}C NMR (75.5 MHz, DMSO-d_6) 55.4 (CH_2), 55.7 (3-C), 56.1 (OMe), 60.0 (OMe), 78.6 (CCH), 78.9 (CCH), 102.5 (8-C), 111.8 (6-C), 112.3 (4a- C_q), 115.4 (6'-C), 116.8 (3'-C), 120.4 (CN), 122.5 (2'-C), 129.9 (5-C), 143.6 (1'-C), 144.4 (4'-C), 148.6 (5'-C), 153.4 (8a- C_q), 156.9 (7-C), 160.4 (2-C); HR-MS (ESI, m/z) for $\text{C}_{21}\text{H}_{18}\text{O}_4\text{N}_2^{79}\text{Br}$ [$\text{M}^+ + \text{H}$] calcd. 441.04445, found 441.04419.

Biological assays

Cell lines and culture conditions

The following cell lines were used: 518A2 melanoma (Department of Radiotherapy, Medical University of Vienna, Austria)^[15], HeLa cervix carcinoma, KBV1^{vbl} (ACC-149 cervix carcinoma, MCF7 [ACC-115]) breast carcinoma, U-87 glioblastoma, HT-29 (ACC-299), HCT-116 (ACC-581) and HCT-116p53-/- colon carcinoma, EA.hy926 (ATCC® CRL-2922TM) endothelial hybrid cells, and HDFa (ATCC® PCS-201-012TM) adult human dermal fibroblasts. The cells were maintained in Dulbecco's Modified Eagle Medium with 10% fetal bovine serum (20% for HDFa cells) and 1% ZellShield® at 37 °C, 5% CO_2 , and 95% humidity. KB-V1^{vbl} cells were treated with 340 nM vinblastine to retain vinblastine resistance. Only mycoplasma-free cultures were used.

In vitro cytotoxicity assay

An 3-(4, 5-dimethylthiazol-2-yl)-2, 5-diphenyl tetrazolium bromid (MTT) assay was used for antiproliferative studies. Cancer cells (5×10^4 cells/mL, 100 μL /well) were placed in 96-well plates (10×10^4 cells/mL for HDFa and U87 cells), and the cells were incubated for 24 h at 5% CO_2 and 95% humidity. Then, cells were treated with test compounds (at various concentrations) or solely with DMSO as a negative control for 72 h. Then, 12.5 μL of a 0.5% MTT solution in phosphate-buffered saline (PBS) was added to the cells, followed by incubation for 2 h at 37 °C. After centrifugation of the plates ($300 \times g$, 5 min, 4 °C), the medium was discarded, and 25 μL of DMSO containing 10% SDS and 0.6% acetic acid was added, followed by incubation at 37 °C for at least 1 h. Formazan absorbance at $\lambda = 570$ nm was measured using a Tecan infinite F200 microplate reader and corrected for the background ($\lambda = 630$ nm). The 50% inhibitory concentration (IC_{50}) values were calculated from dose-response curves (means \pm SD, four independent experiments) compared to DMSO-treated control cells, which were set to 100%. GraphPad Prism 9 was used for curve-fitting.

Microtubule immunofluorescence staining

518A2 melanoma cells (10×10^4 cells/mL, 0.5 mL/well) were placed on coverslips in 24-well plates followed by incubation at 37 °C, 5% CO_2 , and 95% humidity. The cells were treated with test compounds and controls (25 and 100 nm) for 0.5, 1, 3, and 6 h and washed with cytoskeletal buffer (100 mM PIPES, 3 mM MgCl_2 , 138 mM KCl, 2 mM EGTA, 300 mM sucrose, pH 6.8). Fixation and permeabilization were performed for 5 min with 3.7% formaldehyde and 0.2% Triton X-100 in a cytoskeletal buffer. The cells were fixed with cold EtOH for 10 s, rehydrated in PBS, and blocked with 1% bovine serum albumin in PBS for 30 min. The microtubules were stained for 1 h with primary (anti- α -tubulin, mouse monoclonal antibody) and secondary antibodies (goat anti-mouse IgG-AF-546, Invitrogen) and washed with PBS between each treatment. Nuclei were stained using DAPI (1 $\mu\text{g}/\text{mL}$ in PBS) for 30 min. The coverslips were placed in

Roti®-Mount FluorCare. Microtubules ($\lambda_{\text{ex}} = 488 \text{ nm}$, $\lambda_{\text{em}} = 507 \text{ nm}$) and nuclei ($\lambda_{\text{ex}} = 358 \text{ nm}$, $\lambda_{\text{em}} = 461 \text{ nm}$) were documented by confocal microscopy (Leica TCS SP5 confocal microscope, 630 × magnification) and edited with *ImageJ*.

Intracellular localization

518A2 melanoma cells (7.5×10^4 cells/mL, 0.5 mL/well) were placed on coverslips in 24-well plates and cultivated for 24 h. Cells were treated with 3 (25 μM , 0.4% tween 80 in PBS) for 10 min at room temperature. After fixation in 3.7 % formaldehyde for 15 min and washing with PBS, the cells were incubated with the “click-solution” (2 mM CuSO_4 , 5 mM sodium ascorbate, 0.1 mM 3-azido-7-hydroxycoumarin, 1% bovine serum albumin in PBS) for 30 min and washed with PBS. The nuclei were counterstained with Nuclear Green LCS1 for another 30 min, and the coverslips were mounted in Roti®-Mount FluorCare. The clicked test compound ($\lambda_{\text{ex}} = 404 \text{ nm}$, $\lambda_{\text{em}} = 477 \text{ nm}$) and nuclei ($\lambda_{\text{ex}} = 488 \text{ nm}$, $\lambda_{\text{em}} = 507 \text{ nm}$) were analyzed with a Leica TCS SP5 confocal microscope, and the obtained images were edited with *ImageJ*.

Cell-cycle analysis

518A2 melanoma cells (10×10^4 cells/mL, 3 mL/well) were cultivated in six-well plates for 24 h. After the treatment with test compounds (10 and 25 nM), C-A4 (10 and 25 nM), or DMSO (vehicle) for an additional 24 h, the cells were trypsinized, centrifuged (300 × g, 5 min, 4 °C), and fixed in 70% EtOH for min. 24 h. For FACS measurement, cells were washed in PBS and stained with propidium iodide solution (50 $\mu\text{g/mL}$ PI, 50 $\mu\text{g/mL}$ RNase A in 0.1% sodium citrate) for 30 min at 37 °C. The DNA content of at least 10000 single cells was determined using a Beckmann Coulter Cytomics FC500 flow cytometer ($\lambda_{\text{ex}} = 488 \text{ nm}$, $\lambda_{\text{em}} = 570 \text{ nm}$). CXP software (Beckman Coulter) was used to analyze the cells in the cell cycle phases (sub-G1, G1, S, G2/M).

Tube-formation assay

EA.hy926 endothelial hybrid cells were maintained for 24 h in EndoPrime low-serum endothelial medium and seeded (3×10^5 cells/mL, 50 μL /well) on basement membrane-like matrix Matrigel® on Ibidi μ -Slides. After treatment with test compounds for 4 h until tubular structures had formed in the control wells, results were documented using a Zeiss Axiovert 135 light microscope. Cell vitality was measured using the MTT assay and was above 75% compared to solvent-treated cells. Experiments were performed in triplicate.

Zebrafish angiogenesis assay

Transgenic zebrafish (*Tg(fli1:EGFP, casper* mutant) were bred at 28 °C.^[16] After fertilization, the eggs were transferred to E3-medium (5 mM NaCl, 0.17 mM KCl, 0.33 mM CaCl, 0.33 mM MgSO_4 , 0.01% methylene blue, pH 7.2), followed by incubation for 24 h. The chorion was manually removed, and the larvae were treated with test compounds or solvent in six-well plates (30 fish per concentration, 5 mL/well) for 48 h. The fluorescent vasculature was documented with a Leica MZ10F and Zeiss AxioCam MRrc. To quantify the angiogenesis, the sub-intestinal vein (SIV) area was measured using *ImageJ* and expressed as means \pm SD with the control set to 100%. The significance of SIV reduction through substance treatment was assessed using one-way analysis of variance (ANOVA), * $P < 0.05$; ** $P < 0.01$; *** $P < 0.001$; **** $P < 0.0001$, with Dunnett’s multiple comparison test (GraphPad Prism 9).

Luciferase-dependent MYB activity assay

Compounds were tested using the HEK-MYB-Luc reporter cell line, which allows a doxycycline-dependent induction of MYB expression and harbors an MYB-dependent luciferase reporter plasmid, as previously described^[17,18]. After 16 h of substance treatment (0.0001-3 μM), luciferase activities were analyzed as described^[11].

RESULTS

The test compounds 2A-R were obtained from 3-methoxyphenol, malononitrile, the corresponding aryl aldehyde, and a cat. amount of Et₃N in acetonitrile [Scheme 1]. Synthesis and analysis of the known compounds 2B, 2O, and 2R were as described^[5,14]. The new compounds 2A, 2C-N, 2P, and 2Q were colorless solids. The structures of the test compounds were confirmed by NMR, IR, and MS analyses. The compounds are racemic mixtures, and no efforts to separate enantiomers were performed. The yields were generally low but acceptable considering the simple one-pot reaction and workup and the commercially available starting compounds [Table 1].

The new propargyl ether derivative 3 was prepared to conduct localization studies of this compound within cancer cells [Scheme 2]. 3-Propargyloxyphenol was obtained from the reaction of resorcinol with 1.2 equiv. propargyl bromide (80% in toluene) in DMF under basic conditions (K₂CO₃)^[19]. Harsher conditions (reflux for 5 h in EtOH) were necessary to synthesize 3 by the described three-component reaction compared with the synthesis conditions of compounds 2A-R. 3 was obtained as an off-white solid in low yields only.

The antiproliferative activity of compounds 2A-R and 3 was evaluated in nine tumor and hybrid cell lines from six entities and compared with previously published data of the known compounds 1A and 1B [Table 2]^[13,20].

The presentation of the cytotoxicity screening results was simplified by determining the average IC₅₀ values of all cell lines and sorting them based on their antiproliferative activity [Table 3]. The halogen atom did not have any major effect on the activity among the compounds with a 3-halo-4, 5-dimethoxyphenyl group (2A, 2B, and 2C). By contrast, in the group of 3, 5-dichloro- to 3, 5-diiodo-4-methoxyphenyl derivatives 2D, 2E, and 2F, a distinct increase in activity was observed from the dichloro compound 2D via the dibromo 2E to the diiodo derivative 2F. Several striking effects were observed in addition to this trend. Comparing the structure of 1C (coumarin-based) and 2F (7-methoxy-4*H*-chromene), a clear increase in antiproliferative activity based on the methoxychromene structure was observed, while the IC₅₀ values of the 4*H*-naphtho(1, 2-*b*)pyran-3-carbonitriles (1A) and the 7-methoxy-4*H*-chromenes (2R) were both in the nanomolar range. Some compounds showed certain tumor cell line-specific activities, surpassing positive controls 1A and 1B. 2C was particularly active against HCT116 p53-deficient colon carcinoma cells, verapamil-treated KB-V1^{vbl} cervix carcinoma cells and MCF-7 breast cancer cells, whereas 2F and 2O were highly active against multidrug-resistant HT-29 colon carcinoma cells. The 1A-analog 2R showed slightly less overall activity but had a much stronger effect on MCF-7 breast cancer cells than 1A. The vinblastine-resistant KB-V1^{vbl} cells were treated with the P-glycoprotein (P-gp) blocker verapamil to identify synergy effects^[21]. Compounds 2I, 2B, 2C, and 2E showed 12-, 14-, 20- and 320-fold lower IC₅₀ values combined with verapamil (1 μM), assuming an inhibition of the efflux pumps increases the substance efficiency by blocked drug removal via the P-gp membrane transporter. A comparison of compounds 2B and 3, prepared for intracellular localization purposes, showed a substantial conformity of activity, indicating a similar mode of action and accumulation behavior in most tumor cell lines. However, compound 2B was more active against verapamil-treated KB-V1^{vbl} cells than against untreated cells and HeLa cells (which is the parent cell line of KB-3-1, from which KB-V1^{vbl} cells are derived), while 3 was more active against HeLa cells and KB-V1^{vbl} cells in the absence of verapamil than against verapamil-treated KB-V1^{vbl} cells.

The most active derivatives 2A-C and 2E-F and the positive control 1A were tested for their toxic effects on non-malignant HDFa cells [Table 3]. The selectivity index (SI) was calculated as a measure of selectivity toward cancer cells compared to non-malignant cells. 2B, 2C, and 2F displayed exceptionally high SI values, highlighting their potential as anticancer drug candidates.

Table 1. Yields of the syntheses of compounds 2A-R

^[a]Means of min. four independent experiments (± SD); ^[b]plus verapamil; ^[c]Köhler et al.^[20]; ^[d]Köhler et al.^[13].

For a more detailed investigation of possible drug mechanisms, compounds 2A-C and 2F were tested for their influence on the cell cycle of 518A2 melanoma cells. FACS analysis at doses of 25 nM revealed a significant G2/M cell-cycle arrest for these compounds and the positive control combretastatin A4 (CA4), but to varying extents [Figure 2].

**Scheme 1.** Reagents and conditions: (i) Malononitrile; aryl aldehyde; cat. Et₃N; MeCN; rt; 3-16 h.**Scheme 2.** Reagents and conditions: (i) cat. piperidine; EtOH; reflux; 5 h; 11%.

Among the compounds 2A-C, the 3-chloro-4, 5-dimethoxyphenyl derivative 2A showed more significant cell-cycle arrest than its 3-bromo and 3-iodo congeners 2B and 2C. However, an opposite effect was observed for the 3, 5-dihalo-4-methoxyphenyl derivatives 2D-F, where the 3, 5-diiodo-4-methoxyphenyl derivative 2F triggered by far the most significant arrest. The analogous 3, 5-dichloro (2D) and 3, 5-dibromo (2E) compounds induced only a slight increase in G2/M phase cells (data not shown). Substance 2F arrested about 74% of cells before or during mitosis and exceeded the C-A4 control. C-A4, 1A, and 1B caused G2/M arrest by microtubule depolymerization, thus preventing the formation of a functional spindle apparatus required for cell division^[7,11,22].

Because of the structural similarity of the new cell cycle arresting compounds 2A-C and 2F to the known tubulin-depolymerizing agent C-A4, the effects on the microtubule cytoskeleton were investigated. Time-dependent imaging of 518A2 melanoma cells was applied to provide insights into the dynamics of the depolymerization process [Figure 3].

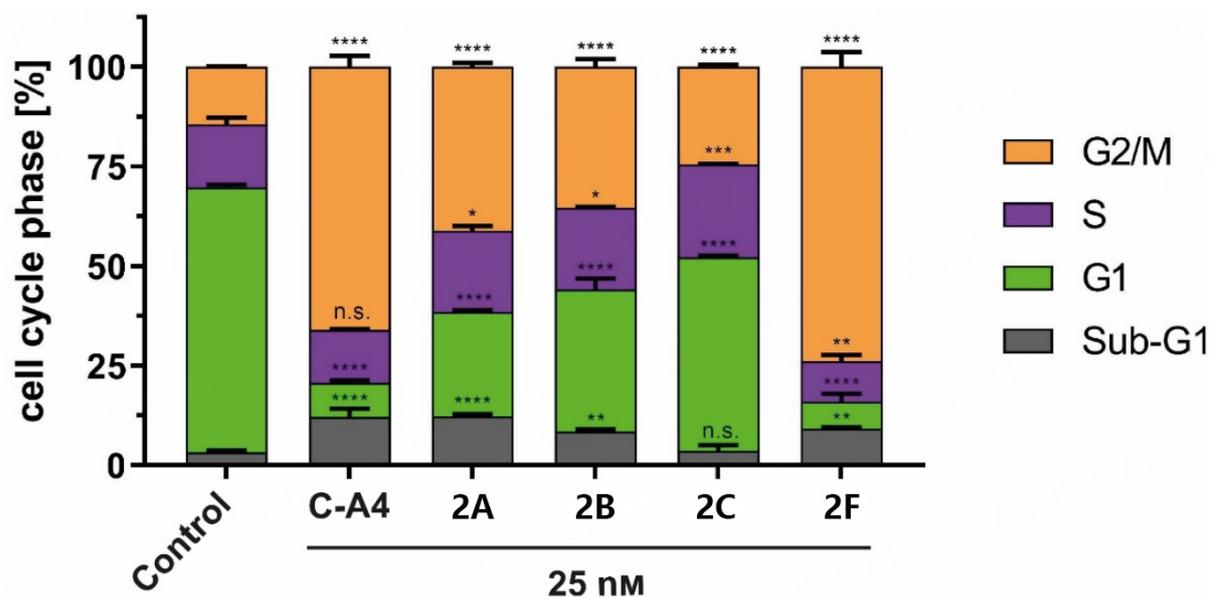

Figure 2. Cell cycle events of 518A2 melanoma cells treated with 2A-C and 2F (25 nM) for 24 h. Positive control (C-A4) and solvent (DMSO) were treated similarly to the substances. Measurements were carried out in triplicate and expressed as means \pm SD with GraphPad Prism. Significance is expressed as n.s. $P > 0.05$; * $P < 0.05$; ** $P < 0.01$; *** $P < 0.001$; **** $P < 0.0001$ against control (two-way ANOVA, with Dunnett's multiple comparison test).

In solvent-treated cells, the tubulin cytoskeleton consists of fine filaments extending throughout the cytoplasm. Upon treatment with test compounds 2A-C and 2F, these filaments were initially shortened and fragmented, leading to their destruction and distribution within the cytoplasm. However, the timing of this disintegration process was highly dependent on the substance used. For instance, 2A-C showed a breakdown of the cytoskeleton after 6 h, whereas 2F led to a change in the microtubule structure after 1 h. A similar effect was observed for the C-A4 control after 30 min, which can be attributed to a faster uptake or higher target affinity.

The alkynyl derivative 3 was designed to investigate compound uptake and localization within tumor cells. The propargyl group allows orthogonal fluorescence labeling with 3-azido-7-hydroxycoumarin using a copper-catalyzed click reaction. After 10 min, a distinct increase in fluorescence was observed within the treated cells, with most of the fluorescence found in the cytoplasm [Figure 4]. This finding suggests an accumulation of 3 in the cytoplasm, supporting the hypothesis that cytoplasmic tubulin is the primary target for 3 and its close analogs used in this study. The conformity of the basic structure and the antiproliferative activity of 3 with compound 2 suggests a similar mechanism.

In addition to antiproliferative and cytotoxic effects, microtubule-destabilizing agents possess additional antitumor properties^[23]. In the case of C-A4, anti-angiogenic and vascular disruptive effects have been demonstrated. In this context, the tube-formation assay is a suitable method to observe the effects on the two-dimensional (2D) vessel structures by EA.hy926 cells^[24]. The inhibition of cell migration and the development of cell-cell junctions (necessary for tube formation) by 2A-C and 2F were investigated [Figure 5]. At 100 nM, all four test compounds showed anti-angiogenic effects on EA.hy926 cells seeded on Matrigel®. The cells could not form a cross-linked 2D structure within 4 h, as with the negative control or at 25 nM substance concentration. Even if cell-cell junctions were formed in isolated cases, most cells agglomerated due to their spatial proximity. In addition, rounding was observed in many cells, as in C-A4 treated cells, presumably because of microtubule-destabilizing effects.

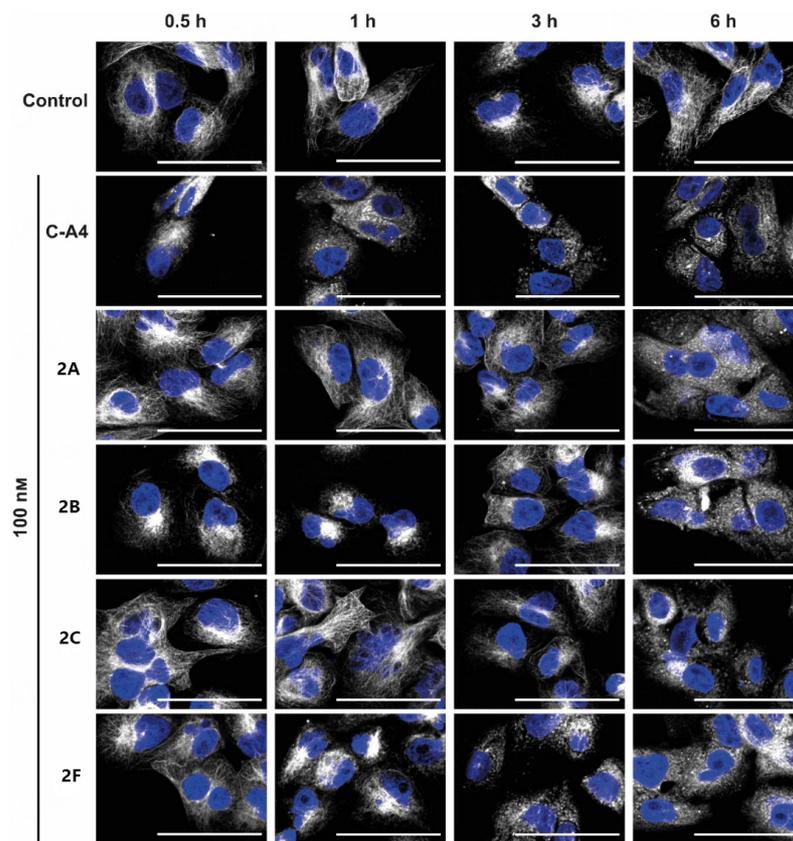

Figure 3. Immunofluorescence images of 518A2 melanoma cells treated with compounds 2A-C; 2F; and CA4 (100 nM) or vehicle (DMSO) for 0.5, 1, 3, and 6 h. Representative images (of two experiments) illustrate stained microtubules (white) and nuclei (blue). The scale bar corresponds to 100 μ m, magnification of 630 \times .

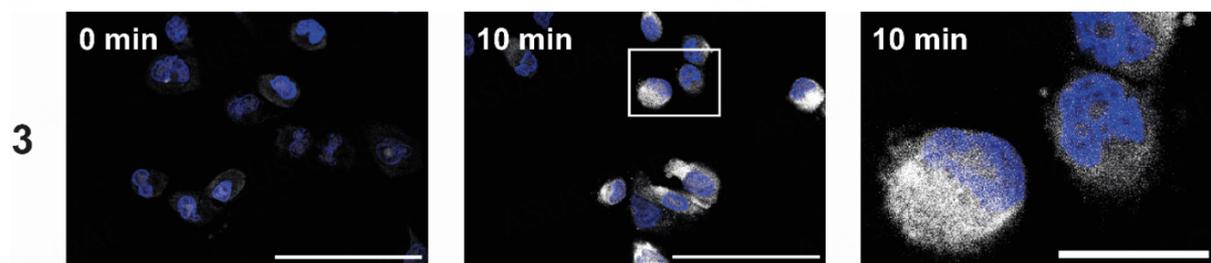

Figure 4. Intracellular localization of 3 (25 μ M) using melanoma cells (518A2) after 10 min. The uptake was visualized using a Cu(I)-catalyzed reaction with 3-azido-7-hydroxycoumarin (white), and the nuclei were counterstained (Nuclear Green, blue). The right image shows the magnified section marked with a white box. The experiment was carried out in duplicate. The scale bar corresponds to 100 μ m (left) or 25 μ m (right), magnification of 630 \times .

The development of blood vessels is based on a complex mechanism with various regulators, which are essential targets for the treatment of tumor growth. Angiogenesis can be seen in the embryonal development of zebrafish larvae, where the SIV can be used to measure anti-angiogenic effects^[25]. After exposure of 24-h-old zebrafish embryos to substances 2A-C and 2F or positive control axitinib for 48 h, we

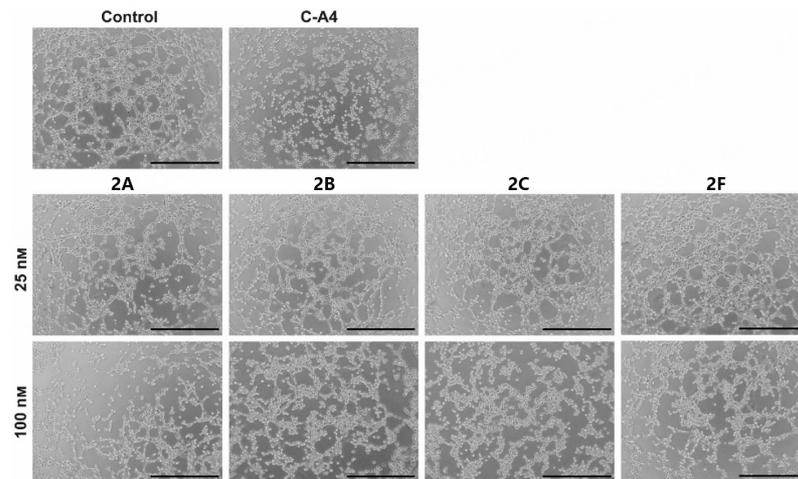

Figure 5. Images show EA.hy926 cells seeded on Matrigel® after 4 h treatment with substances 2A-C; 2F (25, 100 nM); and C-A4 (25 nM) or vehicle (DMSO). Representative images of a min. of two experiments. The scale bar corresponds to 500 μm, magnification of 100×.

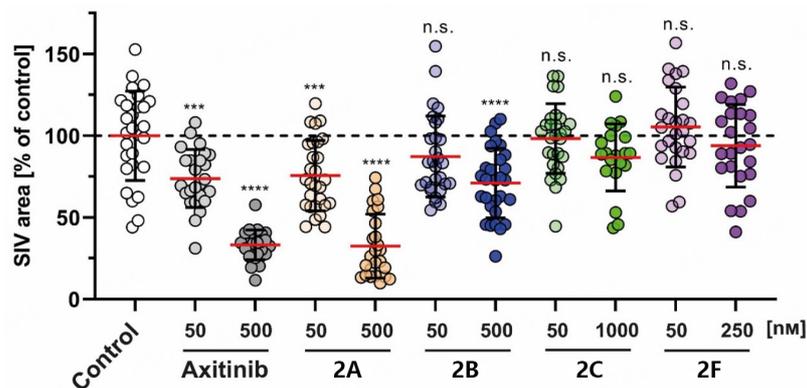

Figure 6. Effects of 2A; 2B (50, 500 nM); 2C (50, 1000 nM); and 2F (50, 250 nM) on the SIV growth of zebrafish larvae (24 hpf) after treatment (48 h). Positive controls used axitinib (50, 500 nM). Negative controls used equivalent amounts of DMSO. The SIV area was quantified using ImageJ and expressed as mean ± SD of at least 20 zebrafish. The significance is expressed as n.s. $P > 0.05$; *** $P < 0.001$; **** $P < 0.0001$ against control (one-way ANOVA, with Dunnett’s multiple comparison test).

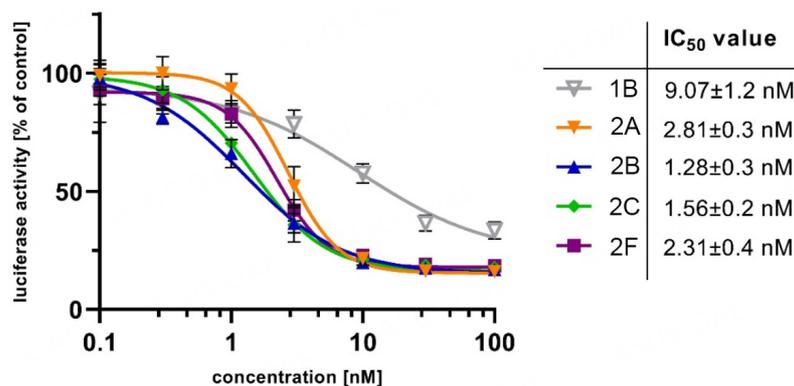

Figure 7. Inhibition of MYB activity in HEK-293 cells containing the reporter plasmid pGL4-5xMRE(GG)-Myc and the expression vector for MYB-2KR, upon treatment with compounds 1B; 2A-C; and 2F (0.1-100 nM) for 16 h. IC₅₀ values were calculated with at least four independent experiments using GraphPad Prism 9.

measured the SIV area and compared it to solvent-treated fish [Figure 6]. Here, 2F showed no significant change in blood vessel growth, and 2F had a toxic effect above 250 nM. 2B and 2C showed no SIV decrease in the tolerated concentration range. However, 2A inhibited angiogenesis to an extent comparable to the known inhibitor axitinib^[26]. This finding suggests a different mechanism of action for 2A, a bimodal compound with selective antiproliferative properties against cancer cells and angiogenesis-inhibiting features.

Due to their structural similarity to the potent MYB inhibitor 1B (data to be published elsewhere), compounds 2A-C and 2F were tested for their MYB-inhibitory activity [Figure 7]. Inhibition of MYB activity by 2A-C and 2F (1.28-2.81 nM) was superior to the inhibition by reference compound 1B (9.07 nM). Because the values are very close, it is challenging to identify a structure-dependent activity trend; however, the activity was in the order 2B > 2C > 2F > 2A.

DISCUSSION

This study's objective was to develop and optimize the lead structures 1A, 1B, and 1C. For this reason, we reduced the size of the benzo[*h*]chromene backbone to a 7-methoxy-4*H*-chromene structure, which led to increased activity. In addition, various phenyl substituents were tested to optimize the lead structure. Initial cytotoxicity studies against nine cancer cell lines confirmed that the C-A4-derived 3-iodo-, 3-bromo-, and 3-chloro-4, 5-dimethoxyphenyl motifs (2A-C) and the analogous 3, 5-diiodo- and 3, 5-dibromo-4-methoxyphenyl derivatives (2E-F) are excellent pharmacophores with selectivity against malignant cells. Only the 3, 5-dichloro-4-methoxyphenyl stands out with only micromolar IC₅₀ values. Interestingly, differences in the specificity for HeLa cells, derived KB-V1^{Vbl} cells, and KB-V1^{Vbl} cells treated with the P-gp inhibitor verapamil were observed for the close analogs 2B and 3. 2B is more active against the parent HeLa cells than against the vinblastine-resistant KB-V1^{Vbl} cells. In contrast, the addition of verapamil strongly sensitized the KB-V1^{Vbl} cells to treatment with 2B, leading to a higher activity of 2B against verapamil-treated KB-V1^{Vbl} cells than against HeLa cells. A comparable hypersensitizing effect of verapamil was observed for KB-V1^{Vbl} cells treated with 2A, 2C, and 2I, surpassing their activity against HeLa cells, which may have explanations beyond mere P-gp inhibition by verapamil. The hypersensitivity effects of resistant P-gp-overexpressing cancer cells upon verapamil treatment were reported (e.g., based on disrupted energy homeostasis upon ATP depletion), which might lead to enhanced anticancer activity combined with other active drug candidates such as 2A-C (but not 2F) compared with their activity against related cell lines without (overexpressed) P-gp transporter^[27]. For unknown reasons, compound 3 showed only slightly reduced activity against KB-V1^{Vbl} cells when combined with verapamil than against HeLa cells.

In addition, a reversal of P-gp- and BCRP-mediated resistance was documented for the 3-chloro-4-fluoroanilino-derivative gefitinib, an approved EGFR inhibitor^[28,29]. However, the new 3-chloro-4-fluorophenyl derivative 2J appears to be a substrate of P-gp. Among the remaining fluorophenyl derivatives, 2, 3-difluorophenyl 2M and 2, 5-difluorophenyl 2N were identified as P-gp substrates, while 3, 5-difluorophenyl 2O and 3, 4, 5-trifluorophenyl 2P showed no dependence on P-gp, indicating a considerable influence of the fluoro-substitution pattern on the activity against P-gp-overexpressing cells (also compared with the effects of 3, 4-difluorophenyl derivative 2I mentioned above).

Because P-gp tends to have relatively hydrophobic substrates with aromatic rings, substituting methoxy groups with halogen atoms may already have an efflux-attenuating effect due to increased hydrophilicity^[30]. Treatment with P-gp modulators can provide more significant cytotoxicity by reducing effective concentrations by 100-fold (paclitaxel) or 351-fold (vinblastine) in MDR colorectal cancer SW620/Ad300 cells^[31,32].

The test compounds were obtained and tested as racemic mixtures. An increase in activity might be achieved by the separation of the enantiomers of the active derivatives and evaluating the separated enantiomers via MTT assay to identify any enantiomers which are more active or less active than the mixture. Instead of separating racemic mixtures, chiral synthetic procedures (e.g., using chiral organic bases instead of piperidine or triethylamine) might be applied to generate enantiopure compounds for biological testing.

The evaluation of the four most active test compounds (2A-C and 2F) revealed a correlation between the rate of microtubule destruction and the cell-cycle arrest in the G₂/M phase in 518A2 melanoma cells. Compared with C-A4, 2F showed almost equal efficacy and led to early morphological changes in the microtubules (i.e., within 1 h). Localization of the structurally related alkynyl derivative 3 in the cytosol confirmed the accumulation near the cytoplasmic target. As previously demonstrated for the controls 1C and C-A4, the influence on angiogenesis (essential for tumor growth and metastases) was investigated for the test substances^[13,33]. Using the 2D tube-formation assay, the concentration-dependent impairment of cell motility and intercellular junctions could be demonstrated, probably due to the damaged tubulin cytoskeleton. Nevertheless, this model can only partially simulate the complex mechanisms of blood vessel formation, which is why the substances were also tested for anti-angiogenic effects in zebrafish. This assay offers the possibility of estimating toxicity in a vertebrate and investigating the direct influence on the angiogenesis of the so-called SIVs. Surprisingly, only 2A showed a significant decrease in SIV growth, which occurred independently of its antiproliferative and microtubule-associated effects. As a third potential target, the inhibitory effect on the transcription factor MYB was tested and revealed the enhancement by three- to seven-fold compared to the previously discovered inhibitor 1B^[11]. Overexpression of MYB in leukemias and various solid cancers such as colon and ER-positive breast cancers contributes to their development and thus represents a valuable target^[34-39]. The rapid development of resistance to selective chemotherapeutics (e.g., kinase inhibitors, including RAF inhibitors) is a problem that can be overcome by addressing various targets by drugs with dual or multimodal mechanisms of action such as dual BRAF/HDAC inhibitors^[40,41]. In this context, compound 2A represents a promising scaffold that can be used for further optimization and advanced stages of preclinical anticancer testing.

DECLARATIONS

Authors' contributions

The manuscript was written through the contributions of all authors.

Conceptualization: Köhler LHF, Klempnauer KH, Schobert R, Biersack B

Methodology: Köhler LHF, Reich S, Yusenko M, Biersack B

Formal analysis: Köhler LHF, Yusenko M, Biersack B

Abstract

Tumor Necrosis Factor-Related Apoptosis-Inducing Ligand, also called apo-2 ligand (TRAIL/Apo-2L), is a cytokine that triggers apoptosis by binding to TRAIL-R1 (DR4) and TRAIL-R2 (DR5) death receptors. Apoptosis occurs through either the extrinsic or intrinsic pathway. The administration of recombinant human TRAIL (rhTRAIL) or TRAIL-receptor (TRAIL-R) agonists promotes apoptosis preferentially in cancerous cells over normal cells *in vitro*; this phenomenon has also been observed in clinical studies. The limited efficacy of rhTRAIL in clinical trials could be attributed to drug resistance, short half-life, targeted delivery issues, and off-target toxicities. Nanoparticles are excellent drug and gene delivery systems characterized by improved permeability and retention, increased stability and biocompatibility, and precision targeting. In this review, we discuss resistance mechanisms to TRAIL and methods to overcome TRAIL resistance by using nanoparticle-based formulations developed for the delivery of TRAIL peptides, TRAIL-R agonists, and TRAIL genes to cancer cells. We also discuss combinatorial approaches of chemotherapeutic drugs with TRAIL. These studies demonstrate TRAIL's potential as an anticancer agent.

Keywords: TRAIL, cancer cells, nanoparticles, apoptosis, nanomedicine

INTRODUCTION

Cancer is the aberrant growth of cells capable of invading and metastasizing to other body parts. It is one of the leading causes of death, with approximately 10 million deaths expected globally by 2020, according to

the World Health Organization. There are various treatment options, including surgery, chemotherapy, targeted therapy, radiation therapy, immunotherapy, and hormone therapy^[1]. One branch of chemo/radiotherapy is targeted therapy that targets the tumor alone (for example, tumor vasculature or intracellular organelles, leaving the surrounding cells unaffected). This approach results in precise treatment of the tumor alone, reducing the drawbacks associated with the process^[2]. Among the many targeted therapies is Tumor Necrosis Factor (TNF)-Related Apoptosis-Inducing Ligand, also known as Apo-2 ligand (TRAIL/Apo-2L).

TRAIL/Apo-2L is a type II transmembrane protein of the TNF superfamily of ligands. TRAIL binds to TRAIL-Receptor 1/Death Receptor 4 (TRAIL-R1/DR4), TRAIL-Receptor 2/Death Receptor 5 (TRAIL-R2/DR5), TRAIL-Receptor 3/Decoy Receptor 1 (TRAIL-R3/DcR1), and TRAIL-Receptor 4/Decoy Receptor 2 (TRAIL-R4/DcR2). It also binds to osteoprotegerin (OPG), which is soluble^[3,4]. TRAIL selectively promotes apoptosis in cancer cells by the extrinsic (receptor-mediated) and intrinsic (mitochondria-mediated) pathways^[5-7]. Apoptosis is a well-ordered and well-coordinated cellular process that maintains homeostasis in physiological and diseased conditions. In the extrinsic pathway, trimerization and subsequent receptor activation occur upon binding of TRAIL to its respective DR4 and DR5 death receptors, which leads to Death Inducing Signaling Complex (DISC) formation^[8]. The intrinsic pathway includes mitochondrial outer membrane permeabilization (MOMP) and apoptosome formation^[9,10]. Intrinsic and extrinsic mechanisms activate the executioner caspases (caspase-3/7), which cause DNA degradation and result in cell death. Here, we elaborate on the TRAIL-induced apoptotic pathways, resistance mechanisms exhibited by cancer cells to TRAIL therapy, and current approaches to overcome the resistance and utilize TRAIL as a potential cancer therapeutic agent.

TRAIL and TRAIL receptors

TRAIL is a transmembrane protein belonging to the type II superfamily of ligands, coded by the gene TNFSF10 positioned at 3q26 on human chromosome number 3. In its monomeric form, TRAIL comprises 281 amino acids with a molecular mass of approximately 32.5 kDa. A loop formed by 12-16 amino acids near the N-terminus is critical for binding of TRAIL to its receptors and its cytotoxic activity^[11]. TRAIL expression as a homotrimer is maintained by a zinc ion bound to cysteines necessary for its stability, solubility, and bio-activity^[12]. TRAIL associates with DR4, DR5, DcR1, and DcR2, composed of a cysteine-rich domain (CRD), a transmembrane domain, and a death domain (DD), of which CRDs are extracellular, and DDs are intracellular [Figure 1]. The presence or absence of these domains characterizes TRAIL receptor structure and function. The type I transmembrane proteins (DR4 and DR5) are TRAIL agonists, whereas DcR1 and DcR2 are antagonists. DR4 and DR5 include an intracellular DD responsible for apoptosis induction. Unlike DR4 and DR5, DcR1 and DcR2 cannot trigger apoptosis due to the lack of a DD in the former and the presence of a non-functional truncated DD in the latter^[13]. TRAIL also binds to osteoprotegerin (OPG), a receptor secreted as a soluble dimer. TRAIL binding to OPG occurs with low affinity. Other TNF family members bind with greater affinity to OPG, activating bone remodeling pathways^[14].

TRAIL-induced apoptosis: extrinsic and intrinsic pathways

DR4 and DR5 are cell surface death receptors that include a cytoplasmic DD. In the extrinsic apoptosis pathway, TRAIL binds to its respective death receptors, resulting in the recruitment via homotypic interactions of the Fas-associated death domain (FADD), an adapter protein to their intracellular death domains. FADD then recruits initiator caspase-8 and caspase-10 to its death effector domain (DED) region, forming the multi-protein DISC. The activation of caspases-8 and -10 leads to cleavage and activation of effector caspase-3, -6, and -7, resulting in cell death [Figure 2]^[15-18].

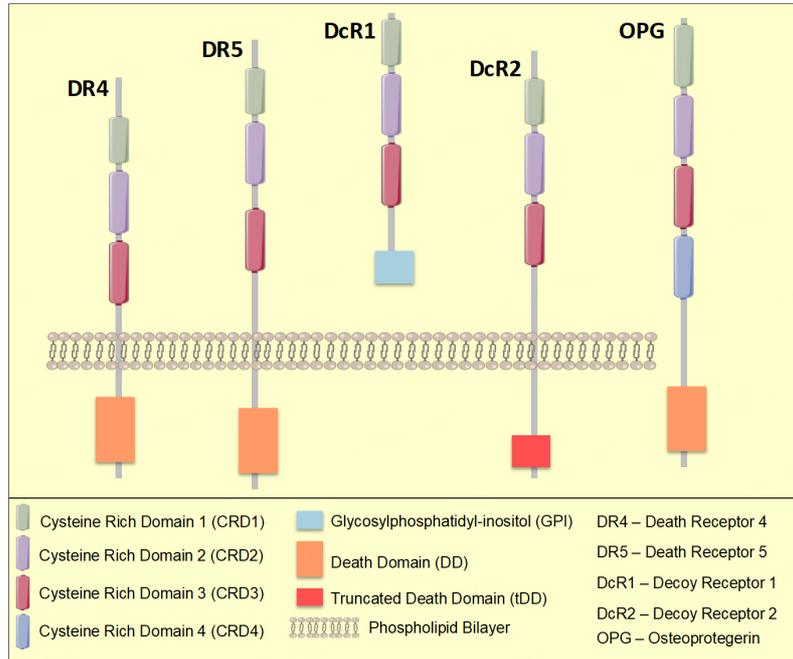

Figure 1. Structure of TRAIL receptors. TRAIL binds to death receptors DR4 (TRAIL-R1) and DR5 (TRAIL-R2) at the extracellular domains. The death domains (DD) on the cytoplasmic side lead to recruitment of other DD containing proteins that lead to apoptosis. TRAIL decoy receptors lack the cytoplasmic DD or have a truncated DD which fails to trigger apoptosis. OPG is a soluble receptor of TRAIL with low affinity.

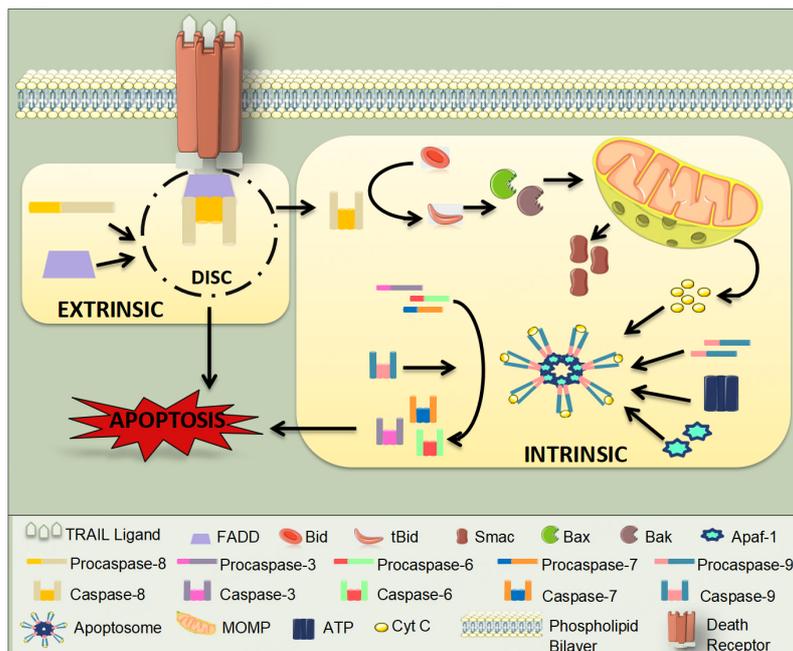

Figure 2. TRAIL-Induced Apoptosis: Cross talk between the Extrinsic and Intrinsic Pathways. TRAIL binding to death receptors leads to its trimerization on the cell surface and formation of DISC. Caspase-8 gets activated in the DISC and triggers the extrinsic pathway of apoptosis. Activated caspase-8 also leads to activation of the mitochondrial pathway or intrinsic pathway of apoptosis resulting in activation of caspase-9 and executioner caspases-3 and -7. Several checkpoints of apoptosis, like increase in anti-apoptotic proteins (IAPs), Bcl-xL etc are also represented at various stages of apoptosis. ATP: Adenosine triphosphate; DISC: Death Inducing Signaling Complex; FADD: Fas-associated death domain; MOMP: mitochondrial outer membrane permeabilization.

DNA damage, loss of survival factors, and cell cycle checkpoint defects trigger the intrinsic apoptosis pathway; the extrinsic and the intrinsic pathways are interrelated. In the intrinsic pathway, there is a cleavage of BH3-interacting domain death agonist (Bid) to truncated Bid (tBid)^[19] in the presence of activated caspase-8 that brings about tBid translocation to the mitochondria and causes MOMP through activation of B-cell lymphoma 2 (Bcl-2) associated x-protein (Bax) and Bcl-2 homologous antagonist/killer (Bak). Mitochondria subsequently release cytochrome C^[20] and mitochondria-derived activator of caspase (Smac)^[21] into the cytosol, where cytochrome C interacts with adenosine triphosphate (ATP) and apoptotic peptidase-activating factor-1 (Apaf-1) to associate with initiator pro-caspase-9 into a signaling complex. This is an apoptosome where caspase-9 becomes activated and activates effector caspases-3, 6, and 7 to trigger apoptosis [Figure 2]^[8,10,22].

TRAIL AND CANCER THERAPY

TRAIL is a potential candidate for targeted therapy in cancer due to its selective induction of apoptosis via death receptor-4 and -5 expressed on the surface of target cells. The two primary treatment methods are the administration of recombinant TRAIL protein (small peptide or full-length protein) or TRAIL-receptor (TRAIL-R) agonists^[23]. However, the short half-life of TRAIL protein in serum and the inefficacious administration of the agonists *in vivo* have hampered its therapeutic use^[24]. Moreover, many cancerous cells have been discovered to be TRAIL-resistant^[25]. Several groups have tried to decipher the resistance mechanisms in various cancers and various ways to sensitize cells to TRAIL^[26-30]. Several explanations have been offered for TRAIL resistance, some of which are discussed below.

Mechanisms of cancer cell resistance to TRAIL

TRAIL receptor expression and status

TRAIL induces apoptosis by binding to DR4 and DR5 death receptors. Loss of DR4 and DR5 expression because of constitutive endocytosis results in TRAIL resistance and is observed in some breast cancer cells. The comparison of six cell lines of human breast cancer (SKBR3, MDA-MB-468, MCF7, MDA-MB-231, T47D, and BT474) treated with recombinant human TRAIL (rhTRAIL) and antibodies against death receptor 4 (DR4) and death receptor 5 (DR5) for the apoptotic response showed the loss of expression of DR4 and DR5 in some cell lines that accounted to their antibody resistance. The derangement of clathrin-dependent endocytosis signaling elements (adapter protein 2 and clathrin) by pharmacologic inhibitors like phenyl arsine oxide, PAO (a general inhibitor of endocytosis), and chlorpromazine (an inhibitor of clathrin-mediated endocytosis) restored the death receptors' expression on the cell surface, making TRAIL-resistant cells susceptible to TRAIL-induced apoptosis [Figure 3]^[31]. In another study, DR5-B, a receptor-selective TRAIL variant, caused independent internalization of DR5; the comparison of the kinetics of TRAIL-mediated internalization and subsequent DR4 and DR5 recycling in sensitive (HCT116 and Jurkat) and resistant (HT-29 and A549) tumor cell lines of various origins revealed that TRAIL stimulated DR4 and DR5 receptor internalization in a dose-related manner. This expression of the receptor on the cell surface was restored after TRAIL internalization and elimination observed by the addition of cycloheximide and brefeldin A, which hindered the process, suggesting that death receptors undergo constitutive endocytosis^[32].

Apart from receptor endocytosis, mutations in death receptors^[33] and expression of decoy receptors lacking the functional intracellular DD may play a key role in apoptosis induced by TRAIL^[34]. DcRs, especially decoy receptor 4, might compete for binding to TRAIL or may disrupt trimerization of the death receptors when co-expressed on the same cell^[35]. Post-translational modifications of the receptors also influence the sensitivity of the cells to TRAIL. O-glycosylation of TRAIL-R2 was found to control cell sensitivity to TRAIL^[36], while N-glycosylation of TRAIL-R1 increased its apoptotic efficacy^[37].

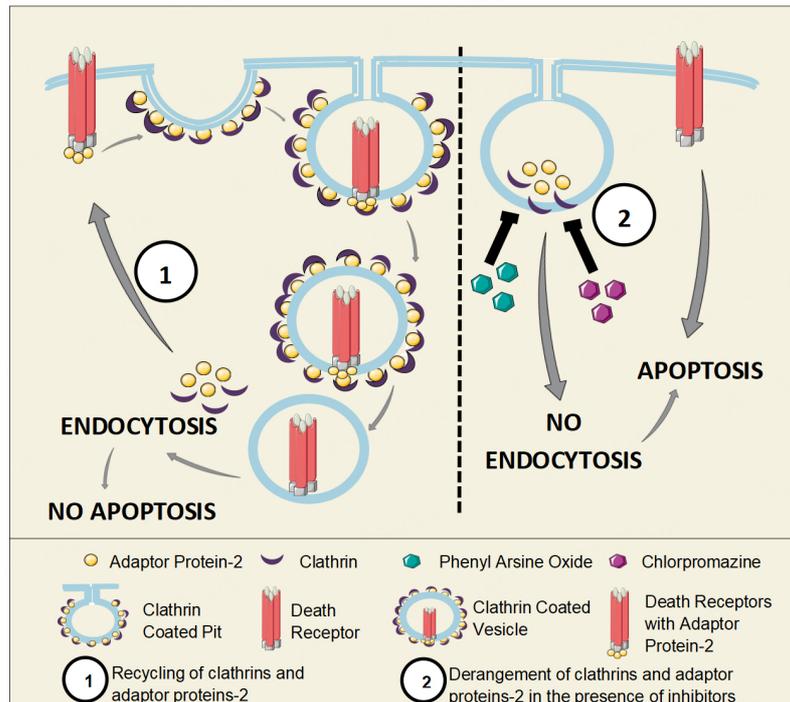

Figure 3. TRAIL Receptor endocytosis. Death receptors are constitutively recycled by clathrin mediated endocytosis. Lack of death receptors leads to TRAIL resistance. After endocytosis of the receptor, clathrin and adaptor proteins (AP2) are recycled to the cell membrane to continue with more endocytosis of the receptors. Pharmacological inhibitors like PAO or chlorpromazine prevent the arrangement of clathrin and AP2 at the vesicles, hence prevent endocytosis, resulting in persistent expression of the death receptors at the surface and increased apoptosis.

FADD defects and caspase-8

Cancer cells require FADD (an adapter protein) and caspase-8 for apoptosis mediated by DR4 and DR5. FADD recruitment by TRAIL results in the activation of pro-caspase-8, DISC formation, and apoptosis [Figure 2]. Defective FADD proteins do not allow TRAIL to recruit FADD and inhibit initiator caspases activation, resulting in TRAIL resistance. Experiments on FADD-deficient^(-/-) mouse embryonic fibroblasts revealed that DR4 uses a FADD-independent apoptotic mechanism^[38]. In another study, the transfection of mouse DR4/5, human DR4, or human DR5 into FADD-deficient mouse embryonic fibroblast cells conferred resistance to TRAIL-mediated cell death. However, they were vulnerable to TRAIL-mediated death when heterozygous FADD^(+/-) or FADD^(-/-) cells were reconstituted with a FADD retroviral construct^[39].

Overexpression of cFLIP

The non-functional pro-caspase homolog and an anti-apoptotic protein known as cellular Flice-like inhibitory protein (cFLIP) is crucial in controlling TRAIL-induced apoptosis^[40]; cFLIP binds to FADD and prevents recruitment of caspase-8/-10 to DISC, thereby inhibiting their activation [Figure 2]^[41-43]. In one study, DR5-positive and TRAIL-resistant IGR cells expressed enhanced TRAIL sensitivity with the downregulation of cFLIP. In TRAIL-sensitive and RPM-EP melanoma cells expressing DR5, TRAIL-mediated apoptosis inhibition was observed; due to the expression of cFLIP, TRAIL-R1 negative melanoma cells could not undergo apoptosis induced by TRAIL^[44]. A study on epithelial-mesenchymal transition (EMT) showed that high expression of cFLIPs in the exogenous region caused resistance to apoptosis triggered by TRAIL, and deletion of cFLIPs was sufficient to overcome TRAIL resistance in carcinoma cell lines; when ML327 (an isoxazole-based small chemical) was induced into an immortalized mouse mammary epithelial cell line, there was a partial reversal of TGF- β -induced EMT^[45].

CARP-dependent degradation of active caspase-8

CARPs are caspase-8 and -10-associated ring proteins that belong to a class of apoptotic inhibitors that bind to and negatively control caspases. Active caspases are essential in cancer cell death. The overexpression of CARPs in cancerous cells leads to the degradation of active caspases, which in turn causes a rise in the levels of cFLIP and, subsequently, TRAIL resistance. In one study, parental DLD1 human colon cancer cells developed TRAIL resistance after siRNA-mediated suppression of caspase-8 expression. When caspase-8 protein expression was restored through stable transfection, the DLD1/TRAIL-R cell line regained its TRAIL sensitivity, suggesting that the DLD1/TRAIL-R cells' TRAIL resistance may be due to low levels of caspase-8 protein expression. A 30%-50% increase in CARP-1 and -2 mRNA levels was observed in DLD1/TRAIL-R compared to a DLD1 cell line^[46]. In another study, RNA interference-mediated silencing of CARPs resulted in H460 human lung cancer cell sensitization to death ligands due to activation of caspases; caspase-8 and -10 cleavage in reaction to the ligands were elevated in H460 cells after CARP-1 or -2 siRNA treatment and TNF- α /cycloheximide or TRAIL exposure^[47].

Loss of Bax/Bak function (Bax Mutations)

The Bcl-2 antagonist/killer (Bak), and Bcl-2-associated X-protein (Bax), members of the Bcl-2 family, are core regulators of the intrinsic apoptotic pathway. Bax and Bak oligomerize and form pores in the mitochondrial outer membrane through which cytochrome C is released [Figure 2]. Cytochrome C triggers the intrinsic pathway^[48-50]. A study of TRAIL-resistant leukemia cells lacking Bax and Bak showed no release of apoptogenic proteins from mitochondria. When Bax was transduced into Bax/Bak deficient leukemic cells, they exhibited sensitivity to TRAIL^[51]. Cells lacking functional Bax treated with the chemopreventive agent sulindac and other non-steroidal anti-inflammatory agents completely deactivated the apoptotic pathway in human colorectal cancer cells. Loss of Bax did not affect TRAIL-induced caspase-8 activation or Bid cleavage but inhibited the mitochondrial release of Smac/Diablo and cytochrome C^[52].

Bcl-2/Bcl-xL overexpression

B-cell lymphoma 2 (Bcl-2) and B-cell lymphoma-extra large (Bcl-xL) are the anti-apoptotic Bcl-2 family proteins that inhibit mitochondria-dependent cell death pathways by hindering the movement of Bax from the cytosol to mitochondria [Figure 2]. In response to TRAIL treatment, apoptosis was reduced by Bcl-2 overexpression, causing TRAIL resistance^[53-55]. Combining TRAIL with the protein synthesis inhibitor cycloheximide improved the sensitivity of the vector control cells to the triggering of apoptosis in SH-EP neuroblastoma cells^[56]. Overexpression of Bcl-2 and Bcl-xL resulted in the reduction of TRAIL-induced cleavage of caspase-8 and Bid, cleaved blockage of caspase-3, -7, and -9 in non-small-cell lung cancer (NSCLC) and the cleavage of caspase substrates like PARP in glioblastoma, neuroblastoma, and breast cancer cell lines^[57]. Bcl-2 overexpression inhibited TRAIL-induced Bax activation, loss of MOMP, and cleavage of caspase-8 into p43/p41 and p18 active fragments, cleavage of Bid, and processing of the caspase-3 p20 fragment into the p17/p12 active fragments in SH-EP neuroblastoma cells^[58]. Bcl-xL overexpression was found in T47D and SKBR3 breast cancer cell lines resistant to TRAIL. Silencing Bcl-xL increased TRAIL-induced activation of caspase-3/7 in the estrogen receptor-positive cell line T47D and the HER2-amplified cell line SKBR3^[59].

Overexpression of inhibitor of apoptosis proteins

Caspase activation is crucial for apoptosis. The family of anti-apoptotic proteins includes baculovirus repeat domain-containing proteins, also called inhibitor of apoptosis proteins (IAPs). These proteins consist of a (BIR) domain and a zinc ion binding site that coordinates protein-protein interaction and regulates the

activity of caspases. IAPs cause TRAIL resistance by inhibiting the activation of caspases downstream [Figure 2], thus blocking cell death^[60-62]. In one study, when rhTRAIL alone or combined with Smac mimetics GDC-0152 or birinapant was used to treat non-iodine-retaining follicular thyroid carcinoma (FTC) cell lines, FTC133 and TT2609-bib2 resulted in FTC cell lines sensitization to apoptosis induced by TRAIL through cIAP1/2 degradation^[60]. In another study, TRAIL sensitivity was restored in resistant cells and primary leukemic blasts upon treatment with XIAP inhibitors. The impacts of numerous anti-leukemic drugs could be used to overcome TRAIL resistance in leukemic cells via XIAP downregulation^[63].

Reduction in smac/diablo release

A mitochondrial protein called the second mitochondria-derived activator of caspases (Smac) or direct inhibitor of apoptosis-binding protein with low pI (Diablo) binds to XIAP and eliminates the inhibitory effect of XIAP on caspase activation. Reduced release of Smac/Diablo causes a rise in the concentration of IAPs, inhibiting apoptosis^[64-66]. SH122, a Smac-mimetic, significantly sensitized prostate cancer cell lines (DU145 and LNCaP) to TRAIL^[67]. TRAIL-resistant lines associated with higher levels of XIAP released more Smac/Diablo than TRAIL-sensitive cells^[68].

Activation of various mitogen-activated protein kinases/nuclear factor-kappa B subunits

Mitogen-activated protein kinases (MAPK) and nuclear factor-kappa B (NFkB) show opposing activities concerning TRAIL-induced cell death. The association of truncated Bid (tBid) with mitochondria to release cytochrome C is inhibited by the MAPK pathway. NFkB activation results in elevated levels of the anti-apoptotic proteins Bcl-xL and XIAP, leading to TRAIL resistance. NFkB suppression decreased resistance to TRAIL in various cancers^[69,70]. Lovastatin, an NFkB inactivator, sensitized human glioblastoma cell lines (A172 and U87) that were TRAIL-resistant. The sensitization to TRAIL is attributed to increased levels of DR5 and dysregulation of the MAPK pathway^[71]; c-Rel, an NFkB subunit regulates TRAIL-induced apoptosis in pancreatic ductal adenocarcinoma cells and transfection with siRNA against c-Rel induced apoptosis in TRAIL-resistant cells^[72].

Akt pathway activation

The phosphatidylinositol 3-kinase-protein kinase B (PI3K-Akt) pathway is an intracellular signal transduction mechanism that stimulates cell growth and angiogenesis upon extracellular signals. Akt overexpression causes cancer cells to become highly resistant to TRAIL, while Akt knockdown causes resistant cancer cells to become more susceptible^[73]. Inhibiting the Akt pathway with LY294002 (a PI3K inhibitor) or Akt knockdown sensitized TRAIL-resistant T47D breast cancer cells through cleavage of PARP^[74]. Treatment of TRAIL-resistant MB-IT R and NALM-24 R (acute lymphoblastic leukemia cells) with LY294002 and TRAIL resulted in the activation of pro-caspase-8 and caspase-3^[75]. Phosphatase and tensin homolog (PTEN), a tumor suppressor, negatively regulated the Akt pathway; PTEN-deficient cells were more resistant to TRAIL than PTEN(+/+) mouse prostate epithelial cells. Overexpressing a mutant PTEN made PTEN-positive cells resistant to TRAIL, suggesting that PTEN plays a part in TRAIL sensitivity. Overexpression of mutant PTEN showed increased resistance to TRAIL in T47D breast cancer cell lines resistant to TRAIL^[74]. In SH-EP neuroblastoma cells, silencing the PI3K subunits p110 α and p110 β caused a selective downregulation in Akt phosphorylation. Combining TRAIL and PI103 (a PI3K inhibitor) led to an increase in broken caspases-8, -3, and -9, the conversion of Bid into tBid, and a decrease in the protein levels of Mcl-1, XIAP, survivin, cFLIPL, and cFLIPS^[58]. El-Diery and colleagues described the role of PI3-Akt signaling in TRAIL- and radiation-induced gastrointestinal apoptosis. Activation PI3/Akt pathway protected gut cells from TRAIL-induced apoptosis but not from IR-induced apoptosis^[76]. Akt activation reduced the sensitivity of epithelial ovarian cancer cells to TRAIL. PI3K or Akt inhibitors sensitized TRAIL-resistant SKOV3ip1 and COV2 cells. In TRAIL-resistant cells, low levels of Bid were observed due to overexpression of Akt^[77].

Studies of TRAIL in cancer clinical trials

Because TRAIL triggers apoptosis specifically in cancer cells as opposed to tumor cells, several formulations of TRAIL protein and agonistic antibodies were tried in animal models and in clinical trials. Recombinant human TRAIL preferably promoted programmed cell death in cancerous cells over normal cells and exhibited minimal to no toxicity when injected systemically in animals^[78]. This finding resulted in several treatment trials of biological agents targeting TRAIL receptors, including agonistic antibodies to DR4, DR5, and rhTRAIL^[79] [Table 1]. The clinical evaluation of TRAIL and its agonistic antibodies as anticancer treatments selectively killed cancerous cells^[94]. Despite promising results in preclinical studies, TRAIL-based therapies carry several disadvantages.

A randomized phase II study showed that a dual DR4 and DR5 agonist called dulanermin did not enhance the response of NSCLC patients to standard chemotherapy (paclitaxel, carboplatin, and bevacizumab)^[95]. In a phase II study, the combination of mapatumumab with carboplatin and paclitaxel in advanced NSCLC patients showed no clinical benefit in unselected patients. No improvements were seen in disease control rates, overall survival, or median progression-free survival upon adding mapatumumab^[96]. Tigatuzumab, a TRAIL-R2 agonist and a humanized monoclonal antibody with sorafenib, was tested in patients with advanced hepatocellular carcinoma in a phase II randomized study of safety and tolerability. Tigatuzumab with sorafenib (compared with sorafenib alone) in individuals with advanced hepatocellular cancer did not fulfill its primary efficacy endpoint, i.e., time-to-progression, although tigatuzumab with sorafenib is well tolerated in hepatocellular carcinoma^[97]. Tigatuzumab did not increase the effectiveness of carboplatin/paclitaxel in patients with advanced NSCLC^[98]. In a phase II clinical trial, Tigatuzumab with nanoparticle-albumin-bound paclitaxel appeared to enhance apoptosis in patients with triple-negative breast cancer^[99]. Conatumumab, a fully human monoclonal IgG1 antibody that activates DR5 in combination with 5-fluorouracil, leucovorin, oxaliplatin (mFOLFOX6) and bevacizumab (bev), was tested for safety, tolerability, and efficacy in previously-untreated metastatic colorectal cancer patients. In the primary treatment of metastatic colorectal cancer patients, conatumumab with mFOLFOX6/bev showed no better efficacy than the same chemotherapy with a placebo^[100].

The limited therapeutic potential is due to TRAIL resistance in several cancers^[101]. The development of nanotechnology appears to be a promising strategy with several nano-based formulations of TRAIL and agonistic antibodies that help increase the circulating half-life and biodistribution of TRAIL in addition to its improved targeted delivery to tumor tissue.

NANOPARTICLE-BASED DRUG AND GENE DELIVERY SYSTEMS

Nanoparticles (NPs), also known as ultrafine particles, are a wide class of materials with sizes ranging between 1 to 100 nanometers. At present, a wide variety of nanoparticles serve as drug and gene delivery systems due to improved permeability and retention effect, increased stability and biocompatibility, and precision targeting^[102]. Nanoparticles can be classified into many types, one among them being organic and inorganic nanoparticles based on the addition of organic and inorganic elements, respectively [Figure 4]. There is another type of nanoparticles, the hybrid nanoparticles, the conjugates of organic and/or inorganic materials. These hybrid nanoparticles help to overcome the drawbacks of the conventional nanoparticulate delivery systems, such as low water solubility, non-specific targeting, and poor therapeutic outcomes^[103]. In the below sections, we will give an overview of nanoparticle-based TRAIL therapy in different cancers. Nanoparticle formulations were tested in delivering recombinant TRAIL protein along with the TRAIL gene and the TRAIL receptor agonists in various models.

Table 1. TRAIL-R agonists/recombinant TRAIL in clinical trials

TRAIL-R agonists/ recombinant TRAIL	Mechanism	Cancer type	Clinical trials	References
AMG 951 (Dulanermin) (recombinant human TRAIL)	DR4 and DR5 activation	NSCLC	Phase-II	NCT00508625 ^[80]

Nanoparticle-mediated TRAIL drug delivery

The various nanoparticles formulated to deliver TRAIL protein are discussed in detail below and [Table 2](#).

Carbon-based nanoparticles

Carbon nanotubes, particularly single-wall carbon nanotubes (SWCNTs), are used in many physical and medicinal applications owing to their substantial flexibility, high mechanical resilience, and hydrophobicity. SWCNTs quickly diffuse in an aqueous medium. TRAIL-based SWCNT nanovectors showed greater efficiency than TRAIL alone in the induction of cancer cell death. Nanovectorization of TRAIL entails tagging TRAIL to SWCNTs to mimic membrane-bound TRAIL. His-tagged TRAIL was fused to SWCNT-pyrene-butyric acid N-hydroxysuccinimide ester (PSE)-polyethylene glycol (PEG) to produce functional nanoparticles. The pro-apoptotic potential of these SWCNT-PSE-PEG-TRAILs (also called NPTs) is increased by almost 20-fold in various human tumor cell lines (HCT116- colon adenocarcinoma cells, H1703-squamous NSCLC cells, HepG2-hepatocarcinoma cells, and HUH-hepatoblastoma cells) due to increased levels of caspase-8 and enhanced DISC formation^[104].

Another form of carbon-based nanoparticles is made from graphene, an allotrope of carbon. A graphene-based co-delivery nanosystem composed of graphene oxide, a PEG linker, and a furin-cleaved peptide

Table 2. Nanoparticle-based formulations of TRAIL protein for the treatment of various cancers

Nanoparticle type	Cancer type	Mechanisms to enhance TRAIL sensitivity	Reference
Single-walled carbon nanotubes	Colon adenocarcinoma, Squamous NSCLC, hepatocarcinoma, hepatoblastoma	Increased caspase-8 levels and enhanced DISC formation	[104]
Graphene nanosystem with doxorubicin	Lung & colon adenocarcinomas	Increased death receptor expression	[105]
Graphene quantum dots	Colon cancer	Increased pro-caspase-8 activation	[107]
Nanogold particles	Non-small cell lung cancer	Increased DR5 expression levels	[108]
Gold nanoparticles	Non-small cell lung cancer	Increased Drp1 recruitment to the mitochondria; Dysfunctioning of mitochondria	[109]
Silver-cysteine particles coated with polyethylene glycol	Colon cancer	Increased Bax and cleaved PARP; Decreased Bcl2 protein	[110]
Silver nanoparticles	Glioblastoma	Activation of death receptors; Increased caspase function	[111]
Double-edged lipid nanoparticles with doxorubicin	Hematological & epithelial carcinoma	Downregulation of FLIP and XIAP	[112]
LUV-TRAIL with doxorubicin	Breast cancer	Enhanced caspase-8 activation	[113]
LUV-TRAIL	Histiocytic lymphoma	Increased Bid, cleaved PARP, caspase-8, -3 & -10 levels; Enhanced DISC recruitment	[114]
LUV-type liposomes	Non-small cell lung cancer	Activation of caspase-8 & -3	[115]
LUV-TRAIL	Colon cancer	Increased caspase levels	[116]
Lipid nanoparticles	Hepatic fibrosis	Increased pro-apoptotic levels; Decreased uPA levels	[117]
Lumazine synthase protein cage nanoparticles	Epidermoid cancer	Intrinsic & extrinsic pathway activation	[118]
Ferumoxytol comprised of iron oxide nanoparticles	Colorectal cancer	Upregulation of DR5 levels; Overexpressed cleaved PARP	[120]
Magnetic ferric oxide nanoparticles	Glioma	Increased cleaved caspase-3 & cleaved PARP levels Increased pro-apoptotic potential	[121]
Maghemite nanoparticles	Breast & lung cancers	Increased pro-apoptotic potential Activation of caspase-3; Downregulation of Bcl-2 & BclxL; Upregulation of Bax & Bad; Increased death receptor levels	[122]
Iron oxide magnetic nanoparticles with actein	Non-small cell lung cancer	Activation of caspase-3; Downregulation of Bcl-2 & BclxL; Upregulation of Bax & Bad; Increased death receptor levels Increased pro-apoptotic potential	[123]
Iron oxide nanoclusters	Breast cancer	Increased pro-apoptotic potential Enhanced caspase-3 and -8 levels	[124]
SPION/TRAIL nanocomplex hydrogels	Glioblastoma	Enhanced caspase-3 and -8 levels Decreased survivin expression	[128]
NCL-240-loaded polymeric micelles	Ovarian cancer	Decreased survivin expression Increased caspase-3 & -7 levels; Decreased surviving & Bcl-2 levels	[129]
PEI-PLGA nanoparticle	Breast cancer	Increased caspase-3 & -7 levels; Decreased surviving & Bcl-2 levels Increased caspase-8 levels	[130]
Polymeric nanoparticles	Glioblastoma	Increased caspase-8 levels Increased caspase activity	[131]
Micellar nanoparticle with doxorubicin	Colorectal cancer	Increased caspase activity Increased caspase-3 & cleaved PARP levels	[132]
PCEC nanoparticles with curcumin	Colon cancer	Increased caspase-3 & cleaved PARP levels	[135]

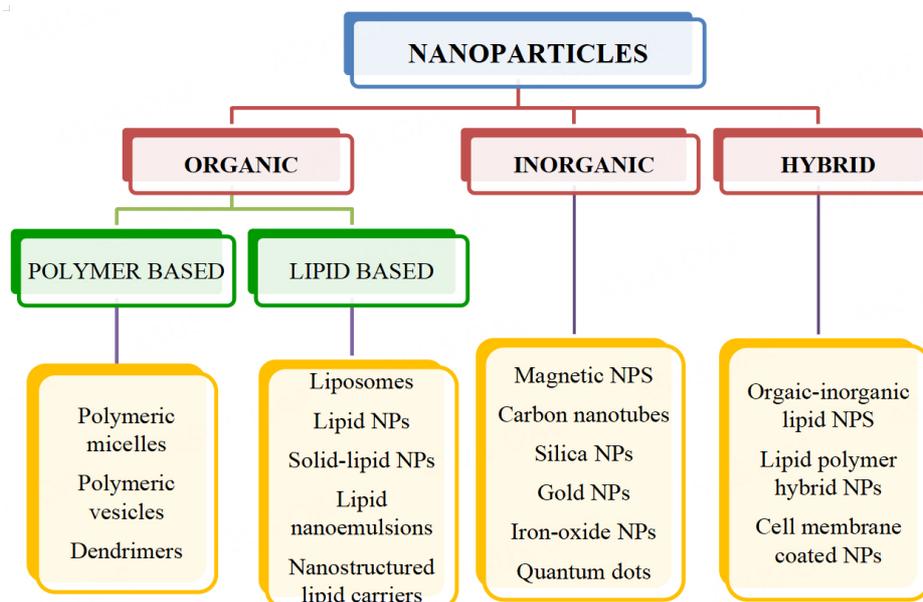

Figure 4. Types of Nanoparticles. Nanoparticles are classified based on the material used to prepare the various particles, organic, inorganic or hybrid. Different kinds of these formulations are represented here. NPs: Nanoparticles.

encapsulated with TRAIL and doxorubicin (Dox) resulted in the efficient release of TRAIL and Dox to their sites of action by digesting the peptide linker by furin with the increased expression of death receptors in lung and colon adenocarcinoma cells^[105].

Docking studies of TRAIL nanovectorization were performed using graphene nanoflakes as a potential cargo for TRAIL. These studies showed that when adsorbed on graphene, TRAIL self-assembling and TRAIL affinities enhanced efficacy towards the targeted cancer cell. TRAIL bound to DR4 and DR5 more effectively when transported by graphene nanoflakes^[106]. The synthesis of a novel nanohybrid system, sTRAIL (TRAIL fused with crystalline bacterial cell surface layer (S layer) protein), combined with graphene quantum dots or GQDs elevated the functional stability of TRAIL by improving pro-caspase-8 activation and mitochondria-dependent cell death in doxorubicin-pretreated human colon cancer cells (HT-29) when compared to S-TRAIL alone. The GQDs appeared to offer a surface for the S-TRAIL to self-assemble, facilitating TRAIL monomer oligomerization and enhancing apoptosis^[107].

Gold nanoparticles

Nanogold-TRAIL complexes are nanogold coated with TRAIL protein. In the NSCLC microenvironment, M2 macrophages exhibit anti-inflammatory and pro-tumorigenic effects, while M1 macrophages exhibit antitumorigenic effects. Elimination of the M2 macrophages aids tumor destruction; hence, these M2 macrophages serve as potential targets. *In vitro* targeting M2 macrophages (derived from THP-1 monocytes) with nanogold-TRAIL particles led to 30-fold higher cytotoxicity. This enhanced cytotoxicity is attributed to increased surface-level DR5 expression and changes in the O-glycosylation pattern of the death receptor^[108]. AuNPs (other nanoparticles made of gold) enhanced TRAIL sensitivity through dynamin-related protein 1 (Drp1)-mediated apoptotic and autophagic mitochondrial fission in NSCLC cells. AuNPs with TRAIL exhibited greater potency to promote apoptosis in NSCLC cells than TRAIL alone due to a rise in mitochondrial recruitment of Drp1 that led to dysfunctioning of mitochondria and induction of autophagy^[109].

Silver nanoparticles

Experiments with silver-cysteine nanoparticles and TRAIL-conjugated silver nanoparticles coated with PEG (AgCTP NPs) showed that AgCTPNPs exhibited apoptotic effects in HT-29 colon cancer cell line *in vitro* with substantial differences in the expression levels of Bax, Bcl-2, and cleaved PARP protein^[110]. TRAIL-conjugated AgNPs (TRAIL-AgNPs) induced death receptor activation in T98 G TRAIL-Resistant (TR) glioblastoma cells. The combination of TRAIL to silver nanoparticles (AgNPs) increased the functioning of caspases in TR glioblastoma cells, but TRAIL and AgNPs alone did not. Moreover, TRAIL-AgNPs-treated TR cells exhibited lower CHK1 expression than TRAIL-treated cells^[111].

Lipid-based nanoparticles

Membrane-bound TRAIL in lipid nanoparticles, also known as large unilamellar vesicles (LUV)-TRAIL showed increased cytotoxic activity *in vitro* compared to soluble recombinant TRAIL in human sarcoma cells. LUV-TRAIL and anticancer drugs showed increased cytotoxicity against human sarcoma cells. LUV-TRAIL combined with flavopiridol (FVP) reduced human sarcoma cells' long-term clonogenic survival and triggered apoptosis by downregulating FLIP and XIAP and activating caspases, compared to soluble TRAIL (sTRAIL) alone^[112]. LUV-TRAIL loaded with doxorubicin (Dox) in the liposomal lumen, known as LUVDOX-TRAIL, improved cytotoxic potential by enhanced caspase-8 activation in the tumor xenograft model of breast cancer cells^[113].

LUV with tethered recombinant TRAIL (rTRAIL) was prepared and tested against U937 histiocytic lymphoma cells. LUV-TRAIL-induced cell death on U937 cells by causing cleavage of caspases faster than sTRAIL. Levels of Bid, cleaved PARP-1, caspase-8, -3, and -10 increased and enhanced recruitment of DISC upon treatment with LUV-TRAIL^[114].

LUV-type liposomes coated with human sTRAIL were also used to treat NSCLC. Treatment of A549 cells with LUV-TRAIL activated caspases-8 and -3, compared with sTRAIL. LUV-TRAIL combined with antitumor medications such as CDK inhibitors, FVP, and SNS-032 further sensitized A549 NSCLC cells to LUV-TRAIL-induced apoptosis^[115]. In HCT-116 and HT29 colon cancer cells, DR5 was more effectively activated by TRAIL-coated lipid nanoparticles (LUV-TRAIL) than by sTRAIL. When cells were exposed to various types of TRAIL, the pan-caspase inhibitor Z-VAD-FMK completely blocked cell death, suggesting that LUV-TRAIL-induced cell death is a caspase-dependent mechanism^[116]. Lipid nanoparticles embedded with recombinant human TRAIL gave rise to significant apoptosis in hepatic fibrosis. Levels of the pro-apoptotic proteins were highly expressed, and the anti-apoptotic protein (uPA) levels were significantly decreased by a self-made drug carrier pPB-SSL with rhTRAIL protein^[117].

Lumazine nanoparticles

A multiple ligand-displaying nanoplatfrom, lumazine synthase protein cage nanoparticle isolated from *Aquifexaeolicus* (AaLS) with TRAIL and EGFR binding affibody (EGFRAfb) via a SpyTag/SpyCatcher protein-ligation system (to form AaLS/TRAIL/EGFRAfb) exhibited TRAIL-mediated apoptosis in TRAIL-resistant and EGFR-overexpressing A431 epidermoid cancer cells *in vitro* through synergistic activation of the extrinsic and intrinsic apoptotic pathways^[118].

Albumin nanoparticles

Albumin-bound NP technology was modified slightly to create TRAIL/Dox human serum albumin (HSA)-NPs, loaded with Dox and TRAIL nanoparticles. Using HCT116 colon cancer cells, the synergistic cytotoxicity and apoptotic activity of TRAIL/Dox HSA-NPs were assessed. Results from tumor tissues demonstrated that TRAIL/Dox HSA-NPs significantly increased apoptosis, while Dox HSA-NPs did so at a slightly lower level^[119].

Magnetic/Iron oxide nanoparticles

Reactive oxygen species play critical roles in TRAIL-induced apoptosis. Iron oxide nanoparticles (iron oxide NPs) with ferumoxytol as its primary component spontaneously unite to form nanocomplexes with TRAIL/Apo-2L (NanoTRAIL). An investigation of the cell viability of HCT-116 (TRAIL-sensitive), SW-480 (TRAIL-intermediately resistant), and HT-29 (TRAIL-resistant) after treatments with saline, Apo-2L, iron oxide NPs, and NanoTRAIL resulted in a more modest TRAIL/Apo-2L response in HT29 than with other cell lines; there was a more significant anti-colorectal cancer tumor effect than with TRAIL/Apo-2L treatment alone in HT-29 cells with the upregulation of DR5 expression increased TRAIL/Apo-2L sensitivity and significant apoptosis. TRAIL sensitivity in the TRAIL/Apo-2L-resistant HT29 cells was due to activating JNK and increasing the expression of cleaved PARP^[120].

Treating U251 cell-derived glioma xenografts with TRAIL conjugated to magnetic ferric oxide nanoparticles resulted in increased apoptosis, decreased tumor volume, and more prolonged survival. Conjugation of TRAIL to NP showed higher apoptosis levels than free recombinant TRAIL by increasing caspase-3, -8, and cleaved PARP levels^[121]. Maghemite nanoparticles coated with TRAIL protein (CO-TRAIL@NPs-NH and NH-TRAIL@NPs-CO) enhanced apoptosis in human breast (MDA-MB-231) and lung (H1703) carcinoma cell lines compared to free TRAIL by increasing the pro-apoptotic potential^[122].

Iron oxide (Fe₃O₄) magnetic nanoparticles combined with actein, a triterpene glycoside isolated from the rhizomes of *Cimicifuga foetida*, contributed to apoptosis in NSCLC. The induction of apoptosis in NSCLC cells resulted in the stimulation of the caspase-3 signaling pathway, which was identified by a decrease in levels of the anti-apoptotic proteins Bcl2 and Bcl-xL, increase in the pro-apoptotic signals Bax and Bad, and elevated levels of death receptors^[123]. Interestingly, iron oxide nanoclusters (NCs) exhibited a synergistic effect with the TRAIL receptor. The engraftment of TRAIL onto NCs increased pro-apoptotic potential via nanoparticle-mediated magnetic hyperthermia (MHT) or photothermia in MDA-MB-231 wild-type and TRAIL receptor-deficient cells^[124].

When compared to free recombinant TRAIL, magnetic ferric oxide nanoparticles enhanced apoptosis activity against several human glioma cells. There were NP-TRAIL molecules at the tumor site and a notable increase in glioma cell apoptosis in U251-derived glioma xenografts, which were examined for their effects on programmed cell death, tumor volume, survival, rhodamine-tagged NPs, and xenografts^[125].

Polymer-based nanoparticles

Elastin-like polypeptides (ELPs) are potential thermosensitive biopolymers and polymeric drug delivery systems. The ability to induce apoptosis was three times greater when RGD-TRAIL was expressed coupled with ELPs than when RGD-TRAIL was expressed alone. When a single dose of the RGD-TRAIL-ELP nanoparticle was administered intraperitoneally, the COLO-205 tumor xenograft model showed nearly total tumor shrinkage. Protein electrophoresis revealed a 3.4-fold increase in the RGD-TRAIL-ELP trimer content than RGD-TRAIL^[126]. P(RGD) proteinoids (where RGD is a tripeptide) comprising arginine, glycine, and aspartic acid, and proteinoid nanocapsules (NCs) were synthesized for targeted tumor therapy. TRAIL-P(RGD) nanocapsules induced cytotoxicity in CAOV-3 ovarian cancer cells more so than hollow P(RGD) nanocapsules which are atoxic in CAOV-3 cells. Dox-encapsulated P(RGD) nanocapsules also showed significant cytotoxicity in CAOV-3 cells^[127].

SPION/TRAIL nanocomplex hydrogels, an MHT-mediated TRAIL release system with positively-charged TRAIL and hydrophobic superparamagnetic iron oxide nanoparticles (SPIONs) complexed with negatively-charged poly(organophosphazene) polymers via ionic and hydrophobic interactions, is used for combination therapy for multiple mild MHT and simultaneously MHT-induced TRAIL release. Hyperthermia restored the sensitivity of intrinsic TRAIL-resistant human glioblastoma (U87 MG) cancer cells and enhanced TRAIL-induced apoptosis by activating caspases-3 and -8^[128].

A multifunctional nanoparticle system with a combination of a pro-apoptotic drug (NCL-240), TRAIL, and anti-survivin siRNA was used to test anticancer effects in various cancer cells. The NCL-240-loaded polymeric micelles (mNCL-240) and the combination of NCL-240-loaded, TRAIL-conjugated polymeric micelles (mNCL-240-loaded/TRAIL) showed significantly more cytotoxicity than single-drug formulations in all tested cell lines. Treating A2780 and U-87 MG cells with transferrin polymer micelles (Tf PM) improved the cytotoxic activity of NCL240 formulations, especially at higher doses. It was observed that mSurvivin (anti-survivin siRNA-S-S-PE mixed micelles) significantly downregulated survivin expression in ovarian cancer cells, A2780, compared to free anti-survivin siRNA and scrambled siRNA^[129].

Hyaluronic acid (HA)-decorated polyethylenimine-poly(D,L-lactide-co-glycolide) (PEI-PLGA) nanoparticle (NP) (also known as HA/PPNP) with gambogic acid (GA) and TRAIL plasmid (pTRAIL) showed synergistic effects against breast cancer cells. Increased caspases-3 and -7 were observed in MDA-MB-231 cells treated with GA-HA/PPNPs, pTRAIL-HA/PPNPs, and GA/pTRAIL-HA/PPNPs by 2.39-, 1.18-, and 4.55-fold, respectively, after treatment of cells for 24 h compared to HA/PPNPs alone. Increased caspase-8 levels were also observed with pTRAIL-HA/PPNPs and GA/pTRAIL-HA/PPNPs by 1.47- and 1.55-fold, respectively, compared to untreated controls. Cells treated with GA/pTRAIL-HA/PPNPs showed the lowest expression levels of survivin and Bcl-2 anti-apoptotic proteins^[130]. The polymeric nanoparticle-engineered human adipose-derived stem cells (hADSCs) overexpressing TRAIL served as drug-delivery vehicles for targeting and eliminating glioblastoma multiforme (GBM) cells *in vivo*. The co-culturing of plasmid human TRAIL-laden nanoparticles (NPs/pTRAIL)-engineered hADSCs with patient-derived malignant glioma xenograft cells (D-270 MG) resulted in significant apoptosis and death in glioma cells (compared to controls) through an increase in levels of caspase-8 and the caspase cascade^[131]. The delivery of micellar nanoparticles self-assembled from a biodegradable cationic copolymer P(MDS-co-CES) with TRAIL and Dox showed synergistic cytotoxic effects in TRAIL-resistant SW480 colorectal cancer cells. In cells treated with nanoparticles, in the presence of ZVAD-FMK, a pan-caspase inhibitor gave rise to TRAIL sensitivity, suggesting that apoptosis depends on caspase activity^[132].

N-[(2-hydroxy-5-nitrophenyl)amino] carbonothioyl-3, 5-dimethylbenzamide (DM-PIT-1)-loaded polyethylene glycol and phosphatidylethanolamine (PEG-PE) micelles modified with TRAIL were used against TRAIL-resistant U87MG cells. In contrast to PEG-PE micelles loaded with DM-PIT-1, drug-free PEG-PE micelles modified with TRAIL are not cytotoxic for U87MG cells. The synergistic effect and the significantly increased cell death were caused by the extra attachment of TRAIL to drug-loaded micelles. Compared to groups treated with typical DM-PIT-1-loaded micelles, all groups treated with TRAIL-modified DM-PIT-1-loaded PEG-PE micelles significantly reduced viability in U87MG cells^[133]. PEGylated heparin, poly-L-lysine nanoparticles with TRAIL called TRAIL-PEG-NPs, had apparent apoptotic effects when administered *in vitro* and *in vivo*. TRAIL-PEG-NPs induced time-dependent apoptotic cell death and efficiently suppressed mean tumor growth with mean tumor growth inhibition^[134]. The hydrophobic drug curcumin (Cur) encapsulated into the inner core of biodegradable poly (ε-caprolactone)-poly (ethylene glycol)-poly (ε-caprolactone) nanoparticles with TRAIL protein (TRAIL-Cur-NPs) was evaluated for their efficacy to treat HCT116 human colon carcinoma cells. Compared to the free TRAIL + Cur group, protein

expression of cleaved caspase-3 and cleaved PARP was slightly higher in the TRAIL-Cur-NPs group. The overexpression of DR4 and DR5 synergistically increased the anticancer efficacy of TRAIL and Cur.^[135] TRAIL-modified and cabazitaxel (CTX)-loaded polymer micelles (TRAIL-M-CTX) were synthesized to test the anticancer efficacy against TRAIL-resistant MCF7 breast cancer cells. Synergistic effects of apoptosis were observed in MCF7 cells treated with TRAIL-loaded nanoparticles than in CTX and TRAIL alone treated cells^[136].

Nanoparticle-mediated TRAIL gene delivery

Several studies described the use of TRAIL protein-based nanoparticles. These trials have been successful but are limited by the relatively short half-life of the ligand, targeted delivery to the tumor cells, and proper presentability to the death receptors on the membrane. Hence, novel approaches have been attempted, one of which is delivering the TRAIL gene to the tumor cells instead of the protein^[137]. This section summarizes studies of TRAIL gene-based nanoparticles [Table 3].

Magnetic/Iron oxide nanoparticles

The TRAIL gene combined with polyethyleneimine-coated magnetic iron oxide nanoparticles (also known as polyMAG-1000) triggered significant apoptosis in MCF-7 breast cancer cells^[138].

The transfection of the TRAIL gene with polyethyleneamine-coated polyMAG-1000 combined with anticancer drug cisplatin/cis-diamminedichloroplatinum(II) (CDDP) triggered apoptosis in A2780/DDP ovarian cancer cells. Compared to TRAIL gene transfection or CDDP therapy alone, more apoptosis was seen in the presence of the medication. Cytochrome C release and the caspase-9 cleavage pathway were linked to the triggering of apoptosis in A2780/DDP cells^[139].

GBM is among the most aggressive types of brain cancer. The successful delivery of TRAIL-encoded plasmid DNA into human T98G GBM cells with chitosan-polyethylene glycol-polyethyleneimine copolymer and CTX-coated iron oxide nanoparticles successfully induced a three-fold increase in apoptosis compared to control cells^[24].

A nanosystem for magnetofection was used to create magnetic nanoparticles carrying the TRAIL gene and chitosan. In a melanoma pulmonary metastatic mouse model, the mouse melanoma cell line B16F10 was injected, and the mice were monitored for metastatic tumor formation in the lungs. These animals were then given a systemic injection of the abovementioned nanoparticles through the tail vein. Nanoparticles reaching the lungs were activated to express the TRAIL gene by an external magnetic field applied at the rib cage. There was a significant increase in tumor cell death and suppression of the development of metastatic melanoma^[140]. In another study, the authors constructed a Fe₃O₄-PEI-plasmid complex (FPP) in which positively-charged PEI altered iron oxide nanoparticles to enable them to carry the negatively-charged plasmid pACTERT expressing TRAIL. *In vitro* and *in vivo* apoptosis of SACC-83 adenocystic carcinoma cells was successfully induced by FPP-mediated TRAIL gene transfer.

A substantial increase in apoptosis was observed in transfected SACC-83 cells. An analysis of anticancer properties of the magnetic complex-TRAIL in mice showed significantly smaller tumor size after transfection than the control groups^[141].

Gold nanoparticles

The combination of the secretable trimeric Tumor Necrosis Factor-Related Apoptosis-Inducing Ligand (stTRAIL) gene and PEI-capped gold nanoparticles (AuNPs) increased the inhibition of cell proliferation

Table 3. Nanoparticle-based formulations of TRAIL gene for the treatment of various cancers

Nanoparticle type	Cancer type	Mechanisms to enhance TRAIL sensitivity	Reference
PEI-coated superparamagnetic iron oxide nanoparticles with cisplatin	Ovarian cancer	Cytochrome-C release and caspase-9 cleavage	[139]
Chitosan magnetic nanoparticles	Melanoma	Activation of caspase-3	[140]
PEI-capped gold nanoparticles	Hepatoma	Increased stTRAIL's mRNA and protein levels; Increased caspase-8 and -3 levels	[142]
Zein nanoparticles	Liver cancer	Increased p53 expression; Decreased MMP-2 expression	[143]
NIR light absorbing conjugated polymer nanoparticles	Breast cancer	Increased caspase-8 cleavage	[144]
Poly(beta-amino ester) nanoparticles	Liver cancer	Increased DR5 expression	[145]
Triazine modified PAMAM dendrimer	Osteosarcoma	Increased caspase-3, -7, cleaved PARP levels	[149]
RRPHC polymeric nanoparticles	Melanoma	Increased caspase-9 & -3 levels	[150]
Poly(beta-amino ester) nanoparticles	Lung cancer	Increased DR4 & DR5 expression levels	[151]
RRPHC nanoparticles	Colorectal cancer	Increased cleaved caspase-9 & -3 levels Increased levels of cleaved caspase-3 & -9 levels	[152]
PEI-R8 heparin nanogel	Colon cancer	Increased levels of cleaved caspase-3 & -9 levels	[153]
γ -PGA/Mo β -CD-SSPEI pDNA nanocomplexes	Colon & cervical cancers	Increased DR5 & cleaved PARP levels	[154]
PEI-CD/Ad-Dox/pDNA supramolecular nanoparticles	Ovarian cancer	Increased apoptotic protein levels	[155]
LCPP nanoparticles	Hepatocellular carcinoma	Increased DR5 expression phosphorylation	[157]
Lipid-Protamine-DNA nanoparticles		Decreased mTOR phosphorylation; Increased AMPK-alpha	[158]
Cationic albumin-pegylated nanoparticles	Glioma	Increased cleaved p17 fragment; Increased caspase-3 levels	[160]

and promoted apoptosis in heat-shocked hepatoma cells; there was increases in the levels of stTRAIL mRNA and protein and caspases-8 and -3^[142].

Zein nanoparticles

Zein is a protein derived from maize that is prolamine-rich and is used as a nanocarrier because of its distinct structure, physicochemical characteristics, and self-assembly process. The growth rate and cell viability of HepG2 liver tumor cells treated with TRAIL-loaded zein nanoparticles (ZNPs) were lower than untreated cells in a concentration-dependent manner. Treatment with TRAIL genes packaged into ZNPs resulted in less MMP-2 expression in liver homogenates than untreated ones^[143].

Nano-polymers

Conjugated polymer nanoparticles (CPNs) that absorb near-infrared light were developed to remotely control and induce TRAIL-mediated apoptotic signaling to boost apoptosis in TRAIL-resistant cancer cells^[144]. In response to heat shock, the promoter of a heat shock protein initiated transcription of the TRAIL gene; as a result, breast cancer cells expressed the TRAIL protein, activating the TRAIL-mediated death signaling pathway. The CPNs simultaneously produce W-7 (a calmodulin antagonist) which promotes caspase-8 cleavage and increases cancer cell death. *In vitro* and *in vivo* tests revealed that CPNs/W-7/pTRAIL has a considerable synergistic therapeutic effect on breast cancer and is barely toxic when exposed to near-infrared light. In HepG2 cancer cells, poly(beta-amino ester) nanoparticles (PBAE NPs), engineered with a cDNA sequence coding a secretable TRAIL protein or sTRAIL, initiated apoptosis by increased DR5 expression on the cell surface and a 40-fold increase in cell death, reprogramming liver cancer cells to produce TRAIL protein^[145]. The combination of positively-charged polymer, PEI-modified Fe₃O₄ magnetic

nanoparticles, and negatively-charged pACTERT-EGFP through electrostatic interaction resulted in a new magnetic nanovector (pACTERT-TRAIL) with antitumor properties in cell lines and xenograft models of oral squamous cell carcinoma^[146].

Polyamidoamine (PAMAM) dendrimers are distinctive nanostructures and are effective non-viral carriers because of their highly branched, three-dimensional structure with high loading capacity and lack of toxicity. Modifying G4 and G5 PAMAM dendrimers with alkyl carboxylate-PEG and cholesterol triggered apoptosis in colon cancer cells *in vitro* and *in vivo*. *In vivo*, there was a significantly higher therapeutic index of the plasmid TRAIL in modified PAMAM dendrimer (pTRAIL) than in unmodified PAMAM. Cells treated with the PAMAM G4 derivative coupled with alkyl-PEG and cholesterol (F5-G4) and TRAIL (F5-G4-TRAIL) and PAMAM G5 derivative with alkyl-PEG and cholesterol (F5-G5) and TRAIL (F5-G5-TRAIL) demonstrated 20.1% and 24.14%, of cell death, respectively^[147].

The combination of D- α -tocopheryl polyethylene glycol 1000 succinate-b-poly (ϵ -caprolactone-ran-glycolide), also known as TPGS-b-(PCL-ran-PGA) (a biodegradable diblock copolymer), PEI, and TRAIL showed anticancer effects *in vitro* and *in vivo* in HeLa cells. SCID mice carrying HeLa tumor xenografts showed increased cytotoxicity when treated with nanoparticles loaded with TRAIL^[148]. Triazine, a molecule with DNA binding capacity, modified on a PAMAM dendrimer tagged with green fluorescence protein and TRAIL reporter gene (G5-DAT66/pTRAIL complex), was constructed and treated against an osteosarcoma cell line (MG-63). Higher levels of apoptosis were observed in cells treated with dendrimer and TRAIL complexes than in cells treated with dendrimer or TRAIL alone, with increased levels of caspase-3, -7, and cleaved PARP^[149]. The design of core-shell ternary systems consisting of fluorinated polymers (PFs) binding with a plasmid (pDNA) and a negatively-charged multifunctional RRP (arginyl-glycyl-aspartic acid (RGD)-cell-penetrating peptide (R8)-PEG-sodium hyaluronate/(RGD-R8-PEG-HA) shell, also known as RRP/PF/pDNA (RRPHC) ternary complex or HA (sodium hyaluronate) shell, also known as HA/PF/pDNA (HAC) ternary complex for the delivery of pUNO1-mTRAIL (mouse TRAIL) plasmid was successful in causing apoptosis in B16F10 mouse melanoma cell line. Transfection with the complexes containing mTRAIL significantly inhibited the growth of the B16F10 cells and induced elevated apoptosis effect with increased expression levels of pro-apoptotic proteins (cleaved caspase-9 and cleaved caspase-3). The RRPHC/mTRAIL complexes induced a comparable apoptosis effect higher than that of HAC/mTRAIL ternary complexes^[150].

Several human cancer cell cultures can be transfected *in vitro* by DNA-containing polymeric nanoparticles based on PBAEs, leading to cell death. Recombinant human TRAIL (rhTRAIL) was not as successful as the PBAE/TRAIL-DNA therapy in killing H446 lung cancer cells, which also demonstrated high levels of DR4 protein expression, high levels of DR5, and low levels of DcR1 and DcR2 expression^[151]. According to a study on the anticancer activity of the spontaneous nucleus-targeting core PF33/hTRAIL, HAC/hTRAIL, and RRPHC/hTRAIL complexes on HCT116 colorectal cancer cells, the TRAIL protein was significantly more highly expressed in the groups treated with PF33/hTRAIL and RRPHC/hTRAIL than in the groups treated with HAC/hTRAIL. The expression of cleaved caspase-9 and -3 proteins showed similar results, suggesting that the hTRAIL is responsible for apoptotic action^[152]. A novel PEI-RRRRRRR (R8)-heparin (HPR) nanogel with a plasmid containing human TRAIL gene (HPR/phTRAIL) showed higher levels of cleaved caspase-3 and -9 in HCT-116 colon cancer cells. HPR nanogel delivered phTRAIL into HCT-116 cells to express hTRAIL protein and significantly induced apoptosis^[153].

Carbon-based nanoparticles

In HCT8/ADR and HeLa cells, the cytotoxic activity of pDNA nanocomplexes containing PGA/Mo-CD-SSPEI and redox-sensitive bioreducible PEI with plasmid TRAIL was assessed in the presence and absence of monensin. By increasing DR5 and cleaved PARP levels, the pTRAIL-induced apoptotic rate in HCT8/ADR and HeLa cells was greater than that of the control groups. These findings suggest that the RGD-PGA/Mo-CD-SSPEIpTRAIL and PGA/Mo-CD-SSPEIpTRAIL groups had significant levels of TRAIL protein expression in the tumors. The dual-targeting RGD-PGA surface coating provided the best cancer cell treatment efficacy^[154].

Dox and TRAIL therapeutic gene-loaded PEI-CD/Ad-Dox/pDNA supramolecular nanoparticles (SNPs) were assayed for treating ovarian cancers. The PEI-CD/Ad-Dox SNP included in the pTRAIL prevented ovarian tumor growth *in vivo* and significantly increased the survival time of tumor-bearing mice. Free medication and plasmid-loaded PEI-CD/Ad-Dox were tested in an *in vitro* retention experiment on SKOV-3 ovarian tumors, with PEI-CD/Ad-Dox/pTRAIL exhibiting the highest levels of cytotoxicity. When different groups were compared, more apoptotic cells and more significant expression of apoptotic proteins were found in the SNP-treated group^[155].

Lipid-based nanoparticles

The TRAIL gene carrying cationic nanoliposomes (pDsRed1-CI-TRAIL/Lipofectamine 2000) transfected into dendritic cells induced apoptosis in LoVo colorectal cancerous cells *in vitro* and *in vivo*^[156]. The synthesis of a tumor-targeted lipid/calcium/phosphate/protamine (LCPP) nanoparticle to deliver TRAIL pDNA into hepatocellular carcinoma (HCC) cells with an HCC-targeting peptide (SP94) gave rise to apoptosis. Due to the stimulation of calmodulin-dependent protein kinase II, SP1, and calcium signaling, SP94-LCPP NPs carrying TRAIL pDNA dramatically enhanced TRAIL expression and triggered TRAIL-mediated cytotoxicity in human (Hep3B, JHH-7) and murine (HCA-1) HCC cells. Compared to previous treatments, TRAIL pDNA supplied by SP94-LCPP NPs dramatically boosted the number of apoptotic cells in orthotopic HCA-1 tumors. Compared to the single treatments, the combination of sorafenib with NP-induced TRAIL production caused HCC cells to undergo significantly higher levels of apoptosis^[157].

A novel lipid (1, 2-di-(9Z-octadecenoyl)-3-biguanide-propane (DOBP)) was encapsulated with TNF-related apoptosis-inducing ligand plasmids (TRAIL plasmids) into lipid-protamine-DNA nanoparticles (LPD NPs) for systemic gene delivery. Comparing 1, 2-di-(9Z-octadecenoyl)-3-trimethylammonium-propane (DOTAP)-LPD-TRAIL nanoparticles to DOBP-LPD TRAIL nanoparticles, it was clear that the latter were significantly less effective at slowing tumor growth. In contrast to phosphate-buffered saline and Lipo-DOTAP, tumor tissues treated with metformin and Lipo-DOBP showed significantly greater levels of AMPK-alpha phosphorylation, while mTOR phosphorylation was downregulated^[158].

The synthesis of another type of nanoparticles (rHDL/PEI-LA/pTRAIL) comprising a reconstituted high-density lipoprotein (rHDL), lauric acid-coupled polyethyleneimine (PEI-LA) as an amphipathic positively-charged polymer with pTRAIL was engineered into mesenchymal stem cells (MSCs) for the treatment of lung metastasis of melanoma. *In vitro* and *in vivo*, the rHDL-mediated TRAIL-engineered MSCs had a promising potential to target the B16F10 pulmonary melanoma metastases^[159].

Albumin-based nanoparticles

TRAIL gene delivered with plasmid pORF-hTRAIL (pDNA), incorporated into cationic albumin-conjugated pegylated nanoparticles (CBSA-NP), was evaluated as a non-viral vector for gene therapy of gliomas; hTRAIL-mediated apoptosis was assessed by immunohistochemical analysis for active caspase-3

using an antibody that detected the cleaved p17 fragment at 14 days after intravenous administration of CBSA-NP-hTRAIL, which was confirmed by the presence of p17-positive tumor cells^[160].

CONCLUSION

TRAIL is an apoptosis-inducing ligand that kills cancer cells without affecting normal cells. TRAIL binds to specific death receptors on the cell surface and triggers the apoptosis extrinsic and intrinsic pathways. The targeted killing of specific tumor cells makes it a promising molecule for cancer treatment. TRAIL receptor agonists designed to bind and activate death receptors in the absence of TRAIL proved promising. Interestingly, TRAIL failed in clinical trials due to its relatively short half-life, decreased protein stability, reduced bioavailability, and resistant mechanisms exhibited by cancer cells to evade apoptosis. For successful therapy, the bioavailability of TRAIL was enhanced by synthesizing soluble and stable peptides of TRAIL and encapsulating them in nano-formulations that aided the targeted delivery of stable, active TRAIL to tumor cells. Various organic, inorganic, and hybrid nanoparticles carrying the TRAIL protein, gene, or receptor agonists were tested in *in vitro* studies in several cancer cell lines. Nanoparticle-mediated TRAIL delivery significantly enhanced apoptosis by increasing death receptor clustering, DISC formation, and caspase activation. Combinatorial treatment of tumor cells with nano-TRAIL and other chemotherapeutic agents also sensitized the resistant cancer cells to TRAIL. These studies suggest that applying nanotechnology to TRAIL therapy is successful in cell lines and preclinical animal models. Further experimentation and standardization are required for the success of nano-formulations of TRAIL.

Insights are required to search for biomarkers that can mark cells as TRAIL-sensitive, novel methods to deliver TRAIL precisely, and the use of TRAIL combined with other medications/natural products to overcome resistance. One compelling approach is the application of TRAIL nanoparticles in cancer treatment for the delivery of TRAIL protein or gene to tumor cells.

Abstract

Aim: The study aims to analyze the effect of long-term incubation of ER α -positive MCF7 breast cancer cells with 4-hydroxytamoxifen (HT) on their sensitivity to tubulin polymerization inhibitor docetaxel.

Methods: The analysis of cell viability was performed by the MTT method. The expression of signaling proteins was analyzed by immunoblotting and flow cytometry. ER α activity was evaluated by gene reporter assay. To establish hormone-resistant subline MCF7, breast cancer cells were treated with 4-hydroxytamoxifen for 12 months.

Results: The developed MCF7/HT subline has lost sensitivity to 4-hydroxytamoxifen, and the resistance index was 2. Increased Akt activity (2.2-fold) and decreased ER α expression (1.5-fold) were revealed in MCF7/HT cells. The activity of the estrogen receptor α was reduced (1.5-fold) in MCF7/HT. Evaluation of class III β -tubulin expression (TUBB3), a marker associated with metastasis, revealed the following trends: higher expression of TUBB3 was detected in triple-negative breast cancer MDA-MB-231 cells compared to hormone-responsive MCF7 cells ($P < 0.05$). The lowest expression of TUBB3 was found in hormone-resistant MCF7/HT cells (MCF7/HT < MCF7 < MDA-MB-231, approximately 1:2:4). High TUBB3 expression strongly correlated with docetaxel resistance: IC₅₀ value of docetaxel for MDA-MB-231 cells was greater than that for MCF7 cells, whereas resistant MCF7/HT cells

were the most sensitive to the drug. The accumulation of cleaved PARP (a 1.6-fold increase) and Bcl-2 downregulation (1.8-fold) were more pronounced in docetaxel-treated resistant cells ($P < 0.05$). The expression of cyclin D1 decreased (2.8-fold) only in resistant cells after 4 nM docetaxel treatment, while this marker was unchanged in parental MCF7 breast cancer cells.

Conclusion: Further development of taxane-based chemotherapy for hormone-resistant cancer looks highly promising, especially for cancers with low TUBB3 expression.

Keywords: Cancer, docetaxel, 4-hydroxytamoxifen, class III β -tubulin, resistance, breast cancer, estrogen receptors alpha

INTRODUCTION

Breast cancer is considered a major cause of death from cancer in women around the world^[1]. Breast cancer has several various molecular subtypes, and more than 65%-70% of breast tumours are hormone receptor-positive (ER α +)^[2]. ER α -positive cancers are initially driven by hormone activation of estrogen receptor α , which in turn, induces pro-proliferative/pro-oncogenic cascades^[3]. This fact explains the effectiveness of therapies that target the hormone molecular pathway in ER α -positive breast cancer^[4]. The first antiestrogen for ER α -positive breast cancer treatment was tamoxifen, a selective estrogen receptor modulator, inhibiting the activity of the estrogen receptor alpha (ER α)^[5,6]. The mechanism of its action in breast cells is the competition with endogenous estrogens for binding estrogen receptor α ; thus, tamoxifen inhibits the estrogen-driven, pro-proliferative transcription program in breast cancer cells^[6,7] and also activates G-protein-coupled ER (GPER1)^[8]. In some cases, long-term tamoxifen treatment leads to the development of resistance, cellular mechanisms of which are complex and not fully clear. They include regulation of ESR1 expression by epigenetic factors^[9], mutations of ESR1^[10], alternative splicing events^[11], alterations in the hormone-binding domain^[10], differential recruitment of coregulators^[12], factors of the tumor microenvironment^[13] and many others^[14,15]. One of the major mechanisms of the development of hormone resistance is dysregulation of the PI3K/AKT/mTOR pathway that cross-talks with estrogen-mediated signaling^[16]. Inhibition of the PI3K/AKT/mTOR pathway results in reduced cell proliferation and survival, but this activates compensatory mechanisms that confer resistance to inhibitors. In several studies, it was shown that activation of the Akt pathway was associated with tamoxifen resistance in breast cancer cells, poor prognosis and decreased relapse-free survival, and increased incidence of relapse with distant metastases^[17-19].

β III-tubulin is a well-known tubulin isotype. Monomers of α - and β -tubulin spontaneously assemble and polymerize to form the microtubules, cytoskeletal polymers involved in critical cellular processes such as mitosis, cell motility, and intracellular transport. Moreover, β -tubulins are GTPases as well and regulate the kinetics of microtubule assembly and disassembly^[20]. β III-tubulin is overexpressed in many tumours, including resistant tumours^[21,22], and is regulated by hormones^[23]. Docetaxel, a taxane, is an antimicrotubule agent effective in the treatment of patients with breast cancer^[24]. Researchers are conducting extensive investigation of this drug to improve treatment efficacy and delivery selectivity^[25-27]. The study aims to analyze the effect of long-term incubation of ER α -positive breast cancer cells with 4-hydroxytamoxifen on their sensitivity to a tubulin polymerization inhibitor docetaxel.

METHODS

Cell lines and compounds

The triple-negative MDA-MB-231 and hormone-dependent MCF7 breast cancer cell lines were purchased from ATCC collection. The cells were maintained in a standard DMEM medium (Gibco) supplemented

with 10% fetal bovine serum (FBS, HyClone) at 37 °C, 5% CO₂ and 80%-85% humidity (NuAire CO₂ incubator).

4-hydroxytamoxifen and docetaxel were purchased from Cayman Chemical Company; drug solutions were stored at -70 °C. MCF7/HT cell line was obtained by long-term (for 12 months) cultivation of parental MCF7 cells with antiestrogen 4-hydroxytamoxifen at a concentration of 5 μM. The verification of acquired hormone resistance in MCF7/HT was done by the MTT test.

The analysis of cell viability

The analysis of cell viability was performed by the MTT test^[28] as described earlier in the work^[29]. The cells were seeded at a density of 4×10^4 cells per well in 24-well plates (Corning) in 900 μL of the medium. The solutions of the tested compounds (4-hydroxytamoxifen, docetaxel) with different concentrations in 100 μL of the medium were added 24 h after the seeding. The cells were cultivated for 72 h, then the medium was removed, and the MTT reagent (3-[4,5-dimethylthiazol-2-yl]-2, 5-diphenyltetrazolium bromide) dissolved in the medium was added to the final concentration of 0.2 mg/mL to each well and incubated for 1 h. After that, the medium was removed, and MTT formazan purple crystals were dissolved in DMSO (300 μL per well). Absorbance was measured at 571 nm with a MultiScan reader (ThermoFisher). The half-maximal inhibitory concentrations (IC₅₀) were determined with GraphPad Prism.

Assessment of ER α activity

MCF7 and MCF7/HT cells were seeded onto a 24-well plate containing a standard cell culture medium with a density of 1.7×10^5 cells/well. After 24 h, the cells were transfected with the ERE-LUC plasmid containing the luciferase gene under the ER α -dependent promoters^[30], and co-transfected with β -galactosidase plasmid. The transfection was performed for 6 h at 37 °C using Lipofectamine 2000 in a medium containing 2% steroid-free serum, then the medium was replaced by a standard medium supplemented with 10% steroid-free serum. The activity of luciferase was assessed according to a Promega protocol using an Infinite M200-Pro, and β -galactosidase activity was assessed using colorimetric assay and MultiScan FC. The internal control values were used to normalize the luciferase/ β -galactosidase activities. ER α activity was represented as the mean \pm SD for the three independent experiments.

Immunoblotting and densitometry

Immunoblotting with modifications was performed as described earlier^[31]. ER α , phospho-Akt, Akt, cleaved PARP, Bcl-2, Bad, phospho-ERKs, ERKs, phospho-S6K, S6K and cyclin D1 expression was evaluated using Cell Signalling Technology (CST) antibodies. Antibodies to α -tubulin (CST) were applied to normalize and control the loading of samples into a gel. Secondary antibodies to rabbit Ig conjugated with horseradish peroxidase were used for the detection (Jackson ImmunoResearch). ECL detection reagents for analysis were prepared according to Mruk and Cheng's protocol^[32]. ImageQuant LAS 4000 imager (GE Healthcare) was used to detect signals. Densitometry for the tested proteins/ α -tubulin ratio was carried out using ImageJ software.

Flow cytometry

TUBB3 expression was evaluated by immunofluorescence assay and flow cytometry^[33]. The cell suspensions at a concentration of 4×10^5 cells/ml were incubated for 1.5 h with primary monoclonal anti-TUBB3 antibody (clone EP1569Y, Abcam, UK) at room temperature in the dark; the suspensions were then incubated for 1.5 h with secondary anti-rabbit antibody conjugated with DyLight[®]650 (ab98510, Abcam, UK) at + 4°C in the dark. The final dilution for both antibodies was 1:500. Cell fluorescence was measured using the Navios flow cytometer (Beckman Coulter, USA). Two indicators of β III-tubulin expression were evaluated by FlowJo 10.0.8 (FlowJo, USA): the geometric mean of fluorescence (arb. units) and level of the

marker expression (number of specific fluorescent cells). The level of TUBB3 expression was calculated by the Kolmogorov-Smirnov test as the ratio of specifically fluorescent cells to the control cells incubated with secondary antibodies only. The distribution of cells according to fluorescence intensity was visualized using WinMDI 2.9 software.

Statistical analysis

All data are presented as mean values and standard deviation (mean \pm std. deviation). Student's t-test (GraphPad Prism 9, USA) at $P < 0.05$ was considered to indicate a statistically significant result.

RESULTS

In vitro experiments are an important part of any study in biology and medicine. Their importance is particularly reinforced by modern standards of ethics in science. So, there is a need to analyze the relationship between the doses of a drug given to patients and the concentration of the compound in the culture medium. Are such doses comparable? We first analyzed data from experiments with hormones and their antagonists. The level of 17 β -estradiol undergoes significant changes in premenopausal women; usually, the level of this hormone is between 30 and 400 pg/mL^[34-37]. Thus, we cannot talk about an average level of 17 β -estradiol in plasma; in experimental studies, most researchers apply a dose of 17 β -estradiol that induces the expression of responsive genes, 10 nM or 2.7 ng/mL^[38,39]. We see similar trends for antiestrogens, which are used as 17 β -estradiol competitors (selective estrogen receptor modulators, SERMs). In the plasma of breast cancer patients who receive tamoxifen, from 391 to 484 ng/mL of the major metabolites of this drug (tamoxifen, N-desmethyltamoxifen, hydroxytamoxifen, endoxifen) were determined^[40,41]. In *in vitro* experiments, the IC₅₀ values of tamoxifen usually exceed the level of 500 ng/mL and were 1-20 μ g/mL^[42-44]. A slightly different situation is observed in the case of chemotherapeutics, in particular docetaxel. The plasma concentration of docetaxel reaches 3737 nM clinically^[45], whereas in cell culture experiments, the IC₅₀ values do not exceed 10 nM^[46-48]. Thus, the hormonal drugs are used in higher doses in experiments, while docetaxel is applied in *in vitro* experiments at doses lower than those in the plasma of patients receiving drug treatment. The observations described are consistent with the duration of treatment; hormone therapy is prescribed for long courses (up to 10 years), whereas chemotherapy can be prescribed in short courses due to its high toxicity. In the *in vitro* study presented here, we started from the IC₅₀ values for 4-hydroxytamoxifen and assessment of hormonal signaling in obtained resistant cells.

MCF7/HT was obtained by long-term cultivation of MCF7 breast cancer cells with 4-hydroxytamoxifen. The established MCF7/HT subline has lost sensitivity to 4-hydroxytamoxifen (HT), which was confirmed by the MTT test: the viability of MCF7/HT in the presence of higher concentrations of 4-hydroxytamoxifen compared to MCF7 indicates the developed resistance, the resistance index (IC₅₀ of MCF7/HT divided by IC₅₀ of MCF7) was 2 [Figure 1A].

It is known that the acquisition of tamoxifen resistance in MCF7 cells is accompanied by the impaired activation of the PI3K/Akt/PTEN pathway and down-regulation of ER α ^[17,49,50]. Following the literature data, we have revealed that Akt activity (p-Akt) in MCF7/HT was increased by 2.2-fold [Figure 1B and C]. Moreover, ER α expression was decreased by 1.5-fold.

To assess ER α activity, the cells were transfected with the plasmids containing the luciferase gene under the estrogen receptor α -dependent promoters (ERE-LUC). The activity of ER α was induced by its physiological ligand, 17 β -estradiol^[30,52]. As can be seen in Figure 2, the induced activity of the estrogen receptor α in MCF7/HT cells was decreased by 1.5-fold ($P < 0.05$) when compared to that in parental cells. This indicates a partial loss of hormonal dependence of the breast cancer cells after long-term incubation with 4-hydroxytamoxifen.

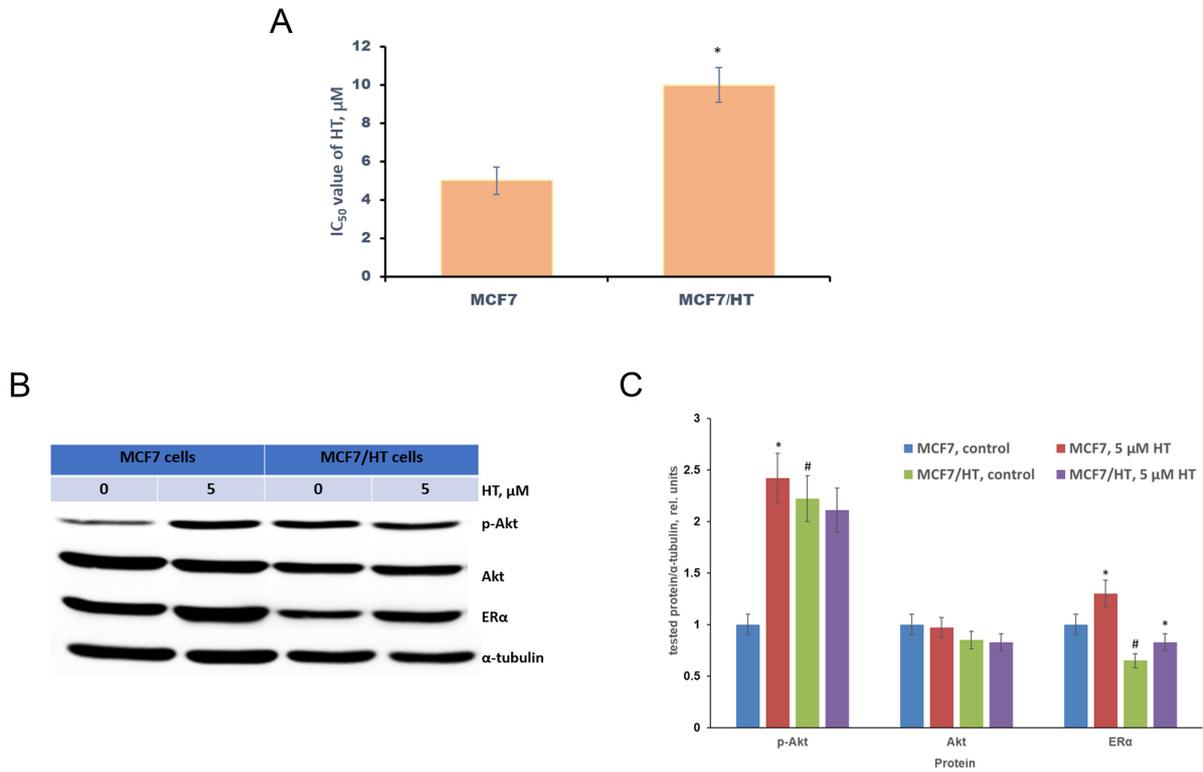

Figure 1. Characteristics of the obtained subline MCF7/HT. (A) - the viability of MCF7/HT and MCF7 cells in the presence of 4-hydroxytamoxifen (HT), * $P < 0.05$; (B) - Representative immunoblotting images for sensitive MCF7 and resistant MCF/HT cells with antibodies against ER α , p-Akt, and Akt; the cells were treated with 5 μ M HT for 24 h and then subjected to immunoblot analysis; (C) - Densitometry for immunoblotting data ($n = 3$) was performed using ImageJ software (Wayne Rasband, NIH). The protocol for analysis was provided by The University of Queensland with the recommendations from the work^[51], * $P < 0.05$ vs. corresponding control cells; # $P < 0.05$ vs. MCF7 cells.

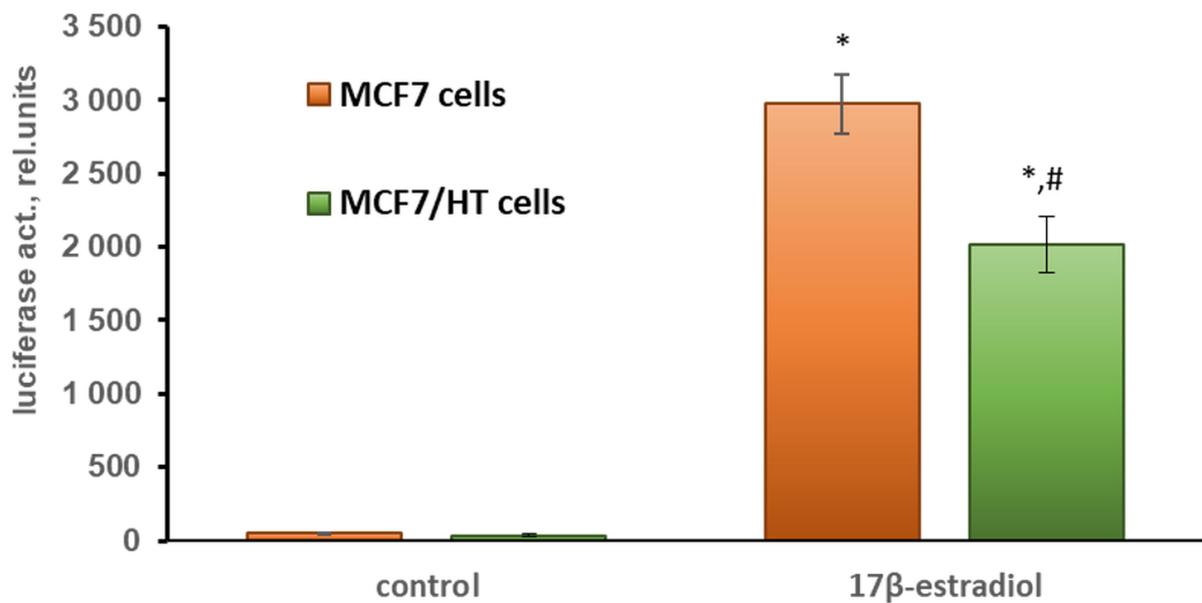

Figure 2. 17 β -estradiol-induced activity of ER α in MCF7 cells assessed by gene reporter assay; * $P < 0.05$ vs. control cells; # $P < 0.05$ vs. MCF7 cells treated with 10 nM 17 β -estradiol. The mean values of three independent experiments are shown.

In subsequent experiments, we used MDA-MB-231 cells which are triple-negative; these cells are hormone-resistant *de novo*^[53]. Analysis of β III-tubulin (TUBB3) expression revealed the following trends: the level of TUBB3 expression was high and the same in all three studied cell lines, while the geometric mean of the marker expression differed dramatically [Figure 3].

Higher expression of TUBB3 was detected in triple-negative breast cancer MDA-MB-231 cells compared to hormone-responsive MCF7 cells [Figure 3]. The lowest TUBB3 expression was found in hormone-resistant MCF7/HT cells; the geometric mean of the marker was reduced by more than 2 and 4 times in comparison with MCF7 and MDA-MB-231 cells, respectively. Figure 3 shows one of the typical experiments for the evaluation of TUBB3 protein expression in the studied cell lines.

High TUBB3 expression strongly correlated ($P < 0.05$) with docetaxel resistance: IC₅₀ value of docetaxel for MDA-MB-231 cells was greater than that for MCF7 cells, hormone-resistant MCF7/HT cells were the most sensitive to the drug [Figure 4].

In subsequent experiments, changes in signaling pathways induced by docetaxel were analyzed. MCF7 and MCF7/HT cells were treated with docetaxel and then protein expression was analyzed in the obtained samples. There are many ways of detecting apoptosis in cells, one of such approaches is to determine the level of cleaved PARP (poly (ADP-ribose) polymerase)^[54]. The cleaved PARP may be considered a marker of apoptosis. As shown in Figure 5, incubation of cells with the drug leads to a dose-dependent increase in cleaved PARP expression. This indicates that docetaxel causes apoptosis. It is important to note that the accumulation of cleaved PARP is more pronounced in DCT-treated resistant cells (1.6-fold). Regulation of cell death pathways occurs with the participation of proteins from various families. The balance between proapoptotic and antiapoptotic proteins is usually observed in unchanged cells. Activation of antiapoptotic pathways is often detected in tumor cells. The expression of the antiapoptotic factor Bcl-2 was analyzed in MCF7 and MCF7/HT cells. Docetaxel caused a decrease in Bcl-2 expression in both cell lines, but the observed effects were more prominent in the resistant ones treated with 4 nM DCT (1.8-fold). Analysis of the expression of the proapoptotic protein Bad showed no differences between sensitive and resistant cells.

Docetaxel caused significant activation of ERKs in both cell lines ($P < 0.05$) and its effect was dose-dependent, as shown in Figure 5. The S6 kinase (S6K) is one of the effectors of the mammalian Target Of Rapamycin (mTOR); S6K regulates protein synthesis and cell growth. The overexpressed S6K was found in a variety of tumors and correlated to poor prognosis in cancers^[55]. Amaral *et al.* described that S6Ks isoforms contribute to migration, viability, resistance to docetaxel and tumor formation of cancer cells^[55]. We tested whether S6K is involved in the cell response to docetaxel. As shown in Figure 5, there were no differences in S6K expression between MCF7 and MCF7/HT cells. High activity of S6K was detected in all obtained samples, while docetaxel did not alter its activity or expression in both cell lines [Figure 5]. Intriguingly, the expression of the cell cycle regulator cyclin D1 decreased (2.8-fold) only in resistant cells after docetaxel treatment, while this marker was unchanged in parental MCF7 cells.

DISCUSSION

The interest in β III-tubulin in cancer research is related to its role in drug tolerance of various tumours, particularly to taxanes, that block tubulin depolymerization, thereby increasing the content of polymerized tubulin and arresting cellular functions. Overexpression of β III-tubulin was found in many tumours. TUBB3 expression was associated with a poor response to various drugs, including docetaxel, paclitaxel,

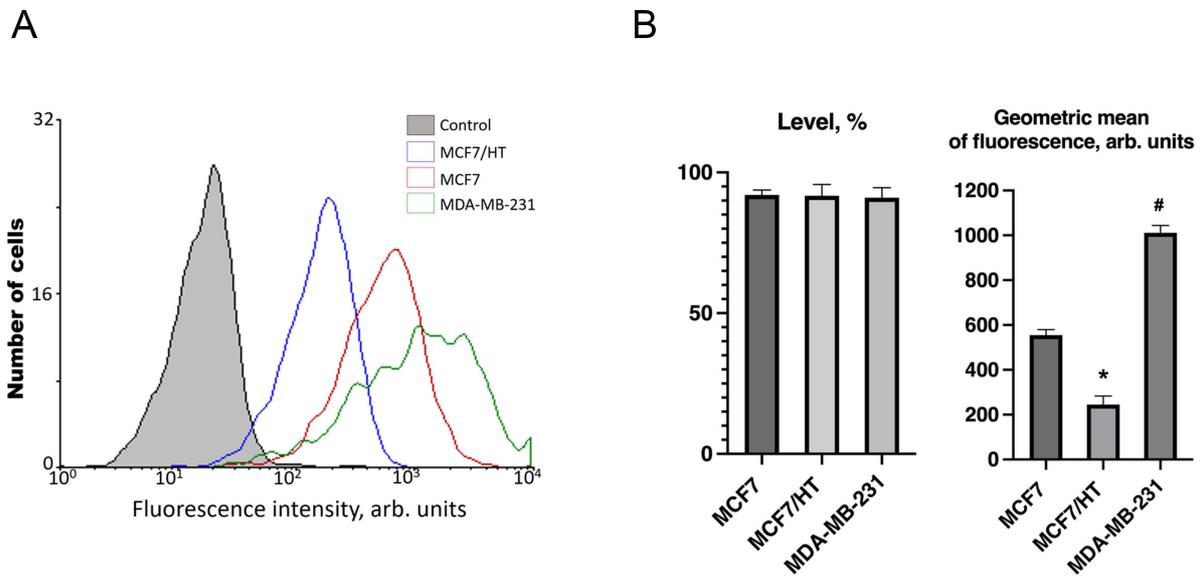

Figure 3. β III-tubulin expression in breast cancer cell lines. (A) - Representative diagram of β III-tubulin expression. The abscissa is the intensity of specific fluorescence in the channel of an FL6 flow cytometer (arb. units); the ordinate axis is the number of cells. Control - autofluorescence of samples; (B) - A difference in TUBB3 expression was revealed between the cell lines, and the intensity of the marker expression increased in the following order ($n = 3$): MCF7/HT < MCF7 < MDA-MB-231 (approximately, 1:2:4). * $P < 0.05$ vs. MCF7 and MDA-MB-231, # $P < 0.05$ vs. MCF7 and MCF7/HT.

cancers, including bladder, lung, ovarian, breast, prostate, and rectal cancers. Moreover, β III-tubulin expression was positively correlated with lymphatic metastasis and tumor differentiation^[23]. TUBB3 is also involved in docetaxel (DCT) and cabazitaxel (CBZ) resistance. LY294002, a PI3K inhibitor, re-sensitized DCT-resistant cell lines to docetaxel and CBZ-resistant cell lines to cabazitaxel (CBZ). The combination of DCT/CBZ and LY294002 could be potential strategy for the treatment of prostate cancer^[56].

Several approaches have been developed to enhance the action of docetaxel. In preclinical projects, researchers use specific nucleotides against signaling RNAs to modulate the action of docetaxel. Dr Razi Soofiyan *et al.* described very interesting experiments with siRNA-mediated silencing of CIP2A^[57,58]. CIP2A silencing enhanced the sensitivity of cancer cells to DCT by strengthening drug-induced cell growth

inhibition and apoptosis. The authors concluded that CIP2A silencing may potentiate the antiproliferative effects of docetaxel and this might be a promising therapeutic approach in prostate cancer treatment. cMET is considered as a target in the work by Dr Majidi Zolbanin *et al.*^[59]. The mucin1 aptamer-conjugated chitosan nanoparticles, containing docetaxel and cMET siRNA, were suggested by authors for the treatment of mucin1-positive metastatic breast cancers.

The molecular pathway of ERKs plays a crucial role in the growth and death of normal and cancer cells^[60]. Depending on the stimulus, activity of ERKs mediates various antiproliferative signals, such as apoptosis and autophagy^[61-63]. Chemotherapeutic and other DNA damage agents, including etoposide, doxorubicin, ionizing radiation and ultraviolet irradiation (UV), activate protein kinase ERK1/2 in various cells^[61,64]. Previously published data are in good agreement with our observations on ERK activity in cells after DCT treatment. Lucie Chauvin *et al.* discuss the possible role of ERK in maintaining the survival of docetaxel-treated cells in the work^[65]. Authors demonstrated that docetaxel supports a survival signaling pathway through a mechanism depending on PKC and ERKs in the MDA-MB-231 breast cancer cells. Thus, the use of combinations of docetaxel with ERK inhibitors could be a promising strategy for future studies of breast cancers.

The relationship between β III-tubulin expression and taxane-resistance of tumours is being extensively studied. For example, Maahs *et al.* have studied β III-tubulin expression as a predictor of resistance in patients with metastatic castration-resistant prostate cancer and have revealed that patients with a high expression of TUBB3 had a lower survivability and worse response rates to docetaxel as indicated by a 10% or greater decrease in prostate-specific antigen (PSA) compared to a 50% or more decrease in patients with a low β III-tubulin who have a better response rate to docetaxel^[66].

De Donato *et al.* have considered TUBB3 as a gateway for survival PIM1 signals^[67]. The cells are exposed to microenvironmental stressors and PIM1 was incorporated into the cytoskeleton through GBP1 and β III-tubulin, which ultimately leads to drug resistance. Moreover, De Donato *et al.* have found a statistically significant up-regulation of class III beta-tubulin in the paclitaxel-resistant ovarian tumors^[67]. Similarly, Roque *et al.* have found that TUBB3 overexpression in clear cell carcinoma of the ovary discriminates poor prognosis. High TUBB3 expression is a marker for sensitivity to patupilone and may contribute to resistance to paclitaxel^[68].

The results of our study are consistent with the evidence described above: the cells with the highest β III-tubulin expression (MDA-MB-231) were resistant to docetaxel and the cells with the lowest β III-tubulin expression (MCF7/HT) were sensitive to docetaxel. Several researches show that β III-tubulin expression in cancer cells is regulated by hormones. Saussede-Aim *et al.* showed that 17β -estradiol exposure causes an up-regulation of β III-tubulin in ER α -positive MCF7 breast cancer cells, and estrogen receptor modulators (e.g. tamoxifen) reduce the β III-tubulin level in ER α -positive breast cancer cells, but did not affect the β III-tubulin level in ER α -negative MDA-MB-231 cells^[69]. This mentioned observation is in good agreement with our data. We have shown that estrogen receptor α activity is decreased in the hormone-resistant cells, and the hormone dependence of the cells decreases accordingly. A decrease in β III-tubulin expression may be associated with these changes in hormone signaling of cancer cells. There is also evidence that androgens modulate TUBB3 expression: in prostate cancer cells and patient tumors, androgen ablation correlates with high TUBB3 levels^[70]. In another work, an increase in β III-tubulin was revealed in androgen-starved and androgen receptors knockdown human prostate adenocarcinoma cells LNCaP^[71].

Consistent with these facts, MCF7/HT in our study had the lowest activity of ER α along with the lowest β III-tubulin level; on the contrary, MDA-MB-231 with no ER α at all had the highest β III-tubulin level. Docetaxel affected the expression of a number of signaling proteins in MCF7 and MCF7/HT breast cancer cells. The accumulation of cleaved PARP (a marker of apoptosis) and Bcl-2 downregulation were more pronounced in resistant cells. Moreover, the expression of cyclin D1 decreased only in resistant cells after docetaxel treatment, while this marker was unchanged in parental MCF7 cells. Interestingly, according to several clinical trials, a high level of TUBB3 is associated with negativity for estrogen and progesterone receptors in breast cancer patients^[72,73] and, as a result, with worse disease-free and overall survival^[73,74].

In conclusion, high Akt activity (a 2.2-fold increase) and decreased activity of the estrogen receptor α (1.5-fold) were found in established hormone-resistant MCF7/HT cells. It is intriguing that the expression of TUBB3, metastasis-associated tubulin, was lowered in the hormone-resistant cells. The hormone-resistant cells were characterized by high sensitivity to tubulin polymerization inhibitor docetaxel, belonging to taxanes. The significant accumulation of cleaved PARP (1.6-fold) and Bcl-2 downregulation (1.8-fold) were revealed in DCT-treated MCF7/HT cells. Thus, further development of taxane-based chemotherapy for hormone-resistant cancer with low TUBB3 expression looks highly promising.

Abstract

Despite scientific advances in the Oncology field, cancer remains a leading cause of death worldwide. Molecular and cellular heterogeneity of head and neck squamous cell carcinoma (HNSCC) is a significant contributor to the unpredictability of the clinical response and failure in cancer treatment. Cancer stem cells (CSCs) are recognized as a subpopulation of tumor cells that can drive and maintain tumorigenesis and metastasis, leading to poor prognosis in different types of cancer. CSCs exhibit a high level of plasticity, quickly adapting to the tumor microenvironment changes, and are intrinsically resistant to current chemo and radiotherapies. The mechanisms of CSC-mediated therapy resistance are not fully understood. However, they include different strategies used by CSCs to overcome challenges imposed by treatment, such as activation of DNA repair system, anti-apoptotic mechanisms, acquisition of quiescent state and Epithelial-mesenchymal transition, increased drug efflux capacity, hypoxic environment, protection by the CSC niche, overexpression of stemness related genes, and immune surveillance. Complete elimination of CSCs seems to be the main target for achieving tumor control and improving overall survival for cancer patients. This review will focus on the multi-factorial mechanisms by which CSCs are resistant to radiotherapy and chemotherapy in HNSCC, supporting the use of possible strategies to overcome therapy failure.

Keywords: Head and neck squamous cell carcinoma, cancer stem cell, chemotherapy, radiotherapy, therapy resistance

INTRODUCTION

Head and neck malignancies are now the seventh most common type of cancer worldwide^[1]. More than 90% of head and neck tumors are derived from mucosa epithelium and are diagnosed as squamous cell carcinoma (HNSCC). Although sharing identical histological subtypes, HNSCC can be divided into at least two genetic subclasses based on the absence or participation of human papillomavirus (HPV) in carcinogenesis^[2]. The oral cavity represents the main subsite for HPV-negative tumors and the oropharynx for HPV-positive ones^[3]. Moreover, these subgroups also differ in clinical profile, tumor behavior, survival rates, and prognoses^[4].

The mainstay treatment for HNSCC consists of surgery with adjuvant or neoadjuvant chemotherapy and radiotherapy. More recently, immunotherapy with checkpoint inhibitors has been indicated for recurrent and metastatic HNSCC with promising results, although only a subset of patients with HNSCC has shown a response to this therapy^[5]. TNM stage of the disease and anatomic subsites influence therapeutic options for HNSCC. While radical surgeries are the first choice for locally advanced oral cancer, the main treatment for oropharyngeal tumors is chemoradiotherapy, regardless of HPV status. Nowadays, transoral surgeries (robotics and laser microsurgery) have also been performed in the oropharynx region^[6].

Despite the advances in current therapy, the prognosis of HNSCC remains poor. More than half of patients die from the disease or complications within a short period, varying from a few months to five years^[7]. The primary cause of mortality is related to resistance to therapy which leads to local recurrence, cervical lymph node metastasis, and occasionally, distant organ metastasis^[6]. Tumor heterogeneity and cancer stem cells (CSCs) are known to enhance metastatic dissemination and therapeutic resistance, contributing to lethality^[8].

CSCs represent a small but critical subpopulation of cells in the tumor capable of self-renewal and multilineage differentiation and regenerating a tumor when serially transplanted into mice models^[9]. Since tumors can regrow from a single CSC, cancer treatment success may be attributed to the complete eradication of CSCs populations^[8].

Besides, CSCs also demonstrate cellular plasticity; they can reversibly switch between different stem cell phenotypes and between a stem and non-stem cell state^[10]. CSCs activity is modulated by different signals and cellular interactions provided by the tumor microenvironment, allowing CSCs to achieve highly invasive and aggressive behavior or resist conventional therapies. Thus, activating the Epithelial-to-Mesenchymal Transition (EMT) program by the CSCs represents a valuable strategy to promote invasion, metastasis, and treatment resistance^[10-12].

CSCs may originate from adult stem cells or progenitor cells in which the accumulation of mutations over time leads to the activation of transcriptional gene signatures and signaling pathways related to the maintenance of stem cell phenotype and malignant transformation^[13-15]. Moreover, differentiated cells can also acquire stemness traits due to genetic instability throughout their division process and dedifferentiate, acquiring stem cell properties^[16,17]. It is essential to highlight that malignant cells can dedifferentiate and acquire stem cell characteristics under challenging situations, including exposure to chemotherapy and radiotherapy^[18].

In HNSCC, Prince *et al.* first described the presence of a small fraction of CD44-positive cells capable of generating new tumors when inoculated in immunocompromised mice and re-establishing original tumor heterogeneity^[19]. Moreover, this subpopulation expressed the *Bmi1* gene, a stemness marker involved in tumorigenesis and self-renewal^[19]. Since then, other common HNSCC CSC markers, such as CD44, ALDH1, CD133, c-Met, and Bmi-1, have been described^[20-22]. ALDH1 is considered a highly specific CSC marker, mainly when evaluated with CD44^[20]. Moreover, based on CD44 and EpCAM expression levels, CSCs in oral squamous cell carcinoma (OSCC) seem to switch between two distinct phenotypes. First, CD44^{high}/EpCAM^{high} presents an epithelial morphology and colony formation capability, and second, CD44^{high}/EpCAM^{low} has a mesenchymal morphology (EMT profile) with high invasive potential, metastasis and radioresistance ability^[10,23]. More recently, LIN28A and LIN28B proteins, located in the cytoplasm and nucleus/nucleoli, respectively, were identified as reprogramming factors that can lead to the de-differentiation of malignant oral squamous cancer cells into CSCs and contribute to their immune evasion^[24].

For other types of cancers, distinct CSCs can be identified and isolated by fluorescence-activated cell sorting (FACS) using phenotypic surface markers alone or in combination. More than 40 surface markers are known to identify CSCs in solid tumors, and the majority are derived from embryonic or adult stem cells^[25]. In general, high positivity of CD44, CD24, CD133, CD90, EpCAM, and Aldehyde Dehydrogenase 1 (ALDH1), and elimination of Hoechst 3334 dye *via* ABC transporters are the most used markers^[26]. The isolated CSCs can be propagated *in vitro* as spheroids or used in organoid cultures. Moreover, spheroid cultures are CSCs enriched, show self-renewal ability *in vitro* and *in vivo*, and generate tumors that resemble the original tumor heterogeneity and differentiation^[27].

More recently, in addition to the conventional 2D cell culture, 3D culture models have been used to represent tumor microenvironment heterogeneities properly and reproduce patients' tumor behavior. Engelmann L. *et al.* developed a 3D Organotypic Co-Culture (3D-OTCs) utilizing HNSCC fresh tissue (non-HPV driven and HPV-driven) placed on top of dermal equivalents (human fibroblasts cultured on a viscose fiber fabric) and analyzed samples' behavior^[28]. All non-HPV-driven 3D-OTCs were capable of proliferating cancer cells for up to 21 days and exhibited a heterogeneous, invasive, and expansive growth pattern^[28]. In the same context, Miserocchi G. *et al.* developed a 3D culture using HPV-positive and HPV-negative HNSCC cells in a collagen-based scaffold. They suggested that the 3D model might induce more mesenchymal phenotypes than 2D cultures^[29]. Also, in this study, HPV-negative cells presented an upregulation of FLT1 and ABCA3 when seeded in scaffolds, overexpressed EMT-related genes, and increased migration ability compared to HPV-positive cells^[29]. Based on these findings, collagen-based scaffolds seem to activate drug-resistance mechanisms reassuring the ability of 3D scaffolds to reproduce HNSCC tumor microenvironment impeded by other *in vitro* systems. Accordingly, regarding response to treatment analyses, 3D culture is promising in the future of HNSCC and CSC research.

Several associations between clinicopathological characteristics and CSCs have been appointed in HNSCC, including tumor size, regional and distant metastases, perineural invasion, radiation failure, and poor disease-free survival^[30]. A previous study of our group explored CSCs markers in tongue tumors and found that the overexpression of CD44 was related to worst overall survival, and Nanog and Oct4 were associated with regional metastasis and death^[31]. Ma *et al.* suggested that CD133⁺ cells could be responsible for aggressiveness and chemoresistance in oral tumors^[32]. A meta-analysis study by Fan *et al.* showed that the CSCs markers, CD133, Nanog, and Oct4, could have a prognosis value in HNSCC patients^[33]. In light of recent events in CSCs markers, there is now some discovery about non-coding RNAs (ncRNAs) used as biomarkers of cancer development and tumor stage determination^[34].

MicroRNAs are a type of sncRNA that regulate biological processes. Each miRNA can control target genes and accentuate their potential influence on almost every genetic pathway. Hsieh PL *et al.* demonstrated that ncRNA molecules associated with CSCs are responsible for acquiring and maintaining cancer stemness^[35]. Let-7 genes family act as a tumor suppressor. Lin28B-let-7 pathway positively regulates the expression of stemness factors Oct4 and Sox2; it causes a switch of non-CSCs to CSCs with tumor starting and self-renewal characteristics in oral CSC^[36].

MicroRNA-200 family is another group of genes related to CSC; expression levels of miR-200c were downregulated in ALDH1+/CD44+ HNSCC with BMI1 overexpression. Also, an expression of let-7c or let-7d in oral CSCs suppressed stemness and the radio/chemoresistance hallmarks through suppression of IL-8 or EMT markers, respectively^[37,38]. MicroRNA-494 acts as a tumor suppressor or oncogenic factor. An increase of miR-494 can inhibit ALDH1 activity, CD133 positivity, and other stemness signatures in ALDH1+CD44+ oral cancer cells. In the same way, activation of miR-494 inactivates Bmi-1 and ADAM10 expression in OSCC-CSCs^[39]; also, miR-494-3p may enhance the radiosensitivity and induce a senescence pathway in oral cancer cells^[40].

In this scenario, it is essential to highlight that CSCs are not easily eliminated by conventional therapies, meaning that after the effective depletion of the bulk of the tumor, residual CSCs populations may survive, drive and sustain cancer recurrence, invasiveness, and therapy resistance^[41]. Moreover, CSCs are considered intrinsically resistant to chemo and radiotherapy. It is also possible that the CSCs and their close descendants give rise to therapeutic-resistant malignant cells that accumulated mutations caused by genotoxic therapies^[42]. CSCs adopt different strategies to overcome the challenges imposed by treatment, including the acquisition of dormancy, which is influenced by the CSC niche and immune surveillance, increased drug efflux capacity, activation of DNA repair machinery and decreased activation of apoptosis^[43]. This review will focus on the mechanisms that lead to CSC resistance to radiotherapy and chemotherapy in HNSCC.

RADIORESISTANCE AND CSC

In HNSCC patients, radiotherapy (RDT) is a common choice of treatment to achieve cancer control after surgery and/or current chemotherapy^[6]. Usually, on weekdays patients receive a dose of 70 Gy that can be administered through standard fractionation (2 Gy, once a day) or via accelerated fractionation and hyperfractionation (twice a day)^[44]. Fractionation guarantees that cancer cells will eventually be exposed to radiation in all cell cycle phases, favoring DNA damage and cell fate. Nevertheless, this process also activates important protein regulators of DNA damage response, such as ataxia-telangiectasia mutated (ATM) and ataxia-telangiectasia and Rad3-related protein (ATR), which will be decisive in treatment response^[45].

Tumor response or failure to ionizing radiation is mainly associated with the classical 4 R's of radiobiology: repair of sublethal DNA damage, reassortment of cells in the cell cycle, cell repopulation, and reoxygenation of hypoxic areas^[46]. Efficient cell death by RDT depends on producing unreparable damage involving DNA double-strand breaks (DSBs); however, most radiation-induced DNA damage is sublethal. DNA repair systems include base excision repair (BER), nucleotide excision repair (NER), homologous recombination (HR), non-homologous end joining (NHEJ), and mismatch repair (MMR) pathways^[47]. In this context, CSCs seem to hold elevated levels of proteins responsible for NHEJ and HR and an increased DSB repair capacity^[23].

If tumor recurrences occur within six months following radiation, tumors are considered radioresistant^[48]. Mechanisms involved in radioresistance are not fully understood, but accumulated evidence indicates that

cancer stem cells (CSCs) are decisive in this process^[46,49]. In general, therapeutic resistance refers to the ability of cancer cells to recover and repair DNA damage and regrow after tumor therapy^[50], being higher in CSCs than non-CSC^[51]. This ability is mainly related to the increased regulation of DNA repair genes, DNA-damage checkpoints, and anti-apoptotic proteins^[52,53].

Furthermore, it has been recognized that a CSC subpopulation exhibiting a mesenchymal profile (CD44^{high}/CD24^{low}) presents an even higher level of DNA repair following RDT^[23]. Besides, irradiation activates stemness pathways and induces CSC phenotypes in non-stem cancer cells. Up-regulation of CSCs genes, such as Sox2 and Oct3/4, may be observed after radiation, contributing to tumor radioresistance^[53]. The plasticity of CSCs dramatically interferes with identifying and eliminating CSCs during cancer therapies^[54].

Radiation promotes an arrest of CSCs in the G2/M phase, which allows active DNA repair. Moreover, after radiation, there is a noticeable discrepancy between the higher rates of self-renewal and proliferative abilities of CSCs compared to their lower apoptosis activation, favoring tumor growth^[52]. In oral cancer cell lines, changes in CSCs content (ALDH+) are associated with an increase in the rates of sub-lethal damage repair (SLDR), which enables efficient cell repair and reduces tumor control capabilities^[55]. Duration of the exposure to the fractionated dose-delivery of radiation seems to influence radioresistance mechanisms driven by SLDR, suggesting that reduced overall dose-delivery time on radiotherapy could favor CSCs control^[55].

Besides the DNA repair process, activation of checkpoint responses after radiation damage also participates in the radioresistance of several tumors, including HNSCC. Cell cycle progression is delayed to allow DNA repair through activation of signaling pathways such as ataxia telangiectasia mutated (ATM)-checkpoint kinase 2 (Chk2) and ATM-Rad3-related (ATR)- checkpoint kinase (Chk1)^[56]. CSCs appear to enhance response to DNA damage activating Chk2 in invasive oral cancer^[23]. Inhibition of Chk1 was suggested as a therapeutic target in HNSCC that contributes to the failure of DNA replication and intensification of DNA damage^[57].

Induction of apoptosis represents one of the primary mechanisms by which cancer cells are eliminated in cancer therapies^[58]. Reduced cleaved caspase proteins showed the apoptotic resistance of CSCs in oral cancer after irradiation^[23]. Resistance mechanisms evolving upregulation of anti-apoptotic proteins such as Bcl-2 and inhibitor of apoptosis (IAP) are commonly found in tumor cells, especially in CSCs^[59]. Radiation can activate X-linked IAP (XIAP), another IAP family member that inhibits apoptosis mediated by mitochondrial and caspase-3 pathways^[60]. Besides apoptosis regulation, Bcl-2 family members also participate in cell migration, invasion, and metastasis^[61]. In this focus, an inhibitor of Bcl-2 combined with Cetuximab and radiation showed excellent results in eliminating CSCs in HNSCC cell lines^[62].

Another widely studied mechanism of CSCs contributing to radioresistance and poor prognosis in HNSCC is related to hypoxia, i.e., low oxygen levels caused by insufficient blood supply to tumor tissues^[63,64]. A hypoxic tumor environment can interfere directly with the potential of radiation to damage DNA cells and indirectly regulate the expression of genes related to aggressiveness and response to treatment. Additionally, hypoxia is essential in protecting the CSCs niche from radiation effects and in acquiring and maintaining CSC-like phenotype^[65].

In HNSCC, hypoxia-inducible factor-1 α (HIF-1 α), a transcriptional regulator of oxygen homeostasis, is enhanced in CSCs subpopulations in response to radiation^[66]. Furthermore, hypoxia upregulates CSCs

genes such as *Sox2* and *Nanog*, consequently contributing to the survival of tumor cells after radiation^[67]. Linge *et al.* showed a correlation between high tumor recurrence after postoperative radiochemotherapy in locally advanced HNSCC patients, increased expression of CSCs markers, and high hypoxia-induced gene signature expression^[68]. Strategies for hypoxic modifications such as hyperbaric oxygenation or nitroimidazoles significantly reduced locoregional recurrence after radiation in HNSCC^[69].

In the same context, reactive oxygen species (ROS) and redox-regulatory mechanisms can regulate DNA damage and resistance to irradiation. Accumulation of ROS and DNA damage of cancer cells is associated with the effectiveness of radiotherapy^[70]. Unlike non-CSCs, CSCs present a high antioxidant capacity that coordinates the activity of free-radical scavengers and protects cells from induced-radiation death^[70,71]. This low ROS state presented by CSCs is also related to the quiescent state of HNSCC stem cells and enhanced tumorigenic potentials *in vitro* and *in vivo*^[72]. Interestingly, GDF15 (growth differentiation factor 15), a member of the TGF- β superfamily, participates in ROS suppression in HNSCC, contributing to radioresistance and acquisition of the CSC phenotype^[73]. Boivin *et al.* showed that redox-modulating by inhibiting GSH antioxidant system previous to radiation is an accurate strategy to eliminate highly tumorigenic CSCs^[74].

Considering the better prognosis of HNSCC HPV-positive patients, it seems that HPV may influence several molecular mechanisms involved in CSC's radiosensitivity^[75,76]. Rieckmann *et al.* demonstrated a limited capacity of DSB repair in HPV/p16-positive cancer cells^[77]. HPV-positive tumors are believed to present less radioresistant CSCs subpopulations due to their reduced repopulation ability during radiation therapy^[78]. Reid *et al.* explored irradiation behavioral responses of CSCs with CD44⁺ ALDH⁺ phenotype in 6 HPV positive and negative HNSCC cell lines^[79]. Their principal findings showed that HPV status did not influence the inherent proportions of CSCs, which were changed in both groups in response to radiation. HPV-negative samples showed a significant increase in CSCs densities, probably reflecting their remarkable repopulating ability after treatment^[79]. Other studies demonstrated that HPV-negative cell lines seem more capable of dedifferentiating from non-CSCs to CSCs in response to radiation than HPV-positive cell lines^[80]. In addition, low levels of functional TP53 expressed by HPV-positive cells may contribute to inducing apoptosis following radiotherapy^[81].

In an attempt to address this issue, the literature has found that cisplatin-sensitization has helped overcome resistance to radiation in many patients. In a recent study, Routila *et al.* appointed *Oct4* as a good marker for identifying radioresistance and cisplatin-sensitive tumors, which could help distinguish patients who should receive cisplatin-sensitization from those who would not benefit from this therapy^[82]. In summary, *Oct4* positivity reduced cancer cell apoptosis, favoring cell viability after irradiation. At the same time, *Oct4* can contribute to cisplatin mechanisms inhibiting DNA repair activation^[82]. In radioresistance, *Oct4* driving activates the oncogene Cancerous Inhibitor of Protein Phosphatase 2A (CIP2A), which promotes malignant cell growth and proliferation^[50].

Despite technological developments, RDT still promotes long-term toxicities compromising the quality of life and is often associated with potential tumor resistance^[6,83]. CSCs act as key players in regulating different mechanisms of DNA damage repair and other regulators of cell death after irradiation, such as hypoxia, apoptosis, and ROS [Figure 1]. At this point, we believe that RDT is insufficient to eliminate CSCs in HNSCC, explaining the high recurrence rates of these tumors. Thus, further investigation is required to comprehend and overcome CSC's radioresistance and improve treatment success and overall survival in cancer patients.

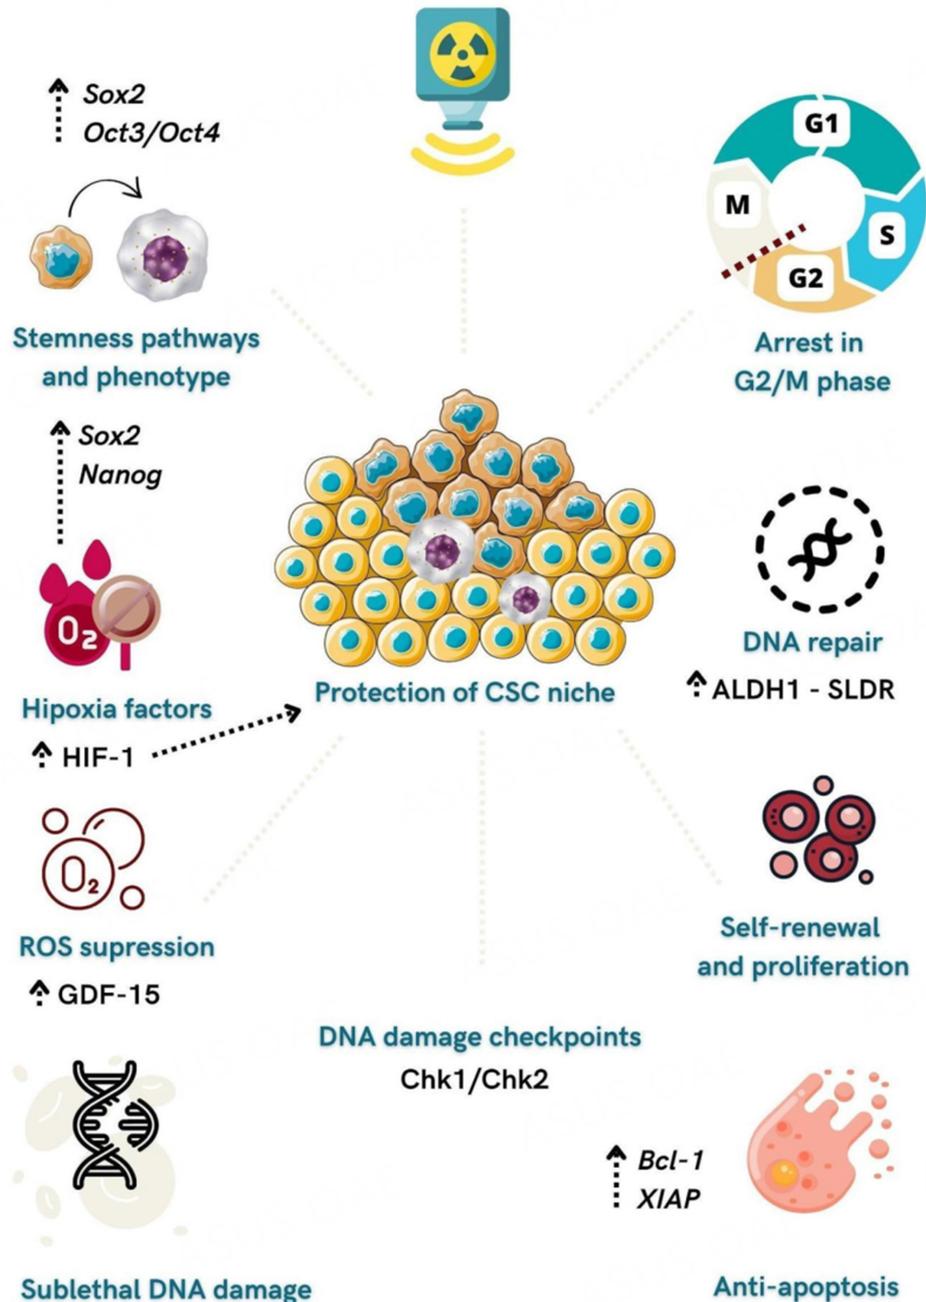

Figure 1. Mechanisms related to CSCs radioresistance in HNSCC. Radiation can activate stemness pathways such as Sox-2 and Oct3/4 and induce CSC phenotype in non-stem cancer cells. Radiation promotes an arrest of CSCs in the G2/M phase and activates Chk2 and Chk1, which delays cell cycle progression and allows DNA repair. Overexpression of CSC marker ALDH1 leads to increased rates of sublethal damage repair (SLDR), enabling efficient cell repair and reducing tumor control capabilities. CSCs upregulate anti-apoptotic proteins such as Bcl-2 and X-linked inhibitors of apoptosis (XIAP). Hypoxia upregulates CSCs genes (Sox2 and Nanog) and is essential in protecting the CSCs niche from radiation effects. GDF15 (growth differentiation factor 15) participates in ROS suppression in HNSCC, contributing to radioresistance and acquisition of the CSC phenotype.

CHEMOTHERAPY RESISTANCE AND CSC

HNSCC in stage I or II (early tumors) is curable with higher survival rates after surgery or radiotherapy alone. In contrast, over 60% of stage III or IV HNSCC (locoregionally advanced) require advanced

therapeutic options such as surgery followed by radiotherapy with or without chemotherapy^[7]. Currently, the standard chemotherapy regimens for stage III or IV, as well as recurrent and metastatic HNSCC, are based on cisplatin, 5-fluorouracil (5-FU), and docetaxel/paclitaxel^[84-86].

Chemotherapeutic drugs exert different biological effects on tumor cells, relying on specific mechanisms of action. Cisplatin is a platinum-based alkylating agent that creates inter- or intra-strand cross-links or transfers alkyl groups to the guanine residues of DNA, generating mispairing formation in DNA bases and avoiding strand separation during DNA synthesis^[87]. On the other hand, 5-FU is a pyrimidine antagonist antimetabolite that interferes with essential biosynthetic pathways, disturbs the DNA/RNA synthesis, or causes the formation of DNA strand breaks through inhibition of particular enzymes or incorporation of false structural analogs of pyrimidine/purine into DNA^[88]. Docetaxel is a topoisomerase II inhibitor that impairs DNA replication and causes DNA strand breaks. Paclitaxel is a taxane that modifies the function/formation of spindle microtubules by inhibition of nuclear division (mitotic arrest in metaphase), leading to cell death^[87]. In this context, it is essential to highlight that most chemotherapeutics' success relies on the drugs' ability to decrease tumor size or induce short-term remission. This measure of success is intuitive, and many medications evaluated by these criteria are used in effective chemotherapeutic regimens^[89].

Although the chemotherapeutic scenario seems broad, mortality from HNSCC continues to rise worldwide^[90]. As reviewed by Bukowski *et al.*, part of this problem may be a reflection of drug resistance, which leads to a reduction of the therapeutic efficacy and is related to over 90% mortality of cancer patients^[91]. Multi-drug resistance (MDR) of cancer cells during chemotherapy can be associated with a variety of mechanisms, including enhanced efflux of drugs, drug activation or inactivation, genetic factors (gene mutations, amplifications, and epigenetic alterations), growth factors, increased DNA repair capacity, inactivation of apoptosis machinery, increased autophagy, and elevated metabolism of xenobiotics, or even any combination of these mechanisms^[91-93]. In addition, establishing a tumor microenvironment (TME) promotes tumor progression and chemoresistance through a collection of soluble proteins and insoluble vesicles secreted by tumor cells. This cell-to-cell communication among various cell types required to form the TME, such as mesenchymal stromal cells, immune cells, and vascular endothelial cells, influences the function of cells in the TME, shapes the premetastatic niche, and is an essential contributor to the development of chemoresistance^[94].

Tumor heterogeneity is a significant complicating factor in cancer treatment and is also strictly associated with chemotherapy resistance, impacting poor prognosis for HNSCC patients^[95]. Specifically, the presence of the CSCs has been associated with resistance to chemotherapeutic agents such as cisplatin, bortezomib, etoposide, 5-FU, and doxorubicin^[92,96]. Most importantly, many studies have demonstrated that treatment with these drugs enhances the CSCs fraction in different solid tumors and favors EMT traits, leading to treatment resistance and cancer progression^[97,98]. In addition, the acquisition of resistance to a specific drug generally tends to multiply resistance to unrelated compounds in CSCs and malignant cells, which under treatment pressure, can acquire a stem-like phenotype and become therapeutic resistant^[18].

CSCs were identified as crucial players in the acquisition of drug resistance and unresponsiveness to current chemotherapies against cancer by activating different cellular signaling pathways and mechanisms [Figure 2]. The main reasons found in the literature rely on intrinsic properties of CSCs, such as the (1) inherent quiescent state that enables them to evade the actions of drugs that target rapidly proliferating cells; (2) high levels of drug efflux pumps and detoxifying enzymes; (3) increased DNA self-repair capacity; (4) specific expression of anti-apoptotic and prosurvival proteins; (5) acquisition of the EMT-phenotype; (6)

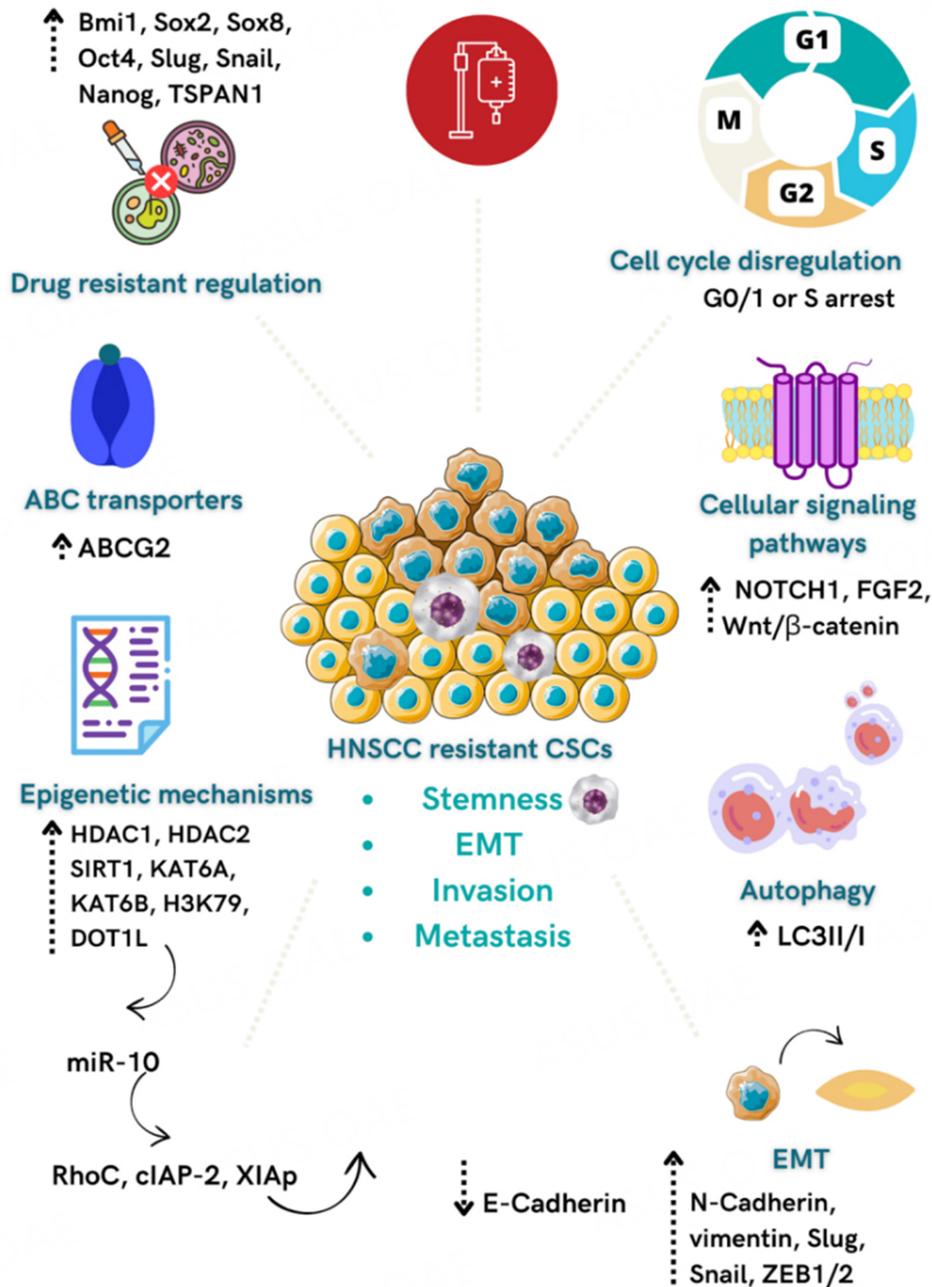

Figure 2. Mechanisms related to CSCs' chemoresistance in HNSCC. Overexpression of *Bmi1*, *Sox2*, *Sox8*, *Oct4*, *Slug*, *Snail*, *Nanog*, and *TSPAN1* genes leads to the acquisition of drug resistance and stemness, EMT, and metastasis. CSCs activate signaling pathways such as the NOTCH1, FGF2, and Wnt/ β -catenin to promote chemoresistance and stemness. Increased expression of ABC transporters, mainly ABCG2, the activation of EMT, cell cycle deregulation, increased autophagy, and activation of epigenetic mechanisms, such as up-regulation of miR-10, are involved with CSC's chemoresistance in HNSCC.

oxidative modulation; (7) epigenetic modifications and (6) activation of the specific signaling pathways^[90,99-103]. In addition, the role of the TME in sustaining the CSCs niche is also gaining substantial importance in promoting resistance to chemotherapy as an extrinsic factor^[101]. The TME shapes the morphology and functional features of CSCs, mainly influencing (1) cellular plasticity; (2) hypoxia; (3) metabolic reprogramming; (4) activation of specific signaling pathways; and (5) cell-to-cell interactions^[100].

Several *in vitro* studies found that stemness-related genes are overexpressed in HNSCC cell lines resistant mainly to Cisplatin, 5-FU, doxorubicin, and docetaxel. *Sox2*, *Oct4*, *CD44*, *Bmi1*, *ALDH1*, and *Nanog* were the genes most frequently associated with the CSC phenotype. Also, EMT markers (*Slug*, *ZEB1*, *Twist*, *Snail*), as well as drug efflux transporters (*ABCG2*, *ABCC1/ABCC2/ABCC3/ABCC4/ABCC5*, *ABCB1*), epigenetic alterations (*HDAC1/HDAC2*, *SIRT1*, *KAT6A/KAT6B*), and specific signaling pathways such as Wnt/ β -catenin and *NOTCH1*. These mechanisms endow CSCs to survive against standard cancer therapies and promote tumorigenesis, recurrence, and metastasis after chemotherapy [Table 1](#)^[99,104-107].

Interestingly, when considering the CSC phenotype and plasticity in chemoresistant HNSCC tumor samples and cell lines, members of the regulator of embryonic stem cell *Sox* and *Oct4* are highlighted over the classical *CD44*, *Bmi1*, and even *ALDH1* CSCs biomarkers. *Sox2* was associated with clinicopathological parameters of worse outcomes in HNSCC patients and a mediator of therapy resistance *in vitro*. Functionally, *Sox2* induced the expression of the anti-apoptotic protein *Bcl-2* and enhanced resistance to apoptosis-inducing agents, including cisplatin^[108]. Accordingly, Lee *et al.* found that *Sox2* overexpression was correlated with tumor recurrence and poor prognosis in HNSCC, contributing significantly to the acquisition of stem cell traits *in vitro*^[109]. Ectopic expression of *Sox2* in HNSCC cells induced stemness by positive regulation of *Oct4* and *Nanog* and co-expression of *CD44*. In addition, endogenous levels of *Sox2* were significantly higher in *ALDH1* high cells. At the same time, the downregulation of *Sox2* was followed by *Oct4* and *Nanog* down-regulation, decrease in stemness, invasion, EMT mediators, *in vivo* tumorigenicity, and frequency of *CD44*⁺ cells. Moreover, *Sox2* enhances the chemoresistance of CSCs to cisplatin, possibly by inhibiting *ABCG2* expression and resistance to oxidative stress in *CD44*⁺ *CD271*⁺ CSCs in HNSCC^[109].

Xie *et al.* found that *Sox8* expression was positively associated with chemotherapeutic resistance, higher lymph node metastasis, advanced tumor stage, and shorter overall survival in HNSCC patients^[110]. Also, the expression of *Sox8* in cisplatin-resistant HNSCC cell lines is responsible for orchestrating the acquisition of the CSC phenotype *via* *ABCG2*, *Sox2*, *Oct4*, and *Bmi1* expression but also resistance to therapy and activation of EMT and Wnt/ β -catenin pathway, favoring tumor invasion and progression. These findings indicate that *Sox8* could be used as a biomarker and a possible target to eradicate the CSCs and increase tumor response to standard therapies toward HNSCC^[110].

Several *in vitro* studies investigating the relevance of CSCs on chemoresistance initially characterize the CSCs subpopulation based on the expression levels of *CD44* and *ALDH1*. Nör *et al.* showed that treatment with low doses of cisplatin promotes *Bmi1* and *Oct44* expression and increases the CSCs fraction identified as *CD44*^{high} *ALDH*^{high}, indicating that these cells are intrinsically resistant to treatment and can expand after therapy^[111]. The study by Chen *et al.* elegantly confirmed that *Bmi1*⁺ CSCs are enriched *in vivo* after treatment with cisplatin, being able to reconstitute the tumor heterogeneity and are the main responsible for recurrence^[112]. Kulsum *et al.* found that HNSCC cell lines resistant to cisplatin and 5-FU showed enrichment of *CD44*⁺ *ALDH1*⁺ subpopulation, stemness, expression of *ABCG2*, *Sox2*, *Nanog*, *Oct4*, and *NOTCH1* genes, and G0/G1 or S phase arrest^[113]. One of the mechanisms by which the *CD44*^{high}/*ALDH1*^{high} cells become resistant may be the upregulation of the *DOT1L* and monomethyl l-H3K79 that lead to miR-10 activation, resulting in cytoskeleton remodeling *via* *RhoC* and upregulation of prosurvival molecules such as *cIAP-2* and *XIAP*^[114]. Another mechanism associated with cisplatin resistance of *CD44*^{high}/*ALDH1*^{high} is the secretion of *FGF2*. Most importantly, cisplatin combined with *FGFR2* inhibition decreased the percentage of *CD44*^{high}/*ALDH1*^{high}, and no CSCs enrichment was noticed after cisplatin exposure, indicating that blocking *FGFR* is an attractive target to eliminate the CSCs in HNSCC^[115].

Table 1. The main mechanisms involved in chemotherapy resistance of cancer stem cells in HNSCC

Author	Type of study	Drug and concentration	Cell line	CSC isolation	Associated genes	Main findings
Oliveira et al. ^[96]	<i>In vitro</i>	Cisplatin (9-92 μM)	CAL-27 CisR and SCC-9CRR	ALDH1 ⁺ CD44 ⁺	<i>HDAC1, HDAC2, SIRT1, KAT6A, KAT6B, ZEB1, Bmi1</i>	<ul style="list-style-type: none"> • The mRNA levels of <i>HDAC1, HDAC2, SIRT1, KAT6A, and KAT6B</i> were up-regulated in cisplatin-resistant cell lines, indicating activation of epigenetic mechanisms for chemoresistance acquisition • Activation of EMT program via association of epigenetic regulators and <i>ZEB1</i> is involved with resistance to cisplatin • CSC subpopulation increased in cell lines with increasing levels of cisplatin resistance, which was also associated with high expression of <i>Bmi1</i>
Lee et al. ^[109]	<i>In vitro, in vivo</i>	Cisplatin (5- 50 μM)	SNU1041 and FaDu	ALDH1 ^{high} CD44 ⁺	<i>Oct4, Sox2, Nanog, Twist, Snail, Slug</i>	<ul style="list-style-type: none"> • <i>SOX2</i> overexpression is associated with recurrence and contributes significantly to acquiring stem cell traits in HNSCC cell lines • <i>SOX2</i> expression is high in ALDH1^{high} CD44⁺ cells, and its down-regulation was followed by <i>Oct4</i> and <i>Nanog</i> down-regulation, decrease in stemness, invasion, EMT, and frequency of CD44⁺ cells • <i>SOX2</i> contributes to the resistance of CSCs to cisplatin, and its inhibition decreases CSCs viability, possibly by the inhibition of <i>ABCG2</i>. • Downregulation of <i>ABCG2</i> in CSCs overexpressing <i>SOX2</i> restored drug sensitivity after cisplatin treatment
Xie et al. ^[110]	<i>In vitro, in vivo</i>	Cisplatin (1-10 μM)	SCC9-res cells CAL27-res	CD44 ⁺ CD24 ⁻	<i>Oct4, Sox2, Bmi1, SOX8, ABCG2</i>	<ul style="list-style-type: none"> • Cisplatin-resistant HNSCC cell lines acquire CSCs properties, characterized by increased <i>Oct4, Sox2, Bmi1, and ABCG2</i> expression, self-renewal potential, EMT activation, and tumorigenesis <i>in vivo</i>, which was mediated by <i>SOX8</i> upregulation • <i>SOX8</i> knockdown decreases the expression of CSCs associated genes as well as <i>ABCG2</i> and inhibits sphere formation, CD44⁺ CD24⁻ fraction, migration, and invasion in cisplatin-resistant cell lines • EMT was successfully reversed after <i>SOX8</i> knockdown and inhibited metastasis • Moreover, <i>SOX8</i> knockdown repressed tumor metastasis mainly due to inhibition of the Wnt/ β-catenin signaling pathway through the transcriptional regulation of <i>FZD7</i>
Nör et al. ^[111]	<i>In vitro, in vivo</i>	Cisplatin (different concentrations)	UM-SCC-1, UM-SCC-22A, and UM-SCC-22B	ALDH ^{high} CD44 ^{high}	<i>Bmi1, Oct4</i>	<ul style="list-style-type: none"> • Exposure to 2μM cisplatin for 24h showed no impact on cell survival in malignant cells. However, when sorted ALDH^{high} CD44^{high} cells were exposed, cisplatin doubled the CSCs fraction • Low concentrations of cisplatin-induced the expression of <i>Bmi1</i> and <i>Oct4</i> genes, CD44, and orosphere formation in unsorted and sorted CSCs, indicating that this therapy contributes to the acquisition and maintenance of stemness
Chen et al. ^[112]	<i>In vivo</i>	Cisplatin (1mg/Kg body weight)	SCC1, SCC1R, SCC9, SCC22B, SCC23, SCC23R, HN13	<i>Bmi1</i> ⁺ EpCAM ⁺ (primary mouse)	-	<ul style="list-style-type: none"> • <i>Bmi1</i> identifies a population of CSCs responsible for HNSCC initiation, progression, and metastasis using an elegant <i>in vivo</i> model

Author et al. [ref]	Model	Treatment	Cell Lines	Markers	Genes	Findings
Kulsum et al. [113]	<i>In vitro</i> , <i>in vivo</i>	Cisplatin (2-32 μ M), Docetaxel (2-15nM) and 5-FU (5-100 μ M)	Hep-2, Hep-2 CisR, Cal-27, Cal-27 CisR, Cal-27 5FUR, Cal-27 Dox	CD44 ⁺ , CD133 ⁺ , ALDH1A1 ⁺	<i>Oct4</i> , <i>Sox2</i> , <i>Nanog</i> , <i>CD44</i> , <i>NOTCH1</i> , <i>CD133</i> , <i>ALDH1A1</i> , <i>ABCG2</i>	<p>HNSCC) ALDH^{high} CD44⁺ EpCAM⁺ (Primary human HNSCC)</p> <p>of genetic lineage tracing Bmi1⁺ CSCs are located in lymph nodes and in the invasive front of HNSCC, mediating invasive behavior and metastasis</p> <ul style="list-style-type: none"> ● Bmi1⁺ CSCs are enriched after <i>in vivo</i> treatment with cisplatin and were able to reconstitute the tumor heterogeneity after therapy, indicating that these cells are one of the major causes of recurrence ● Targeting Bmi1⁺ CSCs with Bmi1 or AP-1 inhibitors and the tumor bulk with cisplatin resulted in improved therapeutic outcomes, reduced tumor size, and the incidence of lymph node metastasis <i>in vivo</i>
Bourguignon et al. [114]	<i>In vitro</i>	Cisplatin (different concentrations)	HSC-3	ALDH ^{high} CD44 ^{high}	<i>Oct4</i> , <i>Sox2</i> , <i>Nanog</i>	<ul style="list-style-type: none"> ● Cell lines resistant to cisplatin and 5-FU showed enrichment of CD44⁺, CD133⁺ and ALDH1A1⁺ CSCs, increased expression of <i>ABCG2</i>, <i>Sox2</i>, <i>Nanog</i>, <i>Oct4</i>, and <i>NOTCH1</i> genes, and cell cycle dysregulation, characterized by G0/G1 or S phase arrest ● Increased spheroid formation and migration were also observed in resistant cell lines ● <i>Oct4</i>, <i>Sox2</i>, and <i>Nanog</i> expression represent driving forces behind the induction of drug-induced chemoresistance in HNSCC ● Depletion of ALDH1A1 with small molecule inhibitor (NCT-501) in resistant cell lines inhibited tumor burden <i>in vivo</i> and increased the efficacy of cisplatin in patient-derived <i>ex vivo</i> explant
McDermott et al. [115]	<i>In vitro</i> , <i>in vivo</i>	Cisplatin (2 μ M)	UM-SCC-1 and UM-SCC-22B	ALDH ^{high} CD44 ^{high}	-	<ul style="list-style-type: none"> ● HA (matrix hyaluronan) promotes aggressiveness in highly tumorigenic ALDH^{high} CD44^{high} tumor cells ● Up-regulation of <i>DOT1L</i> and monomethyl I-H3K79 lead to miR-10 production in HA-treated CSCs ● miR-10 increases the cytoskeleton regulator RhoC in CSCs and <i>DOT1L</i> signaling inhibition via <i>DOT1L</i> siRNA or anti-miR-10b inhibitor decreases RhoC, tumor cell migration/invasion, expression of survival proteins (cIAP-2 and XIAP) and contributes to increasing chemosensitivity ● Inhibition of cIAP-2 or XIAP expression enhances cisplatin-induced chemosensitivity in ALDH^{high} CD44^{high} CSCs ● Taken together, <i>DOT1L</i> and miR-10 are important targets for future therapies to decrease stemness, induce CSCs death and increase its susceptibility to standard chemotherapy
Elkashty et al. [117]	<i>In vitro</i> , <i>in vivo</i>	Cisplatin (0.817 μ g/mL) 5-FU (3.644 μ g/mL)	SCC12 and SCC38	CD44 ⁺ CD271 ⁺	<i>Oct4</i> , <i>Sox2</i>	<ul style="list-style-type: none"> ● <i>FGF2</i> and <i>EREG</i> mRNA were increased in cisplatin-treated ALDH^{high} CD44^{high} ● TNFα, IFNγ, IL-6, and NF-κB signaling pathways were associated with cisplatin resistance in ALDH^{high} CD44^{high} cells ● FGFR1-4 inhibition, together with cisplatin treatment, promoted a 50% reduction in ALDH^{high} CD44^{high} ● After <i>FGFR2</i> knockdown, cisplatin no longer increased the ALDH^{high} CD44^{high} CSC in HNSCC cell lines ● Therapeutic inhibition of FGFR might contribute to eliminating ALDH^{high} CD44^{high} cisplatin-resistant CSCs
						<ul style="list-style-type: none"> ● CD44⁺ CD271⁺ cells showed increased resistance to oxidative stress in HNSCC (which is a cytotoxic effect of cisplatin) and higher expression of <i>Bmi1</i>, <i>Oct4</i>, <i>Sox2</i>, <i>SMO</i>, and <i>GLI1</i> genes after exposure

Yu et al. ^[119]	<i>In vitro, in vivo</i>	Cisplatin (6.25-100 μM), 5-FU (6.25-100 μM) and doxorubicin (1.25-20 μM)	OECM1-SP SCC25-SP	Side Population (SP)	<i>CD133, ABCG2, ALDH1A1</i>	<p>to cisplatin and 5-FU</p> <ul style="list-style-type: none"> ● CD133 was significantly up-regulated in SP cells, which also demonstrated high chemoresistance and expression of ABCG2 ● Depletion of CD133 was associated with decreased SP frequency and attenuated <i>in vivo</i> tumor formation ● Targeting CD133 together with cisplatin treatment abrogated the proliferation of SP cells in HNSCC, indicating that CD133 is a promising therapeutic target to overcome drug resistance in CSCs
Moon et al. ^[120]	<i>In vitro, in vivo</i>	Cisplatin (5-100 μM)	YD8, SNU1041, KU-SCC1 and KU-SCC3	CD44 ⁺	<i>Slug</i>	<ul style="list-style-type: none"> ● CD44⁺ cells showed high expression of Slug and were significantly resistant to cisplatin, which was also associated with an elevated expression of ABC transporters

CD44 is frequently associated with other potential markers of CSC aiming for efficient enrichment of this subpopulation within HNSCC cell lines and tissues. Galbiatti-Dias *et al.* identified the CSC profile of HNSCC cell lines as CD44^{high} CD133^{high} CD117^{high} profile^[116]. This CSCs subpopulation demonstrated higher migration capacity and more resistance to Paclitaxel chemotherapy, in addition to an up-regulation of CD44 and down-regulation of *EGFR* transcripts in the HN13 oral cancer cell line^[116]. Elkashty *et al.* combined the positivity of CD44 to CD271 (p75NTR), a described marker of CSC in many tumors^[117], to isolate an enriched subpopulation of CSCs, followed by their characterization *in vitro*, *in vivo*, and HNSCC tissue samples. The authors found that CD44⁺ CD271⁺ cells exhibited higher cell proliferation, sphere/colony formation, chemoresistance to cisplatin and 5-FU, and radioresistance, upregulation of CSCs-related genes (*Sox2*, *Oct4*, *Bmi1*, *Smo*, and *GLI1*), and *in vivo* tumorigenicity^[117]. These combined cell markers also showed increased expression in patients with advanced disease.

A study from Oh *et al.* demonstrated that CD44⁺ cells derived from primary HNSCC had increased expression of ABCG2 and enriched side population^[118]. Yu *et al.* found that side population cells characterized by the CD133⁺ phenotype show elevated chemoresistance and ABCG2 expression, which was abrogated by combining cisplatin with CD133-targeted therapy^[119]. Moreover, *Snail* is overexpressed in CD44⁺ CSCs and associated with cisplatin resistance and high expression of ABC transporters^[120]. Interestingly, the percentage of *Oct4* positive cells increases significantly after treatment with 5-FU, cisplatin, and paclitaxel^[121], and increased expression of ABCC6 was associated with increased resistance to cisplatin in *Oct4* overexpressing cells, indicating that this poorly explored ABC transporter may be relevant to resistance acquisition in HNSCC^[122]. Thus, constitutive or acquisition of stem cell and EMT-associated genes are involved with the up-regulation of drug transporters pumps and multi-drug resistance.

The process of EMT is tightly linked with the CSC's biology and chemoresistance in HNSCC. CSCs keep their EMT phenotype until depositing in the distant sites of metastasis (a migratory phenotype), where they change their phenotype toward attaining a MET morphology to proliferate rapidly, causing tumor outgrowth (a proliferative phenotype)^[123]. This rapid cellular proliferation leads to hypoxia in the nearby milieu, thereby exacerbating tumor resistance to therapy^[124]. Masui *et al.* observed that the CSC-like phenotype is induced after *Snail*-overexpression and is associated with increased CD44⁺/ALDH⁺ in HNSCC cell lines^[125]. The EMT and CSC phenotype acquisition in *Snail* overexpressing cells also decreased chemosensitivity. Similarly, Ota *et al.* demonstrated that *Snail*-induced EMT was associated with increased stemness, inducing *in vivo* cancer invasive progression and enhancement of chemoresistance^[126]. A recent study from Oliveira *et al.* demonstrated that the CSC subpopulation and activation of the EMT program, characterized by down-regulation of E-cadherin and up-regulation of vimentin, mainly *via* association of epigenetic regulators and ZEB1, is involved with resistance to cisplatin in HNSCC cell lines^[96].

It is worth mentioning that the ability of tumor cells to dynamically adapt to signals provided by the tumor microenvironment and/or induced in response to therapy is obtained by the property of cell plasticity at different stages of tumor progression. Cancer cell plasticity reflects genetic and epigenetic alterations in tumor cells, promoting phenotypical diversity and contributing to intra-tumor heterogeneity^[127]. EMT and CSCs states are the two most studied axes of tumor cell plasticity and are often tacitly assumed to be synonymous^[128]. This is because both cell plasticity axes appear to drive one another *in silico*, *in vitro*, and *in vivo* studies^[129]. Notably, both mathematical modeling studies and experimental observations have reported that EMT is also not a unidirectional process since there are one or more hybrid epithelial/ mesenchymal (E/M) states between the two extremes of pure epithelial or pure mesenchymal phenotypes^[130,131] during EMT. For this reason, the term Epithelial-Mesenchymal Plasticity (EMP) has been used as a more accurate description of the process.

The same is true for CSC since there may be subsets of CSCs defined as epithelial, mesenchymal, and hybrid E/M (E-CSCs, M-CSCs, H-CSCs)^[132,133]. According to Sahoo *et al.* 2022^[128], the emerging evidence points to EMT and stemness being semi-independent axes, i.e., not every cell undergoing EMT may acquire stemness and not every cell switching to be a CSC is mandated to show one or more features of EMT. These authors recently proposed a mathematical model to understand the interconnectivity between the EMP and stemness axes aiming to elucidate the critical cellular processes driving metastasis. This model allows many possible couplings between EMP and stemness, showing that all phenotypes - epithelial, mesenchymal, and hybrid E/M - have the potential to be stem-like; however, this potential is likely to be maximum for hybrid E/M cells^[128]. On the other hand, tumor cells exhibiting an amoeboid phenotype belong to the utterly

mesenchymal end of the EMP spectrum but show high stemness and metastatic potential^[134]. So, many stem cell phenotypes exist across the EMP spectrum that would only be identified based on single-cell RNA sequencing approaches^[128].

Garcia-Mayea *et al.* showed that CSCs isolated by sphere formation in non-adherent conditions were more resistant to cisplatin and 5-FU, possibly due to the increased levels of LC3II/I, indicating that autophagy may be involved in within-drug resistance of CSCs^[135]. Recently, using the same CSC model, these authors identified by RNAseq the *TSPAN1* (Tetraspanin 1) gene as an essential modulator of chemoresistance in HNSCC^[136]. Blocking *TSPAN1* demonstrated encouraging *in vivo* results, leading to impaired tumor growth, EMT acquisition, and metastasis spreading. Another possible target to eliminate HNSCC CSCs and cisplatin resistance is the SDCBP (Syndecan-binding protein), a central contributor in different phases of the metastasis cascade^[137,138]. Upon fibronectin and extracellular molecule engagement, SDCBP, as an adaptor protein, interacts with Src and forms a stable complex with FAK in the cellular membrane leading to long-term Src activation. As a result, downstream target signaling pathways such as NF- κ B and TGF- β are activated, promoting EMT, tumor migration, invasion, metastasis, and cisplatin resistance^[138]. Lee *et al.* showed that Wnt/ β -catenin signaling is activated in CSCs, and β -catenin overexpression drives the acquisition of CSCs properties as self-renewal, stem cell marker expression, including *Oct4*, and chemoresistance^[139]. In hypoxic conditions, HIF-1 α activates NOTCH1, which is responsible for stemness, EMT activation, and resistance to cisplatin in CD44⁺ cells^[140].

All these exposed findings reveal how broad and complex the process of resistance to the chemotherapeutics available today for treatment could be. It also guides us to seek new and innovative drugs focused on CSCs, such as targeted therapy and immunotherapy, for better treatment and prognosis of HNSCC patients. Notably, the plasticity of CSCs must also be considered since their dynamic phenotype switch may be responsible for different levels of resistance even in the same tumor type. As pointed out by Biddle & Marles^[141], an effective biomarker should be precise in correlating the presence of phenotypically plastic CSCs with tumor aggressiveness and therapeutic resistance. It would allow more accurate clinical decisions, such as neck dissection and chemotherapy regimens in HNSCC. More recent evidence highlights some meaningful advances, for example, monoclonal antibody therapy anti-CD44v6 and other markers related to EMT signaling pathways activation, such as the Notch, WNT, and ERK/ MAPK pathways. Although, in terms of clinical safety, targeting CSC-specific processes is not well established yet.

CONCLUDING REMARKS

The presence of CSCs in HNSCC and other solid tumors is associated with tumor heterogeneity and resistance to standard therapies. Target CSCs therapy is very challenging as these cells are a dynamic and plastic population capable of switching between different phenotypes and activation states according to the stimuli provided by the TME. As a result, the frequency of CSCs and their spatial localization in the primary tumor and metastatic foci may be variable, leading to different levels of tumor resistance after treatment. Many studies demonstrated that after radio and chemotherapy, CSCs are enriched and guide tumor recurrence and progression.

In this scenario, it is mandatory to characterize the CSCs and their mechanisms of interactions with the TME in HNSCC to better design targeted therapies that efficiently eliminate these cells in combination with standard treatment and/or immunotherapy. Disrupting the TME can lead to hypoxia inhibition and disturb the CSC niche, facilitating CSCs sensitization to chemotherapy. Moreover, CSCs interaction with different cell types in the TME may be impaired, facilitating its elimination and response to standard treatment. It is essential to highlight that CSCs have an efficient drug efflux machinery that should be considered as

possible targets to improve drug accumulation within this subpopulation of tumor cells. Targeting signaling pathways involved with acquiring stemness, such as the Wnt/ β -catenin, FGF, and NOTCH1 in HNSCC, may also be an attractive strategy to eliminate the CSCs and drug resistance. Taken together, CSCs are a relevant target to achieve control of disease and treatment response in HNSCC as they represent significant drivers of tumor resistance. Future studies, especially those using cutting-edge methodologies such as scRNAseq, will help to identify new CSCs targets and cellular interactions that can be used to develop new multi-faceted adjuvant therapies.

Abstract

In response to the changing availability of nutrients and oxygen in the bone marrow microenvironment, acute myeloid leukemia (AML) cells continuously adjust their metabolic state. To meet the biochemical demands of their increased proliferation, AML cells strongly depend on mitochondrial oxidative phosphorylation (OXPHOS). Recent data indicate that a subset of AML cells remains quiescent and survives through metabolic activation of fatty acid oxidation (FAO), which causes uncoupling of mitochondrial OXPHOS and facilitates chemoresistance. For targeting these metabolic vulnerabilities of AML cells, inhibitors of OXPHOS and FAO have been developed and investigated for their therapeutic potential. Recent experimental and clinical evidence has revealed that drug-resistant AML cells and leukemic stem cells rewire metabolic pathways through interaction with BM stromal cells, enabling them to acquire resistance against OXPHOS and FAO inhibitors. These acquired resistance mechanisms compensate for the metabolic targeting by inhibitors. Several chemotherapy/targeted therapy regimens in combination with OXPHOS and FAO inhibitors are under development to target these compensatory pathways.

INTRODUCTION

Acute myeloid leukemia (AML) comprises a highly aggressive, biologically heterogeneous group of hematopoietic disorders involving one or more cytogenetically or molecularly abnormal cell clones. It is primarily a disease of older adults. The standard of care for relapsed and refractory AML has progressed minimally in the past 30 years, with survival rates of less than 12% for patients over 65 years old^[1]. Thus, novel therapeutic strategies that are more effective and carry a lower risk of organ damage than current treatments are urgently needed.

AML cells always face two major metabolic challenges: their high rate of proliferation imposes increased bioenergetic demands, and fluctuations in the availability of external nutrients and oxygen in the bone marrow (BM) microenvironment threaten cellular survival. In the BM, AML cells constantly modulate their metabolic state to adapt to this fluctuating microenvironment, shifting between quiescent, proliferative, and differentiated states^[2-4]. Highly proliferative AML cells, drug-resistant AML cells, and leukemia stem cells (LSCs) that remain quiescent have been shown to depend on oxidative phosphorylation (OXPHOS). LSCs differ from bulk leukemia cells in that they possess stem cell characteristics including abnormal self-renewal capacity and drug resistance. Persistence of LSCs in the BM microenvironment after chemotherapy is considered an important factor in AML relapse^[5]. Both quiescent AML cells and LSCs survive through metabolic activation of fatty acid oxidation (FAO) along with OXPHOS in their mitochondria. Hence, the reprogramming of energy metabolism processes in AML cells is recognized as a potential therapeutic target. Inhibition of OXPHOS and FAO can disrupt metabolic homeostasis, increase reactive oxygen species (ROS) production, and cause apoptosis in AML cells^[2,6,7]. However, inhibition of this altered energy metabolism triggers various adaptive mechanisms in AML cells through their interaction with BM stromal cells. Thus, the BM microenvironment provides a setting in which secondary resistance to OXPHOS inhibition can develop, thereby contributing to the survival of AML cells. Therefore, strategies combining chemotherapy and specific molecular targeted therapy may have promise for eliminating BM-resident AML cells and LSCs.

In this review, we summarize the current state of knowledge about mitochondrial OXPHOS and fatty acid metabolism in residual AML cells in the BM microenvironment. We further describe the molecular mechanism by which AML cells acquire resistance to OXPHOS and FAO inhibitors. Finally, we evaluate potential therapeutic regimens combining OXPHOS and FAO inhibitors to target the metabolic vulnerabilities of BM-resident chemoresistant leukemia cells and LSCs.

MAIN TEXT

The BM microenvironment reprograms OXPHOS in AML cells

AML cells' dependence on OXPHOS in the BM microenvironment

Whereas circulating AML cells are effectively eliminated by drug treatment, AML cells residing in the BM acquire resistance to chemotherapy. The BM microenvironment provides growth factors for leukemic cells, promotes immunosuppression, and supports leukemic cell survival. In response, leukemia cells adapt their metabolic state to this constantly changing environment^[7-9].

Energy metabolism encompasses the molecular pathways whose products are involved in cellular energy production in the form of ATP. In leukemic cells, energy metabolism relies on OXPHOS and associated

catabolic pathways, including glycolysis and fatty acid metabolism. The energy required for ATP production is produced by the mitochondrial potential, which causes protons to reenter the mitochondria through complex V. Fatty acid metabolism also supplies acetyl-CoA to the tricarboxylic acid (TCA) cycle through FAO [Figure 1].

Recently, the molecular mechanisms by which AML cells undergo metabolic reprogramming and those underlying the antileukemic efficacy of OXPHOS inhibitors have been demonstrated^[7,10]. Actively proliferating AML cells respond to their increased energy and substrate demands via upregulation of OXPHOS, glycolysis, and related biochemical pathways. In turn, their bioenergetic efficacy strongly depends on extrinsic signals from the microenvironment^[11].

The leukemic BM microenvironment is generally hypoxic; during disease progression, hypoxic areas in the BM expand^[12-14]. Indeed, AML cells so strongly depend on OXPHOS for metabolism that they might cause hypoxia in the BM environment. These hypoxic niches are expanded, in part, through activation of the transcription factor hypoxia-inducible factor 1 α (HIF-1 α)^[12,15]. Transcriptional complexes often include metabolic enzymes, which locally supply substrates and cofactors to these complexes^[16]. For this reason, OXPHOS itself and the transcription factors that regulate it are attractive targets for novel therapeutic interventions.

The persistence of LSCs and treatment-resistant AML cells in the BM remains the major cause of failure to eradicate AML. Cancer stem cells were initially identified in AML^[17,18] and subsequently validated in solid tumors. Across cancers, cancer stem cells share two important features: they can self-renew and produce differentiated progeny. The OXPHOS-dependent survival mechanism of LSCs is common to several solid tumor stem cells. For example, pancreatic cancer stem cells use OXPHOS for survival by accumulating the transcription coactivator peroxisome proliferator-activated receptor coactivator-1 α (PGC-1 α), which enhances mitochondrial biogenesis and the oxygen consumption rate and is sensitive to inhibitors of mitochondrial respiration^[19]. Reliance on OXPHOS has also been observed in other solid-tumor stem cells, including those in brain^[10] and breast cancers^[20].

Several recent studies have revealed how AML LSCs exploit OXPHOS^[21]. The transcriptional and epigenetic signatures of leukemia-initiating LSCs are largely mutation-independent^[22-25]. Instead, rewired cellular metabolism has been increasingly recognized to play a significant role in LSC maintenance and treatment resistance in AML^[26]. In LSCs, several components of the electron transport chain (ETC) complexes I and V have been shown to be more abundant than in normal hematopoietic stem cells (HSCs)^[27]. Notably, AML LSCs overexpress antiapoptotic BCL-2, which has been shown to regulate ATP/ADP exchange across the mitochondrial membrane by facilitating regulation of voltage-dependent anion channels and adenine nucleotides,^[28,29] preventing the loss of coupled mitochondrial respiration during apoptosis^[30].

Rewiring of mitochondrial function facilitates AML resistance to OXPHOS inhibition

Understanding the crosstalk between AML cells and their microenvironment is critical to targeting the pathways involved in the metabolic reprogramming of chemoresistant AML cells and LSCs. In preclinical studies, most AML models responded to inhibition of OXPHOS via targeting of ETC complex I^[3]. However, several clinical trials have shown that the efficacy of these OXPHOS inhibitors is limited^[31,32]. In trials of several types of solid tumors, one putative complex I inhibitor, carboxyamidotriazole, had no clinical benefit^[31]. Mouse studies of BAY87-2243, a novel complex I inhibitor, demonstrated antitumor activity and no toxic effects, but the phase I trial was terminated because of unexpected toxic effects^[32]. These findings indicate that OXPHOS inhibitors have a narrow therapeutic window and emphasize the need to better

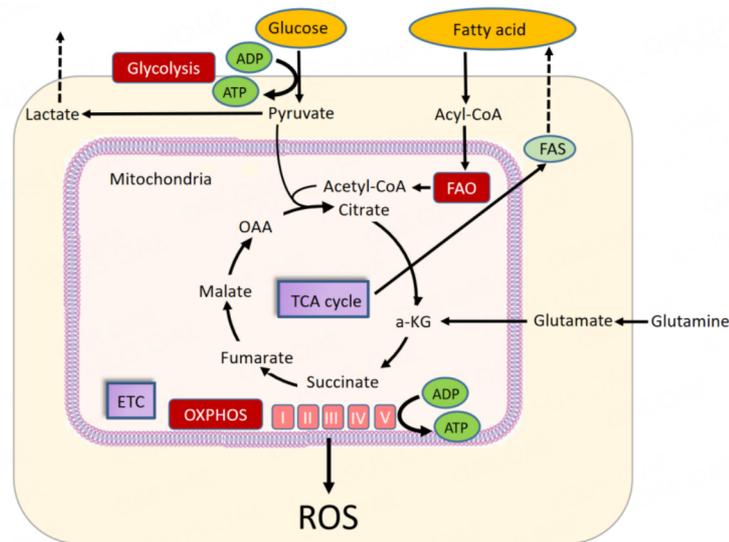

Figure 1. Energy metabolism in AML. Glucose is converted to pyruvate by glycolysis. Pyruvate is converted to acetyl-CoA for use in the tricarboxylic acid (TCA) cycle. ATP is produced by oxidative phosphorylation (OXPHOS) in the TCA cycle and electron transport chain (ETC). Fatty acid metabolism supplies acetyl-CoA to the TCA cycle via β -oxidation of fatty acids (FAO). Glutamine metabolism is the process of converting glutamine to glutamic acid. a-KG: Alpha-ketoglutarate; FAS: fatty acid synthase; OAA: oxaloacetic acid; ROS: reactive oxygen species.

understand how the BM microenvironment enables AML cells to become resistant to the metabolic stress caused by OXPHOS inhibition.

One such mechanism occurring in the tumor microenvironment is the horizontal transfer of mitochondrial DNA from host to tumor cells. Studies using *in vivo* models have shown that this transfer reestablishes respiration and promotes tumorigenesis^[33]. In OXPHOS-dependent AML cells, OXPHOS inhibition induced formation of tunneling nanotubes that enabled this mitochondrial DNA trafficking from BM stroma cells to AML cells^[34]. In the formation of tunneling nanotubes, a filopodium-like protrusion is extended from one cell to another^[35]. This process is positively regulated by activation of motor proteins such as Rho GTPases through actin polymerization^[36,37] and filopodia formation through focal adhesion^[38]. In addition, a recent study showed that a transmembrane complex gap junction channel opens under ROS-induced oxidative stress via PI3K-Akt activation to enable the transfer of mitochondrial DNA from stromal cells in the BM to HSCs [Figure 2]^[39].

OXPHOS inhibition-induced horizontal transfer of mitochondria from BM stromal cells to AML cells is accompanied by endogenous mitochondrial fission and elimination of damaged mitochondria by mitophagy, both of which contribute to AML cell survival^[34,40]. As the process by which damaged mitochondria are segregated for elimination by autophagy, mitochondrial fission is central to mitophagy^[41-44]. Cellular metabolism and cell survival require efficient mitophagy^[40,45]. Because of the centrality of these processes in the maintenance of mitochondrial function, both mitochondrial fission and crosstalk with BM stroma cells via tunneling nanotubes may be another mechanism by which AML cells develop resistance to OXPHOS inhibition^[46].

LSCs have low rates of energy metabolism and cannot upregulate glycolysis after OXPHOS inhibition. Thus, they are particularly sensitive to OXPHOS blockade^[47,48]. However, LSCs are able to maintain their stemness by mitochondrial fission and mitophagy, which balance mitochondrial functions such as energy

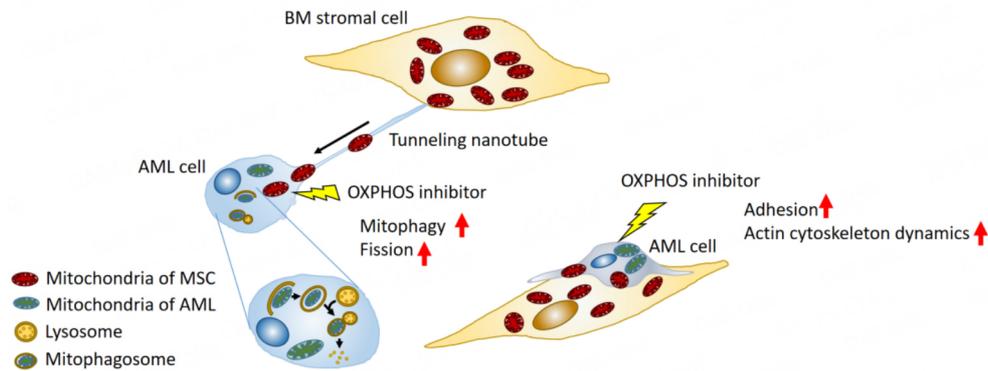

Figure 2. Secondary resistance to oxidative phosphorylation (OXPHOS) inhibition through bone marrow mesenchymal stem cells. OXPPOS inhibition stimulates cell adhesion and actin dynamics in AML cells. The bone marrow (BM) microenvironment facilitates the development of secondary resistance to OXPPOS inhibition by supporting direct mitochondrial trafficking via tunneling nanotubes from BM stromal cells to AML cells. This trafficking is accompanied by mitophagy and mitochondrial fission. MSC: Mesenchymal stem cell.

production, ROS generation, and apoptosis regulation^[44]. Given these competing pressures, LSCs have a fragile mitochondrial network. Thus, blocking both OXPPOS and other metabolic pathways is a promising strategy for overcoming OXPPOS resistance associated with the BM microenvironment. Two possible targets include the enzyme ASS1 and the lipid metabolism protein LRP1, both of which are overexpressed in OXPPOS inhibitor-treated AML cells *in vivo*. ASS1 is essential for the biosynthesis of arginine^[49], and LRP1 contributes to hemin-induced autophagy in leukemia cells^[50,51]. Further investigations will improve our understanding of how these enzymes shape the responses of LSCs to the metabolic and energetic effects of OXPPOS inhibition.

Several repurposed drugs have been shown to inhibit OXPPOS. Biguanides, including metformin, are routinely used for diabetes treatment and have been proposed for use in cancer because they inhibit complex I of the ETC in cancer cells^[52]. However, metformin carries a risk of severe lactic acidosis^[53,54], which is a safety concern for cancer patients. In addition, because high OXPPOS levels play a key role in cytarabine resistance, treatments combining cytarabine with OXPPOS inhibitors might be more effective than monotherapy with either type of agent^[33]. Recently, a novel lipoate analog, devimistat, an inhibitor of two key TCA cycle enzymes, the pyruvate dehydrogenase and α -ketoglutarate dehydrogenase complexes^[55,56], showed a satisfactory safety profile in AML patients. In a phase I study, patients with relapsed or refractory AML who received a combination of devimistat with cytarabine and mitoxantrone had a complete remission rate of 50%^[57].

In a phase II study of this combination, responses were observed in older patients but not in younger patients. In addition, RNA sequencing analysis showed a decrease in expression of mitochondria-related genes with aging, suggesting that age-related reduction in mitochondrial quality may be related to devimistat response^[58]. These are encouraging findings that indicate that this approach would be particularly effective for older patients with the highest unmet medical needs. In sum, the judicious use of novel OXPPOS inhibitors in combination treatments may add to armamentarium of currently available therapeutics.

FAO metabolism of AML cells and LSCs in the fatty acid-abundant BM microenvironment

FAO of AML cells in the BM microenvironment

Adipocytes in the BM microenvironment support the survival of several types of tumor cells by stimulating FAO through fatty acid transfer^[59]. While it was reported that BM adipocytes occupy approximately 60% of

the BM in 65-year-old individuals^[60], the development of BM adipocytes varies across different skeletal regions, and single-point iliac biopsy may not represent the BM environment of the skeletal system containing the red marrow and yellow marrow. In a previous study, leukemic cells have been shown to colonize in both red and yellow marrow regions, adhere to the cortical bone in the spine, and have enhanced activity in the proximal/distal femur^[61]. In addition, radiation therapy accelerates the differentiation of mesenchymal stem cells into adipocytes in BM^[62]. Such temporal and spatial changes in the BM microenvironment may play a key role in leukemia's dynamic adaptation of FAO and in leukemia cells' interactions with BM stromal cells.

AML cells generally obtain fatty acids for FAO from the extracellular microenvironment through lipolysis of stored triglycerides^[63]. FAO is metabolically activated to promote leukemic cell survival by remodeling and lipolysis of BM adipocytes. FAO is an essential source of mitochondrial NADH and FADH₂ for the ETC and provides acetyl-CoA to the TCA cycle to produce ATP^[64]. BM adipocytes supply long-chain fatty acids, which are then taken up into the cytoplasm via the scavenger receptor CD36^[65,66]. Fatty acids activation is a two-step reaction. In the first step, the fatty acids form acyl-CoA in the cytoplasm. Then, FAO breaks down acyl-CoA to form acetyl-CoA in the mitochondria. Carnitine O-palmitoyltransferase 1 (CPT1) catalyzes a rate-limiting step of FAO; this enzyme conjugates fatty acids to carnitine, which is required for fatty acids to translocate from the cytoplasm to the mitochondria^[67]. The internalized fatty acids are further transferred to the AML cell nucleus by the lipid chaperone fatty acid-binding protein 4 (FABP4). In the nucleus, the fatty acids ligate to peroxisome proliferator-activated receptor γ (PPAR)^[68]. Activated PPAR induces downstream target genes, including *CD36*, *FABP4*, and the antiapoptotic *BCL2* [Figure 3]^[69].

As with AML cells, the specific BM microenvironment created by the interaction between LSCs and stromal adipocytes supports the metabolic demands of LSCs. LSCs induce adipocyte lipolysis, which drives FAO in LSCs and facilitates their survival^[70,71]. Therefore, CD36 and CPT1 are potential targets for AML. A CD36 neutralizing antibody inhibited metastasis of human melanoma and breast cancer cells^[72], and inhibition of CPT1 caused mitochondrial damage leading to cell death in primary AML cells^[67].

FABP4 is important in FAO and cancer cell survival in both solid and hematologic cancers. Adipocytes are known to serve as fatty acid reservoirs in breast cancer and melanoma^[73,74]. Ovarian cancer cells also survive and proliferate in an adipocyte-rich microenvironment^[75]. When primary human omental adipocytes were co-cultured with ovarian cancer cells, the adipocytes underwent lipolysis, and FAO was induced in the cancer cells^[63]. These processes are mediated by adipokines including interleukin-8 and by upregulation of FABP4 both in adipocytes and ovarian tumor cells. In studies of leukemia, AML cells co-cultured with BM adipocytes exhibited higher levels of FABP4^[69], and knockdown of FABP4 prolonged survival in a mouse model of leukemia^[71]. Thus, FABP4's critical role in cancer cell survival involves its interactions with adipocytes.

Activation of β -adrenergic receptors, along with a G protein-coupled cascade that stimulates the lipolytic enzyme hormone-sensitive lipase (HSL), induces lipolysis of adipocytes^[76,77]. Ovarian cancer cells have been found to upregulate HSL phosphorylation, thereby stimulating the release of free fatty acids from adipocytes^[63]. AML blasts also induce HSL phosphorylation and, thus, activation of lipolysis in BM adipocytes^[71].

BM adipocytes also increase AML cells' expression of adiponectin and its downstream target, AMP-activated protein kinase (AMPK), a stress response kinase^[69]. AMPK, an important modulator of energy metabolism, is activated upon ATP depletion. Its functions include upregulation of fatty acid uptake, FAO,

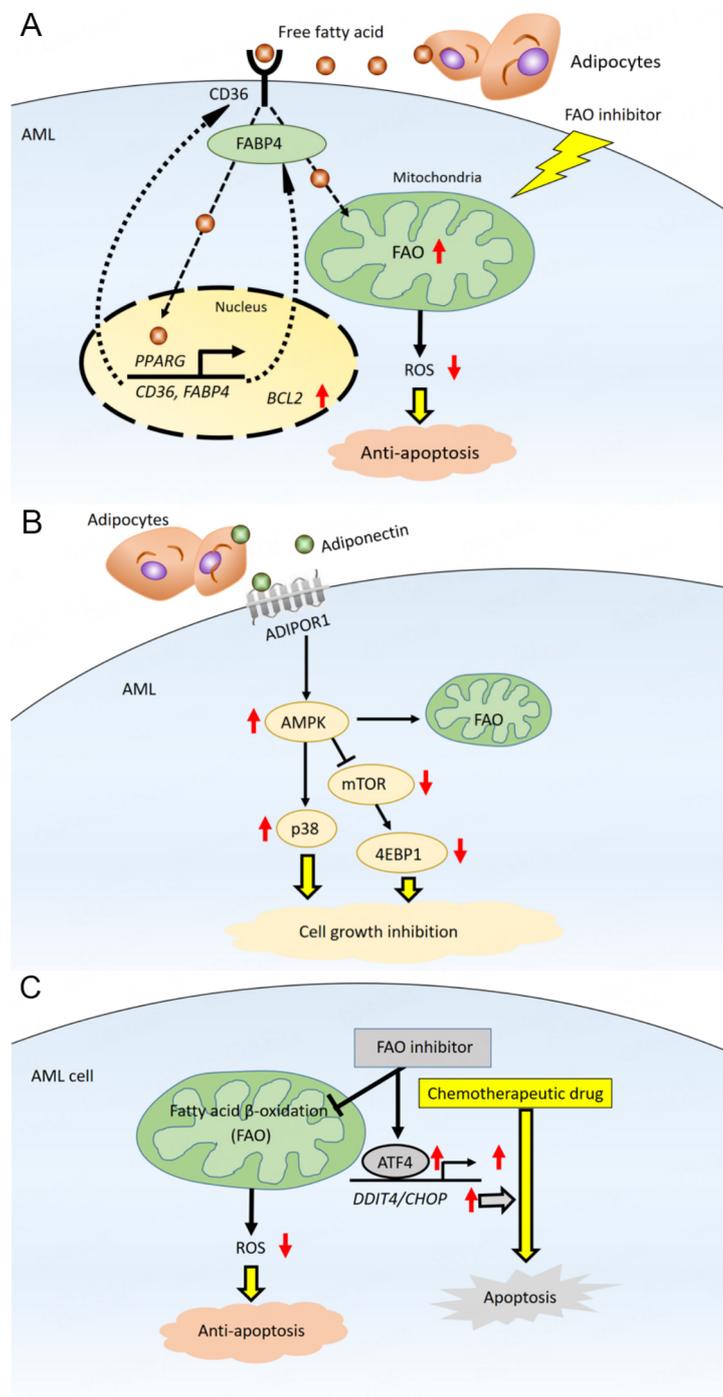

Figure 3. Bone marrow adipocytes promote fatty acid metabolism in AML. (A) Fatty acids derived through lipolysis of stored triglycerides in adipocytes induce upregulation of *PPARG*, *CD36*, and *FABP4* gene transcription, which stimulates fatty acid endocytosis. In mitochondria, fatty acids are metabolized through fatty acid oxidation (FAO), decreasing mitochondrial reactive oxygen species (ROS) formation and intracellular oxidative stress, thereby reducing apoptosis; (B) transcriptional regulation and fatty acid metabolism pathways maintain AML cells in a quiescent state. Activation of AMPK, upregulation of p38 and associated induction of autophagy, and upregulation of antiapoptotic HSP chaperone proteins in this state lead to chemoresistance; (C) in mitochondria, fatty acids are consumed for FAO, resulting in diminished formation of mitochondrial ROS and decreased intracellular oxidative stress. Inhibition of FAO induces an integrated stress response that stimulates transcriptional activation of ATF4 and promotes apoptosis induced by chemotherapy. ADIPOR1: Adiponectin receptor 1; ATF4: activating transcription factor 4; AMPK: AMP-activated protein kinase; FABP4: fatty acid binding protein 4; p38: p38 mitogen-activated protein kinase.

and regulation of autophagy^[78,79]. Levels of adiponectin, much of which is supplied by BM adipocytes, have been shown to increase during cancer therapy^[80], and to promote chemotherapy resistance in myeloma cells via inducing adipokine secretion of adipokines and activating AMPK-dependent autophagy^[81,82]. AMPK also positively regulates responses of an antiapoptotic chaperone heat shock protein that binds to denatured and unfolded proteins and promotes protein refolding or degradation to support AML cell survival^[79]. In sum, leukemic cells often rely on fatty acids when they undergo metabolic stress, and the NADH and FADH₂ generated by FAO support ATP production, redox homeostasis, biosynthesis, and cell survival.

FAO is involved in the interactions between LSCs and BM stromal cells^[83]. LSCs rely on fatty acid uptake and consumption to shape their adaptation to the conditions of the BM microenvironment, their response to drugs, and their development of drug resistance^[69]. Several such mechanisms have been identified. Mitochondrial uncoupling in AML cells negatively regulates Bak-dependent mitochondrial permeability transition^[84]. In a study using samples from patients with relapsed AML, LSCs acquired the ability to counteract the loss of amino acid metabolism by upregulating FAO^[85]. Specifically, this mechanism may underlie the development of resistance to treatment with azacitidine/venetoclax, a common induction regimen used mainly in older patients with AML^[85,86]. In addition, a preclinical study demonstrated that cytarabine-resistant AML cells had enhanced FAO and OXPHOS^[66]. Thus, targeting the metabolic vulnerabilities of chemoresistant LSCs, such as their dependence on FAO, may be a useful strategy for eradicating these cells.

FAO inhibitors and resistance acquired by compensatory metabolism in the BM microenvironment

FAO inhibition disrupts metabolic homeostasis, increases ROS levels, and induces expression of the integrated stress response mediator ATF4 in AML cells, all of which contribute to apoptosis^[87]. Numerous studies have reported the anti-AML effect of inhibition of CPT1, the major rate-limiting enzyme in FAO^[67,84,87,88]. CPT1 positively controls FAO by conjugating fatty acids with carnitine to transfer fatty acids into the mitochondrial matrix. Etomoxir is a pharmacological inhibitor of CPT1A, one of the isoforms of CPT1^[89], frequently used to block free fatty acids from entering the mitochondria via CPT1. Although the clinical use of etomoxir has ceased because of adverse effects^[90], the CPT1 inhibitor perhexiline can sensitize breast cancer cells to paclitaxel^[91], and other CPT1 inhibitors^[92] are currently being investigated for use in cancer therapy. The CPT1A inhibitor ST1326 has been shown to cause cell growth arrest, mitochondrial damage, and apoptosis in AML cells in a dose- and time-dependent manner^[67]. Another novel FAO inhibitor, avocatin B, which is derived from avocados, decreased NADPH levels that were increased by FAO through acetyl-CoA and NADH production, inducing ROS-dependent cell death in AML cells^[93,94]. Finally, the fatty acid synthase inhibitor orlistat has induced apoptosis in leukemic cells^[2].

The intramitochondrial FAO enzyme very long-chain acyl-CoA dehydrogenase (VLCAD) is critical in supporting both FAO and OXPHOS in AML cells and LSCs. Recently, preclinical studies have demonstrated the antileukemia activity of a novel small-molecule VLCAD inhibitor, a polyhydroxylated fatty alcohol with a terminal alkyne (AYNE)^[95]. AYNE reduced mitochondrial respiration by altering FAO, which led to reduced ATP production in AML cells, even though AYNE also moderately upregulated glycolysis. In a mouse model, pharmacological inhibition of VLCAD with AYNE significantly reduced the repopulation potential of leukemia cells and was well tolerated^[95]. Notably, normal HSCs compensate for this reduced replicative capacity through glycolysis which maintains their ATP levels and thus their viability^[95,96]. These findings demonstrate the importance of focusing on the specific metabolic vulnerabilities of residual AML cells and LSCs that survive chemotherapy-induced stress. Unfortunately, only a few FAO inhibitors have advanced from preclinical to clinical studies [Table 1].

Table 1. FAO inhibitors in clinical trials on cancer treatment

Compounds	Targeted enzyme	Clinical applications	Phase	ClinicalTrials.gov Identifier	Verified
Trimetazidine	3-ketoacyl-C3-ketoacyl-CoA thiolase	Advanced Hepatocellular Carcinoma	Phase 3	NCT03278444	September 2017
Trimetazidine	3-ketoacyl-C3-ketoacyl-CoA thiolase	Intermediate-stage Hepatocellular Carcinoma	Phase 3	NCT03274427	September 2017
Ranolazine	3-ketoacyl-C3-ketoacyl-CoA thiolase	Prostate Cancers	N//A (Pilot Study)	NCT01992016	December 2018

Because AML is heterogeneous and multiclonal, blocking only one part of this complex metabolic system may allow residual cells to adapt metabolically. For instance, it has been shown that BM-derived stromal cells, including adipocytes, diminish the antileukemia effects of FAO inhibitors in AML cells by increasing glycolysis and glucose and free fatty acid uptake^[87]. This compensatory induction of glycolysis is a sustained source of ATP to AML cells and, in turn, induces substantial lactate production. Similarly, FAO-deficient *Abcb11*-knockout mice exhibited high FABP4 and CD36 expression and free fatty acid uptake^[97]. In sum, it is clear that FAO inhibition initiates several different adaptive mechanisms that promote AML cell survival in the BM microenvironment.

For this reason, treatment options based on combination regimens have been tested. Although FAO inhibition alone can trigger compensatory activation of other metabolic pathways, FAO inhibitors can also synergize with conventional antitumor agents such as paclitaxel^[91]. For example, FAO and OXPHOS are increased in cytarabine-resistant AML cells; FAO inhibition with etomoxir induced a metabolic shift from high to low OXPHOS, sensitizing the cells to cytarabine^[66]. Similarly, the combination of avocatin B and cytarabine synergized to enhance ROS production and induce apoptosis in AML cells co-cultured with BM adipocytes^[87]. The role of avocatin B in apoptosis induction was attributed to activation of endoplasmic reticulum stress-induced ATF4^[87]. These findings suggest that AML cells treated with cytarabine exhibit increased dependence on FAO, which may account for the synergism of cytarabine and FAO inhibitors.

CONCLUSIONS

AML cells and LSCs both strongly depend on the production of mitochondrial biomass and on OXPHOS^[66] and FAO^[84] for survival. Compared to healthy HSCs, AML cells and LSCs are more susceptible to mitochondrial stress because their respiratory chain reserve capacity is lower^[98]. These characteristic differences in the metabolism of AML cells and their normal hematopoietic-cell counterparts represent a specific vulnerability of leukemia cells and therefore are drawing a great deal of attention as targets for AML therapy. The results of studies in preclinical models using agents that target fatty acid metabolism have been encouraging.

Although they are vulnerable to the targeting of their metabolic pathways, AML cells, drawing on microenvironmental factors, can adapt to metabolic stress by activating metabolic bypass processes. Several *in vivo* studies and clinical trials have shown that the use of metabolic inhibitors alone is ineffective both because of their narrow therapeutic window and because of these adaptive mechanisms^[87]. Alternatively, inhibition of FAO and other metabolic mechanisms along with conventional chemotherapy or targeted therapy may synergistically eradicate chemotherapy-resistant AML cells present in the BM.

In conclusion, understanding AML cell metabolism in the specific context of the BM microenvironment is crucial to improving therapies for AML. Because characteristics of the BM microenvironment enable the acquisition of resistance to OXPHOS and FAO inhibitors, drug combination strategies that interfere with

these adaptations are needed. A more comprehensive understanding of the mechanisms of AML cell metabolism in future studies may reveal new treatment options targeting OXPHOS and FAO, enhance the efficacy of chemotherapeutic agents that target related pathways, reduce the toxicity of these agents, and enable the translation of new combinations of agents into clinically applicable treatment strategies.

Abstract

The use of the BCL2 inhibitor venetoclax has transformed the management of patients with acute myeloid leukemia (AML) who are ineligible for intensive chemotherapy. By triggering intrinsic apoptosis, the drug is an excellent illustration of how our greater understanding of molecular cell death pathways can be translated into the clinic. Nevertheless, most venetoclax-treated patients will relapse, suggesting the need to target additional regulated cell death pathways. To highlight advances in this strategy, we review the recognized regulated cell death pathways, including apoptosis, necroptosis, ferroptosis and autophagy. Next, we detail the therapeutic opportunities to trigger regulated cell death in AML. Finally, we describe the main drug discovery challenges for regulated cell death inducers and their translation into clinical trials. A better knowledge of the molecular pathways regulating cell death represents a promising strategy to develop new drugs to cure resistant or refractory AML patients, particularly those resistant to intrinsic apoptosis.

Keywords: Acute myeloid leukemia, regulated cell death, apoptosis, ferroptosis, necroptosis, autophagy

INTRODUCTION

Regulated cell death (RCD) is a biologically controlled process that differs from accidental cell death (ACD) by its reliance on defined molecular signaling pathways and tight regulation. Its well-defined nature implies that it can be modulated by pharmacological or genetic interventions contrary to ACD^[1-3]. Schweichel and Merker were the first to report the presence of three distinct cell death morphologies: type I (apoptosis), type II cell (cell death associated with autophagy) and type III (necrosis)^[4]. While apoptosis is the most well-known RCD, many other pathways and molecular characteristics have subsequently been described^[2]. A better understanding of the mechanisms driving RCD may lead to the discovery of new anticancer drugs or the repositioning of older drugs to treat aggressive cancers.

Acute myeloid leukemia (AML) is a severe hematological malignancy driven by various molecular alterations and mainly occurring in adults > 60 years old. Treatment modalities of newly diagnosed AML depend on age, general conditions, comorbidities, and molecular risk factors based on cytogenetics and the presence of molecular alterations. These mutations are integrated together with cytogenetic abnormalities in the widely used and recently updated ELN 2022 classifications^[5,6]. More than 60% of younger patients will be cured by an intensive cytotoxic therapy (ICT) induction based on the association of anthracyclin and cytarabine (7 + 3), followed by consolidations with high doses of cytarabine and/or allogeneic stem cell transplantation^[7]. Half of the patients > 65 years cannot receive ICT because of age, poor general status, or comorbidities. In this context, the hypomethylating agents (HMA) decitabine and azacitidine (AZA) have been associated with complete response rates of 20-30% and 10-month survival^[8,9], highlighting the need for more effective treatments for older and not adequately fit patients.

BCL-2 inhibition is an excellent illustration of how the molecular understanding of RCD has led to the rapid development of a drug that has transformed the therapeutic treatment landscape for older AML patients. Venetoclax (VEN) in combination with the hypomethylating agent AZA has become part of standard frontline therapy for patients not eligible for ICT by improving the rates of response and overall survival compared with AZA monotherapy^[10,11]. However, 10% to 50% of newly diagnosed patients with AML will not respond to VEN-AZA. In addition, half of the patients have relapsed by 18 months and no plateau is seen on overall survival curves. In the population of VEN-AZA refractory or relapsed patients, response rate and overall survival are poor (20% and 2.4 months, respectively)^[12,13]. The combination of VEN with ICT is also associated with high response, but 3% to 15% of patients do not respond to the treatment^[14]. Altogether, these data show that targeting RCD is a valuable strategy and has already improved the efficacy of the current AML therapeutic strategies. However, there is a real need to develop new drugs to go beyond BCL2 inhibition in AML^[13]. In this review, we will discuss the main RCD pathways, describe their therapeutic targeting and discuss the main challenges for translating preclinical results into the clinic.

REGULATED CELL DEATH PATHWAYS

Intrinsic apoptotic pathway

Proapoptotic and antiapoptotic members of the BCL2 protein family share one to four BCL2 homology (BH) domains and control intrinsic apoptosis^[15,16]. Under physiological conditions, BCL2-associated X (BAX) resides in the cytosol in an inactive conformation while BCL2 antagonist/killer 1 (BAK) is inserted at the outer mitochondrial membrane (OMM) via an $\alpha 9$ helix that connects with voltage-dependent anion channel 2 (VDAC2)^[17]. In response to apoptotic stimuli, BAX and BAK associate to form pores in the OMM, inducing mitochondrial outer membrane permeabilization (MOMP, [Figure 1](#)).

MOMP is regulated by the members of the BCL2 protein family containing a single BH3 domain named BH3-only proteins. The main representatives of this class are p53-upregulated modulator of apoptosis

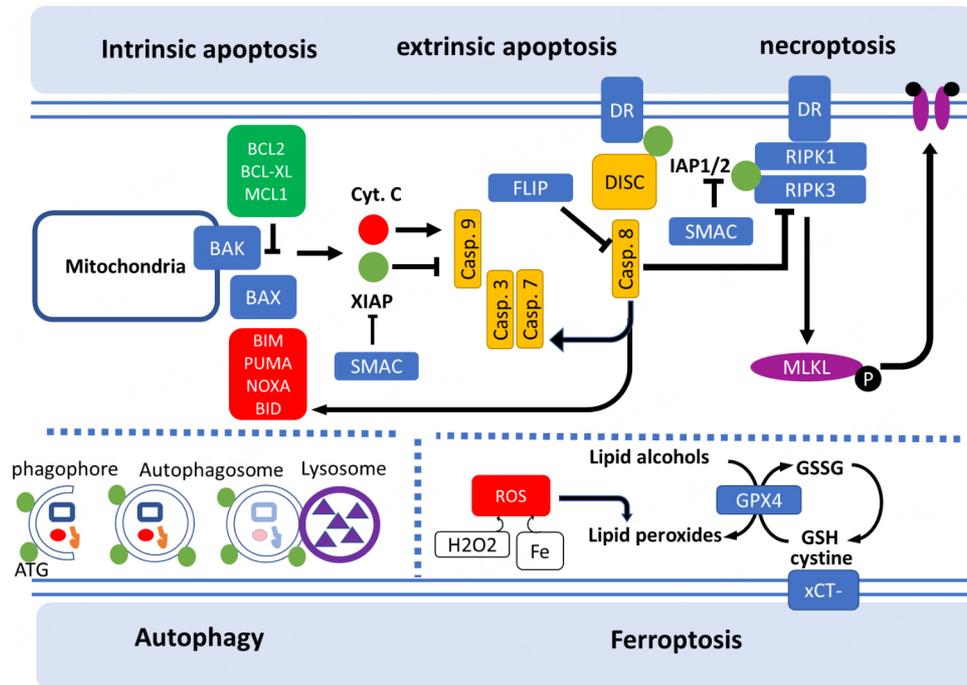

Figure 1. Mechanisms of regulated cell death pathways.

(PUMA), BCL2-like 11 (BCL2L11), also called BCL2-interacting mediator of cell death (BIM), phorbol-12-myristate-13-acetate-induced protein 1 (PMAIP1, also called NOXA) and BH3 interacting domain death agonist (BAD) [18]. All these proteins have a proapoptotic role by directly interacting with BAX and/or BAK to induce MOMP. Conversely, MOMP is blocked by a series of proteins that have an antiapoptotic role. This includes BCL2, BCL2-like 1 (BCL2L1, also known as BCL-X_L), MCL1, BCL2 like 2 (BCL2L2, also known as BCL-W), and BCL2 related protein A1 (BCL2A1, also known as BFL-1) [19]. Other BH3-only proteins, including BCL2-associated agonist of cell death (BAD), BCL2 modifying factor (BMF), or harakiri, BCL2 interacting protein (HRK), have the ability to induce MOMP in the absence of direct interaction with BAX or BAK by limiting the ability of the antiapoptotic BCL2 family members to sequester BAX BAK, or BH3-only activators [20].

MOMP promotes the cytosolic release of cytochrome c (Cyt c) and diablo IAP-binding mitochondrial protein (DIABLO), also known as second mitochondrial activator of caspases [16]. The cytosolic pool of Cyt c binds to apoptotic peptidase activating factor 1 (APAF1) and pro-caspase 9 to form the multiprotein complex called the “apoptosome” responsible for caspase 9 activation. Activated caspase 9 catalyzes the proteolytic activation of the executioner caspase 3 and caspase 7, inducing apoptotic cell death. Blocking post-mitochondrial caspase activation with Z-VAD-fmk and Q-VD-OPh caspase inhibitors delays but does not completely rescue apoptosis *in vitro* and *in vivo* as it induces a switch to other types of RCD [2].

Extrinsic apoptosis

The extrinsic apoptosis pathway is initiated by cell membrane proteins known as death receptors (DR). Proapoptotic death receptors include FAS, also known as APO1 and CD95, the tumor necrosis factor (TNF) receptors TNFR1 and TNFR2 and the TNF-related apoptosis-inducing ligand (TRAIL) receptors DR4 and DR5. DR ligation allows for the assembly of the “death-inducing signaling complex” (DISC), a multiprotein complex that activates caspase 8. At this point, the execution of extrinsic apoptosis driven by DR follows

two distinct pathways. In most cancer cells, caspase 8-mediated cleavage and activation of BID converges with intrinsic apoptosis by triggering a BAX/BAK-dependent MOMP^[21]. However, in some cells, (for instance, mature lymphocytes), the caspase 8-dependent activation of caspase 3 and caspase 7 is sufficient to promote cell death independently of mitochondria and BCL2-family of proteins^[22]. In DR-induced apoptotic intrinsic pathway, caspases are the main executioner of cell death, causing rapid proteolysis, DNA fragmentation and chromatin condensation, which are the hallmarks of apoptosis.

Intrinsic and extrinsic apoptosis are both regulated by the class of inhibitors of apoptosis proteins (IAPs). Among the 8 IAP family members described in humans, the best known is XIAP which inhibits caspases 3, 7, and 9^[23]. IAP proteins are antagonized by SMAC/DIABLO, which is released by mitochondria during MOMP^[24].

Necroptosis

Tumor necrosis factor alpha (TNF- α) is a potent trigger for apoptosis, but it was observed that cells treated with TNF- α and the caspase inhibitor zVAD-fmk were still dying without caspase activation, suggesting the presence of an alternative RCD pathway^[25]. In 2005, Degterev et al. coined the term necroptosis by demonstrating that this unique RCD distinct from necrosis and apoptosis^[26] is initiation by the receptor-interacting protein RIPK1 and could be inhibited by the pharmacological agent necrostatin-1. Indeed, necroptosis is initiated by the activation of the cell death receptors such as TNFR1 and RIPK1 (if caspase 8 is inactive) and depends on the subsequent activation of RIPK3 and the protein complex termed mixed lineage kinase domain-like pseudokinase (MLKL), resulting in the formation of pore on the cell membrane followed by cell death. Nevertheless, several of the upstream signaling elements of extrinsic apoptosis and necroptosis are shared, and sensitivity to each death pathway is regulated by the same set of regulatory molecules, including FLIP, the cellular inhibitors of apoptosis proteins cIAP1 and SMAC/DIABLO^[27].

Ferroptosis

The term ferroptosis was coined in 2012 to describe a cell death that can be triggered by inactivation of the cystine/glutamate antiporter (also known as SLC7A11), leading to depletion of intracellular glutathione (GSH) or direct inhibition of glutathione peroxidase 4 (GPX4). GPX4 inhibition induces an accumulation of reactive oxygen species (ROS), ultimately leading to lipid peroxidation via the iron-dependent Fenton reaction, where H₂O₂ and iron react to generate hydroxyl radicals^[28,29]. Inactivation of GPX4 through depletion of GSH with Erastin or with the direct GPX4 inhibitor RSL3 ultimately results in overwhelming lipid peroxidation that can be rescued by the use of antioxidant ferrostatin-1 or liprostatin-1 that block lipid peroxidation^[30,31]. Ferroptosis is regulated at several levels, including amino acids, lipids (particularly polyunsaturated fatty acids (PUFA)) and iron metabolism^[32-36]. In addition, ferroptosis is regulated by the suppressor protein 1 (FSP1) and dihydroorotate dehydrogenase (DHODH) that reduce ubiquinone (CoQ) to ubiquinol (CoQH₂) on the plasma membrane and inner mitochondrial membrane, respectively. CoQH₂ acts as a superoxide radical-trapping antioxidant and decreases lipid peroxidation, resulting in ferroptosis suppression^[37,38]. Finally, GTP cyclohydrolase-1 (GCH1) and its metabolic derivatives tetrahydrobiopterin/dihydrobiopterin (BH₄/BH₂) are also potent antioxidants protecting against ferroptosis^[39,40]. Ferroptosis is also regulated by the non-canonical activities of TP53 on cellular metabolism in a context-specific manner^[41]. TP53 enhances ferroptosis by inhibiting SLC7A11 expression or increasing expression of spermidine/spermine N1-acetyltransferase 1 (SAT1) and glutaminase 2 (GLS2). Likewise, TP53 can inhibit ferroptosis by reducing dipeptidyl peptidase 4 (DPP4) activity or inducing cyclin-dependent kinase inhibitor 1 A (CDKN1A/p21) expression. Unlike the other RCDs, it remains to be determined whether ferroptosis is a consequence of physiological processes or necessary for development as opposed to only pathophysiological situations^[42].

Autophagy

Macroautophagy (hereafter autophagy) is a ubiquitous catabolic process that involves the degradation of cytoplasmic components, including intracellular organelles, via the lysosomal pathway. The first step of autophagy is the formation of phagophores, followed by the generation of double-membrane autophagosomes regulated by a series of well-conserved autophagy-regulated genes (ATG). Late steps involved the fusion of autophagosomes to lysosomes, leading to cargo degradation by lysosomal enzymes and the recycling of intracellular contents providing fuels for cell growth^[43]. The autophagic response provides cytoprotective effects, as indicated by the fact that blocking autophagy with pharmacological or genetic interventions generally induces cell death through the accumulation of toxic proteins, damaged organelles or undigested autophagosomes toxic for tumor cells^[43]. Autophagy is often activated alongside other RCD, such as ferroptosis, which can be promoted by the autophagic degradation of ferritin, extrinsic apoptosis or necroptosis^[2]. The main features of RCD are summarized in [Table 1](#).

Other cell death pathways

Pyroptosis is an inflammatory form of lytic RCD that frequently occurs in response to microbial infection by forming a multiprotein complex termed the inflammasome, which activates caspase 1 and forms Gasdermin D (GSDMD) dependent plasma-membrane pores^[44]. Pyroptosis is mechanistically distinct from apoptosis and characterized by the absence of DNA fragmentation and the presence of nuclear condensation coupled with cell swelling. Large bubbles eventually form at the plasma membrane and rupture to expel cellular contents.

Mitotic catastrophe is a physiological mechanism by which the cells avoid aneuploidy and hence decrease tumorigenic potential. Accordingly, induction of mitotic catastrophe both precipitates oncogenesis and constitutes a therapeutic endpoint in cancer cells^[45].

Inter-regulation and hierarchy between cell death pathways is complex and not completely understood. For instance, mitotic catastrophe is closely related to apoptosis by their common induction by cellular stress and DNA damage. For this reason, some authors suggest that mitotic catastrophe is not a distinct mechanism of death, but one that can occur through necrosis or apoptosis depending on the molecular profile of the cells^[46]. Other examples of cross-talk between RCD include the link between ferroptosis and autophagy, in particular through ferritin degradation or the involvement of lysosomes in iron storage and redistribution^[47,48]. Depletion of the ferroptosis trigger GPX4 also sensitizes cells to pyroptosis^[49], necroptosis^[50] and apoptosis^[51]. Apoptosis and necroptosis are also linked through caspase 8 cleavage [[Figure 1](#)]. Caspase 8 is also an important player in pyroptosis induction, as it has been shown that genetic lesions in XIAP result in increased inflammation and death-associated caspase-8 and GSDMD processing in diseased tissue^[52]. Common stimuli can also result in different RCD depending on the cell type. For instance, blockage of iron transport into the lysosome can induce ferroptosis in breast cancer stem cells, whereas it induces mitochondrial BAX/BAK-dependent cell death in AML models^[53,54].

RCD INDUCERS IN AML

Apoptotic inducers

Agents targeting intrinsic pathway

Most chemotherapies and radiotherapies are known to induce apoptosis of cancer cells in response to DNA damage or cellular stress^[55]. As a consequence, *in vitro* and *in vivo* evidence indicates that TP53-mutated cells have impaired apoptosis signaling pathways, and these cells are typically less susceptible to cytotoxic chemotherapy^[56].

Table 1. Summary of the main regulated cell death mechanisms

Type of RCD	Trigger	Facilitator	Inhibitor	Executioner
Intrinsic apoptosis	Mitochondrial outer membrane permeabilization by BAX/BAK macropores and cytochrome c release	Proapoptotic factors from the BCL2 family	Antiapoptotic factors from the BCL2 family, Inhibitors of apoptosis (IAPs)	Proteolysis by executioner caspases
Extrinsic apoptosis	Activation of membrane cell death receptors	Death-inducing signaling complex (DISC). SMAC/DIABLO	Inhibitor of apoptosis (IAPs), FLIP	Proteolysis by executioner caspases
Necroptosis	Activation of membrane cell death receptors	RIPK1, RIPK3, SMAC/DIABLO	Caspase 8	Plasma membrane disruption by MLKL
Ferroptosis	Inhibition of GPX4, decrease of cystine uptake	hydroxyl radicals generation through Fenton reaction	Glutathione (GSH), antioxidant defense	Lipid peroxidation of plasma and intracellular membranes
Autophagy	Phagophore formation and fusion to the lysosome	Autophagy-related proteins (ATG)	Inhibition of lysosome acidification	Accumulation of toxic proteins or organelles leading to cellular stress

Inhibitors of BCL2 family members

Besides VEN, several newly developed BCL-2 inhibitors are currently in various stages of investigation in AML and other leukemia models [Table 2]^[13,57-60]. In addition to BCL-2, other members of the BCL-2 family of antiapoptotic proteins (MCL-1, BCL-XL, BFL-1) are the target of small molecules with the goal of inducing BAX/BAK activation and promote intrinsic apoptosis. The antiapoptotic protein MCL-1 plays a critical role in inhibiting BAX/BAK activation. MCL1 dependency on leukemia blasts is associated with resistance to BCL2 inhibition by VEN. Several highly potent direct MCL-1 inhibitors have recently entered preclinical and clinical development [Table 2]^[61-64]. The therapeutic window of these inhibitors is narrow because of the high expression of MCL1 in cardiac and hepatic tissues^[65]. Due to these safety concerns, indirect MCL1 inhibitors are also under evaluation. CDK9 inhibitors are in various stages of evaluation in AML [Table 2]^[66-73]. Addition of alvocidib to ICT improved response rates but not survival in a recently published phase 2 clinical trial^[67]. Novel CDK9 inhibitors are currently in early phase trials [Table 2]^[74-78]. BCL-XL inhibition by navitoclax has been shown to be active in preclinical AML models^[79,80]. Toxicity for platelets limited its clinical development; nevertheless, navitoclax in combination with ICT or targeted therapy is still under evaluation in acute lymphoblastic leukemia^[81] or myelofibrosis (TRANSFORM-1, NCT04472598). Navitoclax in combination with VEN and decitabine may be a valuable option for VEN-refractory AML patients (NCT NCT05222984). Finally, BFL1 (BCL2A1) inhibition may also be an interesting option since the recent discovery of specific inhibitors, but the drug has not been specifically tested in leukemia models^[82,83].

BAX/BAK activators

BAK and BAX are crucial agents in promoting MOMP through protein oligomerization across the OMM. Recent findings showed direct activation of BAX by BTSA1, a pharmacological BAX activator that binds BAX with high affinity and specificity to the N-terminal activation site and induces conformational changes to BAX, leading to BAX-mediated apoptosis^[84]. The histone deacetylase SAHA and its derivatives also have an affinity for BAX and induce its activation [Table 2] but have not been validated in AML models^[85]. Other preclinical studies suggested a mitochondrial membrane-mediated spontaneous model of BAX activation. In this model, MOM plays a big role in orchestrating the turnover between cytosolic and membrane-bound BAX, its interaction through the $\alpha 9$ helix and the formation of macropore into the membrane. It is likely that lipids such as cardiolipin play a crucial role in this model^[86]. Voltage Dependent Anion Channels

(VDACs) are a family of membrane proteins that allow passage of both negatively and positively charged ions, NADH, ATP/ADP and other metabolites across the MOM. In particular, VDAC2 plays a role both in recruiting BAK to the MOM and in inhibiting its activation^[17]. WEHI-9625 is a novel small molecule inducing BAK-mediated apoptosis in mice but is completely inactive against human BAK^[87,88]. We found that ironomycin sequestered iron into lysosomes and subsequently reduced mitochondrial iron load, promoting the recruitment and non-canonical activation of BAX/BAK in AML *in vitro* and *in vivo* models. Crispr Cas9 screens uncovered the key metabolic and mitochondrial factors regulating this modality of non-canonical RCD^[53].

Agents targeting extrinsic pathway

TRAIL Agonism

Agonists of the TNF-related apoptosis-inducing ligand (TRAIL) receptors (DR4/5) have been tested in AML, but response rates are low^[13]. Novel antibodies against TRAILR1 and TRAILR2 have shown promising preclinical data along with synergy with VEN and are currently tested in phase 1 [Table 2]^[89]. Eftozanermin alfa (ABBV-621), a second-generation TRAIL receptor agonist binding to the death-inducing DR4 and DR5 receptors, is currently being tested in solid tumors and hematological malignancies [Table 2]^[90,91].

FLIP inhibition

FLIP (Fas-associated death domain (FADD)-like IL-1 β -converting enzyme-inhibitory protein) is a multifunctional protein that plays a role in regulating the death-inducing signaling complex (DISC) and caspase 8 activation. CDK9 inhibitors and bromodomain inhibitors such as JQ1 have been shown to effectively decrease FLIP expression, leading to enhanced sensitivity to TRAIL-induced cell death in cancer^[92]. Second-generation FLIP inhibitors have shown preclinical activity in multiple cancer cell lines including AML, and have a high potential for synergy with other apoptosis-targeting agents [Table 2]^[93,94].

XIAP inhibition

IAPs act as antiapoptotic proteins by inhibiting caspases and are promising therapeutic targets in AML. Inhibition of XIAP has been shown to sensitize AML cells to chemotherapy or BCL2 inhibitors^[95,96]. Inhibition of XIAP by antisense strategies or peptides that bind and inhibit the BIR3 domain of XIAP has been tested in phase 1 studies^[97-99] but failed in phase 2^[100]. The SMAC/DIABLO mimetics (SM) birinapant is one of the most clinically advanced SM and is currently being tested in clinical trials for the treatment of certain solid and hematological cancers^[101]. Birinapant showed limited efficacy as a single agent^[102]. In a phase 2 randomized, double-blind study, birinapant plus AZA was not superior to AZA alone in advanced myelodysplastic syndromes (MDS) or chronic myelomonocytic leukemias^[103]. The drug is also being tested in combination with chemotherapeutic agents and immune checkpoint inhibitors. Preclinical data also indicate that combination of Birinapant plus the multidrug resistance receptor 1 (MDR1) may circumvent birinapant resistance in AML^[104]. ASTX660/Tolinapant is a dual antagonist of XIAP and cIAP is currently under investigation in phase 1/2 studies in solid tumors and in combination with hypomethylating agents in AML^[105,106]. LCL161, an oral SMAC mimetic, has been tested in patients with myelofibrosis and showed a 30% objective response rate in a recently published phase 2 trial [Table 2]^[107].

Necroptosis inducers

SMAC mimetics combined with caspase 8 inhibition have been shown to trigger necroptosis in AML preclinical models^[108-110]. RIPK1 inhibition enhanced the therapeutic efficacy of the HDAC inhibitor chidamide in FLT3-ITD positive AML, both *in vitro* and *in vivo*^[111,112] and increased the efficacy of differentiating agents^[113]. Other SMAC mimetics in combination with cytarabine or HMA also showed interesting preclinical results^[114]. Therapeutic opportunities for cancer cell death induction through endogenous retroelements (EREs) reactivation have been recently described^[115]. EREs are transcriptionally silent within mammalian genomes due to epigenetic mechanisms. Anticancer therapies targeting the epigenetic machinery reinduces ERE expression, inducing antiviral responses associated with consistent increased phosphorylation of RIPK1/3 and MLKL kinases associated with features of necroptosis in treated tumor cells [Table 2]^[116].

Ferroptosis inducers

Ferroptosis inducers (FINs) belong to four classes^[117]. Class I FINs include pharmacological agents that limit intracellular glutathione (GSH) through the inhibition of the system x_c⁻ cystine/glutamate antiporter, as has been shown in non-leukemic models^[28]. The main molecules of this class, which are active in AML models, are erastin and sulfasalazine^[118,119]. Class II FINs directly inhibit the detoxifying enzyme GPX4. The lead compound in this class is RSL3 which covalently binds to GPX4. The antitumoral effect of GPX4 disruption has been shown in various models, including AML^[120,121]. The FDA-approved alkylating agent altretamine has been shown to directly inhibit GPX4^[122]. Class III FINs target GSH synthesis or cysteine synthetase such as buthionine sulfoximine (BSO), an irreversible inhibitor of rate-limiting enzyme in GSH synthesis, and also cisplatin^[123]. Focusing on AML, APR-246, a drug known to restore the wild-type conformation of mutant TP53 protein, was shown to actually target GSH metabolism^[124,125]. Class IV FINs disrupt the balance of iron metabolism and cellular reactive oxygen species (ROS). Dihydroartemisinin (DHA) belongs to this class^[126-128], as well as drugs interfering with the antioxidant system CoQ10^[37,38] or drugs modulating PUFA metabolism as they are highly sensitive to lipid oxidation [Table 2]^[129,130].

Iron chelation and overload play a crucial role in MDS and AML. Therapeutic interventions that modulate iron content and balance within blast cells are at least partially inducing ferroptosis^[131]. Our group described in detail the mechanism of action of ironomycin that specifically sequesters ferrous iron into the lysosomes, and induces lipid peroxidation and cell death in several models of cancer stem cells as well as in AML through mitochondrial metabolism disruption^[53,54,132].

Agent regulating autophagy

Autophagy deregulation in AML is well documented, but its impact on leukemogenesis remains unclear^[133,134]. For example, in AML harboring an FLT3 internal tandem mutation (ITD), mTORC1 activation downstream the RET receptor tyrosine kinase suppresses FLT3 protein autophagic degradation^[135]. In contrast, blocking autophagy in FLT3-ITD AML can increase the survival of mice with FLT3-ITD-driven AML^[136]. These ambiguous results indicate the complexity of therapeutic intervention based on autophagy in AML. Another layer of complexity lies in the fact that autophagy is a dynamic process. For instance, blocking autophagy cargo can be done at earlier phases (autophagosome biogenesis) or at the later steps (endosome-lysosome fusion).

Autophagy inhibitors

Autophagy inhibition can be achieved by blocking the LC3 interacting regions (LIR) that orchestrate diverse stages of autophagy. This strategy was shown to sensitize cytotoxicity to cytarabine^[137]. Late-stage autophagy inhibitors hydroxychloroquine and/or bafilomycin A1 (BafA1) block lysosomal acidification and are active on leukemia blasts and also sensitize cells to chemotherapy^[138]. A randomized phase 2 study was recently

published testing the addition of hydroxychloroquine to Imatinib in chronic myeloid leukemia and found no significant differences between the two arms^[139]. SAR405, a highly potent small-molecule inhibitor of the phosphatidylinositol 3-kinase catalytic subunit type 3 (PIK3C3)/Vps34, induces a blockage at the late endosome-lysosome step autophagy flux and shows interesting preclinical efficacy in FLT3-ITD AML [Table 1]^[140,141].

Autophagy inducers

The mTORC1/S6K1 pathway is critical for the regulation of autophagy in AML initiation and progression, as reviewed by Ghosh & Kapur^[142]. Therefore, the most studied drugs are the mTORC1 inhibitor sirolimus and everolimus. Despite promising data in preclinical models, clinical studies are ambiguous. Sirolimus combined with the chemotherapy regimen showed a high response rate in patients with baseline mTOR activation^[143]. In a phase 1b study from the GOELAMS, everolimus plus chemotherapy improved the clinical outcomes of patients with AML^[144]. But mTOR inhibition plus conventional chemotherapy did not show a clinical benefit in two other studies^[145,146]. Therefore, mTOR inhibitors still need to be evaluated in AML, and several clinical trials are ongoing (NCT00819546, NCT02638428, NCT01869114).

Pharmacological induction of other cell death pathways

Small-molecule inhibitors of the serine dipeptidases DPP8 and DPP9 (DPP8/9) have been shown to induce pyroptosis in human myeloid cells, including cell lines, primary AML samples and mice models of human leukemia^[147]. Constitutive innate immune activation is a pathogenetic driver of ineffective hematopoiesis and MDS, in particular through the NLRP3 inflammasome^[148,149]. Recent studies found that the inflammasome can be induced by gene mutations involving mRNA splicing by induction of cyclic GMP-AMP synthase/stimulator of IFN genes (cGAS/STING)^[150]. As a consequence, the use of immunotherapies targeting inflammatory responses is the subject of many preclinical and clinical studies^[151]. Mitotic catastrophe is induced by pharmacological agents targeting the mitotic machinery. Cell cycle inhibitors are currently in development in various hematological diseases, including AML^[152,153].

UPCOMING CHALLENGES FOR TARGETING RCD IN AML

The key objectives of translating preclinical results into the clinic are to identify drugs that will treat resistant cells by inducing RCD, detect the population of patients who will respond to a given RCD and design new RCD inducers with high efficacy and low toxicity.

Target resistances with RCD

Cells resistant to treatment, called “persister cancer cells”, are largely responsible for relapse^[154]. These cells develop antiapoptotic mechanisms as well as altered metabolism rendering them more susceptible to alternative RCD, in particular autophagy or ferroptosis that are directly related to the metabolic state of the cells^[155,156]. For instance, preclinical data showed the x_c^- inhibitory activity of salazopyrine and its efficacy against primary AML samples in *ex vivo* cultures and in patient-derived AML models^[118]. These preliminary results led to the hypothesis that the drug could be repositioned in AML. A clinical trial testing the addition of salazopyrine to ICT in older AML patients, named SALMA (EUDRACT no: 2022-001269-11), will be enrolling soon. Another example is the resistance to VEN, which is mediated through various mechanisms, including BCL2 family protein expression and occupation (MCL1 dependency), cellular differentiation state (monocytic versus stem cell-like), cellular metabolic state or sensitivity to mitochondrial machinery disruption^[11]. One of the major limitations that emerged from both *in vitro* and clinical studies with the BH3-mimetics is the low sensitivity of TP53 mutated blasts to this class^[157-159]. Strategies of treatment that overcome TP53-dependent apoptosis can be used, such as ironomycin that directly activates BAX/BAK in a BCL2-family protein-independent manner^[53]. Optimized clinical-grade derivatives of ironomycin with better therapeutic windows are currently under development^[160].

Identify new biomarkers

The second challenge is to identify the population of patients who will benefit from RCD inducers. Recent findings showed that ferroptosis-associated gene signatures can be assessed by transcriptomic methods such as RNA sequencing. These signatures predict survival and could possibly guide therapeutics by selecting patients who could be treated by the use of ferroptosis inducers^[161-164]. Necroptosis transcriptomic signatures have also been found in MDS, indicating that such predictors could identify patients who would benefit from necroptosis inducers^[165]. Functional assays such as BH3-profiling have been shown to be a highly efficient companion test that can predict response to the BH3-mimetics inhibiting BCL2 family proteins^[20,166]. Our team published a translational proof-of-concept study in which relapsed or refractory AML patients were selected according to molecular and *ex vivo* drug sensitivity profiles^[167]. Future clinical trials using companion tests based on molecular or functional approaches will confirm the feasibility and efficacy of this strategy.

Discovery of new RCD inducers

The use of targeted therapies has transformed AML treatment. Small molecule inhibitors of genes that underwent common somatic mutations, such as FLT3 or IDH inhibitors, have been approved recently for AML relapsed or refractory patients^[168]. However, most of the patients cannot benefit from targeted therapies, because of a lack of targetable genetic alterations. On the contrary, BCL2 inhibition success story is based on the AML blast dependency to apoptosis independently of AML targetable mutations. Recent findings showed that AML cells are sensitive to ferroptosis induction, suggesting that efforts should be made to develop new ferroptosis inducers^[169]. A validated approach is to use an unbiased strategy by performing high throughput screening of chemical libraries for their ability to induce ferroptosis (or other RCD) *in vitro* and *in vivo*^[122]. In parallel, a better understanding of the ferroptotic molecular pathways can be obtained using CRISPR Cas-9 resistance screens of a given ferroptosis inducer that will identify crucial genes involved in cell death. We recently used this strategy to uncover the molecular mechanism of ironomycin^[53]. This integrative strategy will help to design new tailored drugs and pave the way for future clinical trials based on RCD.

CONCLUSION

Treatment of AML has remained unchanged for more than 40 years with a one-size-fits-all intensive chemotherapy approach for eligible patients. In 2017, the FDA approved the utilization of two targeted therapies for patients with a molecular alteration in FLT3 or IDH genes^[168]. Another significant advancement was made in 2020 with the publication of the VIALE-A study reporting the efficacy of VEN for the treatment of AML patients who are not eligible for intensive treatment^[10]. Despite higher response and survival rates than before, there is still improvement to be made in the management of AML patients. A better understanding of molecular RCD pathways in collaboration with integrative translational studies will allow the design of new drugs or the repositioning of older ones to overcome resistance in AML.

Intrinsic apoptosis is initiated by the formation of pores permeabilizing the outer membrane of mitochondria (MOMP) induced by the oligomerization of BAX recruited from the cytosol and BAK inserted at the mitochondrial membrane. BAX and BAK interact with a series of antiapoptotic inhibitors proteins (BCL2, BCLXL, MCL1) and proapoptotic activator proteins (BIM, PUMA, NOXA, BID). MOMP induces a release of cytochrome c that cleaves caspase 9 and subsequently activates the effector caspases 3 and 7, leading to cell death. Extrinsic apoptosis is triggered by the ligation of cell death receptors (FAS, TRAIL and TNFR), which allow the assembly of the “death-inducing signaling complex” (DISC) and the

subsequent activation of caspase 8. Caspase 8 induces the cleavage of BID, leading to the activation of BAX and intrinsic apoptosis and the direct activation of caspases 3 and 7, finally leading to cell death. Inhibitors of apoptosis (IAP) family, including XIAP, cIAP1 and cIAP2, are inhibitors of caspase 9 and the death receptor TNFR, whereas FLIP is the inhibitor of caspase 8. SMAC/DIABLO is a major inhibitor of IAPs. Necroptosis is induced by the ligation of cell death receptors and the activation of the receptor-interacting protein RIPK1 and RIPK3 that interacts with protein complex mixed lineage kinase domain-like pseudokinase (MLKL). Phosphorylation of MLKL results in the formation of pores on the cell membrane, followed by cell death. IAPs and Caspase 8 inhibit RIPK1 activation and block necroptosis. Ferroptosis is the result of lipid peroxidation triggered by the direct inhibition of the antioxidant enzyme GPX4 or by the blockage of the x_c^- cystine/glutamate antiporter (xCT-). Depletion of cysteine import and intracellular glutathione (GSH) increases lipid peroxides which is exacerbated by the Fenton reaction, where H_2O_2 and iron react to generate hydroxyl radicals. Autophagy is a process in which cytoplasmic components, including intracellular organelles, are degraded by the lysosomes. The first step of autophagy is the formation of phagophores, followed by the generation of double-membrane autophagosomes regulated by autophagy-regulated genes (ATG) and lysosomal fusion. Autophagy blockage or excess can induce cell death.

Abstract

Recent advances in multiple myeloma therapy have increased the depth of response and ultimately survivals; however, the prognosis remains poor. The BCMA antigen is highly expressed in myeloma cells, thus representing a target for novel therapies. Several agents that target BCMA through different mechanisms, including bispecific T cell engagers drug conjugated to antibody and CAR-T cells, are now available or under development. Immunotherapies targeting BCMA have shown good results in efficacy and safety in multiple myeloma patients previously treated with several lines of therapy. This review will discuss the recent development of anti-BCMA targeted treatments in myeloma, with a special focus on currently available agents.

Keywords: Multiple myeloma, BCMA, belantamab, teclistamab, CART

INTRODUCTION

Multiple myeloma (MM) is a clonal plasma cell (PC) disorder accounting for 10% of hematologic neoplasms^[1]. Novel therapies such as proteasome inhibitors (PI), immunomodulatory drugs (IMiDs), and anti-CD38 monoclonal antibodies (mAbs), together with autologous stem cell transplant (ASCT), have significantly improved treatment outcomes of newly diagnosed MM patients with a continuous increase of the overall survival (OS) that today reaches a median of 10 years^[2-9]. However, MM patients still do relapse

© The Author(s) 2023. **Open Access** This article is licensed under a Creative Commons Attribution 4.0 International License (<https://creativecommons.org/licenses/by/4.0/>), which permits unrestricted use, sharing, adaptation, distribution and reproduction in any medium or format, for any purpose, even commercially, as long as you give appropriate credit to the original author(s) and the source, provide a link to the Creative Commons license, and indicate if changes were made.

and MM is considered an incurable disease^[10,11]. In particular, triple-class refractory (refractory to PI, IMiDs, and anti-CD38 antibody) and penta-refractory (first and second-generation PIs, two generations of IMiDs, anti-CD38 antibody) patients have a median OS of 5.6 months, especially in the presence of high-risk cytogenetics (HR)^[12-20] or positive minimal residual disease^[21-26]. Therefore, novel therapies, especially for relapsed/refractory myeloma patients (RRMM), are necessary^[25-26]. BCMA is a B-cell maturation antigen highly expressed in myeloma cells, thus offering an encouraging potential target for novel treatments^[27-28].

BCMA in multiple myeloma

BCMA, i.e., CD269 or TNFRSF17, is a TNF receptor superfamily 17 member, expressed on differentiated plasma cells and plasmablasts under physiological conditions and nearly on all MM tumor cells^[29-31]. BCMA ligands include APRIL (A Proliferations-Inducing Ligand) and BAFF (B-cell activating factor) which are involved in the maturation and differentiation of PCs^[32]. APRIL can bind to BCMA more avidly than to BAFF, and both can induce BCMA downstream signals to PI3K-PKB/Akt (i.e., phosphoinositide-3-kinase-protein kinase B/Akt), to RAS/MAPK (i.e., rat sarcoma/mitogen-activated protein kinase), and also to NF- κ B (i.e., nuclear factor kappa-B), inducing increased plasma cells proliferation and survival^[31,33-37]. Interestingly, PCs long-term survival in BCMA^{-/-} mice is defective, suggesting BCMA is crucial for a sustained humoral immune response^[38-39].

BCMA is overexpressed in myeloma PCs compared to normal ones, and its expression levels are elevated regardless of the stage of MGUS (monoclonal gammopathy of undetermined significance), SMM (smoldering multiple myeloma), and symptomatic MM^[40-41]. Moreover, compared to healthy controls, APRIL and BAFF serum levels are 5-fold higher in myeloma patients. Recent studies showed that osteoclasts could be stimulated to produce more APRIL by MM cells, thus producing an immunosuppressive microenvironment^[31,35,42]. Interestingly, MM cell proliferation can be reduced, in a mouse xenograft model, by a mAb directed against APRIL. Anti-BCMA immunotherapies, together with APRIL inhibition, can defeat MM-induced immunosuppressive microenvironment and intensify the ADCC (antibody-dependent cell-mediated cytotoxicity) against myeloma cells^[31,35,43].

sBCMA is the soluble form of BCMA, and it is produced by a γ -secretase acting on membrane BCMA^[44]. sBCMA levels have been related to plasma cell infiltration in the bone marrow and may predict MM patients' outcome. Indeed, some studies have shown that after MM treatment, the responsive patients resulted in lower sBCMA levels compared to patients with progressive disease^[45-47]. Moreover, MGUS and SMM patients with higher levels of sBCMA showed a higher risk of progression to MM^[48-49]. Thus, sBCMA might be used as a biomarker for disease progression and treatment response, allowing appropriate therapeutic management in case of drug resistance^[10,50]. Additionally, one preliminary study in patients with non-secretory myeloma, for whom bone marrow aspirate and PET-CT scan are the only methods for disease monitoring, has shown that sBCMA levels correlate with the bone marrow PC infiltration, although this need to be confirmed^[45-46]. Further studies are needed to validate sBCMA as a novel biomarker for MM and no approved diagnostic tool for measuring serum levels of sBCMA is available yet^[10].

Finally, sBCMA reduces BCMA expression on PCs' surface, thus resulting in reduced efficacy of BCMA-targeted therapies and MM cells' immune escape^[27]. Additionally, authors showed that sBCMA at high levels might interfere with anti-BCMA therapy, thus reducing effective binding to MM cells^[51]. Preclinical studies of γ -secretase inhibitor (GSI) have shown that it may decrease sBCMA levels and increase MM cells expressing surface BCMA, thereby improving response to BCMA chimeric antigen receptor T cell (CAR-T) therapy. Hence, the association of a GSI and BCMA-targeting therapy in MM patients is being evaluated in early-phase clinical trials^[2,52].

BCMA-TARGETED TREATMENT IN MULTIPLE MYELOMA

The evidence that BCMA could be a suitable target for effective antitumor activity in preclinical studies led to the development of drugs targeting BCMA with several mechanisms [Figure 1]. Presently, BCMA-targeted therapies available are represented by: antibody-drug conjugates (ADCs), bispecific T cell engager (BiTEs), and chimeric antigen receptor (CAR)-T cells [Table 1]^[53,54].

BCMA antibody drug conjugates

Antibody-drug conjugate (ADC) consists of a monoclonal antibody directed against a tumor- antigen and a cytotoxic agent inducing cell death (payload). ADC is internalized after binding to the related antigen on the tumor cell's surface, then the linker is hydrolyzed inside of the lysosomes or endosomes and the payloads are released to cause cell death. ADCs can selectively target malignant cells with great efficiency on tumor cells and limited toxicities. Auristatin is a tubulin polymerase inhibitor used as a payload for MM^[55-60].

Belantamab Mafodotin (GSK2857916)

Belantamab mafodotin (Bel) is a humanized IgG1 ADC, first-in-class, originally approved by the FDA (US Food and Drug Administration) as monotherapy in relapsed myeloma patients treated with four prior therapies including a proteasome inhibitor, anti-CD38 monoclonal antibody, and an immunomodulatory agent^[61]. Bel is formed by an antibody directed to BCMA and covalently linked to MMAF (the microtubule inhibitor monomethyl auristatin F)^[62]. After binding to BCMA on MM plasma cell, Bel is internalized and MMAF is released, provoking cell-cycle arrest and apoptosis^[63]. Other effects that seem to be mediated by Bel-binding BCMA are ADCC and antibody-dependent cellular phagocytosis (ADCP)^[64,65].

The multicenter phase I trial (DREAMM1) enrolled 73 RRMM patients. An ORR of 60% and PFS of 12 months were reported with acceptable toxicities. Corneal toxicity resulted in the most common non-hematologic side effect^[66,67]. Subsequently, the phase II registrational study DREAMM2 enrolled 196 MM patients. The recommended dose was intravenous 2.5 mg/kg, Q3W. Reported ORR was 31%, with toxicities confirmed as manageable. A program was established to evaluate possible Keratopathy (Risk Evaluation and Mitigation Strategy, REMS) prior to drug administration^[68-71]. Bel is currently being studied in different combination regimens in MM patients. The randomized, phase II study DREAMM4 is investigating Bel with pembrolizumab in patients with MM refractory to multiple lines of therapy. The DREAMM5 is testing Bel with other mAbs, such as isatuximab. The DREAMM-6 trial is exploring the combination of Bel, bortezomib, and dexamethasone *vs.* Bel, lenalidomide, and dexamethasone, while the DREAMM-7 and the DREAMM-8 studies are comparing Bel, bortezomib and dexamethasone *vs.* daratumumab, bortezomib and dexamethasone and Bel, pomalidomide and dexamethasone *vs.* pomalidomide, bortezomib and dexamethasone, respectively. Finally, the DREAMM-9 is testing Bel in the induction therapy in NDMM patients^[2,10,72,73]. However, in November 2022, the FDA withdrew belantamab's US marketing authorization as the DREAMM-3 trial (Bel *vs.* pomalidomide in combination with low-dose dexamethasone in RRMM) did not meet its primary endpoint of PFS (11.2 *vs.* 7 months, HR 1.03; 95%CI: 0.72-1.47). Sustainability could be a reason. Other Bel studies are ongoing, and results are awaited. Other studies including different anti-BCMA mAbs as well as ADCs targeting BCMA are ongoing^[74-76].

BCMA bispecifics

BiTEs are bispecific T cell engagers and represent a different modality of immunotherapy targeting BCMA. These agents are engineered proteins with two different antigen-binding fragments that bind to MM cells and T cells, thus creating an immunological synapse with direct plasma cell killing by T-cells^[77-79]. The two common antigens involved are CD3 and CD16, and BCMA is the target of MM plasma cells. Many studies

Table 1. Characteristics of currently approved BCMA targeted agents

Drug	Mechanism of action	Regimen of administration	Adverse effects	ORR/CR (%) [*]	PFS (months) [*]
Belantamab (ADCs)	Monoclonal antibody conjugated with a cytotoxic agent	Intravenous (every 21 days)	Corneal toxicities Thrombocytopenia	31/3	2.8
Teclistamab (BITEs)	Fully humanized IgG4 bispecific antibody redirecting, CD3-positive T-cells to BCMA	Subcutaneous (weekly)	CRS ICANS Hematological toxicities	63/39	11.3
Idecabtagene Vicleucel (CAR-T)	BCMA targeted CAR-T incorporating anti-BCMA antibody costimulation domain, CD3 ζ signaling domain	Single intravenous infusion	CRS ICANS Hematological toxicities	73/33	8.8
Ciltacabtagene Autoleucel (CAR-T)	BCMA-targeted CAR-T-cell product with two single anti-BCMA domain antibodies, CD3- ζ signaling domain costimulatory domain	Single intravenous infusion	CRS ICANS Hematological toxicities	97/67	Not reached

^{*}Data from the registrational study; CR: complete response; ORR: overall response rate; PFS: progression-free survival.

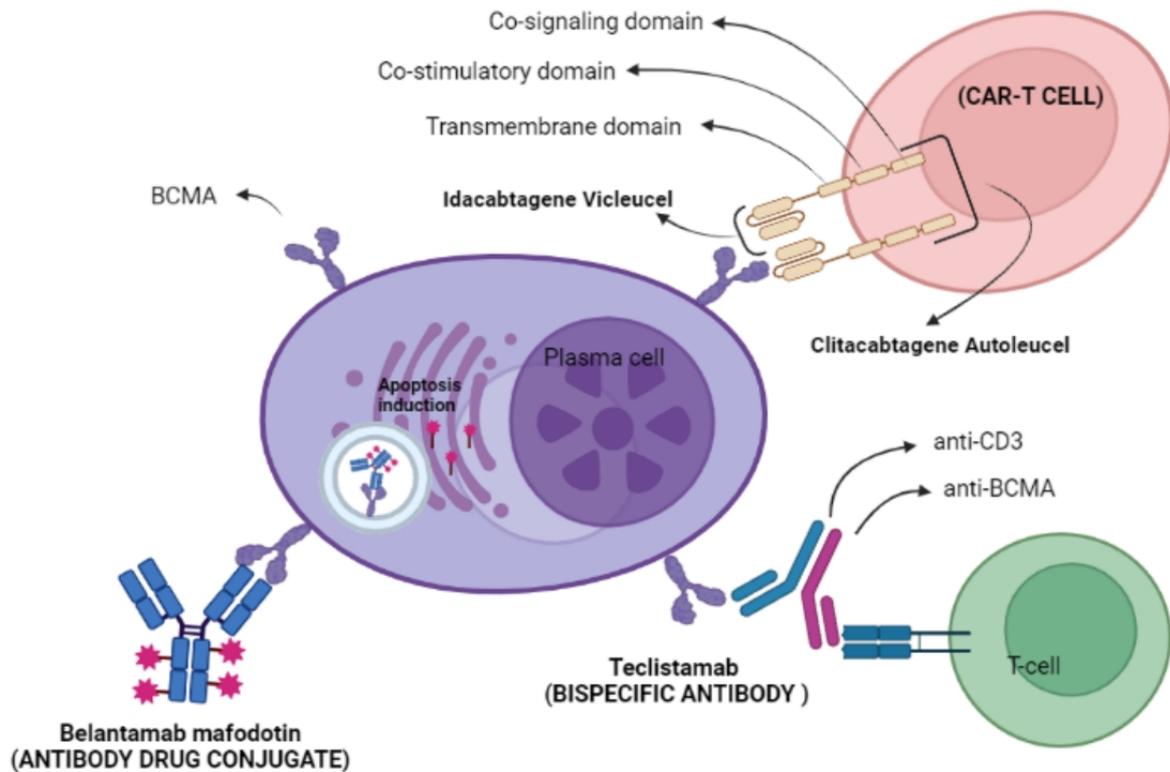

Figure 1. CAR: Chimeric antigen receptor.

with BITEs utilizing BCMA showed great efficacy with moderate toxicity, such as CRS (cytokine release syndrome) and associated neurotoxicity syndrome (ICANS)^[80-82].

Teclistamab (JNJ-64007957)

In the MajesTEC-1 clinical trial, Teclistamab (Tec) was tested as an IgG4 bispecific antibody targeting CD3 on T-cells and BCMA in RRMM. Included patients were heavily pretreated, with two-thirds of them triple-class refractory and 30% penta-refractory. Tec was initially administered intravenously or subcutaneously in different cohorts, and safety was particularly improved, particularly in terms of reduced CRS, for the latter formulation. The recommended dose was 1500 µg/kg weekly subcutaneously, after two escalating doses of 60 and 300 µg/kg. The ORR was 63% (median PFS 11.3 months). CRS was observed in 72% of the patients (only 1 patient with a grade 3) and Il-6 inhibitor tocilizumab was needed in 37% of patients. The most common neurotoxicity reported was headache in 8% of the patients^[83-86]. Those results were followed by Tec authorization for marketing as monotherapy in MM patients who showed disease progression during the last of three prior therapies, including a proteasome inhibitor, an immunomodulatory agent, and an anti-CD38 antibody^[87].

Others BITEs currently studied are Elranatamab (PF-06863135), ABBV-383, and alnuctamab (CC-93269). In addition, novel tri-specific agents that target BCMA are under preclinical evaluation and are demonstrating high clinical potential^[88-97].

BCMA CAR-Ts

CART (Chimeric antigen receptor T) cell therapy act as cell-mediated immunotherapy. Briefly, after an in vitro gene transfer strategy, the patient's T cells acquire the ability to can recognize tumor antigens (mostly used is BCMA) on MM plasma cells and thus destroy them. The CARs are formed by a receptor with an extracellular portion that binds to the antigen and an intracellular signaling domain. Moreover, the extracellular portion is formed by a single-chain variable fragment, i.e., scFv, connected to a transmembrane domain. CD28 is used as a costimulatory molecule. The final product results in a combination effect of mAbs and T cells cytotoxic^[98-103]. Leukapheresis of the patient's T cells is the first step of CART generation. Thereafter, the scFv and costimulatory domains are introduced with a viral vector. Before reinfusion, patients usually receive a conditioning regimen of fludarabine and cyclophosphamide (a chemotherapy regimen used to achieve lymphodepletion) to decrease autologous T cells and permit CARTs proliferation^[104,105].

BCMA represents an ideal target for CAR-T therapy, and to date, two autologous BCMA-targeting CAR-Ts have been approved by the FDA, but several are being investigated in clinical trials^[106-108]. BCMA is also being tested combined with CD19 for CAR-Ts multiple targeting^[109-111]. A good efficacy has been demonstrated in early-phase clinical trials with bispecific CAR-Ts that target BCMA, CD19, or CD38^[112]. Future alternative approaches could be represented by allogenic BCMA CAR-T cells or CAR-NK (CAR-natural killer), which are now investigated in early clinical trials^[113-121].

Ide-Cel, idecabtagene vicleucel (bb2121)

Ide-Cel is a CAR-T of the second generation that targets BCMA. Ide-Cel includes a CD3ζ signaling domain and an scFv, a costimulating domain. A great efficacy has been shown in preclinical experiments against MM plasma cells. It is independent of levels of BCMA expression or sBCMA levels^[107]. Ide-Cel showed an ORR of 85% and a median PFS of 11.8 months in heavily pretreated MM patients in a phase I study. Toxicities such as CRS and ICANS (mostly grade 1-2) were observed in 76% and 42% of patients, respectively^[122]. The KarMMa phase II study was conducted in 128 MM patients who had previously received three or more lines of therapy, including a PI, an IMiD, and an anti-CD38 mAb. CAR-Ts infusion produced an ORR of 73%. Also, MRD negativity at 10⁻⁵ was seen in 26% of the patients (median PFS 8.8 months, 20.2 months when CR was achieved). Of note, when CAR-T was employed in high-risk disease

patients (i.e., penta-refractory disease, extramedullary disease, or high-risk cytogenetic), results were confirmed. Toxicities were acceptable (CRS 84%, but only 7 patients (5%) with \geq grade 3; ICANS 18%, with \geq grade 3 in 4 (3%) MM patients^[123]. Ide-Cel was approved by the US FDA thereafter for MM patients treated with four lines of therapy (comprehensive of a PI, an IMiD, and an anti-CD38 mAb)^[124]. Ide-Cel is now being used in several trials to explore its efficacy in various scenario, including the use in first-line therapy or at early relapse^[125-127].

Cilta-cel ciltacabtagene autoleucel LCAR-B38M/JNJ-4528; Carvykti

Cilta-cel is a CAR-T-cell targeting BCMA with two antibodies to increase the binding avidity, a CD3- ζ signaling domain and a 4-1BB costimulatory domain^[109]. In a recent phase I clinical trial, responses were high (ORR 88%) in RRMM patients after three or more prior lines of therapy (median PFS of 15 months). Toxicities were mostly grade 1-2 (CRS 90%, ICANS in 1 case)^[128]. Subsequently, Cilta-cel was tested in 97 MM patients previously treated with multiple lines of therapy, with 40% of them being penta-refractory (CARTITUDE-1 trial). Interestingly, the response rate was quite high (> VGPR in 95%, MRD undetectable at 10^{-5} was achieved in 92%). Reported CRS and ICANS were similar to the previous study, but hematologic toxicities occurred more frequently (grade 3-4)^[129]. Cilta-cel was then approved by FDA, in February 2022, for RRMM patients treated with > 4 prior lines of therapy including an anti-CD38 mAb, an IMiD, and a PI^[130]. Recent ongoing phase III trials are CARTITUDE-2, evaluating cilta-cel efficacy and safety in different clinical settings in RRMM^[131]; CARTITUDE-4, comparing Cilta-cel vs. pomalidomide, bortezomib and dexamethasone (PvD) vs. daratumumab, pomalidomide and dexamethasone (DPd) in RRMM; CARTITUDE-5, comparing bortezomib, lenalidomide, and dexamethasone (VRd) and Cilta-cel vs. VRd followed by lenalidomide and dexamethasone (Rd) therapy in transplant-ineligible patients MM at diagnosis^[132].

BCMA, DRUG RESISTANCE, AND MM

While the efficacy and safety of BCMA-targeting agents have been demonstrated, data regarding drug resistance are also emerging, though the exact mechanisms of resistance towards these agents have not been fully understood^[133]. Bone disease could be a reservoir for disease recurrence and a mechanism of resistance. Imaging is an important tool to detect residual disease outside the bone marrow or in extramedullary disease, although it is not known how BCMA antigen could be expressed on plasma cells outside the bone marrow. PET-CT is the gold standard technique to detect active disease and translated from lymphomas to MM^[134,135]. In addition, whole body-MRI studies showed equal sensibility vs. PET-CT and can be used^[136]. Downregulation of BCMA on PCs surface could be associated with resistance in a similar way as it has been described for CD19 and CD20 target therapies. Multi-targeted immunotherapies or the combination of BCMA targeting agents with γ -secretase inhibitors could overcome BCMA loss and both strategies are under investigation in clinical trials^[52].

Humoral and cellular immune responses could limit the persistence of BCMA CAR-T, leading to loss of efficacy and disease relapse. Alternative manufacturing processes, such as the application of human scFVs or the removal of the light-chain domain from the CAR antigen-binding domain, have been demonstrated to reduce CAR-T immunogenicity. In addition, BCMA CAR-T persistency could be increased by the addition of a phosphoinositide 3 kinase inhibitor during ex vivo culture to augment the memory-like T cells of the final product. Besides, allogenic CAR-T could overcome resistance related to T cell exhaustion which may be present in RRMM patients^[137-139].

Eventually, the tumor microenvironment is now considered to play a central role in promoting MM cell growth and has also been associated with drug resistance. Combination of BCMA targeting drugs with

immunomodulatory agents could overcome this intrinsic mechanism of resistance, while trials are evaluating the next generation of armored CAR-T cells engineered to secrete immunostimulatory cytokines or antibodies against inhibitory immune checkpoint receptors such as PD-1 and PD-L1.

DISCUSSION

Despite novel therapeutic advantages in recent years, MM remains incurable. BCMA immunotherapies are a novel anti-MM therapeutic approach that holds promise to improve MM survival in the future. ADCs, BITEs, and CAR-T cells are the newest therapeutic options targeting BCMA. Early clinical trials showed great efficacy and safety even IN MM patients treated with > 4 prior therapy lines. Since comparative studies of anti-BCMA targeted therapies are still lacking, it is not yet known whether one of these classes of agents is superior to another; however, they all have unique toxicities and logistical challenges. ADC is an interesting and efficacious therapy, but corneal toxicities need further understanding. Bispecific antibodies are therapies that can be used with excellent clinical activity. Disadvantages of bispecific antibodies could be their short lifetime and the need to start treatment in a hospital setting, as severe CRS/ICANS side effects usually appear at the beginning of therapy.

CAR-T cells are also a great option, as clinical trials reported high response rates in heavily pretreated MM patients. The main drawbacks of CAR-T cells include manufacturing time and expenses, leukapheresis necessity, and use of chemotherapy and infusion in a hospital setting for toxicities management. In addition, a relevant mechanism of resistance could be represented by the limited CAR-T growth and contact with the adverse plasma cell myeloma microenvironment, thus resulting in limited therapeutic effects after one year^[140]. To overcome these problems, new strategies are currently under investigation utilizing combos of drug agents with CAR-T, maintenance therapies after CAR-T, novel methods to extend CAR-T's duration, and implementing CAR-T production^[141]. Additionally, the combination of a checkpoint inhibitor with CAR-Ts is being tested as it may offer an advantage of reducing T cell downfall^[142].

The appropriate timing when to utilize a BCMA-targeted therapy is presently under investigation, with trials evaluating its role in earlier lines of therapy, including frontline. In fact, T cell-stimulating agents, such as CAR-T cells and BITEs, could probably produce deeper and longer responses if used at diagnosis or after only one or two lines of therapy, when MM patients are not heavily treated and may be at lower risk for T cell exhaustion.

In conclusion, therapies that target BCMA will play an important role in MM therapy, with the ambitious purpose of improving the cure rate; however, further investigations are still necessary to better define their real impact in clinical practice.

Abstract

The context-dependent reciprocal interaction between the cancer cells and surrounding fibroblasts is imperative for regulating malignant potential, metabolic reprogramming, immunosuppression, and ECM deposition. However, recent evidence also suggests that cancer-associated fibroblasts induce chemoresistance in cancer cells to various anticancer regimens. Because of the protumorigenic function of cancer-associated fibroblasts, these stromal cell types have emerged as fascinating therapeutic targets for cancer. However, this notion was recently challenged by studies that targeted cancer-associated fibroblasts and highlighted the underlying heterogeneity by identifying a subset of these cells with tumor-restricting functions. Hence, it is imperative to understand the heterogeneity and heterotypic signaling of cancer-associated fibroblasts to target tumor-promoting signaling processes by sparing tumor-restricting ones. In this review, we discuss the heterogeneity and heterotypic signaling of cancer-associated fibroblasts in shaping drug resistance and also list the cancer-associated fibroblast-targeting therapeutics.

Keywords: Tumor microenvironment, CAFs, heterogeneity, ECM, metabolic reprogramming, heterotypic signaling, drug resistance, natural products

INTRODUCTION

Accumulation of genetic or epigenetic aberration may be important for the transformation of normal epithelial cells but not sufficient to induce malignant potential. Context-dependent interaction between cancer cells and tumor microenvironment components is imperative for malignant progression^[1]. Tumor microenvironments consist of various kinds of non-cancerous cells such as fibroblasts, macrophages, mesenchymal stem cells (MSCs), pericytes, endothelial and immune cells, and extracellular matrix (ECM) known as tumor stroma^[2]. Fibroblasts constitute a major component of tumor stroma and exhibit multipronged functions in tumor progression^[3,4].

Fibroblasts could be considered cockroaches of the human body as they thrive under severe stress and can even be isolated from decaying/dead tissue. Fibroblasts are quiescent cell types and synthetically and metabolically less active^[3]. Upon activation, fibroblasts play a critical role in the wound healing process by remodeling ECM as well as secreting various growth factors and chemoattractant cytokines which ultimately regulate epithelial proliferation and immune cell infiltration^[3,5,6]. Dysregulation of their activation leads to the formation of scar and fibrotic diseases. Fibroblasts associated with cancer, termed cancer-associated fibroblasts (CAFs), show functional and molecular differences from normal fibroblasts. Fibroblast activation by the secreted factors, cell-matrix or cell-cell contacts with cancer or other stromal cells leads to the CAF phenotype acquisition^[2,7-9]. CAFs have been reported to exhibit higher migratory and contraction potentials along with synthesizing and remodeling ECM, reminiscent of myofibroblasts^[8,9]. Several reports show that CAFs secrete a myriad of growth factors and cytokines which are critical for several facets of tumor progression. CAFs were known to regulate several hallmarks of cancer by directly influencing cancer cell proliferation, migration, invasion, and angiogenesis^[7-9]. Our earlier study also reported that osteopontin (OPN)-activated CAF-derived CXCL12 promotes epithelial-to-mesenchymal transition (EMT) in breast cancer cells^[8]. Moreover, CAFs are known to shape the tumor immune microenvironment through the elevated expression of immunosuppressive cytokines and immune checkpoint proteins that results in immunosuppression and tumor progression^[10]. More importantly, CAFs are reported to induce drug resistance and cancer relapse in different cancers by different mechanisms including the induction of EMT, activation of stemness pathways, ECM remodeling, and dysregulated metabolism^[11]. Due to their important functions in tumor progression, CAFs have emerged as an intriguing therapeutic target for the clinical control of cancer. However, the studies focused on targeting CAFs for the management of cancer have challenged this dogma. Of note, genetic ablation of the CAF population or fibrosis induces immunosuppressive environment in pancreatic ductal adenocarcinoma (PDAC) which in turn promotes EMT and invasion in cancer cells, leading to tumor progression with poor disease outcomes^[12]. In addition, targeting the hedgehog (Hh) pathway in CAFs led to more aggressive and poorly differentiated PDAC with reduced stromal content and survival^[13,14]. The above report highlights the presence of a subset of CAFs with tumor-restricting functions. Understanding the heterogeneity of CAFs and their heterotypic signaling might help in tailoring therapeutic intervention that selectively targets tumor-promoting CAF population and spares tumor-restraining ones. This review focuses on CAF heterogeneity and heterotypic signaling in regulating drug resistance to cancer therapies. This review also highlights several current CAF-targeted therapies for the treatment of different cancer types.

NORMAL FIBROBLASTS AND ACTIVATED/CANCER-ASSOCIATED FIBROBLASTS

During the generation of the third germ layer or mesoderm, primitive mesenchymal cells (primary mesenchyme) first appear when the epiblast undergoes EMT^[15]. Most of the active mesenchymal cells undergo apoptosis after the completion of tissue development, whereas few cells attain a quiescent phenotype, which was first observed by Virchow^[16] and eventually named fibroblasts. Normal fibroblasts are elongated cells with extended cell processes that exhibit a fusiform or spindle-like shape. These are generally

present in connected tissues where they are embedded within ECM which consists largely of type I collagen and fibronectin^[17]. A specific marker of quiescent fibroblasts is still missing; however, fibroblast-specific protein 1 (FSP1) and vimentin are considered as the closest. Normal fibroblasts also express integrins which are the mediators of the interaction of fibroblasts with their surrounding microenvironment^[17]. Additionally, normal fibroblasts are characterized by low metabolic activity and lack of mobility^[3].

Fibroblasts can be activated to acquire activated/myofibroblast phenotype, which is associated with enhanced proliferative activity and increased synthesis of ECM proteins such as type I collagen, tenascin C, extra domain A (EDA)-splice variant of fibronectin, and secreted protein acidic and rich in cysteine (SPARC)^[17]. Fibroblast activation can be promoted by various stimuli generated from tissue injury or damage, including transforming growth factor beta (TGF- β), epidermal growth factor (EGF), fibroblast growth factor 2 (FGF2), and interferon- γ (IFN γ), interleukin (IL-6), mechano-transductions and enzymes^[17-19]. Upon activation, these cells exhibit prolific protein synthesis and higher contraction potential that is crucial for wound healing and the production of connective tissues^[3]. In physiological conditions, myofibroblasts play a critical role in wound healing and repairing damaged tissues^[19-22]. Upon the completion of their function, these cells are cleared by programmed cell death, apoptosis^[23]. However, if the injury is perpetual or dysregulation of the cell death program of these cells, it can lead to hyperproliferation and accumulation of myofibroblasts which culminates in a condition known as fibrosis^[24-26].

“Tumors are depicted as wounds that do not heal” as they undergo continuous stromal remodeling and vascular growth, reminiscent of the wound repair program. Similar to wound healing process, activated fibroblasts/myofibroblasts are also present in tumors and are known as CAFs^[9]. A diverse set of tumor or stroma-derived factors, including TGF- β 1, OPN, and IL-1 β , drive the transition of resting fibroblasts to CAFs by regulating Akt, ERK, MAPK, SMAD and NF- κ B signaling pathways^[8,27-29]. In an activation state, CAFs attain increased contractibility features and migratory potentials, which enables the CAFs to remodel ECM and aid in reciprocal interaction with cancer cells^[3,30,31]. Different CAF-specific markers were identified to characterize activated CAFs, such as alpha-smooth muscle actin (α -SMA), fibroblast activation protein (FAP), FSP1 (also known as S100A4), Integrin β 1 (CD29), platelet-derived growth factor receptor α or β (PDGFR α/β) or podoplanin (PDPN)^[32]. PDGFRs are a class of RTKs, known to be involved in tumor-fibroblast interactions^[33]. In contrast to wound healing, but similar to organ fibrosis, the fibroblasts at the tumor site remain perpetually activated and form fibrous growth in the tumor, referred to as desmoplastic reaction/stroma^[34]. Moreover, it was observed that senescent fibroblasts, which resemble myofibroblasts, also support preneoplastic tumor growth via secretion of OPN^[35,36].

ORIGIN OF CAFs

The expression of different kinds of markers in CAFs indicates the heterogeneous generation and different cellular sources of these cells. CAFs can be originated from epithelial cells through the EMT [Figure 1]. According to a report, epithelial cells undergo specialized EMT by MMP-driven oxidative stress-associated DNA oxidation and mutations that lead to transdifferentiation of these cells into activated myofibroblasts^[17,37]. This hypothesis is mainly supported by genetic studies conducted on breast cancers. These studies have reported somatic mutations in TP53 and phosphatase and tensin homolog (PTEN), and gene copy number alteration at other loci in stromal CAFs, similar to mutations in epithelial cells. Moreover, p53 inactivation in stromal fibroblasts and genetic inactivation of PTEN in CAFs promote tumor progression in breast carcinoma models^[38-40]. Collectively, these data indicate that the tumor-promoting activity of CAFs may depend on somatic mutations in these tumor suppressor genes. In addition, somatic alterations were frequently detected (> 30%) in tumor cell-surrounding fibroblasts^[39,40]. Similarly, CAFs might be generated from cancerous epithelial cells by EMT [Figure 1]^[41]. The EMT renders cancer cells to

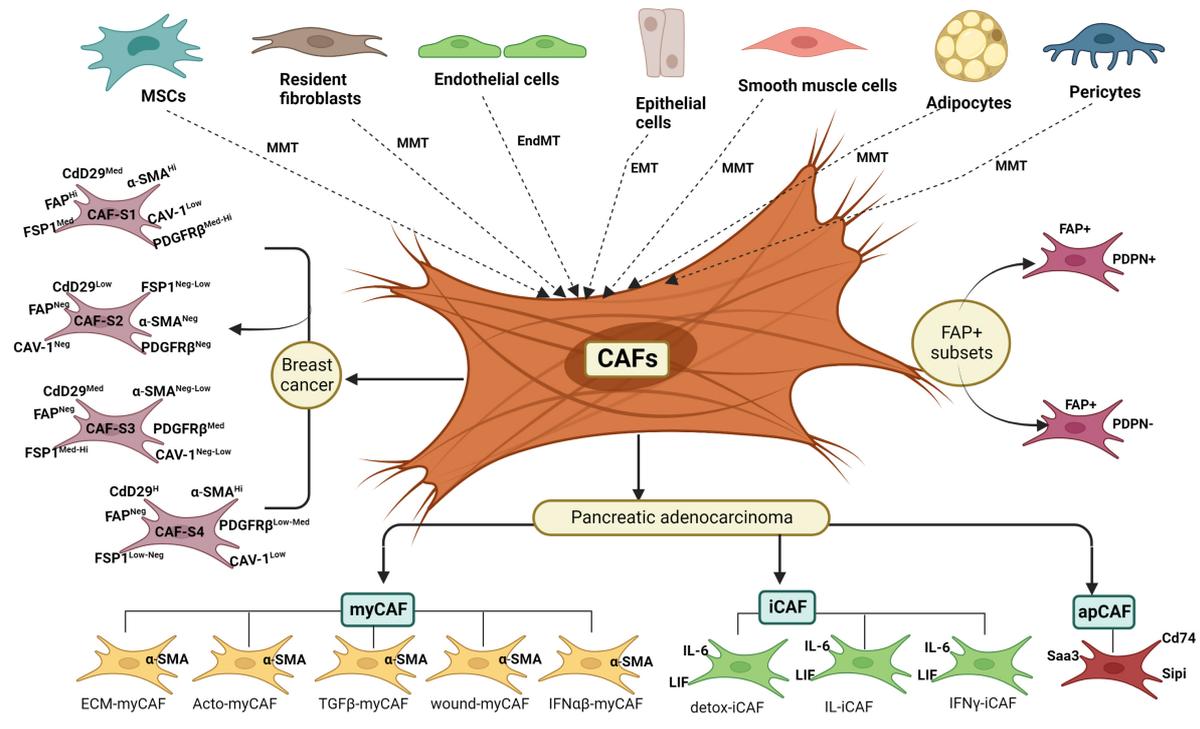

Figure 1. Origin and heterogeneity of cancer-associated fibroblasts. CAFs in the tumor microenvironment can be originated from MSCs, fibroblasts, adipocytes, pericytes, smooth muscle, endothelial and epithelial cells through the different trans-differentiation programs. Varieties of CAF subsets have been identified in cancer types of different tissue origins. The different subsets of CAFs show different functions and molecular features. CAF-S1 to CAF-S4 subsets are present in breast cancer. myCAF, iCAF and apCAF subsets are observed in PDAC. Several cancers exhibit overlapping populations of CAF subsets.

acquire mesenchymal phenotype and higher migration and contraction potentials^[15]. This EMT program induced by platelet-derived growth factor (PDGF), TGF β , EGF, etc., and is facilitated by the activation of mesenchymal specific transcription factors like Snail, Slug, Twist and FOXC2^[15,42]. Tumor-associated endothelial cells might contribute to the CAF population [Figure 1]. A previous study has shown that endothelial cells are transdifferentiated into CAFs via endothelial to mesenchymal transition (EndMT) by losing expression of CD31 and gaining the expression of FSP-1 and α -SMA under the TGF- β stimulus^[43]. In another study, auto/paracrine FGF2 has been shown to regulate the TGF- β -induced EndMT in tumor endothelial cells (TECs) via Elk1^[44]. In a similar way, pericytes undergo pericytes to myofibroblast transition (PMT), a mesenchymal-to-mesenchymal transdifferentiation (MMT) process to generate CAFs in a microenvironment [Figure 1]. Hosaka *et al.* have recently reported that vascular pericytes are converted to CAFs by PDGF-BB to promote tumor growth and metastasis. PDGF-BB binds to PDGFR β to induce the PMT program in pericytes^[45]. CAFs are known to be generated from bone marrow-derived mesenchymal stem cells (MSCs) [Figure 1]^[46,47]. Recruitment of MSCs takes place in many pathological conditions such as tissue repair, inflammation, and neoplasia. MSCs are recruited from the bone marrow into the tumors and subjected to activation similar to many inflammatory cells by a plethora of cytokines and growth factors derived from tumor cells or activated stroma^[46-48]. The cytokines involved in the activation are vascular endothelial growth factor (VEGF), hepatocyte growth factor (HGF), basic fibroblast growth factor (bFGF), PDGF, EGF, CCL2, etc.^[49-51]. The previous report showed that labeled MSCs have been shown to localize tumor mass and thus differentiate into pericytes and CAFs by acquiring de novo expression of characteristic markers such as α -SMA, FAP, tenascin-c and thrombospondin1^[52]. Reports have shown that tumor-derived OPN induces MSC transformation into CAFs via MZF1-mediated TGF- β expression to promote more

aggressive local tumor growth and metastasis in breast cancer^[53]. Even though different cell types contribute to CAFs, the major source of CAFs is resident fibroblasts. Resident fibroblasts in tumors undergo fibroblast to myofibroblast transition (FMT), a process of MMT to generate CAFs [Figure 1]^[18]. Various growth factors and cytokines, mechanical forces and cell-cell contacts regulate the FMT process^[8,19,30]. Evaluation of the FMT process in the tumor microenvironment was initially achieved by Kojima *et al.* in the fibroblast and cancer cell co-implantation xenograft model. Their studies have revealed that autocrine activation of TGF- β and SDF-1 (CXCL12) signaling leads to the acquisition of myofibroblast phenotype in fibroblasts^[54]. CBL (CBF1, Suppressor of Hairless, Lag-1) and p53 are considered tumor suppressors in different cancers. Silencing of CBL and p53 in fibroblasts leads to the attainment of CAF phenotype in normal fibroblasts^[55]. Shimoda *et al.* have reported that TIMPless fibroblasts reflects the traits of CAFs. According to their studies, deletion of TIMP instigates the expression of α -SMA in fibroblasts and increases the migration and contraction potentials^[56]. A recent study has described the role of nodal in the conversion of normal fibroblasts to CAFs with snail and TGF- β signaling pathway activation^[57]. In addition, paracrine signaling cues derived from tumor cells play a major role in the acquisition of the CAF phenotype. Tumor-derived TGF- β is known to play a pivotal role in the generation of CAFs from the activation of resident fibroblasts^[58]. Recruitment of fibroblasts into the tumor microenvironment is a prerequisite for CAF generation. A previous study has identified that tumor cell-derived Wnt7a recruits and activates fibroblasts to CAFs to promote tumor aggressiveness. Wnt7a exhibits a fibroblast-activating role by potentiating TGF- β receptor signaling and not relying on canonical Wnt signaling^[59]. Epigenetic switch involving p300-mediated STAT3 acetylation induces the fibroblast activation to CAFs to support tumor invasion^[60]. Mechanical forces and matrix stiffness induce several signaling pathways in the tumor microenvironment that are imperative for tumor aggressiveness. Matrix stiffness elevates the activity of Yes-associated protein (YAP) in nearby fibroblasts, thereby inducing the CAF phenotype in these cells^[19]. Activated fibroblasts are reported to secrete various growth factors, cytokines such as SDF-1, IL-6, CXCL14, CCL5 and CCL7 and proteases such as MMP-2, MMP-9 and uPA to promote EMT in cancer^[18].

HETEROGENEITY OF CAFs

The multipronged actions of CAFs on tumor cells probably reflect their heterogeneous population with context-dependent functions. Although CAFs are known to originate from resident fibroblasts, MSCs, endothelial cells, pericytes, epithelial cells, and adipocytes through trans-differentiation programs, CAF subsets have been represented as distinct cellular states rather than indicating their different cell origins. Costa *et al.* have identified four subsets of CAFs (CAF-S1, CAF-S2, CAF-S3 and CAF-S4) in breast cancer by combining the analysis of six CAF markers [Figure 1]. Higher levels of both CAF-S1 (FAP^{High} CD29^{Med} SMA^{Med-High} FSP1^{Med} PDGFR β ^{Med-High} CAV1^{Low}) and CAF-S4 (FAP^{Neg-Low} CD29^{High} SMA^{High} FSP1^{Low-Med} PDGFR β ^{Low-Med} CAV1^{Low}) subsets are reported in aggressive Her2+ and triple-negative breast cancer (TNBC)^[61]. Moreover, accumulation of FAP^{High} CAF-S1 subset in early luminal breast cancers is associated with distant relapse^[62]. In contrast, the CAF-S2 subset (CD29^{Low} FAP^{Neg} FSP1^{Neg-Low} α -SMA^{Neg} PDGFR β ^{Neg} CAV1^{Neg}) is highly accumulated in the luminal breast cancer subtype whereas CAF-S3 fibroblasts (CD29^{Med} FAP^{Neg} FSP1^{Med-High} α -SMA^{Neg} PDGFR β ^{Med} CAV1^{Low}) is observed in healthy tissues^[61-63]. In addition, CAF-A (ECM remodeling) and CAF-B (myofibroblastic genes) are observed in colorectal cancer (CRC)^[64].

Givel *et al.* have demonstrated fibroblast heterogeneity in high-grade serous ovarian cancers (HGSOC) by defining four subsets of CAFs (CAF-S1 to S4) as described in breast cancer^[65]. Mesenchymal HGSOC consists of high CAF-S1 fibroblasts, which modulate immunosuppressive functions by increasing infiltration, survival, and differentiation of CD25⁺FOXP3⁺ T lymphocytes. SDF-1 β (CXCL12 β) is specifically accumulated in the immunosuppressive CAF-S1 subset. Thus, their data highlight a CXCL12 β -regulated stromal heterogeneity and immunosuppression in mesenchymal HGSOC^[65]. The existence of CAF-S1 and

CAF-S4 molecular signatures has been validated in lung cancer^[66] and head and neck cancer by leveraging publicly available single-cell data^[67]. The presence of these two major CAF-S1/CAF-S4 myfibroblastic subpopulations was validated in different cancer types^[68]. These data suggest the existence of both CAF-S1 and CAF-S4 myfibroblastic cells in distinct cancer types and across species.

Two subsets of CAFs were recently reported in pancreatic adenocarcinoma. One subset displays a matrix-synthesizing myfibroblastic phenotype termed myCAF, whereas another exhibits an immunomodulatory phenotype, inflammatory CAFs named iCAF [Figure 1]. The CAFs proximal to the cancer cells show a myCAF phenotype with higher expression of α -SMA. Distal CAFs from the cancer cells express high levels of proinflammatory cytokines such as IL-6, G-CSF, CXCL1, and LIF and are defined as iCAFs^[69]. IL-1 signaling induces iCAF signature, while TGF- β signaling controls myCAF signature by antagonizing the iCAF phenotype. Another study has demonstrated the two different subpopulations of CAF, named myfibroblastic CAFs (myCAFs) and inflammatory CAFs (iCAFs), by employing a 3D co-culture system of PDAC *in vitro*^[70]. Further, Elyada *et al.* reported the third subtype of CAFs, named antigen-presenting CAFs (apCAFs), using single-cell RNA sequencing (scRNA-seq) in PDAC tissues, and these are characterized by expression of H2-Aa, H2-Ab1 (encoding α , β -chains of MHC II), CD74, secretory leukocyte peptidase inhibitor (SLPI) and serum amyloid A3 (Saa3) genes [Figure 1]. Also, apCAFs possess antioxidant response and are regulated by IFN- γ signaling *in vivo*^[71]. Furthermore, other studies also confirmed the apCAF classification based on the results obtained using scRNA-seq in pancreatic cancer^[72,73]. In addition, transcriptomics study in normal pancreatic cells of KPP mice revealed that cells that express mesothelial signature also show the expression of MHC II genes, implicating that apCAF could be of mesothelial origin^[74]. Later, apCAFs subtype has also been reported in breast and lung cancer^[75-78]. Interestingly, apCAFs activate the CD4 + T lymphocytes, which implies that CAFs have antigen-presenting properties similar to other antigen-presenting cells such as macrophages, dendritic cells and B cells immunomodulatory functions. However, the study on orthotopic murine models of lung cancer showed that lung apCAFs are tumor-suppressive cells^[77]. Another report has revealed the presence of two FAP+ subsets on the basis of PDPN expression [Figure 1]^[79]. The FAP+ PDPN+ fibroblasts show elevated expression of TGF- β signaling proteins and fibrosis-associated genes, whereas FAP+ PDPN- cells displayed less expression of the same genes^[68,71,79]. Moreover, a recent study further classified FAP^{High} CAFs into eight different clusters. Out of these clusters, five clusters (ECM-myCAF, Acto-myCAF, TGF β -myCAF, wound-myCAF and IFN $\alpha\beta$ -myCAF) belong to the myCAF subgroup and three clusters (detox-iCAF, IL-iCAF, IFN γ -iCAF) fall into the iCAF subgroup^[68]. Therefore, CAFs possess multifaceted functions including tumor promotion and prevention based on the gene expression signatures.

CAFS REGULATE DRUG RESISTANCE BY MODULATING CANCER CELL SURVIVAL

Interestingly, cancer cells produce a variety of factors that recruit, activate, and help with the survival of CAFs; nonetheless, CAFs, in return, support cancer cell survival and proliferation by providing appropriate signaling factors which subsequently promote cancer cell resistance. Using mouse models of inflammation-induced gastric cancer, a study reported that at least 20% of CAFs are derived from MSCs of bone marrow, and show the expression of α -SMA, wingless-related integration site 5 α (Wnt5 α), IL-6, bone morphogenetic protein 4 (BMP4), and DNA hypomethylation. MSC-derived CAFs are recruited to dysplastic stomach in TGF- β and SDF-1 α -dependent manner to promote tumor survival^[80]. CAFs provide ovarian cancer cells resistance to cisplatin by secreting cisplatin-induced chemokine (C-C motif) ligand 5 (CCL5), which augments the phosphorylation of STAT3 and Akt in cancer cells. Thus, CAFs play a crucial role in promoting ovarian cancer cell growth by regulating STAT3/PI3K/Akt pathway [Figure 2A]^[81]. Interestingly, a heparin-binding growth factor, midkine (MK), derived from CAFs, provides cisplatin resistance to oral squamous cell carcinoma (OSCC), lung cancer, and ovarian cancer cells by enhancing the expression levels

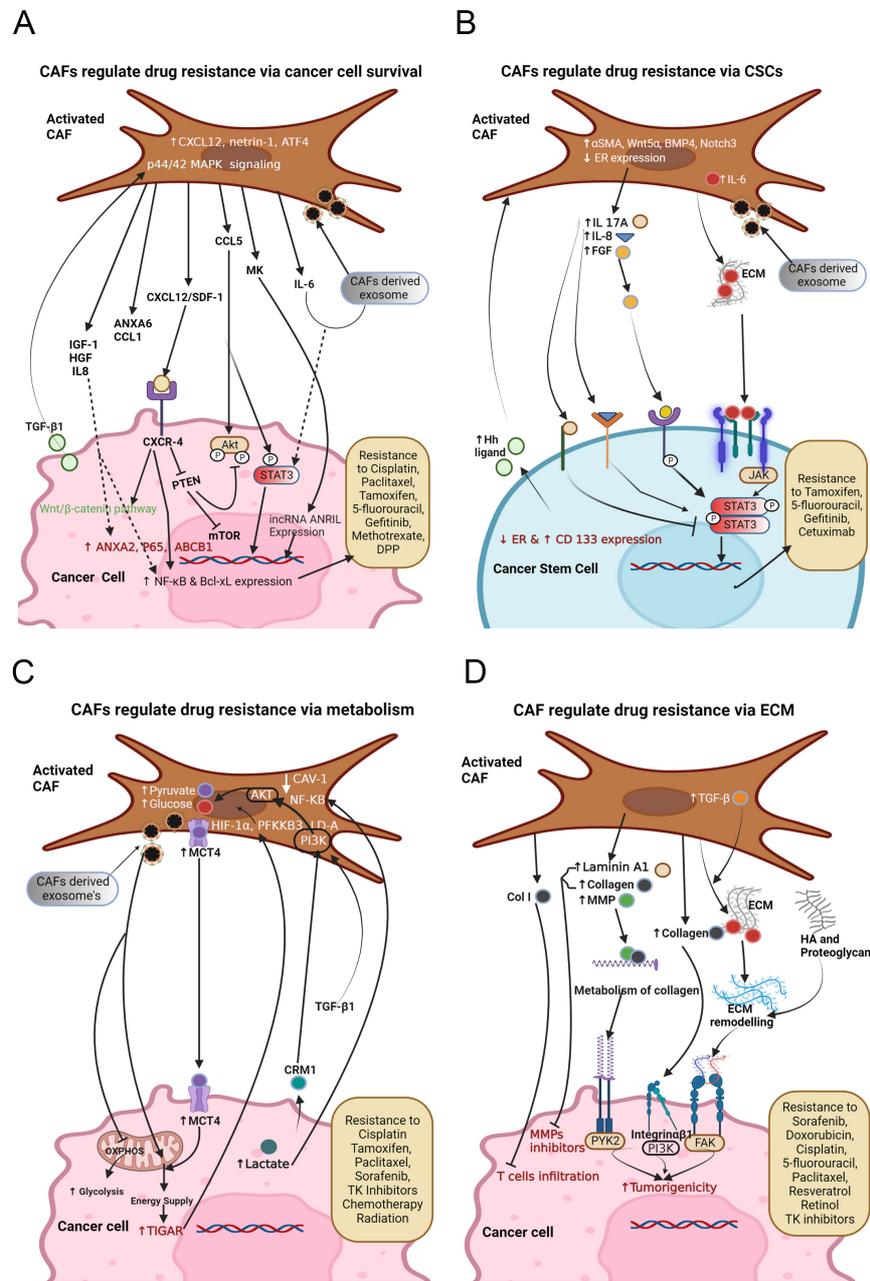

Figure 2. Fibroblast-mediated signaling in shaping the drug resistance in (A) CAFs promote cancer cells survival by secreting ANXA6, CCL1, CXCL 12, CCL5, MK, etc., and the exosomes containing IncRNA ANRIL, miR-196a, miR-103a-3p, miR-24-3p, microRNA-21, microRNA-148b-3p, LPP, CCAL, etc. Also, CAFs show high levels of netrin1, IL-6, and ATF4, which offer cancer cells gemcitabine resistance. TGF- β 1 secreted by cancer cells acts on CAFs to attain 5-fluorouracil (5-FU) and tamoxifen (TAM) resistance. Inhibition of PTEN by CXCL12-CXCR4 binding promotes mTOR signaling and cancer proliferation. MK provides cisplatin resistance by ameliorating the expression of IncRNA-ANRIL; (B) CAFs induce stemness in cancer cells through the activation of STAT3 by IL8, IL6, and FGF and secreting exosomes containing miR-221 and H19 that leads to drug resistance, and STAT3 activation can be inhibited by IL-17A. High levels of α -SMA, Wnt5 α , BMP4 and Notch3 in CAFs and low expression of ER in both CAFs and cancer cells are associated with enriching CSCs and drug resistance; (C) CAFs provide different nutrients to cancer cells. CAF-secreted factors rewire the cancer cell metabolism by the activation of autophagy, mTOR, and TIGAR and suppression of oxidative phosphorylation that leads to drug resistance; (D) CAFs promote drug resistance by ECM deposition. Activation of CAFs by TGF- β 1 or other factors leads to excessive synthesis of ECM proteins such as laminin-A, collagen, and fibronectin. It also induces various MMPs, which leads to ECM modeling that blocks drug effects.

of the lncRNA-ANRIL [Figure 2A]. Therefore, targeting either MK production from CAFs or inhibiting the lncRNA-ANRIL in cancer cells could be the key to cancer treatment^[82]. The mir-1-mediated expression of SDF-1 in CAFs induces the proliferation of lung cancer cells and chemoresistance via CXCR4-dependent pathway involving NF- κ B and Bcl-xL^[83]. CAFs are not only involved in promoting cancer cell viability but also induce EMT in response to drug treatments. An earlier study showed that CAFs promote EMT through the secretion of IGF-1 and HGF. These growth factors enhance the expression and phosphorylation of annexin A2 (ANXA2), which endorse the resistance to the EGFR-TKI (gefitinib) in NSCLC (HCC827 and PC9) cells-harboring EGFR activating mutations [Figure 2A]. Therefore, restricting the CAFs-induced EMT is necessary to subdue TKI-resistance^[84]. EMT transcription factors such as Twist1 and Snail regulate the activation of CAFs in cancers^[30,85]. Expression of Twist1 and Snail in CAFs also associated with the expression of several cytokines including SDF-1, CXCL1 and CCL2 which can regulate cell proliferation and survival^[30,86]. Blanco-Gomez *et al.* demonstrated that loss of SNAI2 in CAFs limit the production of some cytokines such as SDF-1 and CXCL1, CXCL2, IFN- γ and IL-16, thereby impeding breast cancer cell proliferation and metastasis^[86]. Thus, SNAI2 could be considered a therapeutic target to block both proliferation and EMT in tumor cells and cytokine production in CAFs.

Furthermore, CAFs elicit TGF- β -mediated EMT in ovarian cancer cells via IL-6-regulated JAK2/STAT3 pathway to inhibit cancer cell apoptosis and provide paclitaxel resistance^[87]. CAF-secreted SDF-1 stimulates pancreatic cancer progression and aids in gemcitabine resistance by augmenting the expression of SATB-1^[88]. A recent study showed that snail-positive fibroblasts facilitate chemoresistance to 5-fluorouracil and paclitaxel in colorectal cancer (CRC) by secreting CCL1 through the TGF- β /NF- κ B signaling pathway^[89]. In addition, CAFs upregulate the expression of the lipoma-preferred partner (LPP) in microvascular endothelial cells (MECs). The upregulated LPP upshots stress fiber formation and focal adhesion to further enhance the mobility and permeability of endothelial cells, which ultimately resulted in the enhancement of chemoresistance in ovarian cancer^[90]. CAFs elevate human gastric cancer chemoresistance by higher expression of IL-8, which further regulates cell survival pathways including PI3K, Akt, IKK, p65, and ABCB1. Hence, IL-8 derived from CAFs involved in promoting chemoresistance in gastric cancer through NF- κ B activation and upregulation of ABCB1 [Figure 2A]^[91]. Annexin A6 present in CAFs-derived extracellular vesicles plays an important role in inducing drug resistance and tubular network formation in gastric cancer by activation of FAK/YAP axis through the stabilization of β 1 integrin on the surface of cancer cells^[92]. Higher expression of activating transcription factor 4 (ATF4) in PDAC-derived CAFs promotes malignancy and gemcitabine resistance through TGF- β 1/SMAD2/3 axis^[93]. Intriguingly, TGF- β 1 secreted from breast cancer cells activates CAFs in a paracrine manner, contributing to chemoresistance via activating p44/42 MAPK signaling pathway^[94].

Higher expression of CXCL12 in interstitial CAFs contributes to EMT and cisplatin resistance in epithelial ovarian cancer (EOC) via CXCR4/Wnt/ β -catenin pathway^[95]. Additionally, this CAF-derived CXCL12 mediates inhibition of PTEN which is crucial for cancer cell proliferation [Figure 2A]^[96]. Likewise, CAFs are involved in offering cisplatin resistance in HNC cells by exosome-mediated transfer of miR-196a. Upon depletion of CAF-exosomal miR-196a, restoration of cisplatin sensitivity has occurred in HNC cells. Therefore, targeting miR-196a can serve as a better therapeutic approach to overcome cisplatin resistance in HNC cells^[97]. Moreover, CAF-derived, highly expressed, exosomal miR-103a-3p accelerates cisplatin resistance and inhibits apoptosis in NSCLC cells by targeting BCL2- antagonist/killer 1 (Bak1)^[98]. CAF-derived miR-24-3p containing exosomes promote cancer cell resistance to methotrexate by downregulation of the CDX2/HEPH axis in colon cancer^[99]. The CAF-mediated transfer of exosome-containing lncRNA CCAL (colorectal cancer-associated lncRNA) to CRC cells initiates signaling towards gaining resistance to oxaliplatin via the β -catenin pathway. Interaction of CCAL with HuR (human antigen R, an RNA stabilizing

protein) leads to an increase in β -catenin, thereby providing oxaliplatin resistance in CRCs^[100]. CAFs secreted IL-6/exosomal microRNA-21 (miR-21) induces the activation of STAT3 signaling to generate monocytic myeloid-derived suppressor cells (M-MDSCs) to further accelerate cisplatin (DDP). Therefore, inhibition of STAT3 signaling can restore cancer cells' drug sensitivity^[101]. Transfer of CAF derived exosomes-containing miR-148b-3p to bladder cancer cells enhances tumor proliferation, EMT, metastasis, and drug resistance. Mechanistically, miR-148b-3p induces Wnt/ β -catenin pathway by targeting PTEN^[102]. Therefore, overexpression of PTEN might lead to suppression of metastasis, EMT, and drug resistance. CAFs respond to tamoxifen treatment by upregulating the expression of high mobility group box 1 (HMGB1) through GPR30/PI3K/AKT signaling. HMGB1 is involved in the induction of autophagy to increase resistance to tamoxifen in MCF-7 cells via an ERK-mediated manner^[103]. Overall, the above reports suggest that CAF-secreted growth factors, chemokines and exosomes regulate drug resistance by inducing cell survival in different types of cancer.

CAFS REGULATE DRUG RESISTANCE BY MODULATING CANCER STEM CELLS

Cancer stem cells (CSCs) play a pivotal role in tumorigenesis, progression, and drug resistance. CSCs exhibit self-renewal and tumorigenic properties, which enable them to metastasize to distant sites, offering them a favorable environment. Moreover, the microenvironment around CSCs contributes a lot to fostering tumor growth through the modulation of CSC phenotype. The generation of CSCs through EMT is highly conditional on its surrounding matrix. This underscores the vital role of microenvironmental elements like CAFs and their secreted factors in shaping the renewal and maintenance of CSCs^[104].

Stem cell pathways like Wnt signaling are important for maintaining stemness in non-cancerous cells of the colon. An interesting study suggested that cells surrounding the CSCs, especially myofibroblasts, maintain a higher Wnt activity in CSCs and manage to stimulate Wnt signaling in nearby differentiated tumor cells, thereby mending the stemness and tumorigenicity^[105]. In response to the chemotherapy, CAFs express IL-17A, which helps with the self-renewal of cancer-initiating cells (CICs) to facilitate resistance to chemotherapies^[106]. Therefore, targeting IL-17A signaling could impede CICs growth. Additionally, exosomes secreted by fibroblasts in response to chemotherapy are also known to promote the spheregenerating capacity and chemotherapy resistance in CSCs. To validate the role of CAF-derived exosomes in priming CSCs, blockade of exosome release by culturing CAFs in the presence of a specific inhibitor of neutral sphingomyelinase 2, GW4869 resulted in the restoration of chemosensitivity in CSCs^[107]. Hence, blocking CAFs secretion can be an effective approach to increasing the efficacy of chemotherapy in combating cancers. Specifically, fibroblast-derived exosomes-containing Wnts promote Wnt activity in CRC cells to enhance chemoresistance^[108]. The microvesicles (MV) derived from CAF, transfer miR-221 to CSCs to induce hormonal therapy (HT)-resistance. The overall loop of events, including CAFs release of MV, is associated with a reduction of ER expression followed by an increase in Notch expression in CSCs. The increase in Notch further elicits the reduction of ER levels and an increase in CD133 levels in CSCs [Figure 2B]^[109]. Moreover, CAFs are involved in supporting CSCs via combined activation of Wnt/ β -catenin and HGF/Met signaling. CSCs regulate CAFs via secretion of Hh ligand, SHH to activate Hh signaling in a paracrine manner. In turn, CAFs secrete factors that help with CSC's self-renewal and expansion. The treatment of tumors with a Hh inhibitor, vismodegib, led to the reduction of CAF activation and CSC's expansion, thereby delaying the tumor formation and progression. Hence, targeting CAFs using Hh inhibitors can be an effective strategy for breast cancer treatment^[110]. A study reported that Hh-stimulated CAFs contribute to the formation of chemo-resistant CSCs niche through the FGF pathway. Extracellular matrix rich in Hh-activated CAFs, FGF, and fibrillar collagen shape a conducive environment to foster a stem-like phenotype in triple-negative breast cancer (TNBC) cells^[111]. Another study reported that HIF-1 α and CAF-derived TGF- β 2 crosstalk activate the expression of GLI2, a Hh

transcription factor, in CSCs, which further enhances the chemoresistance and stemness of CSCs^[112]. Specifically, CD10 and GPR77-positive subsets of CAFs are associated with chemoresistance by creating a niche for enrichment of CSCs in the multiple cohorts of breast and lung cancer patients. The binding of C5a to GPR77 in CD10 + GPR77 + CAFs in an autocrine manner phosphorylates p65 which ultimately leads to the expression of IL-6, IL-8, CD10, and GPR77. Though GPR77 continues to be part of autocrine cycle, IL-6 and IL-8 regulate CSC's self-renewal^[113]. Additionally, CAFs facilitate chemoresistance and stemness through the transfer of exosomal H19 to CRC. H19 produced by CAFs in CRC stroma mediates CSC phenotype by activating the β -catenin pathway^[114]. The usage of MSC-derived fibroblasts (MSC-DF) has been reported for reciprocally studying the loss-of-function and gain-of-function of the Notch in the regulation of CSCs. It was found that MSC-DF Notch1^{-/-} promoted the formation of spheroids in co-cultured melanoma cells, while MSC-DFN1IC^{+/+} (N1IC: Notch1 intracellular domain, an active form of Notch1) suppressed melanoma cell sphere formation capacity, thereby diminished tumor initiation properties. MSC-DFNotch1^{-/-} could contribute to promoting stemness of melanoma cells by upregulating Sox2/Oct4/Nanog expression^[115]. An earlier report revealed that IL-17A acts as a CSC-maintenance factor and helps with CSC renewal and invasion^[116]. Intriguingly, epigenetic changes in CAFs also play a critical role in maintaining CSC-promoting capacity. A recent study revealed that the loss of H3K27me3 in CAFs leads to the expression of WNT5A, NOG, GREM1, and IGF2, which play an important role in maintaining stem cell niche, stromal-epithelial interaction, and cell growth^[117]. Therefore, it is important to identify players involved in CAF-specific epigenetic changes in order to shed light on epigenetic-centered CAF-targeted therapies. Netrin-1 is highly expressed in CSC and known to regulate stemness. The higher expression of netrin-1 was also found in CAFs and associated with the increasing stemness in cancer cells, thereby mediating drug resistance. Inhibition of intercellular signaling between cancer cells and CAFs using Netrin-1-mAb suppresses the expression of CAF-borne cytokines such as IL-6^[118]. Taken together, CAF-regulated CSCs execute a crucial role in tumor initiation, maintenance, progression, and chemoresistance. Hence, finding a signaling messenger between CSCs and CAFs is indispensable for developing interventions to combat cancer

CAFS REGULATE DRUG RESISTANCE BY MODULATING CANCER CELL METABOLISM

The major energy sources for the survival of unconditionally growing tumor cells are glutamine (Gln) and glucose. Rewiring of cancer cell metabolism enables the survival of cancer cells by providing the building blocks/intermediates for the synthesis of nucleic acids, lipids and proteins. Tumor microenvironment (TME) or CAFs-mediated metabolic reprogramming of cancer cells regulates several signaling cascades that also result in drug resistance^[119].

Notably, a study has shown that exosomes derived from CAFs can reprogram the metabolic machinery by their uptake into cancer cells^[120,121]. These exosomes consist of intact lipids, amino acids, and intermediates of the TCA cycle^[121]. Moreover, these exosomes inhibit mitochondrial OXPHOS, leading to increased glycolysis and Gln-dependent reductive carboxylation in cancer cells [Figure 2C]. It has been reported that CAFs predominantly express glucose uptake proteins in non-small cell lung cancer. Among these, glutamine-fructose-6-phosphate transaminase 2 (GFPT2) plays an important role in glycolysis, thus showing its significance in prognosis^[122]. A previous study showed that epigenetic changes in CAF instigated a cascade of stromal-epithelial interactions to promote prostate cancer growth and resistance to androgen deprivation therapy (ADT). This study revealed that epigenetic silencing of a Ras inhibitor, RASAL3, in prostatic CAFs leads to oncogenic Ras activity that drives macropinocytosis-mediated glutamine synthesis. Interestingly, ADT further strengthens RASAL3 epigenetic silencing and glutamine secretion by CAFs. Therefore, high levels of glutamine have been found in prostate cancer patients after ADT^[123].

Cancer cells, under glucose-deprived states, use aerobic glycolysis as their major energy source, known as the Warburg effect. Pyruvate kinase M2 (PKM2) is overexpressed in NSCLC cell lines and plays a role in mediating the Warburg effect which promotes resistance to cisplatin^[124]. In another phenomenon, aerobic glycolysis in the cancer-associated stroma metabolically supports surrounding cancer cells, which is known as the reverse Warburg effect. This stromal-cancer metabolic coupling enables catabolite transfer to cancer cells for the generation of ATP, induction of proliferation, and reduction of cell death^[125]. Interestingly, cancer cells educate stromal cells to display aerobic glycolysis that mediates multidrug resistance^[126]. Moreover, in the majority of solid tumors, CAFs utilize more glucose and in turn release more lactate in comparison to normal fibroblasts^[127]. Notably, cancer cells induce the Warburg effect in CAFs through activation of the PI3K/AKT pathway via translocation of nuclear G-protein-coupled estrogen receptor (GPER) in a chromosomal region maintenance 1 (CRM1)-dependent manner and abnormal activation of the GPER/cAMP/PKA/CREB signaling pathway^[126]. Consequently, CAFs delivered lactate transporters to cancer cells, which increases drug resistance [Figure 2C]. In contrast, a study by Apicella *et al.* showed that cancer cells expressing EGFR- or MET exhibit increased glycolytic activity leading to elevated levels of lactate. The elevated levels of lactate educate CAFs to secrete higher levels of HGF via an NF- κ B-dependent mechanism that subsequently leads to cancer cell resistance against TKI therapy^[128]. In solid tumors, the hypoxic environment mediates chemoresistance, as its low pH affects the cytotoxicity of mitoxantrone, paclitaxel and topotecan^[129]. It has been reported that under a hypoxic environment, CAFs secrete several factors that activate angiogenic (VEGF) and immunogenic (T-cell mediated cytotoxicity) signaling that is essential for tumor progression^[130,131]. A study showed that hypoxia induces migration, type I collagen expression, and VEGF production in pancreatic stellate cells and mediates resistance to anticancer drugs^[132]. Interestingly, it has been demonstrated that TGF- β expressed by other stromal cells activates fibroblasts and induces ECM production, and stimulates aerobic glycolysis and catabolic metabolism^[133]. It has been observed in a cancer cell-fibroblast co-culture system, oxidative stress-induced autophagy leads to downregulation of caveolin-1 (CAV1) in CAFs and overexpression of TIGAR (TP53- Induced Glycolysis and Apoptosis Regulator) in adjacent cancer cells^[134]. Downregulation of CAV1 in CAFs leads to mitochondrial dysfunction and glycolysis via HIF-1 α and NF- κ B signaling. Therefore, autophagic CAFs prevent cancer cell death by providing substrates for metabolic activity of cancer cells and upregulating TIGAR which confers resistance to tamoxifen-induced apoptosis and autophagy^[135]. In addition, overexpression of TIGAR in cancer cells induces a glycolytic phenotype in CAFs and promotes the expression of HIF-1 α , PFKFB3 (6-phosphofructo-2-kinase/fructose-2,6-biphosphatase 3) and lactate dehydrogenase-A along with increasing glucose uptake [Figure 2C]^[134]. Overexpression of PFKFB3 has been shown to generate resistance to the BCR-ABL TKI in chronic myeloid leukemia (CML)^[136]. Likewise, overexpression of HIF-1 α along with glycolytic isoenzymes has been reported to be strongly associated with chemoresistance in different tumors^[137,138]. Furthermore, CAFs-associated metabolic reprogramming also regulates epigenetic changes for the maintenance of the CAF active state; thereby, catabolic CAFs and anabolic cancer cells are metabolically coupled, contributing to the development of chemoresistant tumors^[139-141]. In addition, the decrease in glucose concentration limits the synthesis of building blocks required for cell proliferation, leading to inhibition of cell proliferation. However, glucose starvation induces AMP-activated protein kinase (AMPK), which is an upstream factor of Hippo signaling; therefore, coupling of the metabolic pathway and Hippo signaling promotes drug resistance^[142]. Metabolic coupling of CAFs and cancer cells is critical for regulating resistance to different therapeutic regimens. Therefore, devising therapeutic interventions to disrupt the metabolic coupling of CAFs and cancer may open new avenues for cancer treatment. However, how cancer cells educate CAFs to trigger resistance-mediating pathways is still poorly known.

CAFS REGULATE DRUG RESISTANCE BY MODULATING ECM

CAFs orchestrate tumor promotion and drug resistance by increasing matrix stiffness via augmenting the expression of ECM components such as hyaluronic acid (HA) and collagens^[143]. Both HA and collagen are known to withstand tensile stress and the activity of collagen receptor, integrin $\alpha 11\beta 1$, is associated with matrix stiffness. It has been reported that in NSCLC, CAFs can promote the stiffness of interstitial collagen by enhancing the expression of integrin $\alpha 11$, leading to tumor progression^[144]. A recent study demonstrated that collagen secreted by CAFs acts in a paracrine manner to regulate the resistance to microtubule-directed chemotherapeutic drugs through integrin $\beta 1$ /PI3K/AKT pathway in breast cancer [Figure 2D]^[145]. The dense number of CAFs was observed to play an important role in desmoplastic reactions in PDAC^[146]. In addition, the CAFs-derived intense desmoplastic response in fibrotic tumors builds a dense ECM barrier that reduces the delivery of any drug to the tumor cells. In breast cancer patients, a progressively noncompliant fibrotic stroma limits the chemotherapeutic efficiency of doxorubicin^[147]. Also, based on desmoplastic scores, CAFs have been divided into high desmoplastic CAFs (HD-CAFs) and low desmoplastic CAFs (LD-CAFs). The NSCLC patients with HD-CAFs showed a high collagen matrix remodeling rate which played a critical role in tumor progression via regulation of invasion and growth^[148]. Likewise, HD-CAFs (alpha-smooth muscle actin positive myofibroblasts) in PDAC are significantly involved in the secretion of type I collagen (Col1) which plays a role in restricting drug delivery and impeding T cell infiltration^[149].

Further, CAFs produce metalloproteinases (MMPs) that enhance tumor invasion by matrix remodeling^[150]. CAFs employ MMP endopeptidases for the degradation of basement membrane (BM) proteins^[151]. A previous study demonstrated the role of CAFs in BM stretching that facilitates the migration of CAFs and tumor cells into the bloodstream and metastasizes to distant organs. Intriguingly, the alternative CAF-dependent mechanism where BM shows a high tendency of stretching due to low expression of type IV collagen and laminin and rendering the head and neck tumor cells resistant to MMP inhibitors^[152]. Another study reported that MMPs derived from CAFs are involved in tamoxifen resistance through EGFR and PI3K/AKT pathways in breast cancer [Figure 2D]^[153].

In addition to this, CAFs also secrete other factors such as caveolin-1 and podoplanin (PDPN), which are associated with wound responses^[154]. The expression of a lymphatic vessel marker, PDPN, by stromal CAFs has been reported as a prognostic indicator in different cancer types. For instance, Yoshida *et al.* have demonstrated that lung adenocarcinoma cells, when co-cultured with the PDPN+ CAFs, show greater drug resistance in comparison to normal cells. Similarly, in postoperative recurrence, PDPN+ patients possess a lower treatment response to EGFR-TKIs compared to PDPN- patients, suggesting the implication of PDPN+ CAFs in regulating drug resistance^[155]. The above information indicates that dense ECM produced by CAFs acts as a mechanical barrier for drug delivery and immune cell infiltration, and it also provides the source for matrix remodeling enzymes and signaling molecules that further impede the efficacy of anticancer therapeutics. Therefore, ECM-depletion strategies might pave the way for the development of next-generation anticancer drugs.

TARGETING CAFS WITH NATURAL PRODUCTS AND ANALOGS

The utilization of natural products for the treatment of different diseases is indeed cost-effective and minimally invasive^[156-158]. Numerous anticancer products have been isolated and characterized from natural sources. Apart from directly showing anticancer activity, they also provide leads for developing potent therapeutic drugs^[159].

CAFs have emerged as an intriguing therapeutic target in cancer due to their indispensable role. CAFs and cancer cells reciprocally crosstalk to regulate several aspects of cancer progression and several growth

factors and cytokines act as a messenger in this crosstalk [Table 1]. Hence, targeting CAFs using natural products will be advantageous for reducing the burden of cancer as well as overcoming deleterious effects caused by drug treatments in cancer patients. Polyphenols present in green tea have potential anticancer activities. Treatment with tea polyphenol, epigallocatechin-3-gallate (EGCG), decreases the serum levels of HGF and VEGF in prostate cancer patients. Since HGF and VEGF are mostly secreted by stromal myofibroblasts in the tumor microenvironment, EGCG can prevent myofibroblast differentiation in prostate cancer^[160]. Gray *et al.* have demonstrated that combinational treatment of EGCG and another polyphenol, luteolin, synergistically reduces TGF- β -induced myofibroblast differentiation and fibronectin synthesis by impeding ERK and RhoA signaling in prostate fibroblasts^[161]. CAFs are one of the key contributors in introducing drug resistance to various anticancer chemotherapeutic agents. It was shown that CAFs are involved in acquiring the resistance to cisplatin by expressing Wnt16^[162]. Quercetin is a member of flavonoids that show antioxidant properties. In this regard, Hu *et al.* have found that quercetin significantly inhibits Wnt16 expression in activated fibroblasts, thereby improving the anticancer effects of cisplatin^[163]. Various reports have shown that curcumin, a phyto-polyphenol pigment found in spice turmeric, exhibits antioxidant, anti-inflammatory, neuroprotective, and anticancer activities against various cancers^[164]. In addition, curcumin also regulates the TME of CAFs. An earlier study has shown that curcumin induces DNA damage-independent and safe-senescence in CAFs by upregulating p16. It also decreases the expression of α -SMA and reduces the migration and invasion potentials of CAFs. Furthermore, curcumin abolishes tumorigenic potentials of CAFs by downregulating the expression of IL-6, SDF-1, MMP-2, MMP-9 and TGF- β ^[165]. In the pancreatic cancer model, curcumin suppresses the expression of α -SMA, vimentin, and secretory factors in CAFs, thereby inhibiting EMT and metastasis of cancer cells^[166]. The above reports indicate that curcumin might have therapeutic potential for impeding the crosstalk between cancer cells and CAFs.

Fraxinellone (FRA) is a member of the limonoids family. Several studies have reported the medicinal properties of FRA, including neuroprotective, antifibrotic, anti-inflammatory, and antitumor functions^[167]. An earlier study has reported that FRA regulates TGF- β signaling in fibrotic liver disease^[168], which hints therapeutic potential of FRA in treating cancer, as both are characterized by the accumulation of myofibroblasts. A recent report demonstrated that FRA-loaded nanoparticle inhibits the CAF phenotype by impeding TGF- β signaling in PDAC^[169]. Mangostin (MG) is a xanthone and exhibits several medicinal properties such as antibacterial, antifungal, antioxidant, anti-inflammatory, anticancer, and cardioprotective effects^[170]. Studies have demonstrated that MG displays antitumor activities by inducing apoptosis and inhibiting angiogenesis, ECM modification, and EMT^[171]. A study has recently demonstrated MG's effect in regulating the tumor stroma. A nano-formulated MG suppresses TGF- β /Smad signaling leading to CAF inactivation and ECM reduction in pancreatic cancer^[172].

Cyclopamine is a steroid alkaloid and the first small-molecule inhibitor of the Hh signaling pathway^[173]. Several reports show that Hh signaling displays a critical role in proliferation and tumor-promoting functions indicating the potential of cyclopamine to reprogram CAFs^[174,175].

Co-delivery of cyclopamine and paclitaxel nanoparticles in pancreatic cancer modulates tumor stroma by disrupting cancer-stroma crosstalk and reducing ECM stiffness^[174]. Chrysin is classified as a member of the flavonoids, which exerts multiple biological effects including antidiabetic, antioxidant, hepatoprotective, anti-inflammatory, and anticancer activities^[176]. Chrysin induces apoptosis in colorectal and gastric cancer cells^[177,178]. A synthetic analog of chrysin named 8-bromo-7-methoxy chrysin inhibits the activation of hepatic stellate cells to CAFs, thereby reducing the stemness of cancer cells by impeding IL-6 and HGF signaling^[179]. We have listed several natural or synthetic drugs for targeting CAFs in Table 2.

Table 1. The interactions between CAFs and cancer cells

Source cells	Factors	Recipient cells	Biological effect of released factors	Affected signaling pathways	Reference
CAFs	CXCL12	Breast cancer	OPN-CAF-derived CXCL12 promotes EMT	ERK1/2 and AKT	[8]
CAFs	CCL5	Ovarian cancer	Cisplatin resistance	STAT3/PI3K/Akt pathway	[81]
CAFs	SDF-1	Lung cancer	Chemoresistance	mir-1/SDF-1/CXCR4/NF-κB/Bcl-xL	[83]
CAFs	IGF-1, HGF	Lung cancer	EMT in NSCLC	IGF1/HGF/ANXA2	[84]
CAFs	IL-6	Ovarian cancer	Paclitaxel resistance	TGFβ/JAK2/STAT3/IL6 pathway	[87]
CAFs	SDF-1	Pancreatic cancer	Gemcitabine resistance	SDF-1/CXCR4/SATB-1 pathway	[88]
CAFs	CCL1	Colorectal cancer	Chemoresistance to 5-FU and paclitaxel	TGF-β/NF-κB pathway	[89]
CAFs	IL-8	Gastric cancer	Cisplatin resistance	NF-κB pathway	[91]
Breast cancer	TGF-β1	CAFs	5-FU and tamoxifen (TAM) resistance	p44/42 MAPK pathway	[94]
CAFs	CXCL12	Ovarian cancer	EMT and cisplatin resistance	CXCR4/Wnt/β-catenin pathway	[95]
CAFs	miR-24-3p	Colon cancer	Resistance to methotrexate	CDX2/HEPH axis	[99]
CAFs	miR-148b-3p	Bladder cancer	EMT, metastasis, and drug resistance	Wnt/β-catenin pathway	[102]
CAFs	IL-17A	Cancer-initiating cells	Resistance to chemotherapies	IL-17A signaling pathway	[106]
CSCs	SHH	CAFs	CSCs expansion	Wnt/β-catenin signaling pathway	[109]
CAFs	TGF-β2	CSCs	Chemoresistance and stemness of CSCs	HIF-1α/TGF-β2-GLI2 pathway	[112]
CAFs	H19	CRC	Elevates stemness in CRCs	miR-675-IGFR signaling circuit & β-catenin pathway	[114]

COMPOUNDS UNDER CLINICAL TRIAL

There are several compounds under clinical trials for targeting the CAFs or CAF-mediated effects for the management of cancer^[198]. Notably, losartan, a small molecular inhibitor, sold under the brand name Cozaar, is used for the treatment of diabetic kidney disease, heart failure, and left ventricular enlargement. It inhibits the angiotensin receptor by blocking binding of angiotensin II. It suppresses collagen and hyaluronan levels, which are known to be synthesized by CAFs, and it is currently under clinical trial^[199]. Defactinib is a small molecular inhibitor of FAK, available under brand names, VS-6063 and PF-04554878. It is under phase II clinical trial for the treatment of patients with KRAS-mutant NSCLC and is known to target downstream signaling of integrins and interfere with CAF actions^[200]. Vitamin D receptor agonist, paricalcitol, is under phase I and II studies to examine the benefit of it in combination with gemcitabine and nab-paclitaxel for the treatment of pancreatic cancer as it is known to normalize pancreatic stellate cells^[201]. Galunisertib is a pharmacological small molecule inhibitor of the TGF-β signaling. Treatment with Galunisertib interferes with TGF-β signaling induced activation of CAFs and immunosuppression. Studies of phase I, and phase II trials are underway to compare the overall survival (OS) of patients with pancreatic cancer after the treatment with a combination of Galunisertib and gemcitabine as compared to gemcitabine alone^[202,203]. IPI-926 (saridegib) and vismodegib are small molecular inhibitors that target Hh signaling and reduce CAF activation, and are under clinical trials^[204,205]. Several compounds for targeting CAFs are under clinical trials [Table 2].

CONCLUSIONS AND FUTURE DIRECTIONS

Stromal fibroblasts constitute a major component of tumor microenvironment. Fibroblasts can thrive in severe adverse conditions because of their intrinsic survival programs and cellular plasticity. Due to this ability, they can withstand insults from anticancer regimens. Simultaneously, these cells activate cell

Table 2. Drugs targeting CAFs for management of cancer

Drug natural	Type of cancer	Target/Interference with		Mechanism	Reference
		CAF's	CAF's functions		
EGCG	Colorectal		↓Glycolytic activity	↓PFK	[180]
Conophylline	HCC	↓ α -SMA	↓IL6, IL8, CCL2, angiogenin, OPN	↓GPR68	[181]
α -mangostin	Pancreatic	↓ α SMA/FAP/fibronectin	↓fibronectin/collagen	↓TGF- β pathway/Smad	[172]
Fraxinellone	Pancreatic	↓ α SMA/FAP/fibronectin	-	↓TGF- β pathway	[169]
Triptonide	Gastric	-	↓IL-6, ↑TIMP2	↓MiR-301a ↑MiR-149	[182]
Chrysin	Liver	-	↓IL-6, HGF	-	[179]
Paeoniflorin	Gastric	-	↓IL-6	↑MicroRNA149	[183]
Resveratrol	CCA	-	↓IL-6	-	[184]
Minnelide	Pancreatic	↓ α -SMA	↓Collagen/fibronectin/periostin/hyaluronan/MMP2/MMP9	↓TGF- β RAR/RXR pathway	[185]
Cyclopamine	Pancreatic	-	↓LOX/hyaluronan	↓Hh pathway	[186]
Polyphyllin I	Gastric	↓FAP	↓HGF	-	[187]
Curcumin	Pancreatic	-	↑E-cadherin, ↓vimentin	-	[166]
Astragaloside IV	Gastric	-	↓M-CSF, ↑TIMP2	↑microRNA-214 ↓microRNA-301a	[188]
Synthetic drugs					
Ursolic acid	PTC	-	↓CXCR4, CXCR7	-	[189]
CFH/OM-L	Hepatic	-	↑E-cadherin, ↓vimentin, N-cadherin, snail protein	-	[190]
Nintedanib	Hepatic	↓ α -SMA	IL-6, IL-8	-	[191]
BTZ and PST		-	-	↑Caspase-3 mediated apoptosis	[192]
Drugs under clinical trial

PEGPH20 and MK-3475	PDAC	-	↓Hyalouronan	-	[195]
AT13148	Advanced solid tumors	-	↓ROCK	-	[196]
IPI-926 and Gemcitabine	Pancreatic	-	-	↓Hh pathway	[197]

α -SMA: A-smooth muscle actin; BTZ: bortezomib; CCA: cholangiocarcinoma; CCL2: C-C motif chemokine ligand 2; CFH/OM-L: CFH peptide (CFHKHKSPALSPVGGG)-decorated liposomal oxymatrine; EGCG: epigallocatechin-3-gallate; FAP: fibroblast activation protein alpha; HCC: hepatocellular carcinoma; Hh: hedgehog; MMP2: matrix metalloproteinase 2; OPN: osteopontin; PFK: phosphofructokinase; PTC: papillary thyroid carcinoma; PST: Panobinostat; TIMP2: tissue inhibitor of metalloproteinase 2.

resistance programs in cancer cells in response to inhibitory effects caused by the treatment modalities. Therefore, it is very important to understand the intrinsic survival programs and cellular plasticity that endure these cells from chemotherapy insults. Since the reciprocal interactions between the cancer cells and CAFs through soluble factors play a crucial role in orchestrating drug resistance programs, it is critical to profile CAF-derived secretome in response to chemotherapy to identify druggable targets. The CAF-mediated direct cell-cell and cell-matrix interactions also shape drug resistance in cancer cells. Hence, investigating the ECM-remodeling and changes in cell adhesion molecules triggered during the

development of drug resistance might provide insights into target proteins. Moreover, the double-edged sword effect of CAF signaling has been well recognized in tumor progression and drug resistance. Dissecting CAF-signaling and its function enables comprehensive identification of signaling pathways required to instigate drug resistance programs and facilitates targeting drug-resistant inducing cues and sparing the inhibitory cues.

DECLARATIONS

Authors' contributions

Abstract

MYC plays a central role in tumorigenesis by orchestrating cell proliferation, growth and survival, among other transformation mechanisms. In particular, MYC has often been associated with lymphomagenesis. In fact, MYC overexpressing lymphomas such as high-grade B-cell lymphoma (HGBL) and double expressor diffuse large B-cell lymphomas (DLBCL), are considered addicted to MYC. In such a context, MYC targeting therapies are of special interest, as MYC withdrawal is expected to result in tumor regression. However, whether high MYC levels are always predictive of increased sensitivity to these approaches is not clear yet. Even though no MYC inhibitor has received regulatory approval to date, substantial efforts have been made to investigate avenues to render MYC a druggable target. Here, we summarize the different classes of molecules currently under development, which mostly target MYC indirectly in aggressive B-cell lymphomas, paying special attention to subtypes with MYC/BCL2 or BCL6 translocations or overexpression.

Keywords: High-grade B-cell lymphoma, double expressor lymphoma, MYC, MYC therapies

INTRODUCTION

High-grade B-cell lymphomas

Lymphomas are very heterogeneous neoplasms that originate from the clonal expansion of B cells, T cells or natural killer (NK) cells^[1]. They are divided into Hodgkin (HL), which represents 10% of the cases, and Non-Hodgkin (NHL), accounting for the remaining 90%^[2]. In 2020, over half a million new cases of NHL were estimated globally^[3]. NHLs are further subdivided according to their cell lineage, maturity of the cells and aggressiveness, following an evidence-based classification. Elaborated by the World Health Organization (WHO), such a classification has served as a global reference for the diagnosis of lymphoid neoplasms since its third edition in 2001 up to the current fifth edition published in 2022 (WHO-HAEM5)^[4]. Additionally, the International Consensus Classification (ICC) recently published a report suggesting that the algorithm for the diagnosis of aggressive B-cell lymphomas, based on the current combination of morphology, immunophenotype, Epstein-Barr encoding region (EBER) *in situ* hybridization, fluorescent *in situ* hybridization (FISH) and B-cell clonality analysis, should be replaced by molecular genetic classification, based on mutational profile, somatic copy number alterations and structural variants, able to distinguish seven genetic subtypes with apparent clinical relevance^[5].

The most common aggressive NHLs in Western countries are diffuse large B-cell lymphoma (DLBCL), Mantle Cell lymphoma (MCL) and Burkitt lymphoma, which account for 31, 6 and 2% of adult cases, respectively^[6]. Owing to their unique genomic features, biological behavior and poor clinical prognosis, the subtypes of DLBCL, formerly known as double-hit (DHL) and triple-hit (THL) lymphomas, were classified in 2016 as a new category, termed “high-grade B-cell lymphoma” (HGBL), with translocations involving *MYC* and *B-Cell Lymphoma 2 (BCL2)* and/or *B-Cell Lymphoma 6 (BCL6)*. In WHO-HAEM5, tumors with *MYC* and *BCL2* rearrangements are named DLBCL/HGBL *MYC/BCL2*, while HGBL-DH-*BCL6* represents a separate entity. HGBL-DH-*BCL6* are biologically less distinctive, hence considered genetic subtypes of either DLBCL, not otherwise specified (NOS) or HGBL, NOS. Complementarily, ICC considers double-hit (DH)-HGBL to comprise two entities: HGBL with *MYC* and *BCL2* rearrangements, with or without *BCL6* rearrangement (HGBL-DH-*BCL2*), and a provisional entity, HGBL-DH-*BCL6*, with *MYC* and *BCL6* rearrangements^[7]. In terms of mutational and gene expression profiles, DLBCL/HGBL *MYC/BCL2* exhibit a mutational signature closer to that of follicular lymphoma (FL), including *Cyclic adenosine monophosphate Response Element Binding Protein (CREBBP)*, *BCL2*, *Lysine Methyltransferase 2D (KMT2D)*, *MYC*, *Enhancer of Zeste Homolog 2 (EZH2)* and *Forkhead box protein O1 (FOXO1)*, while showing a gene expression profile similar to centroblasts of the germinal center (GC) dark zone. In contrast, HGBL-DH-*BCL6* less frequently shows a Germinal center B cell-like (GCB) immunophenotype, is cytogenetically less complex and exhibits impairment of *E2F* targets, but not of the *TP53* and *MYC* signaling pathway, characteristic of DLBCL/HGBL *MYC/BCL2*^[5,7].

DLBCL co-expressing *MYC* and *BCL2*, also known as double expressor lymphomas (DELs), are associated with shorter overall survival (OS) and Progression-Free Survival (PFS). Unlike DHL, whose cell-of-origin (COO) is primarily GCB, DELs are typically activated B cell-like (ABC)^[8]. Further epidemiologic analysis of DHL/THL and DEL cases reveals an incidence of 2%-12% and 19%-34% among the DLBCL, respectively^[9]. Given their dismal outcome, in the last few years since the WHO revised the classification, several reviews in the literature have pinpointed these diseases as an unmet medical need^[8,10-13].

In terms of therapeutic opportunities, DLBCL follow standard rituximab, cyclophosphamide, hydroxydaunorubicin, vincristine and prednisone (R-CHOP) therapy. Although there is no widely accepted standard approach to manage HGBL with *MYC* and *BCL2/BCL6* rearrangements, retrospective comparisons show that DHL cases do better when treated with dose-intensive approaches compared to R-

CHOP, like dose-adjusted etoposide, prednisone, vincristine, cyclophosphamide, hydroxydaunorubicin, and rituximab (DA-EPOCH-R), or cyclophosphamide, doxorubicin, vincristine, high-dose methotrexate/ifosfamide, etoposide, and high-dose cytarabine (R-CODOX-M/R-IVAC). Others have proposed combining it with targeted agents against MYC or BCL2, like lenalidomide, an immunomodulatory agent, which in some contexts causes MYC downregulation, or venetoclax (also known as ABT-199), a highly selective inhibitor of BCL2, as promising new approaches^[14].

Burkitt lymphoma

Burkitt lymphoma (BL) is the most common NHL in children and young adults (representing 40%-50% of pediatric NHL)^[15]. Its definition has remained unchanged both in WHO-HAEM5 and ICC. It is a very aggressive tumor, characterized by MYC rearrangement with immunoglobulin genes and mutations in *Transcription Factor 3 (TCF3)* or its negative regulator *Inhibitor of Protein Binding 3 (ID3)*, as well as coding mutations that affect the B-cell receptor (BCR), G Protein-coupled receptor (GPCR) and Phosphatidylinositol 3-Kinase (PI3K) signaling pathways^[4]. It is associated with a GCB phenotype and is considered highly proliferative^[7]. However, the ICC replaced the provisional entity Burkitt-like lymphoma with 11q aberration with Large B-cell lymphoma with 11q aberration, because it is more resemblant to DLBCL than BL^[5].

In this context, treatment options, although different between adults and children, are mainly reduced to combinatorial chemotherapeutic regimens, like those used in other subtypes of lymphoma^[16].

MYC, BCL2 and BCL6 deregulation and diagnosis of HGBL

The MYC family of oncoproteins is found to be deregulated in up to 70% of human cancers^[17]. In physiological conditions, its expression is tightly regulated at all levels, from transcription to post-translational modifications^[18]. Nonetheless, many of the genetic alterations present in cancer uncouple MYC expression from the usual regulatory constraints, either by constitutive activation of signal transduction pathways [e.g., Neurogenic locus notch homolog protein 1 (Notch), Wingless-related integration site (Wnt) and receptor tyrosine kinases (TKs)], or direct alterations of MYC, such as point mutations leading to protein stabilization, amplifications or translocations^[18,19]. However, MYC overexpression is not always sufficient to drive tumorigenesis and often requires additional mutations, especially in cases where MYC expression induces not only proliferation, but also senescence or apoptosis^[20,21]. Hence, these fail-safe mechanisms need to be disabled for MYC to exert its full pro-tumorigenic function.

Another family of proteins frequently mutated in cancer is BCL2, informally known as “guardians of cell death”^[22]. These protein members display opposing functions to either induce or block the intrinsic apoptotic pathways. Physiologically, a delicate balance between pro- and anti-apoptotic proteins must be maintained^[23]. However, resistance to apoptosis is one of the best-described cancer hallmarks. Thus, in the cancer context, it is common to observe an increase in the expression of anti-apoptotic family members, like BCL2, which happens to be one of the main contributors to B-cell lymphomagenesis^[24]. As with MYC, BCL2 can be deregulated through various mechanisms that include (i) indirect ones, such as the activation of signaling pathways [e.g., Phosphatidylinositol 3-Kinase/Protein Kinase B (PI3K/AKT) or Nuclear Factor kappa-light-chain-enhancer of activated B cells (NF-κB)] and loss of Myeloid Leukemia 1 (MCL-1), and (ii) direct lesions, such as somatic mutations (restricted to FL with increased risk of transformation to DLBCL), amplifications, hypomethylation of the gene promoter or translocations with immunoglobulins^[25]. Interestingly, BCL2 alone is also insufficient to induce full tumor development. Nevertheless, the cooperation of MYC and BCL2 does unleash the neoplastic transformation by simultaneously removing the brakes of cell growth and promoting cell survival^[26,27].

BCL6 belongs to a family of transcription factors key for the germinal center reactions. It functions by recruiting corepressors that block the transcription of over 1,000 genes involved in the proliferation and survival of healthy germinal center B-cells, including cell cycle checkpoints and DNA damage repair-related genes^[28,29]. Notably, both MYC and BCL2 are targets of BCL6, and in normal conditions, this transrepressor downregulates both proteins^[28]. However, there are various direct and indirect mechanisms for BCL6 deregulation. For instance, BCL6 cross-talks with proteins involved in chromatin modifications, such as EZH2, CREBBP and KMT2D. Hence, mutations in these genes can add up to an imbalanced BCL6 activity^[30]. More directly, reduced phosphorylation leading to protein stabilization, as well as translocations or mutations on the first non-coding exon, also result in altered expression of BCL6^[30].

Importantly, 5%-15% of large B-cell lymphomas bear a translocation in MYC and BCL2 or BCL6, and 20%-30% of the cases are double expressors. Double expressors are defined in most studies as displaying $\geq 40\%$ MYC positive and $\geq 50\%$ -70% BCL2 positive cells. Such elevated expression of both proteins is caused by mechanisms other than gene rearrangements, such as amplifications, point mutations or oncogenic activation of signaling pathways^[31,32].

Diagnosis of DHL/THL and DEL

MYC/BCL2 DHL is described as the most common type of DHL (at least 65% of the diagnosed cases), followed by MYC/BCL2/BCL6 THL, being MYC/BCL6 DHL the rarest^[33,34]. The technique of choice to detect rearrangements in MYC(8q24), BCL2(18q21) and/or BCL6(3q27) is Fluorescent In situ Hybridization (FISH). Remarkably, even though most of the MYC/BCL2 cases show overexpression of both proteins, as many as 20% of these patients lack such correlation, with lower MYC levels typically associated with better outcomes. This is also true for the other DHLs and THLs, in which the genomic translocations generally result in high levels of the respective proteins and a worse prognosis^[32].

Accurate diagnosis would appear to require the screening of all DLBCL patients by FISH^[35]. While this has been agreed to be the best practice, as referred to in the WHO classification, the technique is not always routinely available. In Europe, only 40% of the countries have this capability, while another 40% rely only on referral hospitals^[36].

It is important to distinguish DHL from DEL, which is far more common and is also related to poor prognosis. Of note, DELs are usually determined using immunohistochemistry (IHC), a less robust technique than FISH and, thus, more susceptible to variability. Besides, different cut-offs are defined between studies, although most accepted values are 40% positive cells for MYC, 50%-70% for BCL2 and 60% for BCL6^[36,37]. Nowakowski and Czuczman raised the question of whether successful treatments for DHL would equally succeed for DEL, given the inherent differences between their COOs^[37]. Interestingly, Ennishi *et al.* discovered a 104-gene double-hit signature (DHITsig) able to distinguish a subpopulation of patients likely to respond to R-CHOP and identify tumors with potential targetable vulnerabilities. DHITsig-positive tumors, as expected, show more frequent MYC and BCL2 alterations than DHITsig-negative tumors, even though only one-half of the cases harbor MYC/BCL2 rearrangements^[38]. Additionally, Sha *et al.*^[39] described a molecular high-grade (MHG) subgroup of DLBCL patients from a clinical trial investigating the addition of bortezomib to standard R-CHOP therapy. Such a subgroup encompassed most patients with DHL, extending the molecular identification to more than double the size of this poor-prognosis group. The authors suggest that MHG patients could benefit from intensified chemotherapy or novel targeted therapies^[39]. Interestingly, in an independent study from the same authors, Cucco *et al.* identify a novel association between MHG-DLBCL with MYC hotspot mutations that lead to its stabilization and enhance its transforming capacity^[40]. Studies like these emphasize the relevance of expanding our knowledge of the molecular mechanisms underlying the disease to best adequate the treatment.

Given the well-established role of MYC protein in driving lymphoma progression and the numerous preclinical studies in which suppression of MYC activity triggered regression of many tumor types considered MYC-driven^[41-44] - including those where MYC is not deemed the initiating oncogenic lesion^[45,46], it is clear that MYC inhibition could represent an effective treatment avenue.

In this review, we summarize the active preclinical and early-phase clinical research exploring novel approaches for the treatment of HGBL, focusing on MYC targeting therapies.

MYC-targeted therapies

In the last few years, several novel approaches have been explored to improve the poor outcome observed in lymphoma patients with the subtypes of DHL or THL, as well as DEL, even though the latter is not considered an independent entity. Many of the targeted therapies proposed for these specific tumors target MYC only indirectly, causing its downregulation in most cases. Here we list the different compounds classified by their primary mechanism of action [Table 1] and refer to the preclinical and clinical data available for each of them.

Bromodomain extra-terminal inhibitors

Bromodomain extra-terminal (BET) inhibitors have been a promising class of drugs in the cancer field for the past 10 years^[47]. Inhibition of these transcriptional regulators can result in the silencing of MYC expression when it is under the control of super-enhancer elements^[48]. A first-generation BETi, JQ1, for instance, was used in DHL/THL cells and showed the ability to slow down cell growth and induce apoptosis in a dose-dependent manner, and increased the therapeutic effect of the BCL2 inhibitor venetoclax^[49,50]. A similar combination was later tested with another BETi, CPI203, which achieved simultaneous downregulation of MYC and Bcl-2-related protein A1 (BFL-1), overcoming the emergence of resistance to venetoclax both in DHL cultures and tumor xenografts^[51].

Notably, it was expected that high MYC levels would be predictive of enhanced sensitivity to BETi. However, this is not always the case. For example, independent preclinical studies of different hematologic malignancies evidenced that MYC amplification failed to predict the sensitivity to the BETi OXT015^[52]. Moreover, in a Phase I clinical trial with prostate cancer patients, there was a lack of correlation between the reduction in MYC levels and the response to the pan-BET inhibitor Zen-3694^[52]. Similarly, Li *et al.*^[53] demonstrated that several DHL/THL cell lines were as sensitive to various BETis (I-BET-762, JQ1 and OXT015) as U2932, a lymphoma cell line with no MYC rearrangement. Regarding BETi in clinical development for high-grade B-cell lymphoma or other NHLs, a couple of Phase I trials were completed (NCT04089527) or withdrawn (NCT03925428) in 2022 and 2020, respectively, but no reports have been published yet. Encouragingly, Dickinson *et al.*^[54] tested the BETi RO6870810 in combination with venetoclax (a BCL2 inhibitor) and rituximab (an anti-CD20 monoclonal antibody). In this Phase Ib study (NCT03255096), no DHL patients were enrolled, but 10 out of 18 patients (55.6%) were considered DEL. From those, one patient achieved a complete response (CR).

Histone deacetylase inhibitors

Another group of targeted agents that have been under development for even longer (over 30 years) than BETi and represented hope for the treatment of hematologic diseases includes Histone deacetylase (HDAC) inhibitors (HDACi). MYC can recruit epigenetic modifiers, like HDACs, to activate or repress different target genes. Notably, MYC is found acetylated at K423 upon treatment with a pan-HDACi, decreasing MYC transcription due to autoregulation and resulting in apoptosis^[55].

Table 1. Summary of the indirect MYC-targeting approaches and their development stage in high-grade B-cell lymphoma

Compound	Combined with other therapies?	Mechanism of action	Clinical or Preclinical	References
CC-95775	No	Reduction of MYC translation via inhibition of the BET family of proteins (BRD4, BRD3, BRD2 and BRDT)	Phase Ib Completed (NCT04089527)	NA
GSK525762C	+ entinostat		Phase I Withdrawn - Protocol moved to disapproved (NCT03925428)	NA
RO6870810	+ venetoclax with or without rituximab	HDAC inhibitors	Phase Ib Completed (NCT03255096)	Dickinson <i>et al.</i> ^[54]
Chidamide	+ rituximab		Preclinical	Guan <i>et al.</i> ^[57]
	+ high-dose rituximab and chemotherapy followed by auto-HSCT		Clinical - Case Report	Kang <i>et al.</i> ^[58]
	+ venetoclax		Preclinical	Luo <i>et al.</i> ^[59]
Marbostat-100	No		Preclinical	Winkler <i>et al.</i> ^[55]
CKD-581	No		Preclinical	Kim <i>et al.</i> ^[61]
			Phase I Completed (NCT01580371)	NA
CUDC-101	+ gemcitabine		Preclinical	Li <i>et al.</i> ^[62]
Compound 8	No		Preclinical	Zhang <i>et al.</i> ^[63]
Tucidinostat	+ R-CHOP		Phase III Recruiting (NCT04231448)	Zhang <i>et al.</i> ^[64]
Fimepinostat (CUDC-907)	No	Dual HDAC and PI3K inhibitor	Phase II Completed (NCT02674750)	Landsburg <i>et al.</i> ^[65]
VIP152	+ immunotherapy	CDK9 inhibitors	Phase I Recruiting (NCT02635672)	Diamond <i>et al.</i> ^[67]
BTX-A51	No		Phase I Recruiting (NCT04872166)	Ball <i>et al.</i> ^[70]
KB-0742	No		Phase I Recruiting (NCT04718675)	NA
SHC014748M	No	PI3K inhibitors	Phase I Unknown (NCT03588598)	Fan <i>et al.</i> ^[80]
WNY1613	No		Preclinical	Zuo <i>et al.</i> ^[81]
CYH33	No		Preclinical	Chen <i>et al.</i> ^[82]
SAF-248	No		Preclinical	Zhang <i>et al.</i> ^[83]
KA2237	No		Phase I Completed (NCT02679196)	Nastoupil <i>et al.</i> ^[84]
BR101801	No		Phase I/II Recruiting (NCT04018248)	Kim <i>et al.</i> ^[86]
Parsaclisib	+ R-CHOP		Phase I/Ib Recruiting (NCT04323956)	Wang <i>et al.</i> ^[88]
TG-1701	No		Preclinical	Ribeiro <i>et al.</i> ^[90]
Ibrutinib	+ CIT (chemoimmunotherapy)		Phase III Terminated (NCT02703272)	Burke <i>et al.</i> ^[91,92]
Zanubrutinib	+ R-CHOP	BTK inhibitors	Phase II Recruiting (NCT05189197)	NA
Acalabrutinib	+ CAR T cell		Phase II Not yet recruiting (NCT05583149)	NA
	+ ACP-319 (PI3K δ i)		Phase I/II Active, not recruiting (NCT02328014)	Barr <i>et al.</i> ^[94]
Pimozide	+ etoposide		Preclinical	Li <i>et al.</i> ^[100]
CS2164 (Chiauranib)	+ venetoclax		Preclinical	Yuan <i>et al.</i> ^[103]
eFT226	+ AKTi/PI3Ki	USP1 inhibitor	Preclinical	Thompson <i>et al.</i> ^[104]
Ixazomib	+ DA-EPOCH-R	Multitarget inhibitor (VEGFR1, VEGFR2, VEGFR3, and c-Kit, CSF-1R, AURKB)	Phase I/II Active, not recruiting (NCT02481310)	Galvez <i>et al.</i> ^[108]

Bortezomib	+ R-CHOP	eIF4A inhibitor	Phase III Completed (NCT01324596)	Davies <i>et al.</i> ^[109,110]
Alisertib	+ romidepsin	Proteasome inhibitors	Phase I Completed (NCT01897012)	Strati <i>et al.</i> ^[111]
MRT-2359	No	Aurora A kinase inhibitor Degradation of GSTP1 and downregulation of N- and L-MYC	Phase I/II Recruiting (NCT05546268)	Gavory <i>et al.</i> ^[112]

BTK: Bruton's tyrosine kinase; BET: bromodomain extra-terminal; DA-EPOCH-R: dose-adjusted etoposide, prednisone, vincristine, cyclophosphamide, hydroxydaunorubicin, and rituximab; HDAC: Histone deacetylase; R-CHOP: rituximab, cyclophosphamide, hydroxydaunorubicin, vincristine and prednisone; USP1: ubiquitin-specific protease 1; VEGFR: vascular endothelial growth factor receptor.

Overall, though, the accumulated clinical data with these therapeutics has been somewhat disappointing, as they did not fulfill the promise of the *in vitro* and *in vivo* models. Indeed, only certain hematologic tumors seem to benefit from this type of treatment in the clinical setting, with only five approved drugs, of which four are for T-cell lymphoma and one for multiple myeloma. Interestingly, breast cancer was the first indication, outside hematologic malignancies, to get the approval of an HDAC inhibitor as a combinatorial therapy (tucidinostat plus exemestane, an aromatase inhibitor) in 2019^[56].

In the particular case of HGBL, several compounds are under investigation. At the preclinical level, Guan *et al.*^[57] identified the promising combination of chidamide (an HDACi approved by the China Food and Drug Administration for T-cell lymphoma) and rituximab (a monoclonal antibody against CD20) as a potential strategy to treat relapsed/refractory (R/R) DLBCL. Indeed, such a combination led to an impressive reduction of tumor volume in a DLBCL cell line-derived xenograft mouse model. The same authors also report the clinical case of a patient that achieved partial response (PR) after only one cycle and underwent CR after three cycles of treatment^[57]. Similarly, Kang *et al.*^[58] studied the effect of a modified conditioning regimen with chidamide and high-dose rituximab for THL, followed by autologous hematopoietic stem cell transplantation (auto-HSCT), showing 2 CRs, while a third patient, who was insensitive to the chemotherapy, did not respond.

In a different study, Luo *et al.*^[59] proposed the combination of chidamide with venetoclax for the treatment of DHL. They demonstrated a synergistic effect of the compounds both *in vitro* and *in vivo* using SU-DHL-4 (MYC/BCL2 DEL) and DB (MYC/BCL2 rearranged) cell lines. Importantly, chidamide caused a reduction in MYC levels in both cell lines, suggesting that suppression of MYC is achieved regardless of the rearrangement status^[59].

In contrast, the research by Winkler *et al.*^[55] described a new molecule, Marbostat-100 (M-100), an HDAC6 inhibitor that targets almost exclusively lymphoma cells with high MYC levels. Contrary to previous observations with the pan-HDACi MS-275, M-100 caused MYC reduction by proteasomal degradation, while MYC transcription was not affected, and extended survival of transgenic E μ -myc mice *in vivo*. Importantly, the authors underline that MYC needs to be Threonine58 (T58) wild type for its degradation to happen efficiently^[55], as a mutation of this residue on the MYC protein prevents a phosphorylation event critical to its proficient proteasomal degradation^[60]. In fact, Cucco *et al.*^[40] identified a high frequency of MYC T58A and P57S mutations in the MHG subset of DLBCL.

Kim *et al.*^[61] assessed the efficacy of CKD-581, another HDACi that was previously tested in a Phase I clinical trial (NCT01580371), but for which no safety and pharmacokinetic results were published. Preclinically, this broad-spectrum HDACi decreased the expression of both MYC and BCL2 and was able to elicit a significant reduction in tumor growth. Similarly, other recent preclinical studies showed the potential of HDACi for the treatment of some types of NHL^[62,63].

More advanced in their development, tucidinostat and fimepinostat (CUDC-907) have been or are being evaluated in Phase II/III trials (NCT02909777, NCT02674750). Zhang *et al.*^[64] showed improved 2-year progression-free survival (PFS) and overall survival (OS) in DEL patients, as well as a lessened negative prognostic impact of *CREBBP/EP300* (*Histone acetyltransferase p300*) mutations when treated with tucidinostat in combination with R-CHOP. Furthermore, fimepinostat is a dual HDAC and PI3K inhibitor reported to have an objective response rate (ORR) of 15% in patients with relapsed/refractory DLBCL or HGBL with high MYC ($\geq 40\%$). ORR was further increased to 22% when the patients were classified based on a 3-protein biomarker. Such a discovery led the authors to suggest that combinatorial therapies or biomarker-assisted stratification could improve even more the response to treatment^[65].

Cyclin-dependent kinase 7/9 inhibitors

Cyclin-dependent kinase (CDK) inhibitors have been the topic of intense research for two decades. In particular, CDK9 emerged as a druggable target for the development of cancer therapeutics, due to its crucial role in the transcriptional regulation of both short-lived anti-apoptotic proteins and oncogenes, such as *BCL2/6* and *MYC*, critical for the survival of transformed cells^[66].

VIP152 is a potent and highly selective CDK9 inhibitor that, in a Phase I study, led to complete metabolic remission by PET-CT in two out of seven patients with HGBL^[67], and stabilization of the disease in seven out of 30 patients with non-lymphoma solid tumors^[67,68]. Preclinical models using the SU-DHL-10 HGBL cell line in a murine xenograft recapitulated the remission observed clinically in a dose-dependent manner. Additionally, pharmacodynamic biomarker analysis *in vitro* demonstrated a transient downregulation of the mRNA of MYC, MCL-1 and Proliferating Cell Nuclear Antigen (PCNA), resulting in a durable clearance of these oncogenic drivers^[69]. Frigault *et al.*^[69] also reported a transient biomarker modulation in 7 stable HGBL patients of their study when evaluating short-lived transcripts by RNAseq from whole blood samples. In particular, they observed a 70% reduction in MYC, MCL1 and PCNA mRNA post-dose.

Ball *et al.*^[70] presented at the 2022 ASCO annual meeting the interim results of the first-in-human trial of BTX-A51 (NCT04872166), a direct inhibitor of casein kinase 1 α (CK1 α), CDK7 and CDK9 that robustly increases p53 protein levels via CK1 α inhibition, while preferentially decreasing super-enhancer transcription of MYC and MCL-1. In the second part of the study, they are planning to enroll up to 40 additional subjects to evaluate the safety and preliminary efficacy in patients with documented MYC genomically amplified or overexpressed tumors, such as HGBL (NHL)^[71]. BTX-A51 in monotherapy has been found to have an acceptable safety profile and promising antileukemic activity^[71].

Another interesting orally bioavailable CDK9i is KB-0742, which demonstrated preclinical efficacy in AR-dependent castration-resistant prostate cancer^[72] and transcriptionally addicted tumors, such as sarcoma and chordoma^[73]. It is currently being tested in a Phase I clinical trial that includes DLBCL with MYC translocation and Burkitt lymphoma (NCT04718675).

Phosphoinositide 3-kinases inhibitors

PI3K/AKT/mTOR (PAM) signaling is involved in important physiological and pathophysiological functions that drive tumor progression, such as metabolism, cell growth, proliferation, angiogenesis and metastasis^[74]. In particular, different lymphoma subtypes (a subset of DLBCL and BL) have been shown to rely on BCR survival signals mediated by the phosphoinositide 3-kinases (PI3K) pathway to promote the proliferation and survival of malignant B-cells^[75-77]. One of the main downstream targets of the PAM pathway is MYC: phosphorylation at T58 occurs via glycogen synthase kinase 3 (GSK3B), which is a direct target of AKT^[78]. Moreover, activation of mTOR and AKT activity directly increases the translation of MYC^[78] and activation of PAM leads to the phosphorylation and degradation of Mad1, the natural antagonist of MYC^[79]. Pharmacological suppression of this pathway has been proposed as an anti-neoplastic approach. Small-molecule inhibitors targeting PI3K consist of pan-, isoform-specific and dual PI3K/mTOR (Mammalian Target of Rapamycin) inhibitors.

Several groups in China have identified new PI3Ki and tested them against panels of B-cell lymphoma cell lines, including DLBCL and some examples of HGBL, such as DOHH2, SU-DHL-6 and SU-DHL-10:

Fan *et al.*^[80] showed *in vitro* activity of their compound SHC014748M, a PI3K δ inhibitor, which also caused a significant reduction in tumor volume in a xenograft mouse model with the SU-DHL-6 cell line. Remarkably, SHC014748M performed better than idelalisib, an FDA-approved drug for the treatment of NHL. Currently, SHC014748M is being evaluated against indolent relapsed/refractory B-cell NHL, including chronic lymphocytic leukemia (CLL), FL, marginal zone lymphoma (MZL) and Waldenstrom's macroglobulinemia (WM), in a Phase I clinical trial (NCT03588598).

Similarly, Zuo *et al.*^[81] found their candidate WNY1613, also a PI3K δ inhibitor, to exert antiproliferative effects *in vitro* in a panel of NHL cell lines (seven DLBCL, two mantle cell lymphoma (MCL) and one BL). They also demonstrated that their inhibitor can prevent tumor growth in two mouse xenograft models of SU-DHL-6 and JEKO-1 cell lines. The pharmacodynamics and pharmacokinetics of this molecule are under current investigation.

In independent studies, Chen *et al.*^[82] (using CYH33 against PI3K α) and Zhang *et al.*^[83] (using SAF-248 against PI3K δ) evidenced that both compounds were effective in blocking B-cell lymphoma cell growth *in vitro* and *in vivo*, partly by causing the downregulation of MYC. As happened with SHC014748M, SAF-248 displayed superior activity compared to idelalisib, which is also reported to be far more toxic. Importantly, Zhang *et al.* demonstrated that the expression of PI3K α was negatively correlated with the activity of SAF-248 and found multiple oncogenic pathways, such as IL2_STAT5 (Interleukin-2/Signal Transducer and Activator of Transcription 5), IL6_STAT3 (Interleukin-6/Signal Transducer and Activator of Transcription 3), MTORC1 (Mammalian Target Of Rapamycin Complex 1) and MYC, upregulated in tumor tissues upon prolonged treatment with SAF-248 compared to those with short-term administration, possibly pinpointing to an adaptive mechanism of resistance^[83]. In line with this observation, Chen *et al.*^[82] proposed the combination with BETi or HDACi to overcome the adaptive resistance to PI3K inhibition, which could be attributed to increased H3K27Ac and binding of CREB Binding Protein (CBP)/p300 with BRD4 proteins gene loci of a subset of growth factors and receptors.

Some other PI3Ki under clinical development for the treatment of B-cell lymphoma include KA2237, BR101801 and pascalisib. Nastoupil *et al.*^[84] reported KA2237, a dual PI3K β/δ inhibitor, to have a manageable toxicity profile and to be an effective therapeutic option for patients with refractory B-cell lymphoma without an acceptable standard of care option. In a Phase I clinical study with the compound, 19

out of 21 patients were evaluable for response, and 8 of the evaluable ones had DLBCL. Two of the DLBCL patients achieved CRs and another one achieved a PR^[84].

BR101801, a triple inhibitor of PI3K γ/δ and DNA-PK, showed highly potent effects in blocking cellular proliferation of NHL cell lines in preclinical models, including both the indolent and aggressive subtypes^[85]. Clinically, the compound was well tolerated and showed preliminary signs of activity in patients with relapsed/refractory hematologic malignancies. The Phase Ib/II study of BR101801 is warranted in relapsed/refractory NHL^[86].

Finally, pascalisib, the most advanced PI3Ki in clinical development described here, inhibits PI3K δ . Shin *et al.*^[87] found that overexpression of MYC turned some of the DLBCL cell lines insensitive to pascalisib treatment. The resistance could be overcome by the addition of a BETi that reduced MYC levels. Recently, Wang *et al.*^[88] investigated the feasibility of combining pascalisib with standard immunochemotherapy (R-CHOP), seeking signs of efficacy. They chose the population of study to be high-risk lymphoma patients bearing MYC rearrangements or translocations (i.e., HGBL) or overexpression of MYC or BCL2. In the interim report, 13 patients were evaluable, 8 achieved CR, 4 PR and one progressed^[88]. Given the encouraging preliminary efficacy, pascalisib plus R-CHOP could constitute an experimental arm in future frontline DLBCL trials investigating genetic subtype-driven novel therapies.

Bruton's tyrosine kinase inhibitors

Ever since the discovery of the involvement of tyrosine kinases (TK) in cancer, which led to their consideration as valuable targets for cancer treatment, a broad spectrum of TKis has been launched, including Bruton's tyrosine kinase inhibitors (BTKis). Previous genomic studies suggested that some components of the B-cell receptor (BCR) signaling pathway are MYC transcriptional targets. Moreover, it has been demonstrated that, in pre-malignant B cells from the E μ -myc mouse model, MYC overexpression is sufficient to activate BCR and PI3K/AKT signaling pathways, while conferring resistance to pharmacologic inhibitors of the BCR signaling pathway, like BTKis^[89].

For the treatment of B-NHL, some preclinical studies with TG-1701 showed improved efficacy compared to ibrutinib, the first BTKi approved by the FDA, and described MYC downregulation, both at the mRNA and protein level, as part of the signature observed in early-responder patients, as well as in BTKi-sensitive B-NHL cell lines and xenografts^[90].

In this sense, Burke *et al.*^[91] reported promising preliminary efficacy findings in a Phase III clinical trial with pediatric patients with R/R mature B-NHL, who have a poor prognosis, treated with ibrutinib in combination with rituximab, ifosfamide, carboplatin and etoposide (RICE) modified with dexamethasone or with rituximab, vincristine, ifosfamide, carboplatin, idarubicin and dexamethasone (RVICI). More than half of the patients (12/21) responded to the therapies, achieving a total of 5 CR and 7 PR. However, as the final endpoint was event-free survival (EFS), the study was stopped early for futility, given that ibrutinib did not improve EFS in this population in combination with chemotherapy backbones. The authors suggest prioritizing, instead, bispecific antibodies, antibody-drug conjugates and CAR-T cells^[92].

Even though BTKis have shown modest therapeutic activity in DLBCL (i.e., ORR of 23% for ibrutinib in relapsed patients, of 24% for acalabrutinib in DLBCL patients regardless of their molecular subtype, and of 36% for zanubrutinib in ABC DLBCL patients), Yang *et al.*^[93] performed retrospective biomarker assessments and showed that zanubrutinib could have antitumor activity in patients with mutations in Cluster of Differentiation 79-B (CD79B) and Myeloid Differentiation primary response 88 (MYD88).

Hence, they propose future studies to focus on developing mechanism-based treatment combinations and biomarker-driven patient selection. In line with this reflection, Fudan University is evaluating zanubrutinib in combination with the immunochemotherapy R-CHOP in patients with non-GCB DLBCL with co-expression of MYC/BCL2, based on the findings of a posthoc analysis on four studies, in which an ORR of 61% and PFS of 5.4 months was achieved in patients with MYC and BCL2 overexpression treated with zanubrutinib (NCT05189197).

Acalabrutinib, as zanubrutinib, is another potent selective, irreversible BTKi with minimal off-target effects, being evaluated in combination with CAR-T cell therapy or with PI3Ki in Phase II clinical trials (NCT04257578). Barr *et al.*^[94] investigated the combination of acalabrutinib with ACP-319 in relapsed/refractory B-cell NHL. They showed in patients with non-GCB DLBCL an ORR of 63% (10 out of 16 patients; CR rate 25%) with a median duration of response of 8.2 months. Of the ten responders, six were double expressors, overexpressing MYC and BCL2/BCL6. No responses were observed in the nine patients with GCB DLBCL. Another Phase II study should start soon to evaluate the effectiveness and safety of acalabrutinib combined with lisocabtagene maraleucel (liso-cel) in relapsed/refractory aggressive B-cell lymphoma patients (NCT05583149).

MYC/MAX antagonists

While all the approaches listed above have targeted MYC indirectly, there is also the possibility of attacking it directly. Perhaps the most common strategy in this context focuses on the disruption of the interaction of MYC with its natural partner MAX. In this case, most data in the literature are related to the use of small molecules (SM), although MYC lacks significant secondary and tertiary structure when not complexed with other proteins, making specific recognition by SM quite difficult^[95]. The first one to show effect in lymphoma was 10058-F4, which was employed *in vitro* in different BL cell lines and demonstrated that targeting of MYC/MAX interaction could impair lymphoma growth in a time- and dose-dependent manner^[96]. Later on, 7-nitro-*N*-(2-phenylphenyl)-2,1,3-benzoxadiazol-4-amine (10074-G5) was used in Daudi BL cells, where, again, it inhibited cell growth *in vitro*, but failed to affect growth in xenografts in C.B-17 SCID mice, likely due to poor bioavailability^[97]. Another SM, sAJM589, was more recently identified in a Principal Component Analysis (PCA)-based high-throughput screen. sAJM589 was able to inhibit the transcription of MYC target genes in P493-6 BL cells, as well as to suppress the proliferation of diverse MYC-dependent cancer cell lines and anchorage-independent growth of Raji cells^[98]. However, the most advanced MYC/MAX dimerization inhibitor in clinical development is Omomyc, a MYC dominant negative based on the basic helix-loop-helix leucine zipper (b-HLH-Z) domain of the human c-MYC protein, able to form homodimers and heterodimers with MYC and MAX and interfere with MYC transcriptional activity. Omomyc has been used in its transgenic form in BL, in murine lymphoma cell lines obtained from E μ -myc transgenic mice and in Raji cells (wild-type or knock out for FBXO11) *in vitro* and *in vivo* (subcutaneous xenografts), alone or in combination with the BCL6 degrader BI-3802^[99]. In this context, Omomyc blocked cell proliferation and increased apoptosis, effects further improved by combined BCL6 targeting. Remarkably, the first Omomyc-derived drug product, OMO-103, has just successfully completed a Phase I clinical trial (NCT04808362) in all-comers solid tumors. However, its safety and efficacy in hematologic diseases have not been tested in the clinical setting yet. Hopefully, this will soon be the case.

Other inhibitors and degraders

Further preclinical or clinical studies are assessing the efficacy of novel targets or repurposed molecules for the treatment of MYC-overexpressing lymphoma.

Li *et al.*^[100] elucidated the role of ubiquitin-specific protease 1 (USP1) in B-cell lymphoma. USP1 is highly expressed in DLBCL patients and was found to be associated with poorer prognosis. Using pimozone, a USP1 inhibitor, the authors could stop DLBCL cells from cycling. Mechanistically, they found USP1 to stabilize MAX, promoting the transcription of MYC target genes. Importantly, when combined with etoposide, a chemotherapeutic, pimozone blocked the tumor growth in a xenograft mouse model resistant to immunochemotherapy R-CHOP. Since pimozone is already approved by the FDA for the treatment of other diseases and is known to cause low toxicity, the authors propose the combination as an attractive alternative for DLBCL patients resistant to R-CHOP.

On a different note, CS2164 is an orally bioavailable multitargeted inhibitor being evaluated in numerous clinical studies with promising clinical anti-cancer effects and tolerable toxicities^[101]. Deng *et al.* observed a potential role of CS2164 for the treatment of NHLs through the perturbation of multiple signaling cascades (angiogenesis, inflammation and proliferation) by inhibiting the following kinases: vascular endothelial growth factor receptor 1-3 (VEGFR1, VEGFR2 and VEGFR3), platelet-derived growth factor receptor alpha (PDGFR α), receptor tyrosine kinase (c-Kit), kinase Aurora B (AURKB), and chronic inflammation-related kinase (CSF-1R). Specifically, CS2164 showed superior anti-lymphoma activity against MYC-arranged BL models, suggesting it could also have a cytotoxic effect on other MYC-altered malignancies^[102]. Following these observations, Yuan *et al.*^[103] assessed the efficacy of this novel agent in combination with venetoclax using HGBL *in vitro* and *in vivo* models, where they could demonstrate a reduction of MYC and BCL2 protein levels, as well as antitumor efficacy with tolerable toxicities in a xenograft mouse model with MCA cells.

Interestingly, Thompson *et al.* found that activation of the PI3K/mTOR signaling pathway results in the activation of eukaryotic initiation factor-4A (eIF4A), required for the translation of oncoproteins, like MYC. The authors used eFT226 to inhibit the translation of specific mRNAs by promoting eIF4A1 binding to 5'-untranslated regions (UTR) containing polypurine and/or G-quadruplex recognition motifs^[104]. The compound blocked the proliferation of GCB-DLBCL tumor models Pfeiffer and SU-DHL6. When assessing the pharmacodynamic response to the drug, the authors reported downregulation of MYC, Cyclin D1, and BCL6 protein levels in a time- and exposure-dependent manner. Collectively, their results support the clinical development of eFT226 in patients with B-cell malignancies.

A different class of molecules that emerged as an important therapeutic strategy in hematologic malignancies, particularly in multiple myeloma, are proteasome inhibitors^[105]. Ravi *et al.*^[106] demonstrated that ixazomib sensitivity is mediated through checkpoint kinase 1 (CHK1)-dependent MYC function involving histone acetylation, and demonstrated that dual inhibition of CHK1 and MYC induced synergistic cell death with ixazomib. Based on preclinical data showing MYC downregulation, a couple of clinical studies were started to evaluate the efficacy of ixazomib in lymphoma patients with different subtypes (DLBCL, FL, MZL, MCL, transformed FL, DLBCL-FL, and some other indolent forms) in combination with immune- or immunochemotherapy. Graf *et al.*^[107] concluded that once-weekly oral ixazomib showed a favorable safety profile and considerable activity in the frontline treatment of indolent B-cell NHL, with the best results in FL. When combined with a single 4-week course of rituximab, ixazomib achieved durable disease control with very low toxicity in the majority of patients with FL. On the other hand, Galvez *et al.* reported DA-EPOCH-R induction with adjunctive ixazomib followed by maintenance ixazomib to be safe and effective in an older population of HGBL. The ORR after induction was 89%, with an associated CR rate of 61%^[108].

Moreover, Sha *et al.*^[39] reported that the addition of bortezomib to the R-CHOP regimen (RB-CHOP) could be beneficial for the MHG subgroup in a randomized Phase III study (NCT01324596). Indeed, Davies *et al.* presented at the ASH 2022 Annual Meeting extended data on the REMoDL-B trial, where 5-year PFS was significantly improved for MHG patients (PFS 29% with R-CHOP *vs.* 55% with RB-CHOP)^[109,110].

Lastly, Strati *et al.*^[111] recently (2020) discussed the results of their Phase I trial assessing the combination of alisertib (an Aurora A kinase inhibitor) with romidepsin (and HDACi) for the treatment of patients with relapsed/refractory B- and T-cell lymphomas (NCT01897012). Unfortunately, the cytokinesis failure observed in preclinical models when combining both agents only happened in T-cells in the clinical setting. Hence, significant myelosuppression and limited ORR (< 20%) for B-cell NHL patients do not support further clinical evaluation of alisertib.

On a more positive note, novel promising agents, such as MRT-2359, a molecular glue degrader directed against GSTP1 developed by Monte Rosa Therapeutics, are under development. Preclinical results on MRT-2359 were presented last year at the AACR Annual Meeting and the 34th EORTC-NCI-AACR Symposium, with the promise of being effective in MYC-driven tumors addicted to protein translation^[112]. MRT-2359 is being evaluated in a Phase I/II trial that started recruitment very recently (NCT05546268)

CONCLUSION

Assessment of MYC rearrangements or expression is typically used in lymphomas and other hematologic malignancies as a diagnostic tool^[113,114]. These cancers have gained the classification of MYC-associated tumors, because this oncoprotein has been demonstrated to play a key role in the physiopathology of these diseases^[115,116]. In fact, according to the concept of oncogene addiction, multiple studies have shown that MYC inactivation causes tumor regression in the context of lymphomas^[41-44]. In this review, we summarized the approaches explored so far to target MYC-dependency, *in vitro*, *in vivo* and in the clinical setting. However, it is important to stress that most of these approaches have been so far indirect ones and there is no set of experiments that established to which extent different cancer cells are dependent on MYC activity or, in other words, how much MYC inhibition is required to stop their proliferation or cause cell death.

Based on the above, several questions remain still unanswered: (i) would direct MYC inhibition be a more effective therapeutic strategy than indirect targeting of it in the context of lymphoma? (ii) are MYC levels a good predictive biomarker of response to MYC inhibition in every context? (iii) what is the ideal way of assessing MYC function? Would mRNA expression, protein expression, and determination of gene amplifications or rearrangements be sufficient? (iv) is MYC activity a biomarker that can potentially stratify good and bad responders to therapies in general? (v) is it possible to define a unique MYC transcriptional signature shared across various tumor types?

Our knowledge continues to expand as more efforts are dedicated to designing viable therapies that target MYC. Nevertheless, we believe it is critical answering some of the questions above to improve our understanding of MYC biology and develop the best MYC-targeting approaches.

DECLARATIONS

Authors' contributions

Conceptualization, investigation, writing: Martínez-Martín S, Beaulieu ME

Conceptualization, supervision, writing: Soucek L

Availability of data and materials

Not applicable.

Financial support and sponsorship

Research in our laboratory was supported by the Retos-Colaboración [RTC2019-007067-1] grant from the Spanish Ministry of Economy and Competitiveness. We acknowledge VHIO and the Cellex Foundation for providing research facilities and equipment.

Conflicts of interest

Soucek L and Beaulieu ME are co-founders and shareholders of Peptomyc S.L. and inventors of patent application WO2014180889 A8 that covers the use of the Omomyc mini-protein in medicine, held by VHIO and licensed to Peptomyc. Martínez-Martín S is an employee of Peptomyc S.L.

Abstract

FMS-related tyrosine kinase 3 (FLT3) mutations, present in about 25%-30% of acute myeloid leukemia (AML) patients, constitute one of the most frequently detected mutations in these patients. The binding of FLT3L to FLT3 activates the phosphatidylinositol 3-kinase (PI3K) and RAS pathways, producing increased cell proliferation and the inhibition of apoptosis. Two types of FLT3 mutations exist: FLT3-ITD and FLT3-TKD (point mutations in D835 and I836 or deletion of codon I836). A class of drugs, tyrosine-kinase inhibitors (TKI), targeting mutated FLT3, is already available with 1st and 2nd generation molecules, but only midostaurin and gilteritinib are currently approved. However, the emergence of resistance or the selection of clones not responding to FLT3 inhibitors has become an important clinical dilemma, as the duration of clinical responses is generally limited to a few months. This review analyzes the insights into mechanisms of resistance to TKI and poses a particular view on the clinical relevance of this phenomenon. Has resistance been overlooked? Indeed, FLT3 inhibitors have significantly contributed to reducing the negative impact of FLT3 mutations on the prognosis of AML patients who are no longer considered at high risk by the European LeukemiaNet (ELN) 2022. Finally, several ongoing efforts to overcome resistance to FLT3-inhibitors will be presented: new generation FLT3 inhibitors in monotherapy or combined with standard chemotherapy, hypomethylating drugs, or IDH1/2 inhibitors, Bcl2 inhibitors; novel anti-human FLT3 monoclonal

INTRODUCTION

In 1996, the first unexpectedly longer transcripts of FMS-like tyrosine kinase 3 (FLT3) were reported in the transmembrane domain through the juxtamembrane domain of the gene^[1]. This represented a cornerstone discovery in acute myeloid leukemia (AML), since internal tandem duplications (ITD)-FLT3 mutations represent one of the most recurrent alterations, occurring in 22-32% and the remaining 8% including the tyrosine kinase domain (TKD), *de novo* AML^[2,3]. Moreover, FLT3-ITD mutations, particularly those carrying a high FLT3-ITD mutant to wild-type allelic ratio when detected at initial diagnosis, seem to confer a short duration of remission and globally a worse prognosis^[4]. The presence of FLT3-ITD appears to be strongly associated with hyperleukocytosis and high blast percentages in both peripheral blood and bone marrow at presentation^[5]. From a morphologic standpoint, it has been suggested that AML with cup-like nuclei is associated with co-occurring mutations of both NPM1 and ITD- or TKD- FLT3^[6]. Most importantly, we have an interesting class of drugs targeting FLT3, tyrosine-kinase inhibitors (TKI), which have an already long history in the treatment of this cancer. With the availability of 1st and 2nd generation inhibitors, the emergence of resistance or the selection of clones not responding to FLT3 inhibitors has become an important clinical dilemma, probably recalling the challenge of TKI in CML and ALL *BCR: ABL* positive. This review will try to summarize the evidence, from a clinical viewpoint, regarding the development of resistance to FLT3-inhibitors, their real clinical impact in AML patients, and strategies to obviate the development of resistance.

FLT3 GENE AND ITS MOLECULAR FUNCTION

FLT3 (Fms-like tyrosine kinase 3) has strong similarities in its sequence with other members of the class III receptor tyrosine kinase (RTKIII) receptor family (FMS, platelet-derived growth factor receptor (PDGFR) α and β , and KIT)^[7]. FLT3 is composed of an extracellular domain consisting of 5 immunoglobulin-like (Ig-like) domains, and by a cytoplasmic domain with a juxtamembrane domain and two intracellular tyrosine-kinase domains (TKDs)^[8]. Physiologically, FLT3 is expressed over the cytoplasmic membrane of immature myeloid and lymphoid progenitor cells^[9] and is activated by its ligand FLT3L, which can be found in the cytoplasm of bone marrow stromal fibroblasts, T-cells, B-cells, and progenitors CD34+ [Figure 1]^[10]. Noteworthy, FLT3 (CD135) is expressed on the surface of more than half of AML and seems associated with a worse outcome^[11]. The binding of FLT3L to FLT3 activates the phosphatidylinositol 3-kinase (PI3K) and RAS pathways, producing increased proliferation and impaired apoptosis in cells. Moreover, activated PI3K stimulates downstream proteins like 3-phosphoinositide-dependent protein kinase 1 (PDK1), protein kinase B (PKB/AKT) and the mammalian target of rapamycin (mTOR), and PI3K activation hampers apoptosis through phosphorylation of the pro-apoptotic protein BAD, member of the BCL2-family. Moreover, the activation of RAS stimulates other downstream effectors like RAF, MAPK/ERK kinases (MEKs), extracellular-signal-regulated kinase (ERK), and the 90-kDa ribosomal protein S6 kinase (RSK). These downstream effectors can activate signal transducers and activators of transcription (STATs), which lead to the transcription of genes involved in cellular proliferation^[7]. On the other hand, activating genetic mutations of FLT3 can produce the abnormal expression of a constitutively activated tyrosine kinase receptor in AML blasts, which is independent of the physiological FLT3L stimulus^[12].

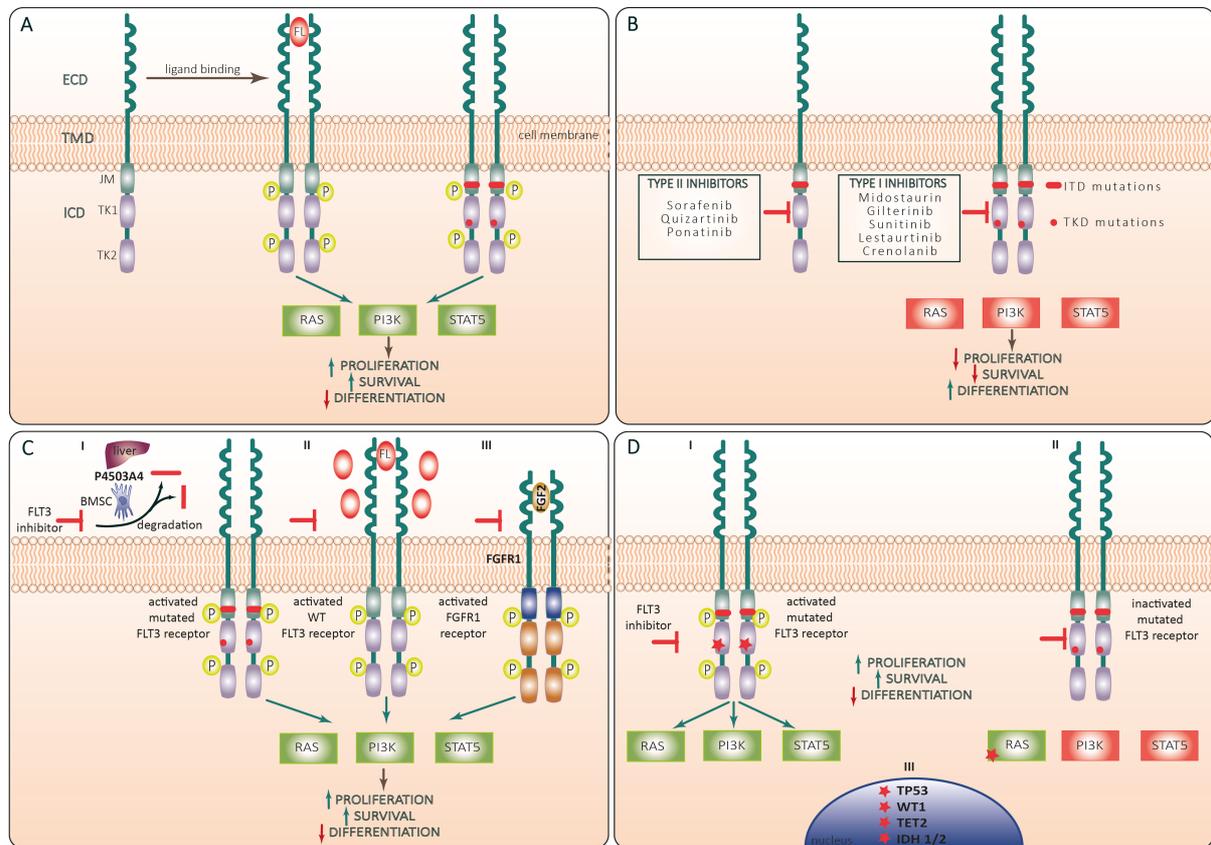

Figure 1. (A) Structure and activation of FLT3 receptor. FLT3 molecule is a tyrosine kinase receptor composed of an extracellular domain (ECD) that comprises 5 immunoglobuline-like repeats, a short transmembrane domain (TMD) and an intracellular domain (ICD) that includes a juxtamembrane (JM) domain followed by two tyrosine kinase (TK) domains (TK1 and TK2). Binding of the FLT3 ligand (FL) to ECD leads to formation of a ternary complex between FL and two receptor subunits with consequent conformational changes and trans-phosphorylation of TK and JM domains. The activated receptor exerts a tyrosine kinase activity against a series of adaptor and effector molecules leading to activation of Ras/Raf/MAPK (RAS) PI3K/Akt (PI3K) and Jak/STAT5 (STAT5) pathways promoting leukemic cell proliferation and survival and suppressing differentiation. Both FLT3-ITD and FLT3-TKD mutations lead to ligand-independent activation of FLT3 signaling; (B) types of FLT3 inhibitors. Type I FLT3 inhibitors interact with the ATP-binding site of the intracellular TK domain (TKD) when the receptor is in active conformation, whereas Type II inhibitors bind to the inactive form of the receptor, thus preventing its activation. Type I inhibitors inhibit FLT3 signaling in AML cells harboring ITD or TKD mutations, whereas Type II inhibitors are active against AML with ITD but not TKD mutations; (C) mechanisms of primary resistance to FLT3 inhibitors: Increased proliferation and survival and decreased differentiation of AML cells may be sustained through (I) Cytochrome P450 3A4-mediated degradation of FLT3-inhibitors by hepatocytes (liver symbol) and BM stromal cells (BMSC); (II) Restoration of FL/FLT3 signaling through compensatory overexpression of wild-type (WT) FLT3 receptor and FL; (III) Activation of common FLT3 and fibroblast growth factor receptor type 1 (FGFR1) downstream target pathways through the increased fibroblast growth factor 2 (FGF2)/FGFR1 signaling; (D) mechanisms of secondary resistance to FLT3 inhibitors: (I) Secondary resistance of FLT3 receptor to pharmacological inhibition may be conferred through newly acquired activating mutations of FLT3 TKD (red asterisk), and upregulation of pro-survival mechanisms through acquired activating mutations in RAS/MAPK pathway genes (II) and epigenetic modifiers like DNMT3A, TET2, IDH2 or transcriptional regulators like WT1 and TP53 (III). Green and red rectangles correspond to activated and inactivated FLT3 downstream signaling pathways, respectively. Yellow "P" circles indicate phosphorylated receptor domains. Green and red arrows indicate positive and negative regulation, respectively.

Two kinds of FLT3 mutations have been individuated: FLT3-ITD and FLT3-TKD (including point mutations in D835 and I836 or deletion of codon I836)^[13]. FLT3-ITD takes place between exons 14 and 15. When AML cells carry FLT3-ITD, PCR products generate a wild-type band and a larger ITD band after electrophoresis. D835 and I836 codons are encoded by the nucleotide GATATC, which forms the Eco-RV restriction site. The amplified products of wild-type FLT3 are digested into two bands by the Eco-RV enzyme, while amplified products with D835-mutations (FLT3-TKD) result in uncut bands, and this

permits a traditional diagnosis^[14]. Nowadays, several methods have been developed or adapted to help identify mutations of FLT3 and aberrant karyotypes (e.g., Multiplex-targeted next-generation sequencing)^[15], and moreover, next-generation sequencing (NGS) techniques for Measurable residual disease (MRD) detection are under development for clinical practice^[16]. Especially in the pre-FLT3 inhibitors era, patients harboring FLT3-ITD had a worse prognosis in terms of OS and relapse-free survival^[17]. Moreover, some studies suggested that a high Mutant-to-wild-type allelic ratio of FLT3-ITD was associated with a worse prognosis^[4,18]. Other studies, however, found no increased risk of relapse in patients with FLT3-ITDhigh^[19]. Other important determinants of prognosis in patients with FLT3-ITD are the karyotype status^[20] and NPM1mut which confers a more favorable outcome^[21,22]. Indeed, patients harboring NPM1mut and FLT3-ITDhigh are classified as intermediate risk in ELN2017^[23]. Different is the case for AML with FLT3-TKD; for these patients, a clear impact on prognosis is not established due to conflicting results^[24-30]. However, in the new ELN2022 classification, probably due to the therapeutic benefit of FLT3 inhibitors in the new AML scenario, all patients with FLT3 mutation are classified as intermediate risk regardless of whether the mutation is detected alone or with other co-mutations. However, after the introduction of FLT3-inhibitors, this prognostic disadvantage of FLT3-mutations seems abrogated, improving levels of MRD^[31,32]. MRD techniques to monitor FLT3 mutations are still being explored. In the next future, the improvement and the standardization of next-generation sequencing analysis could strongly increase and refine the opportunities for monitoring FLT3 mutations during treatment.

CLASS OF DRUGS: FLT3-INHIBITORS

The class of drugs of FLT3-inhibitors can be categorized according to chronological order in 1st generation (sorafenib and midostaurin) and 2nd generation (gilteritinib, quizartinib, crenolanib). Another classification is according to the capacity of the TKI to link the active and inactive status of the mutated FLT3 (Type 1: midostaurin, gilteritinib) or the inactivated only status of FLT3 (Type 2: quizartinib, sorafenib)^[33]. An important clinical implication is that Type 2 inhibitors at therapeutic concentrations are unable to inhibit FLT3-TKD, and, especially for the D835 mutation, this favors the active conformation of FLT3 and alters the binding of TKIs^[34].

Midostaurin is a first-generation TKI of class 1 and was the first drug to be approved for clinical use in FLT3-mutated AML in 2017^[35]. Midostaurin has moderate activity as a single agent, as shown in 92 patients who achieved a reduction of bone marrow blasts in 71% of cases^[36]. This evidence paved the way for a phase III trial of the association of 7 + 3 and midostaurin. From 2008 to 2011, the RATIFY trial enrolled a total of 717 patients harboring a mutated FLT3 (22.6% had the TKD mutation). The 4-year overall survival (OS) rate was 51.4% in the midostaurin group and 44.3% in the placebo group and the Median event-free survival (EFS) was 8.2 months in the midostaurin group vs. 3.0 months^[31]. In a post-hoc analysis in patients with FLT3-TKD, the 5-year EFS rate was significantly extended in patients treated with midostaurin than in the placebo arm (45.2% vs. 30.1%; $P = 0.044$)^[37].

Gilteritinib, which belongs to the 2nd generation of TKI, has more profound single-agent activity than 1st generation drugs and has activity against both FLT3-ITD and TKD mutations^[38]. Indeed, in phase I/II study with gilteritinib, 40% of patients achieved a response, with 19 (8%) reaching complete remission^[39]. This fueled interest in a randomized phase 3 trial comparing gilteritinib against any chemotherapy (selected by investigators) in relapsed/refractory (R/R) AML with mutated FLT3. In the ADMIRAL trial, the median OS was significantly longer in patients treated with gilteritinib than among those receiving chemotherapy (9.3 vs. 5.6 months). The Overall response to gilteritinib was 67.6% and 25.8% for the chemotherapy arm^[17]. These favorable results led to the approval of gilteritinib in the relapsed setting^[40]. Interestingly, with a prolonged follow-up at 2 years after the first analysis, in the gilteritinib arm, the median duration of CR was

23 months and 16 patients remained on gilteritinib for a prolonged time^[41]. Therefore, even if the majority of responding patients also underwent HSCT, there is a subgroup of patients that achieved a prolonged response to gilteritinib.

Sorafenib, a multitargeted TKI, is approved for hepatocellular carcinoma and renal cell carcinoma, but its off-label use in AML, especially after HSCT, is performed in many centers. Sorafenib is active only in FLT3-ITD AML with mild single-agent activity in the relapsed setting^[42,43]. After HSCT, a synergism between sorafenib and allogeneic immunity after HSCT has been hypothesized^[44], even if the data are conflicting^[45]. In a phase II study SORMAIN trial, 43 patients were randomized to receive a prophylactic treatment with sorafenib after HSCT and 40 patients to receive placebo. The 24-month RFS probability was 85% with sorafenib vs. 53.3% with placebo ($P = 0.002$)^[46]. Moreover, different phase II studies explored the addition of sorafenib to standard induction chemotherapy, but failed to improve EFS and survival at the cost of increased toxicity^[47-49].

Quizartinib, a second-generation TKI, was specifically selected from a library of drugs to deeply inhibit FLT3-ITD, while it is inactive against FLT3-TKD^[50]. It has clinical activity as a single agent in the relapsed setting, where 56% of FLT3-ITD-positive patients achieved a composite CR^[51]. However, the FDA expressed concerns about the lack of improvement in EFS, so quizartinib was initially rejected. Recently, the FDA granted quizartinib Priority Review for newly diagnosed (ND) FLT3-ITD+ AML based on data from the QuANTUM-First study. QuANTUM-First was a pivotal trial randomizing quizartinib vs. placebo added to standard 7 + 3 backbone in FLT3-ITD+ AML patients. The OS was significantly prolonged in the quizartinib arm compared to the placebo arm. The median OS was of about 32 months with quizartinib vs. 15 months with placebo, while CR rates were 71.6% and CRi rates 64.9%^[52,53].

Crenolanib, compared to other drugs of the same class, demonstrates some attractive characteristics to target FLT3 mutations in AML. Being a potent type I pan-FLT3 inhibitor, crenolanib is also active in FLT3 TKD mutations^[54]. As a single agent, in R/R AML Crenolanib showed 39% of CRi and 11% of PR among the 18 patients treated^[55], and in another study in 34 evaluable patients, 12% achieved CRi^[56]. However, these responses to crenolanib were transient [Table 1].

MOLECULAR MECHANISMS OF RESISTANCE

The heterogeneity of FLT3-ITD mutations such as length, sequence, and duplication site is unique for every AML patient^[57,58], and this molecular diversity increases the complex biology of FLT3-ITD. As previously reported, FLT3-ITD length mutations are found in the JM domain of the gene in 70% of mutated AML cases, while in the remaining 30%, the duplication region can involve the TKD1 with a different prognostic impact^[30,59]. However, the molecular mechanisms responsible for the differential signaling based on FLT3-ITD sites are not completely understood and can also influence the clinical outcome of patients [Table 2]. The use of FLT3 inhibitors in clinical practice showed a good response rate in mutated AML, both as frontline and relapsed/refractory therapy, but about 30%-40% of patients underwent relapse due to the acquisition or clonal evolution of gene alterations that drive therapy resistance^[17,60,61]. Therefore, resistance to FLT3 inhibitors can be categorized as primary and secondary resistance. During the innate resistance, administration of FLT3 inhibitors at AML diagnosis may be impeded in its efficacy by FLT3 ligand, fibroblast growth factor 2 (FGF2) and stromal cytochrome P450 3A4 (CYP3A4) mediated manner. It is well known that FLT3-mutated AML cells also express high levels of the wild-type FLT3 receptor, and therefore, FL ligand expression is consequently increased during the administration of FLT3 inhibitors. FL ligand binds to the FLT3 receptor and, in turn, restores FLT3 and downstream MAPK signaling, allowing the FLT3-ITD mutated clone to survive during the induction and consolidation therapy^[62]. In this scenario,

Table 1. Clinical trials including targeted FLT3 Inhibitors in adult patients with AML

FGF2 also plays an important role during TKIs resistance. Several studies have demonstrated that FGF2 is highly expressed in bone marrow stromal cells and its binding to FGFR1 receptor in FLT3-ITD mutated cells promotes resistance to FLT3 inhibitors through the activation of the downstream MAPK pathway^[63]. Finally, loss of FLT3 inhibitors efficacy may arise due to insufficient drug concentrations in plasma, as a consequence of its rapid hepatic metabolism and in BM stromal cells, by cytochrome CYP3A4 enzymes^[64]. Secondary resistance to FLT3-TKIs occurs through a variety of mechanisms, and in most cases, patients gain secondary resistance either by acquiring on-target or off-target abnormalities^[65]. The majority of relapsed/refractory patients display on-target FLT3 alterations (26%), acquiring the D835, N676, F691, and Y862 mutations within the TK domain, the most common secondary events identified in AML patients treated with type II FLT3-TKIs^[66]. Off-target mutations, which account for 16% of refractory patients, can occur *de novo* in primary FLT3-mutated clones or be gained by the evolution of other neoplastic clones. These cases are frequently characterized by gene mutations of epigenetic modifiers (DNMT3A, TET2, IDH2). Further genetic mutations leading to an off-target resistance after therapy with FLT3-TKI have been

Table 2. Proposed mechanisms of resistance to FLT3 Inhibitors in AML

	Primary resistance	
Cytochrome P450 3A4-mediated degradation of FLT3-inhibitors	Plasma levels of FLT3 inhibitors can be decreased through their enhanced degradation by hepatocytes and BMSC in Cytochrome P450 3A4-mediated manner	[64]
Restoration of FL/FLT3 signaling through compensatory overexpression of wild-type (WT) FLT3 receptor and FL	FLT3-mutated AML increases the expression of FL binding to WT FLT3 receptor and restores the downstream FLT3-MAPK signaling in WT and FLT3-ITD co-mutated cells	PMID: 27331411 PMID: 21263155
Activation of common FLT3 and fibroblast growth factor receptor type 1 (FGFR1) downstream target pathways through the increased fibroblast growth factor 2 (FGF2)/FGFR1 signaling	FGF2 ligand highly expressed in BMSC binds to FGFR1 receptor in FLT3-ITD mutated cells and activates the downstream MAPK signaling shared by both receptor tyrosine kinases	[63]
	Secondary resistance	
Newly acquired activating mutations of FLT3 TKD	Acquired mutations (D835, N676, F691 and Y862, A627 and others) within FLT3 TK domain confer resistance to different TKI and sustain activation of the downstream effectors	[66,71] PMID: 22858906 PMID: 33780043
Acquired activating mutations in RAS/MAPK pathway genes	Activating mutations in RAS/MAPK pathway genes upregulate pro-survival and pro-proliferative mechanisms in leukemic cells	[66,67,69,74]
Acquired mutations in epigenetic regulators and transcriptional regulators	Acquired mutations in epigenetic modifiers like DNMT3A, TET2, IDH2 or transcriptional regulators like WT1 and TP53 upregulate pro-survival mechanisms and favor leukemic cells survival	[60,67,76]
GM-CSF and IL-3 maintain cell survival without rescuing proliferation	Cytokine-mediated resistance through GM-CSF and IL-3 is dependent on JAK kinase, STAT5, and pro-viral integration site of Moloney murine leukemia virus (PIM) but not MAPK or mammalian target of rapamycin signaling	PMID: 30944098
Novel ATM/mTOR pathway regulating oxidative phosphorylation	Marrow-mediated activation of ATM, in turn, upregulates oxidative phosphorylation via mTOR signaling. mTOR is required for the bone marrow stroma-dependent maintenance of protein translation	PMID: 36259537

AML: Acute myeloid leukemia; BMSC: BM stromal cells; FLT3: FMS-like tyrosine kinase 3; TKD: tyrosine kinase domain.

recently reported in genes of the RAS/MAPK pathway (13%), WT1 (7%), and TP53 (7%)^[66,67]. There is hope that recognizing and understanding the mechanisms that produce FLT3-TKIs resistance will help provide better strategies for the rational design of new agents and, finally, lead to more effective treatment [Table 2].

Acquired mutation on *FLT3* gene

Several studies have demonstrated that TKIs drugs may have an impact on the clonal evolution of FLT3-ITD mutated AML by downregulating certain clones^[68,69]. These findings emphasize the importance of repeated mutation analysis for FLT3-ITD to discriminate between patients in whom TKI may induce long-lasting remission, and from those in whom relapse may originate from subclones, which may carry a FLT3-wild type at diagnosis. As previously discussed, secondary TKD mutations, mainly reported at residues D835/F691 in FLT3-ITD mutated patients treated with TKIs, confer therapy resistance and poor outcomes^[70]. In particular, at AML onset, type II of FLT3-TKIs have an effect on FLT3-TKD mutations, but secondary alterations in the TK domain during the disease progression may confer treatment resistance interfering with the inhibitory activity on FLT3-ITD mutated clones. Acquired alterations at D835, F691 and Y842 residues have been reported in patients who developed resistance to sorafenib or quizartinib, both type II-TKIs^[71]. Although the acquisition of mutations in the TK domain of FLT3 is rarely reported in patients treated with gilteritinib and crenolanib (a type I-TKIs), the gaining of F691L alteration, defined as gatekeeper mutation of FLT3 gene, was frequently observed. This mutation confers substantial resistance to both type I and type II-TKIs^[65]. The latter mutations occur in residues that directly interact with the TKIs and become prevalent in AML clones almost exclusively after treatment with the inhibitors^[72]. Although in FLT3-mutated AML, the addition of midostaurin to standard “7 + 3” treatment regimen has been widely

used in clinical practice, only 60% of patients achieved a CR, and almost half of these cases developed a relapse. Schmalbrock and colleagues^[16] provided novel biological features into the clonal evolution and mechanisms of resistance of FLT3-ITD-mutated AML exposed to midostaurin. They demonstrated that during the disease progression, almost 46% became FLT3-ITD negative and acquired mutations in MAPK pathways, conferring an additional proliferative advantage. By contrast, in AML cases that relapse with FLT3-ITD persistence, they showed a clonal selection of driver mutations in 11% of cases. FLT3-ITD clones persist in the remaining patients during relapse disease, indicating a failure of midostaurin inhibition activity.

Intracellular pathways alterations

The phosphorylation of FLT3 receptor activates several downstream intracellular signaling pathways, such as RAS/MAPK, PI3K/Akt/mTOR, and JAK/STAT5, which are mainly implicated in the survival, proliferation, and differentiation of hematopoietic cells^[73]. During the TKI treatment, clonal selection of cells characterized by activating gene mutations involved in RAS/MAPK pathway is often detected during progression in AML patients who received frontline midostaurin combination therapy^[69] or gilteritinib as monotherapy for relapsed/refractory disease in 2nd line^[67,74,75]. These results suggest that RAS mutations may drive the clonal evolution in relapsed/refractory AML that occurs independently from TKI type administration. Other mechanisms of off-target resistance during FLT3-TKI therapy have been recently described. Alotaibi and colleagues^[67] analyzed the mutational status of patients who relapsed after different FLT3 inhibitors and demonstrated that the most common gene alterations involved alterations in IDHs, NRAS, WT1, and TP53 genes. In particular, they identified in responding patients a higher occurrence of IDH2 alterations at diagnosis as compared to non-responder cases. This data suggests an advantage of combining targeted therapies in AML patients who harbored concomitant FLT3 and IDH2 mutations^[76]. Instead, mutations of NRAS and IDHs genes often occur in leukemia subclones; TET2 alterations are described in FLT3 mutated clones and mainly enriched in crenolanib poor-responders AML. In particular, Zhang *et al.* reported that the mutation type of TET2 gene correlates with a different prognosis in patients treated with crenolanib, suggesting that TET2 truncation mutations may contribute to TKI resistance as compared to missense mutations that did not show a correlation with an unfavorable response to crenolanib^[60].

CLINICAL RELEVANCE OF TKI RESISTANCE

It has been demonstrated that FLT3 inhibitor therapy promotes drug-resistant clonal populations that harbor secondary, on-target FLT3-mutations and that are prone to resistance to numerous TKIs in patients with relapsed AML who possess *FLT3-ITD* mutations^[77]. Prolonged therapy with FLT3-TKIs can exert clonal pressure for the selection of drug-resistant sub-clones with additional mutations that facilitate leukemic proliferation regardless of the *FLT3* kinase's activation state, as well as for sub-clones that are completely lacking FLT3 mutations; this is particularly relevant because relapsed AML is demonstrably a polyclonal disease^[69].

Sorafenib and midostaurin, FLT3 TKIs of 1st-generation, have in proportion a low selectivity for *FLT3* mutations. Nevertheless, the rates of response are augmented with midostaurin and relapse rates show a significant reduction when either drug is administered in association with frontline chemotherapy, like 3 + 7 induction therapy in patients with newly diagnosed (ND-AML), FLT3-^{mut} AML^[31]. *FLT3-ITDs* are patient-specific, and due to the unique positioning and variable extension of the duplicated genomic sequence, there is a wide range of variability. This translates into unique peptide motifs derived from duplicate aminoacidic sequences within the *FLT3* gene. Therefore, many studies have tried to answer the question if diversity of *FLT3-ITD* exerts any effect on the clinical outcome of AML patients^[30,78-81]. In a study conducted

on 151 elderly AML patients who had received standard chemotherapy, Stirewalt *et al.* showed that the length of the ITD (40 *vs.* > 40 base pairs) had an effect on the patients' long-term survival^[78]. According to research by Kayser and colleagues, patients with AML who have *FLT3-ITD* placed into the first tyrosine kinase domain (TKD1) of the *FLT3*-gene present a poorer outcome than those who have *FLT3-ITD* in the juxtamembrane domain (JMD)^[30]. However, a retrospective analysis in 260 patients with AML *FLT3-ITD* positive, which divided *FLT3-ITD* into 3 groups based on its position, was unable to confirm this finding, and just showed a statistical trend towards a link between a more C-terminal location of *FLT3-ITD* and worse survival, but without impacting on EFS^[79]. However, Fisher *et al.* reported data favorable to the assumption that *FLT3-ITDs* located closer to the C-terminus of the *FLT3* gene correlate with an adverse prognosis^[80]. They showed that the localization of the ITD affected the percentage of remission following AML first-line chemotherapy, independently of the allelic burden^[80]. Rucker *et al.* assessed the prognostic and predictive role of *FLT3-ITD* insertion site (IS) considering 452 subjects treated in the RATIFY trial, identifying 265 IS in the tyrosine kinase domain-1 (TKD1) and 43 IS in the juxtamembrane domain (JMD) by NGS^[81]. Four-year OS probabilities significantly differed between JMDsole, JMD/TKD1, and TKD1sole, respectively; specifically, multivariate Cox models for OS and cumulative occurrence of relapse after HSCT identified TKD1sole as a negative prognostic factor^[81].

Gilteritinib and quizartinib, members of the second-generation *FLT3* TKIs, show higher selectivity for *FLT3* mutations. Indeed, when they are used as single agents in patients with *FLT3*-mutated R/R AML, both molecules exhibit clinical activity and have shown survival advantages over salvage approaches^[17,61]. In comparison with quizartinib, gilteritinib showed activity for *FLT3-ITD* and *FLT3-TKD* mutations^[82]. Nevertheless, secondary resistance to gilteritinib can arise via off-target mechanisms, such as the appearance of *NRAS* or similar mutations that activate MAPK signaling downstream of *FLT3*, as well as on-target *FLT3* mutations at a gatekeeper *FLT3* residue (F691L)^[40,74]. As already discussed, gilteritinib has been approved as single-agent therapy for patients with *FLT3*-mutated R/R AML after positive results of ADMIRAL trial^[61,79]. Patients randomized to receive 120 mg of gilteritinib showed a significantly longer median OS than those who received salvage chemotherapies and higher rates of CR^[17]. Furthermore, Perl *et al.*^[39] confronted post-hoc the clinical outcomes in patients with R/R *FLT3*-mutated AML enrolled in CHRYSALIS and ADMIRAL trials^[17,39], with a view on those who were previously exposed to midostaurin or sorafenib against naive patients. Similar to those pre-treated, high rates of overall response emerged among patients treated with a *FLT3* TKI before gilteritinib (CHRYSALIS, 42%; ADMIRAL, 52%) and patients without previous *FLT3* TKI therapy (CHRYSALIS, 43%; ADMIRAL, 55%). Furthermore, in ADMIRAL study, a higher rate of response and a trend toward longer median OS was observed in the arm with gilteritinib *vs.* salvage chemotherapies in patients who had previously received a *FLT3* TKI^[83]. Therefore, these results encouraged the use of gilteritinib in *FLT3*-mutated R/R AML also after prior exposure to sorafenib or midostaurin.

POSSIBLE STRATEGIES TO OVERCOME RESISTANCE

New therapeutic combinations are now being tested in order to potentially reduce the development of resistances to *FLT3* inhibitors or the possible occurrence of new point mutations within the *FLT3* gene during the therapeutic approaches; this would allow an increased rate of response to treatment and a lower cumulative incidence of relapse in *FLT3* mutated patients.

A phase 1 study (NCT02236013) assessed the safety, tolerability, and efficacy of gilteritinib plus 7 + 3 induction, followed by consolidation chemotherapy with high-dose ARA-C, and then a period of maintenance with gilteritinib in adults with ND-AML. The study included 80 patients; the rate of composite CR was 81.8% for all the four doses and 81.6% for patients who received 120 mg of gilteritinib (that represented the maximum tolerated dose). The median follow-up for OS was 35.8 months, with a mOS for

patients with FLT3-mutated disease that was not reached. Serious treatment-related adverse events (AE) took place in 10 patients; the most common nonhematologic AE of grade ≥ 3 were increased liver enzymes, pneumonia, and sepsis/bacteremia^[84]. Recently, the MD Anderson group presented preliminary data from a phase II trial that evaluated the combination of gilteritinib with intensive chemotherapy (CLIA = cladribine, cytarabine and idarubicin) in ND-AML with FLT3 mutation. Twenty-four patients were enrolled; 13 patients (54%) achieved a CR and underwent an allogeneic SCT^[85]. Furthermore, treatment results for those patients with ND-AML, FLT3-mutated considered ineligible for a course of intensive chemotherapy are strongly disappointing. In a pooled analysis of the phase IB and phase III VIALE-A study (HMA + venetoclax), the median OS in FLT3 mutated patients was only 12.5 months, lower than what the 15 months achieved in FLT3 unmutated patients with this regimen^[86]. Moreover, a phase III trial randomized (with a 2:1 ratio) untreated adults with FLT3 mutated AML unfit for intensive induction chemotherapy to gilteritinib (120 mg/day orally) and azacitidine (AZA + GIL) or azacitidine (AZA) alone. In the interim analysis, 123 patients were randomized (AZA + GIL, $n = 74$; AZA, $n = 49$). The median OS was not significantly different between the two arms (9.82 vs. 8.87 months, respectively; $P = 0.753$)^[87]. As the median OS was the primary endpoint of the trial, the study was closed. Moreover, combination therapies to overcome resistance with FLT3 inhibitors and alternative resistance factors like apoptosis (BCL2) have been developed using venetoclax^[88]. Preclinical data suggest that gilteritinib, inhibited the expression of BCL2A1 through the inactivation of STAT5 and alleviated TKI resistance of FLT3-mutated cell lines. Combining gilteritinib and venetoclax that suppresses BCL2A1 could improve the prognosis of AML with FLT3-ITD/D835 mutations^[89].

Some patients harbor IDH and FLT3 mutations at the time point of diagnosis or experience a second mutation while undergoing treatment. Particularly FLT3 mutations are linked to low IDH inhibitors response rates, and treatment-emergent FLT3 mutations also seem to impart therapeutic resistance to these drugs. As a result, there is increased interest in researching combined therapies that target multiple pathways; however, there is currently no information available regarding the clinical experience of combined IDH inhibitors and FLT3 inhibitors therapy. A retrospective analysis identified 12 patients who received concurrent IDH and FLT3 inhibitors therapy, 11 of whom had R/R AML. The composite remission rate was 33%, and the ORR (CR + CRi + MLFS) was 42%, while the treatment combination was well tolerated^[76]. Therefore, a notable proportion of R/R AML patients benefitted from concurrent FLT3 and IDH inhibitors therapy and studies are ongoing to investigate this promising combination.

In FLT3-ITD AML preclinical models, FLT3-ITD inhibition in combination with venetoclax exhibits impressive anti-tumor effectiveness and offers a solid molecular basis for clinical trials. However, the use of selective BCL-2 family inhibitors revealed a new function for BCL-2, BCL-XL, and MCL-1 in FLT3-ITD positive cells' *in vivo* survival, underscoring the necessity of targeting all three proteins for the most effective anti-tumor effect^[88]. An open-label, phase 1b trial (NCT03625505) evaluated the combination of venetoclax and gilteritinib in R/R AML. Among the 54 patients enrolled, 38 patients (74.5%) achieved a response, with a median OS and a median duration of response of 10.5 and 5.6 months, respectively. In a post hoc analysis of the 30 analyzable patients who had achieved a CR with at least one follow-up MRD assessment, 17 (56.7%) achieved molecular clearance defined as FLT3 allelic burden $< 10^{-2}$ ^[90]. The MD Anderson group hypothesized that triplet therapy combining FLT3 inhibitors, venetoclax, and hypomethylating agents (HMAs) would further improve outcomes of FLT3 mutated patients. Therefore, they added FLT3 inhibitors to a regimen of 10-day decitabine with venetoclax in newly diagnosed (ND) and R/R FLT3 mutated patients. In ND patients, the composite complete remission (CRc) rate was 92%, with MRD negativity by flow cytometry in 56% and by next-generation sequencing (NGS) in 91% of responders. In R/R AML, the CRc rate was 62%, with MRD negativity rate by flow cytometry in 63% and by NGS in 100% of

responders^[91]. Therefore, triplet therapy with FLT3 inhibitors, venetoclax, and decitabine seems safe and an excellent frontline option for older patients with ND FLT3 mutated AML, and effective for R/R AML. A transition to allogeneic transplant and post-transplant maintenance with FLT3 inhibitors would offer further improvement in long-term outcomes.

Although midostaurin and gilteritinib have been given FDA approval to treat patients with FLT3-mutations, the effectiveness of these treatments is still constrained by the fact that half of patients die during the first five years from diagnosis. Our actual understandings of the limits of TKIs highlight the demand for alternative therapeutic approaches. Although FLT3 antigen density on AML blasts is substantially lower than - for example, CD20 on lymphoma cells - and is not thought to be sufficient for producing powerful antibody-mediated effector functions, the membrane receptor FLT3 has also been studied as a target for immunotherapy using monoclonal antibodies. AML blasts and normal hematopoietic stem cells (HSCs), to a lesser extent, are selectively bound by the mouse anti-human FLT3 monoclonal antibody (mAb) 4G8. In preclinical models, 4G8 conferred selective reactivity against AML blasts with high FLT3 antigen density after Fc tuning^[92]. Recently, T-cells engineered to express a FLT3-specific chimeric antigen receptor (CAR) were produced and it was shown that they confer robust reactivity against both AML cell lines and primary AML blasts, that express either wild-type FLT3 or FLT3-ITD. Furthermore, it was observed that treatment with crenolanib produced an increased surface expression of FLT3, particularly on *FLT3-ITD* + AML cells. Therefore, it enhanced the recognition by FLT3-CAR T-cells in vitro and *in vivo*^[93]. Sommer *et al.* reported the preclinical evaluation of another off-the-shelf CAR-T cell construct targeting *FLT3*^[94]. This CAR construct with single-chain variable fragments (scFvs) was directed against multiple *FLT3* extracellular epitopes and was investigated for its capacity to direct T-cell selectivity and effector function to FLT3-mut AML cells. AML initial blasts are eliminated by allogeneic FLT3 CAR T cells made from a group of voluntary donors of T-cells; however, these cells are also effective against mouse and human hematopoietic stem and progenitor cells, raising concerns about myelotoxicity. Authors demonstrated that rituximab-mediated reduction of FLT3 CAR T cells following AML eradication permitted bone marrow regeneration without compromising leukemia remission by using a surrogate CAR with an affinity for murine FLT3^[94].

Moreover, bispecific antibody cross-linking of FLT3 and CD3 demonstrated potent anti-leukemia activity against FLT3-mut cells. An anti-FLT3-CD3 immunoglobulin G (IgG)-based bispecific antibody (7,370) with a high affinity for FLT3 and a long half-life was developed to target FLT3-expressing AML blasts regardless of *FLT3* mutational status. In vitro and *in vivo* testing revealed that 7,370 exhibits picomolar potency against AML cell lines. Additionally, 7,370 was able to stimulate T cells from AML patients, refocusing their cytotoxic activity at low effector-to-target ratios on autologous blasts^[95].

Finally, cyclin-dependent kinase 6 (CDK6) is a protein that works as a transcriptional factor, regulating FLT3 and the serine-threonine kinase PIM1, a different step in the process of leukemogenesis^[96]. Uras *et al.* found that FLT3-mutant AML cells are very responsive to palbociclib, one of several available inhibitors of CDK4/6 kinase^[97]. They showed that the cell cycle kinase CDK6 is required for the viability of FLT3-dependent blastic cells and that FLT3-ITD could induce leukemogenesis [Figure 2]^[97].

CONCLUSIONS

One of the most important modifications introduced with the current ELN2022 is that the *FLT3-ITD* allelic ratio is no more included in the ELN risk classification; as a consequence, AML with *FLT3-ITD* (without other adverse-risk genetic lesions) are now comprised into the group of the intermediate-risk and not the high-risk group, this independently from the allelic-ratio or the concurrent presence of *NPM1*-mut. The reasons for this modification are related to methodological difficulties in standardizing the assay adopted to

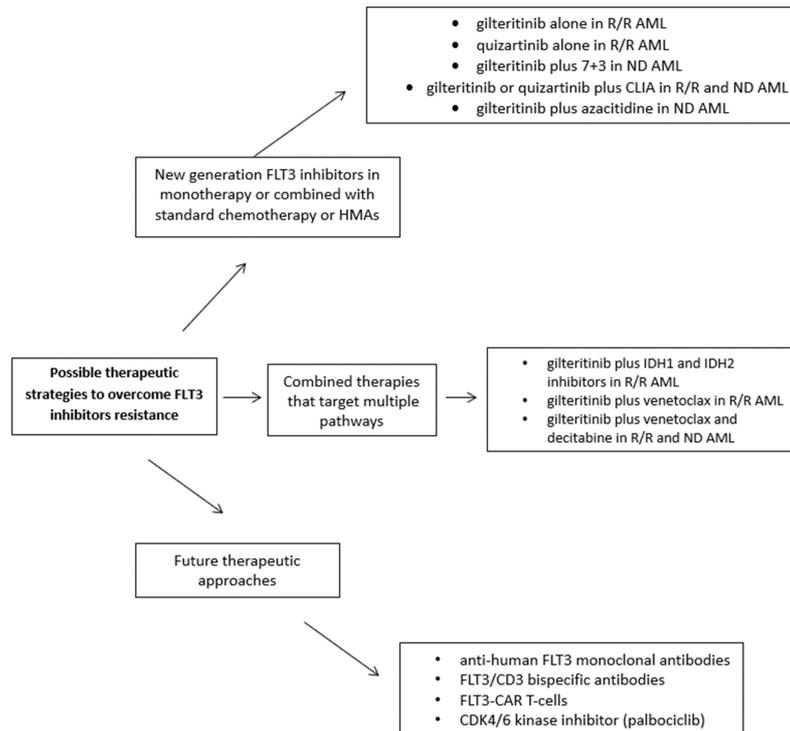

Figure 2. Possible strategies to overcome FLT3-inhibitor resistance.

measure the *FLT3*-ITD allelic ratio in different labs, and the improved effect of midostaurin-based chemotherapy on AML patients with *FLT3*-ITD without *NPM1*-mut^[55,98]. Several mechanisms of resistance to available *FLT3*-inhibitors have been partly elucidated, but it is a process that acts underneath many biologic fields (e.g., the emergence of antibiotic-resistant strains in many bacteria), also with a clonal selection of resistant sub-clones of AML after protracted biological pressure from TKI-inhibitors. Nevertheless, in the ADMIRAL trial, patients who achieved a CR experienced a median duration of this response of 23.0 months, suggesting that the effect is protracted in a subset of patients. However, the cumulative effect of these drugs on patients with AML harboring *FLT3*-mutations has been demonstrated to be largely beneficial in clinical trials and current clinical practice. In Europe, we have only gilteritinib and midostaurin approved in clinical practice, so an exchange for a different TKI is not possible yet.

As a result, we reasoned, is resistance “Much Ado about nothing?” Probably, from the actual clinical perspective, mechanisms of resistance to *FLT3*-inhibitors are somehow overlooked. For patients obtaining a CR after therapy with gilteritinib, if they are transplant eligible, considering an early Allogeneic transplant seems appropriate because the duration of a CR is generally short-lived and gilteritinib may represent a bridge to transplant^[99]. When gilteritinib is given after Allo-transplantation, it results in a significant improvement in overall survival. In brief, exposure to gilteritinib for a limited interval after allo-SCT enhances Graft-*vs.*-Leukemia effects against *FLT3*-ITD+ leukemia without exacerbating GvHD^[100].

Poor results have been reported in patients with R/R *FLT3*-ITD AML, who were treated with standard salvage chemotherapy and had a median OS of 5.5 months and 1- and 5-year OS rates of 25% and 7%, respectively^[101]. On the contrary, the use of single-agent *FLT3* inhibitors has improved survival over chemotherapy in the relapsed setting^[17]. The path of *FLT3* inhibitors is marked by possible strategies to combine different drugs to overcome the emergence of resistance^[91,93]. We hope that these ongoing studies will benefit many patients in the future.

A major problem in current cancer drug treatment is that a subset of cancer cells in many cases survives even highly efficient chemotherapy, and after a while, these remaining cells cause a recurrence of the disease. Moreover, the re-emerging cancer cells often show a multidrug-resistant phenotype, higher proliferation rate, higher invasiveness, and increased metastatic potential, as compared to original cancer. Cancer relapse and multidrug resistance are widely observed also in the most up-to-date, specifically targeted drug- or immunotherapies, causing an unsurmountable clinical inefficiency in cancer eradication.

A widely favored explanation for this relapse phenomenon is the presence of “stem cell-like” cancer cells, surviving therapy within the original tumor mass and then rapidly generating the recurring malignancy. This presumed tumor-initiating cancer stem cell (CSC) population is suggested to be responsible for increased apoptosis and chemoresistance, higher epithelial-mesenchymal transition (EMT) potential, and clinical cancer relapse and metastasis^[1-6]. An alternative proposal suggests the presence of drug-tolerant persister cells (DTPC) with special genetic features among the cancer cells, and this drug-tolerant persister (DTP) cell population may be the source of cancer relapse^[7,8].

© The Author(s) 2023. **Open Access** This article is licensed under a Creative Commons Attribution 4.0 International License (<https://creativecommons.org/licenses/by/4.0/>), which permits unrestricted use, sharing, adaptation, distribution and reproduction in any medium or format, for any purpose, even commercially, as long as you give appropriate credit to the original author(s) and the source, provide a link to the Creative Commons license, and indicate if changes were made.

The major conceptual difference between the two proposed sources of re-occurring tumor cells after drug treatment is discussed in detail in the key reviews by Clevers^[9] and Borst^[10]. In very short, the CSC concept envisions within the heterogeneous tumor (containing mostly variably differentiated cells) the presence of specific, drug-resistant, stem cell-like clonal cells. In contrast, the concept of the DTP cells suggests that some of the cells within the tumor mass can transiently and reversibly up-regulate mechanisms responsible for drug resistance, and the surviving cells variably regain their tumor-forming capacity^[7,8].

Irrespective of the actual mechanisms, the clonal presence or transient formation of these practically immortal cells poses a major challenge for cancer therapy. Thus, the exploration of the basic biology and the clinical features of these CS or DTP cells may bring a new, successful era in cancer chemotherapy, including targeted therapies. Therefore, an elucidation of the key molecular mechanisms regulating CSC/DTP activities could help the development of novel biomarkers and therapeutic targets to predict or combat the most aggressive malignant tumors in patients^[11-14].

The chapters in this special issue e-book aim to explore some of the important features, molecular background, phenotype, and clinical role of the CSCs or DTPCs. Among these, Safa^[15] reviews the drug and apoptosis resistance in the tumor-initiating CSCs, how they display increased self-renewal potential, anticancer drugs and radiation resistance, and show an increased epithelial to mesenchymal transition (EMT) progression. Also, the potential specific treatments targeting CSCs are explored in this chapter. Hansen *et al.*^[16] discuss the presence of leukemia stem cells in AML and focus on the cell surface markers and intracellular transcription factors that can distinguish these leukemia stem cells from normal hemopoietic stem cells. These biomarkers may significantly help to specifically eliminate the stem cell-like leukemic cells and thus improve leukemia treatment.

The chapter by Gupta *et al.*^[17] specifically explores the potential role of CSCs in cancer resistance to immunotherapy. They describe surface markers that are differentially expressed on CSCs and potentially help them to escape from immune surveillance and immune cell-dependent killing. Moreover, they suggest that CSC-released cytokines and other metabolites may result in a decreased anticancer immune response in the tumor microenvironment. All these features may help to devise more effective anticancer immunotherapies.

Koltai^[18] in his chapter raises an interesting issue and concept related to the role of pH in the development of the cancer multidrug resistance phenotype, and the potential use of already existing or repurposed drugs to modulate this resistance. In addition, a chapter by Kim *et al.*^[19] deals with the potential use of herbal extracts to provide effective treatment in lung cancer, by reducing drug resistance and the growth of cancer stem cell-based tumors from an NSCLC model cell line.

It is hoped that this special issue will provide significant value in enhancing the understanding of the role of cells that have a major impact on clinical drug resistance in cancer.

Abstract

Aim: Given the encouraging results of the p53-Mdm2 inhibitor RG7388 in clinical trials and the vital function of miR-16-5p in suppressing cell proliferation, the aim of the present study was to investigate the combined impact of RG7388 and miR-16-5p overexpression on the childhood acute lymphoblastic leukemia (chALL).

Methods: miRTarBase and miRDB, along with KEGG and STRING databases, were used to predict miR-16-5p target genes and explore protein-protein interaction networks, respectively. B- and T-lymphoblastic cell lines, in addition to patient primary cells, were treated with RG7388. Ectopic overexpression of miR-16-5p in Nalm6 cell line was induced through cell electroporation and transfection of microRNA mimics was confirmed by qRT-PCR. Cell viability was evaluated using the MTT assay. Western blot analyses were performed to evaluate the effects of RG7388 and miR-16-5p upregulation on the protein levels of p53 and its downstream target genes in chALL cells. Paired sample t-test was employed for statistical analyses.

Results: MTT assay showed RG7388-induced cytotoxicity in wild-type p53 Nalm6 cell line and p53 functional patient primary cells. However, CCRF-CEM and p53 non-functional leukemic cells indicated drug resistance. Western blot analyses validated the bioinformatics results, confirming the downregulation of WIP1, p53

stabilization, as well as overexpression of p21^{WAF1} and Mdm2 proteins in Nalm6 cells transfected with miR-16-5p. Moreover, enhanced sensitivity to RG7388 was observed in the transfected cells.

Conclusion: This is the first study indicating the mechanistic importance of miR-16-5p overexpression in chALL and its inhibitory role in leukemia treatment when combined with the p53-Mdm2 antagonist, RG7388. These findings might be useful for researchers and clinicians to pave the way for better management of chALL.

Keywords: Pediatric ALL, miR-16-5p, RG7388, *PPM1D*, p53

INTRODUCTION

Acute lymphoblastic leukemia (ALL) is one of the most common blood cancers in children with a low incidence rate of *TP53* mutations at diagnosis, which highlights this type of malignancy as an attractive candidate for treatment with p53-Mdm2 antagonists. Although 85%-90% of patients respond to the treatment, there are subsets that are refractory to the therapy and relapse is prevalent amongst individuals who achieve complete remission^[1,2]. For this reason, new strategies and treatments are necessary to overcome drug resistance.

Cancer treatment has been recently improving with the introduction of targeted therapies to achieve greater specificity and less cytotoxicity. Owing to the main function of p53 in the enhancement of cell cycle arrest, response to DNA repair and apoptosis, enormous efforts have been made to advance new cancer treatments based on p53-targeted therapy. p21 is a well-known determinant of cell cycle arrest, which increases following induction of p53 stabilization and its activity^[3]. The incidence rate of *TP53* mutations at diagnosis is low in various types of blood cancer including ALL (5%-10%). Therefore, activation of the p53 pathway by non-genotoxic inhibitors of mouse double minute 2 homolog (Mdm2) is a promising strategy to improve cancer therapy in hematological malignancies, including ALL^[4]. Recently, small molecule inhibitors of p53-Mdm2 interaction have been developed and entered into early-phase clinical trials for the treatment of diverse types of cancer comprising blood cancer^[5-8]. Amongst those entered into clinical trials, RG7388 has passed phase II clinical trial^[8]. Thus, the prediction of sensitivity to Mdm2 inhibitors and identification of mechanisms of resistance toward Mdm2 inhibitors would be helpful in stratifying patients who might benefit from these therapeutic agents.

p53 levels and its activity are regulated under a complex network of proteins and microRNAs (miRNAs) to maintain normal levels and proper function of p53. The oncogene Protein Phosphatase, Mg²⁺/Mn²⁺ Dependent 1D (*PPM1D*), known as wild-type p53-induced phosphatase 1 (*WIP1*), negatively regulates p53 through different mechanisms, including direct dephosphorylation of p53 and its subsequent inactivation, and dephosphorylation of other proteins involved in the regulation of p53 such as Mdm2 and p53 activating kinases^[9]. Consistent with the inhibitory effect of Wip1 on the p53 pathway, *PPM1D* gene is amplified and overexpressed in different cancer types including leukemia, suggesting that Wip1 may be a potential therapeutic target for leukemia^[10]. Recent studies have demonstrated that selective inhibition of Wip1 leads to increased DNA damage response and sensitivity to anti-cancer agents working through the p53 pathway^[10-13].

microRNAs are a class of small RNAs, with an average of 22 nucleotides in length, which interact with the partially complementary sequences in the 3' untranslated region (3' UTR) of the target mRNA and negatively regulate its expression^[9,14]. Although not proven in childhood ALL, miR-16-5p appears to be a major negative regulator of Wip1 protein expression in some cancers, which affects p53-Wip1 feedback loop^[13] and can regulate cell fate^[12]. miR-16-5p interacts with the 3'-UTR binding site of the human *PPM1D*

gene and directly represses the Wip1 protein expression, a negative regulator of p53, thereby indirectly promoting p53 activity and its pathway^[13]. Previous research showed that miR-16-5p feedback loop with p53 and Wip1 increases sensitivity to doxorubicin^[13] and affects cell fate determination^[12]. Moreover, aberrant expression of miR-16-5p has been reported in chronic lymphocytic leukemia (CLL)^[15,16].

In the present study, it was hypothesized that cell lines and primary samples harboring functional p53 are more sensitive to RG7388 compared to those with dysfunctional p53, and ectopic overexpression of miR-16-5p in cells with functional p53 affects WIP1 mRNA levels, and consequently respond to the p53-Mdm2 antagonist RG7388 in a p53-dependent manner.

METHODS

miR-16-5p-target interaction databases and visualization of protein-protein interaction network

miRTarBase and miRDB validated microRNA-target interactions databases were employed to clarify the interaction between miR-16-5p and PPM1D expression^[17,18]. The Kyoto Encyclopedia of Genes and Genomes database (KEGG) (<http://www.genome.jp/kegg/>) was used as a pathway database to find the p53 pathway map (map04115)^[19]. To visualize protein-protein interaction network between the Wip1 and other proteins with strong confidence (0.700 interaction score), the STRING database (<https://string-db.org/>) was used^[20].

Chemicals and reagents

The small-molecule Mdm2 inhibitor RG7388 (Idasanutlin) was purchased from SelleckChem (Cambridge, UK). RG7388 was dissolved in dimethyl sulfoxide (DMSO) to provide a 10 mM stock solution and stored in small aliquots at -20 °C. miR-CURY LNA™ Universal RT microRNA PCR kit and miR-CURY LNA™ miRNA Mimics (HAS-MIR- 16 -5p & NEGATIVE CONTROL 5 MIRCURY LNA) were purchased from QIAGEN (Hilden, Germany).

Cell lines

The leukemic cell lines Nalm6 and CCRF-CEM were sourced from the Pasteur Institute (Iran) authenticated cell bank. The cells were cultured in RPMI-1640 (Gibco, USA) supplemented with 10% (v/v) FBS (Gibco, USA) and 1% (v/v) penicillin/streptomycin and grown at 37 °C, 5% CO₂ in a humidified atmosphere. The *TP53* status of Nalm6 cell line is wild-type (NALM6 ATCC CRL-3273™) and the CCRF-CEM cell line (CCRF-CEM ATCC CCL-119™) harbors heterozygous *TP53* mutations (c.524G>A; p.R175H, and c.743G>A; p.R248Q).

Patients, sampling and cell isolation

Peripheral blood or bone marrow samples ($n = 10$, 5 females and 5 males) from childhood ALL patients were collected. ALL in these patients was clinically diagnosed and pathologically confirmed by a clinical team through phenotypic, immunologic and cytogenetic techniques in the pediatric department of Sayed-ol-Shohada Hospital (Isfahan, Iran). Informed written consent was obtained in accordance with the Declaration of Helsinki, and with approval from the Ethics Committee of the University of Isfahan (ethics agreement number IR.UI.REC.1397.145). Informed written consent was obtained from the children's parents prior to participation in the study.

2-5 mL of heparinized bone marrow sample or peripheral blood were collected from patients and sent to the Cellular and Molecular Biology Laboratory of the University of Isfahan on ice. Mononuclear cells were extracted and isolated using density gradient Lymphoprep (Axis-Shield Diagnostics Ltd, Oslo, Norway) according to the manufacturer's protocol.

Ex vivo cytotoxicity assay

Cytotoxicity of RG7388 was assessed using MTT cell proliferation kit (Alban, Austria). Growth curves were constructed for Nalm6 and CCRF-CEM cell lines (GraphPad Prism statistical analysis software version 8.) to measure cell doubling time and the optimum seeding density for a subsequent growth inhibition assay. Nalm6 (5×10^5 /mL) and CCRF-CEM (4.5×10^4 /mL) in 100 μ L of medium per well of a 96-well plate were treated with a range of concentrations of RG7388 for 96 and 72 h, respectively (according to their cell doubling time). Then, 10 μ L of MTT solution was added into the wells. 100 μ L DMSO was added after 3 h to dissolve formazan crystals, and absorbance was measured using a stat fax 2000 microplate reader (Awareness Technology, Inc) at 492 nm wavelength. The LC_{50} values, the required concentration of each compound expected to kill 50% of the population, were determined using the statistical software mentioned above.

For patients' samples, primary cells (2×10^6 /mL) in 100 μ L of medium per well of a 96-well plate were exposed to 0.5% DMSO or 0.5 μ M RG7388 ($2 \times LC_{50}$ concentration for Nalm6) for 72 h. This concentration was used since sensitive cells respond to it, and the sensitivity is not due to off-target effects. The proportion of the viable cells was measured by comparison between the absorbance of cells exposed to DMSO, as a control, or RG7388, and calculated using the following formula: (%) = $[100 \times (\text{sample absorbance}) / (\text{control absorbance})]$.

Functional assessment of the p53 pathway

To determine the functional status of p53 in ALL patients' samples (those with enough amount of protein lysates), the modulation of p53 and its transcriptional target gene protein products including Mdm2 and p21^{WAF1} were evaluated following short-term exposure to Mdm2-p53 antagonist RG7388^[21,22].

Western blotting

Nalm6 and CCRF-CEM (2.5×10^5 /mL) were seeded in 2 mL culture media per well of a 6-well plate and treated with 0.5% DMSO and a range of concentrations of RG7388. Primary cells (0.5×10^6 /mL) were also seeded in 2 mL culture media per well of a 6-well plate and exposed to 0.5% DMSO or 0.5 μ M RG7388 ($2 \times LC_{50}$ concentration for Nalm6). Cells were harvested and lysed at 6 h. Lysis buffer (12.5 mL Tris HCL, 2 g SDS, 10 mL Glycerol, 67.5 mL Distilled Water) was applied to harvest the whole-cell lysates, followed by sonication. Bradford solutions (100 MG Coomassie Blue 250 G, 50 mL ethanol 96%, 100 mL orthophosphoric acid 85% and bringing volume to 1000 mL by adding distilled H₂O) were used to estimate the concentration of protein in the cell lysates utilizing NanoDrop ND-1000 Spectrophotometer (Thermo Fisher Scientific, USA).

Hand-poured gradient gels were prepared using Bio-Rad mini gel casting apparatus, and two different acrylamide solutions were applied to separate proteins^[23]. The separated proteins were transferred by perpendicular electrophoresis to a nitrocellulose HybondTM C membrane (Amersham, Buckinghamshire, UK). Monoclonal mouse anti-human primary antibodies Actin 1:250 (#: C4: sc-47778, Santacruz Biotechnology, INC.), Mdm2 1:300 (#: OP46-100UG, Merck Millipore), p21 1:100 (#: OP64, Calbiochem), p53 1:250 (#: 2B2.68: sc-71817, Santacruz Biotechnology, INC.) and Wip1 1:200 (#: F-10: sc-376257, Santacruz Biotechnology, INC.) were used. Secondary goat anti-mouse HRP-conjugated antibodies (#: P0447/P0448, Dako) were applied at 1:1000. 5% milk/1XTBS-Tween (w/v) was used in order to dilute all antibodies. Enhanced chemiluminescence (GE Life Sciences, UK) and X-ray film (Fujifilm, India) were employed to visualize the proteins. Image J software (National Institute of Health, USA) was used to quantify and analyze the intensity of visualized bands, and the results were normalized to DMSO control.

Cell transfection

Harvested Nalm6 cells in the exponential growth phase were resuspended in RPMI-1640 (Gibco, USA) supplemented with 0.5% (v/v) FBS (Gibco, USA). 200 μ L cell suspension containing 2.5×10^6 of cells were transferred into sterile electroporation cuvettes (0.2 cm gap, Bio-Rad, USA) separately (miR-16-5p mimic and negative control). miR-16-5p mimic and negative control (200 nm) (miR-CURY LNA™ miRNA Mimics, Qiagen) were separately added to the cuvettes in the hood just before electroporation, and the cuvettes gently swirled. Then, the cuvette was placed in the holder in the electroporation system (Eppendorf Multiporator®, Germany) at room temperature. Electroporation was performed in accordance with Multiporator® Transfection Protocol with minor changes [Voltage: 250 V, Time constant (τ): 40 μ s, No. of pulses (n): 1] in order to specifically optimize protocol based on the cell type and genetic modifications. After the pulse, the cell suspension was allowed to stand in the cuvette for 5 to 10 minutes at room temperature. Finally, the cell suspension was transferred from the cuvette to 2 mL normal medium in a well of a 6-well plate and incubated for 48 h. In order to determine the impact of overexpression of miR-16-5p on sensitivity to RG7388, 48 h transfected cells were exposed to RG7388 (0.5 μ M) for 6 h. Transfected cells were harvested to evaluate cell viability and silencing assessment.

RNA extraction and cDNA synthesis

Total RNA including preserved miRNAs was extracted from Nalm6 cells and primary samples using TRIZOL reagents (Invitrogen, California, CA) as per the manufacturer's recommendations. The quality of the RNA and its concentration was assessed with a NanoDrop ND-1000 Spectrophotometer (Thermo Fisher Scientific, USA) by the ratio of 260nm:280nm. The complementary DNA (cDNA) for miR-16-5p was synthesized on 200 ng of total RNA using miR-CURY LNA™ microRNA PCR kit (QIAGEN, Germany) and the thermal cycler (GeneAmp PCR Systems, AB Applied Biosystems) according to the manufacturer's guidelines.

Quantitative RT-PCR (qRT-PCR)

Ectopic expression of miR-16-5p was confirmed by real-time PCR assay. qRT-PCR for miR-16-5p converted to cDNA was carried out using the miRCURY LNA SYBR Green PCR kit (Qiagen, Germany), with 50 ng/ μ L of the cDNA samples per 10 μ L final reaction volume, on a Chromo4™ system (BioRad, Foster City, California) as described by the manufacturer. Primers for miR-16-5p quantitative RT-PCR were obtained from Qiagen, and RNU6 small nuclear RNA ((Exiqon, Denmark) was employed as endogenous control for data normalization. $\Delta\Delta$ Ct Method was applied to perform data analysis.

Statistical Analysis

All the presented statistical tests were performed, applying GraphPad Prism version 8.4.3 software. The statistical paired t-test was employed to compare the mean of 3 paired biological repeats, and significant differences are defined as $P < 0.05$.

RESULTS

miR-16-5p is proposed to target WIP1 protein affecting p53 pathway

The miRTarBase experimentally validated microRNA-target interactions database confirmed *PPM1D* as a target for miR-16-5p with strong evidence (Reporter assay, qRT-PCR and Western blot). In terms of miRDB target prediction database, miR-16-5p was at the top 20 miRNAs targeting *PPM1D* expression.

KEGG p53 pathway has shown Wip1 protein as one of the main negative regulators of p53 activity. In addition, Wip1 activates the main negative regulator of p53, Mdm2, and inactivates the kinases which phosphorylate and enhance p53 activity including CHK2 and ATM [Figure 1A]. Furthermore, STRING database confirmed the functional association between Wip1 and p53 and other proteins involved in p53

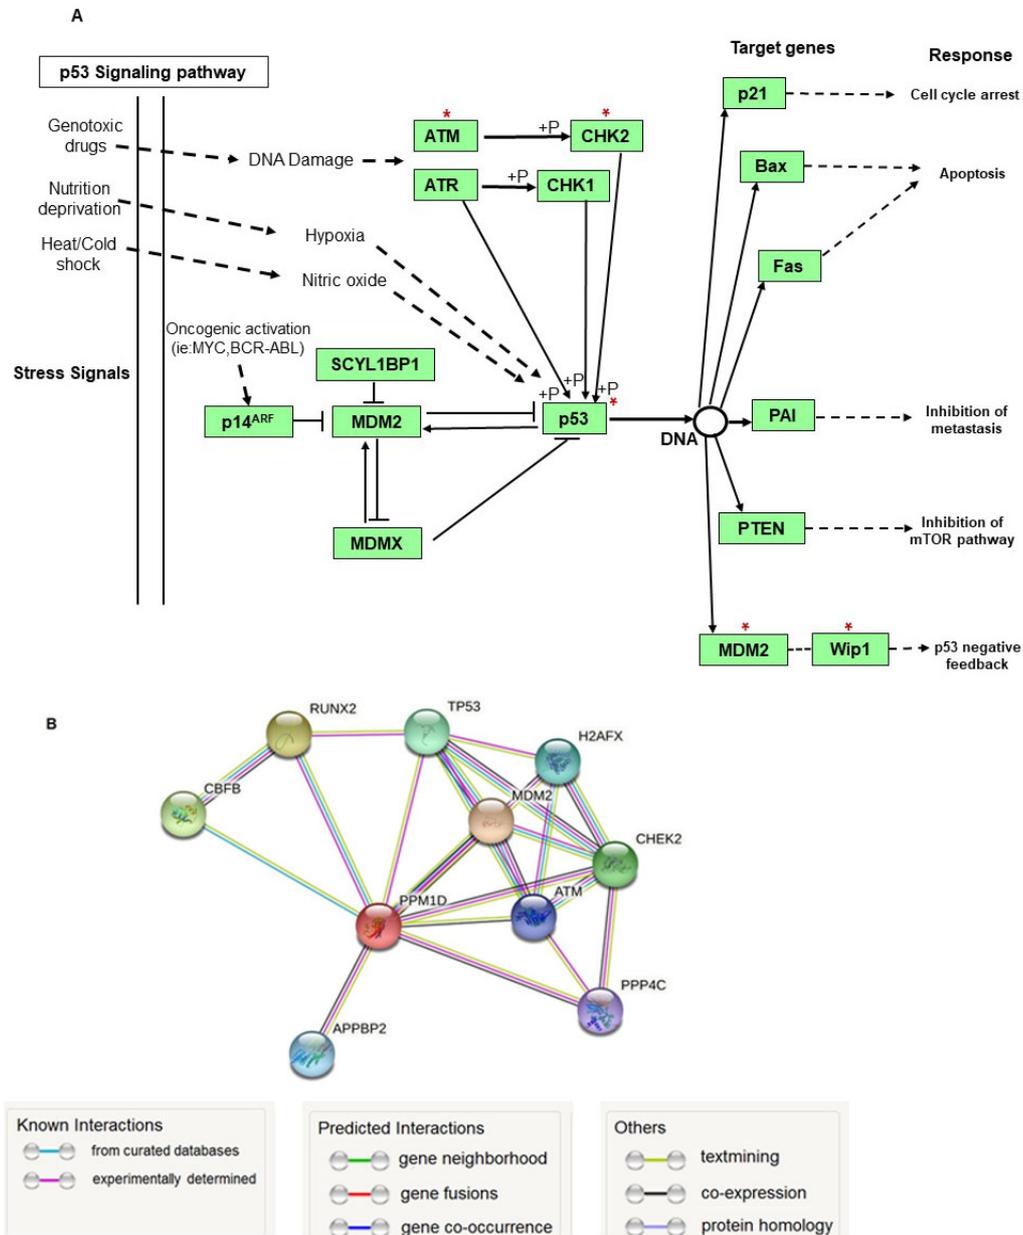

Figure 1. The importance of WIP1 in the p53 signaling pathway and its Protein–protein interaction network. (A) The p53 pathway map (map04115) was provided using the KEGG database. The red stars above each gene represent the genes whose activity is affected by WIP1 via dephosphorylation; (B) WIP1 Protein–protein interaction network was visualized by STRING with high confidence (0.7). The edges represent protein–protein associations which are meant to be specific and meaningful. This does not necessarily mean they are physically binding to each other. activity with a high confidence (0.7 score interaction) [Figure 1B].

The cytotoxic effect of RG7388 on ALL cell lines and primary cultures

The subsequent experiments were carried out to evaluate the sensitivity of two established ALL cell lines and ALL primary cells to RG7388, and the influence of ectopic overexpression of miR-16-5p on this sensitivity. The cytotoxicity of RG7388 and its p53-dependent effect was investigated using the MTT assay on Nalm6 wild-type *TP53* and CCRF-CEM mutant *TP53* cell lines. The LC_{50} values (Lethal Concentration

50%) indicated that wild-type *TP53* Nalm6 cell line was significantly more sensitive to RG7388 (0.27 ± 0.05 (SEM) μM) compared to CCRF-CEM mutant *TP53* cell line ($> 2 \mu\text{M}$) [Figure 2A]. The cytotoxic effect of RG7388 was also investigated on the cell viability of primary cultures generated from materials donated by ALL patients [Table 1]. 10 ALL samples were incubated with DMSO (0.5%) as control and RG7388 (0.5 μM), and they were examined for viability after 72 h using the MTT assay. RG7388 induced a cytotoxic effect on ALL cells, and 60% of those (6 out of 10) were sensitive and 40% (4 out of 10) were resistant to RG7388 with the delivered dose [Figure 2B]. RG7388 led to a significant reduction in the viability of sensitive ALL primary cells compared to their untreated counterpart ($P < 0.05$ or $P < 0.001$), with ALL 278 sample as the most sensitive sample (% viability = $0.66\% \pm 0.04$, $P = 0.0005$). Overall, the median % survival for primary cultures was 53% [Figure 2C]. Notably, 3 out of 4 RG7388 resistant samples (75%) relapsed [Table 1].

Functional activation of the p53 pathway in ALL cell lines and primary cultures in response to RG7388

Functional assessment of the p53 pathway was evaluated by measuring p53 induction and its stabilization following six hours' exposure to RG7388, and consequent overexpression of its downstream targets including Mdm2 and p21^{WAF1} proteins by Western blot. The p53-dependent response to RG7388 showed that RG7388 elevated p53 stabilization and overexpression of p21^{WAF1} and Mdm2 protein levels 6 h after the commencement of treatment in a concentration-dependent manner, and confirmed functional activation of wild-type *TP53* Nalm6 cell line by release from Mdm2. However, as anticipated, it had no impact on the expression of p53-dependent genes in the *TP53*-mutant CCRF-CEM cell line with the delivered dose range of RG7388 [Figure 3A and Supplementary Figure 1].

For the primary cultures with sufficient amount of protein lysates for western blot, there was consistency between MTT assay results and p53 function. RG7388 induced functional stabilization of p53 and expression of its downstream target genes, p21^{WAF1} and MDM2, in ALL samples that showed a significant decrease in their viability rate following treatment with RG7388. Conversely, there was no stabilization of p53 and induction of its downstream targets in primary cultures that were resistant to RG7388 [Figure 3B and Supplementary Figure 2].

RG7388 induces Wip1 expression in a p53-dependent manner

The basal protein levels of Wip1 and its expression levels following treatment with RG7388 at the $1 \times$ and $2 \times$ LC_{50} value for Nalm6 were determined in both Nalm6 and CCRF-CEM cell lines [Figure 3C and Supplementary Figure 3]. RG7388 increased stabilization of p53 protein, with subsequent increased expression of Wip1 protein in Nalm6 cells in a concentration-dependent manner. However, RG7388 failed to stabilize p53 and induce Wip1 in CCRF-CEM cells, indicating p53-dependent expression of Wip1 protein. Notably, both full-length (FL-WIP1) and its previously described shorter isoform (S-WIP1) of Wip1 protein were expressed by CCRF-CEM cell line.

miR-16-5p negatively regulates WIP1 expression and sensitizes Nalm6 cells to RG7388

The p53-Wip1 autoregulatory feedback loop regulates both expression levels of *PPM1D* gene and p53 activity. Previous studies showed that post-transcriptional regulation influences the expression of Wip1 protein and confirmed that miR-16-5p inhibits WIP1 expression through targeting 3'UTR of WIP1 [Figure 4A]. Thus, it is expected that miR-16-5p affects the response to RG7388 through regulating WIP1 in a p53-dependent manner.

To investigate the hypothesis, firstly, Nalm6 cells were transfected with miR-16-5p mimic or scrambled miRNA oligonucleotides as a negative control. Real-time PCR results confirmed high expression of miR-16-5p in Nalm6 cells resulting from the transfection of miR-16-5p mimic after 48 h. A significant

Table 1. Clinicopathological data for 10 samples of pediatric ALL

Patient's number/Variable*	Sex Age (years)	Peripheral blood/Bone marrow	De novo/ Relapsed	Pre-B cell/ T cell	Cytogenetics**	Response to RG7388
ALL 269	Boy (2)	Peripheral blood	De novo	Pre-B cell	No	Sensitive
ALL 270	Girl (2)	Bone marrow	De novo	Pre-B cell	No	Sensitive
ALL 271	Boy (3)	Bone marrow	De novo	Pre-B cell	No	Resistant
ALL 272	Girl (5)	Peripheral blood	Relapsed	Pre-B cell	No	Resistant
ALL 273	Boy (9)	Bone marrow	Relapsed	T cell	No	Resistant
ALL 274	Boy (6)	Bone marrow	De novo	Pre-B cell	T (12, 21)/ETV6-RUNX1	Sensitive

ALL 276	Girl (5)	Peripheral blood	De novo	Pre-B cell	No	Sensitive
ALL 277	Girl (5)	Peripheral blood	Relapsed	T cell	No	Resistant
ALL 278	Boy (12)	Peripheral blood	De novo	Pre-B cell	No	Sensitive

*The blast proportion for all patients' samples was over 70%. **The most common cytogenetics (T (4; 11)/KMT2A-AFF1, T (9; 22)/BCR-ABL1, T (1; 19)/TCF3-PBX1, T (12; 21)/ETV6-RUNX1) were only analyzed.

increase was observed in the ectopic expression of miR-16-5p (by ~ 2.5-fold) compared with DMSO control, mock control, and negative control ($P < 0.05$) [Figure 4B].

We evaluated the protein levels of Wip1, p53, p21^{WAF1} and Mdm2 in Nalm6 treated with RG7388 in the presence of miR-16-5p mimic and negative control in order to investigate the impact of altered levels of miR-16-5p on the expression of the proteins. The high expression of miR-16-5p in Nalm6 led to a significant increase in p53 protein levels (by ~ 3.0 fold) [Figure 4C, 4D], p21^{WAF1} protein levels (by ~ 2.5 fold) [Figure 4C, 4E] and Mdm2 [Figure 4C] compared to Nalm6 transfected with miRNA oligonucleotides as a negative control and DMSO control ($P < 0.05$) irrespective of treatment with RG7388. Interestingly, ectopic overexpression of miR-16-5p significantly suppressed induction of WIP1 in Nalm6 treated with RG7388, while scrambled negative control had no effect on the expression levels of WIP1 after RG7388 treatment. Furthermore, overexpression of miR-16-5p caused a significant upregulation of p53 (by ~ 15.5-fold, $P < 0.01$) [Figure 4C, 4D] and its target genes, p21^{WAF1} (by ~ 2-fold, $P < 0.05$) [Figure 4C, 4E] and Mdm2, in Nalm6 treated with RG7388 compared to negative control treated with RG7388. These results clearly demonstrated that miR-16-5p negatively regulates Wip1 protein levels, which consequently affects the p53 pathway and response to RG7388.

DISCUSSION

Acute lymphoblastic leukemia (ALL) is the most prevalent type of pediatric blood cancer in which *TP53* mutations are infrequent, less than 5%, at diagnosis but rise to about 10% in relapsed ALL^[24]. Although complete remission (CR) is achieved for many patients at the end of the induction phase of treatment, relapse and drug resistance are major challenges in treating cancer^[25]. Recently, p53-Mdm2 binding antagonists have been advanced to restore wild-type p53 function with subsequent induction of cell cycle arrest and apoptosis. These targeted therapeutic agents have shown *in vitro* promising results alone and in

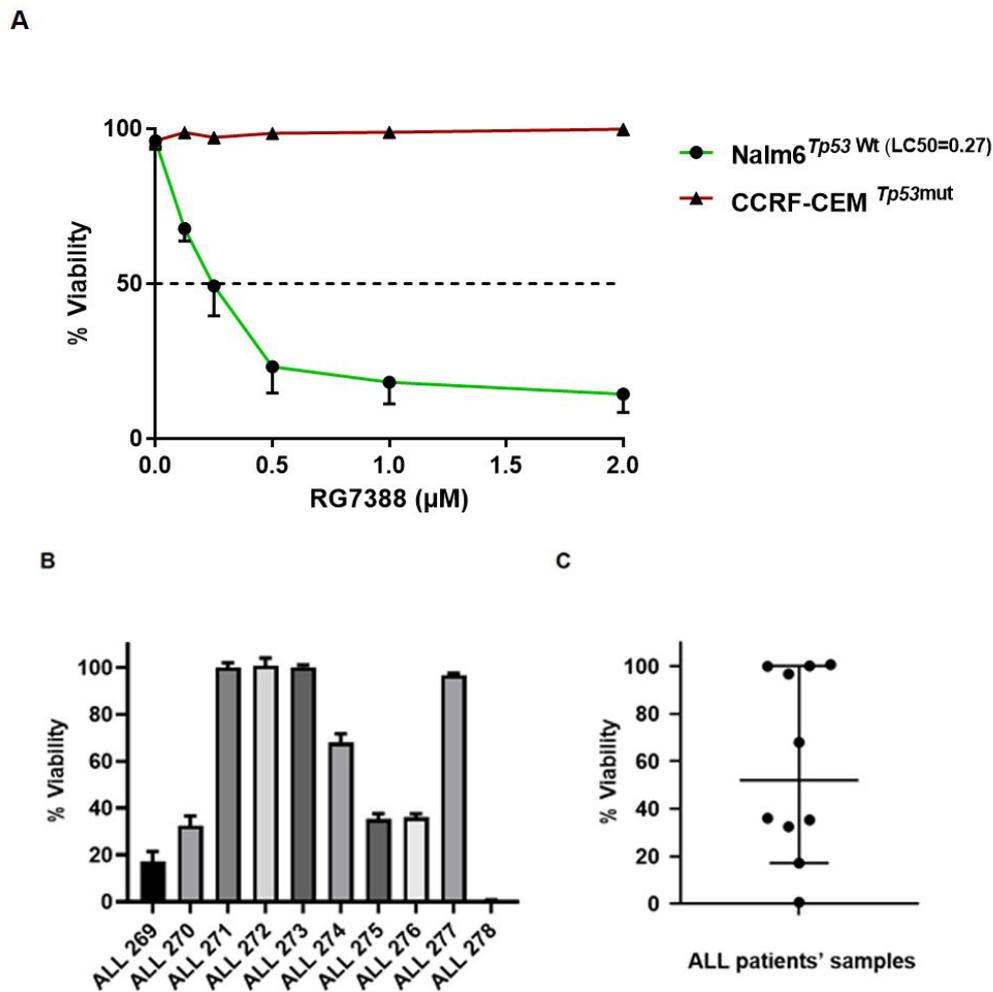

Figure 2. The sensitivity to MDM2 antagonists RG7388 in ALL cell lines and childhood ALL primary cells. (A) Wild-type *TP53* Nalm6 cell line is significantly more sensitive to growth inhibition by RG7388 treatment compared to mutant *TP53* CCRF-CEM cell line; (B) 10 pediatric ALL samples exposed to RG7388 (0.5 μ M) for 72 h. RG7388 markedly decreased cell viability in most samples while assessed by MTT assay; (C) dot-plot of % viability for 10 pediatric ALL samples exposed to RG7388 (0.5 μ M) for 72 h. combined treatments^[26-31], and encouraging clinical trial outcomes in diverse types of cancer including blood malignancies^[8,32-35]. miR-16-5p was previously reported as a post-transcriptional regulator of Wip1 in some types of cancer^[13]. miRTarBase and miRDB microRNA-target interactions databases, KEGG pathway and STRING databases used in this study indicated the critical role of miR-16-5p in p53 activity through targeting PPM1D expression in ALL. Interestingly, the STRING database clearly showed strong interactions between Wip1 and p53 or its regulators comprising ATM, Mdm2 and CHK2 proteins^[20].

The present study evaluated, for the first time, the impact of the Mdm2-p53 binding antagonist RG7388 in ALL cell lines, and primary cultures generated from materials donated by ALL patients. Moreover, this is the first study elucidating the positive effect of ectopic miR-16-5p on increasing sensitivity to RG7388 in *TP53* wild-type leukemic cells.

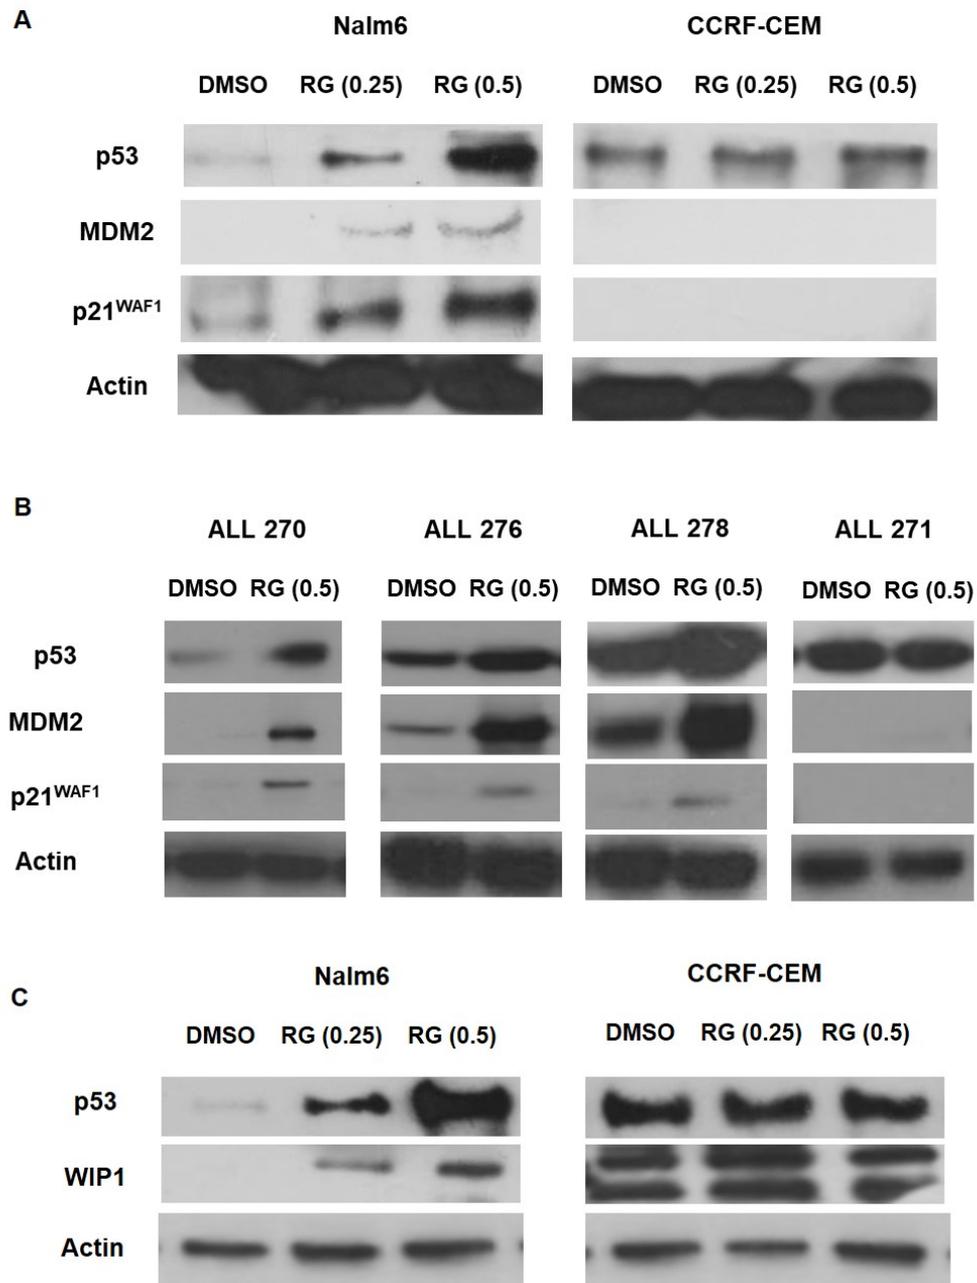

Figure 3. p53 functional stabilization in pediatric ALL cells in response to RG7388. Western blot analysis for (A) established Nalm6 and CCRF-CEM cell lines and (B) representative of patient samples with functional p53 and dysfunctional p53. RG7388 showed stabilization of p53 and upregulation of p53 transcriptional target gene protein levels, MDM2 and p21^{WAF1}, 6 h after the commencement of treatment in wild-type *TP53* Nalm6 and p53 functional ALL cells with the indicated doses (μM). However, it had no effect on downstream transcriptional targets of p53 in mutant *TP53* CCRF-CEM and dysfunctional p53 patient samples with the delivered dose of RG7388 (μM); (C) western blot analysis indicated stabilization of p53 and induction of WIP1 expression following 6 h treatment with indicated doses of RG7388 (μM) in wild-type *TP53* Nalm6 in a concentration manner. Conversely, there was no effect on the p53 stabilization and WIP1 expression in mutant *TP53* CCRF-CEM with the delivered dose range of RG7388 (μM). RG, RG7388. ALL: Acute lymphoblastic leukemia; MDM2: mouse double minute 2 Homolog; WIP1: wild-type p53-induced phosphatase 1.

Among the individual cell lines studied, wild-type *TP53* Nalm6 cell line was significantly more sensitive to RG7388 compared to mutant *TP53* CCRF-CEM cell line, which is in line with its mechanism of action^[35]. These results partially confirm previous limited previous studies that indicated a significant decrease in the

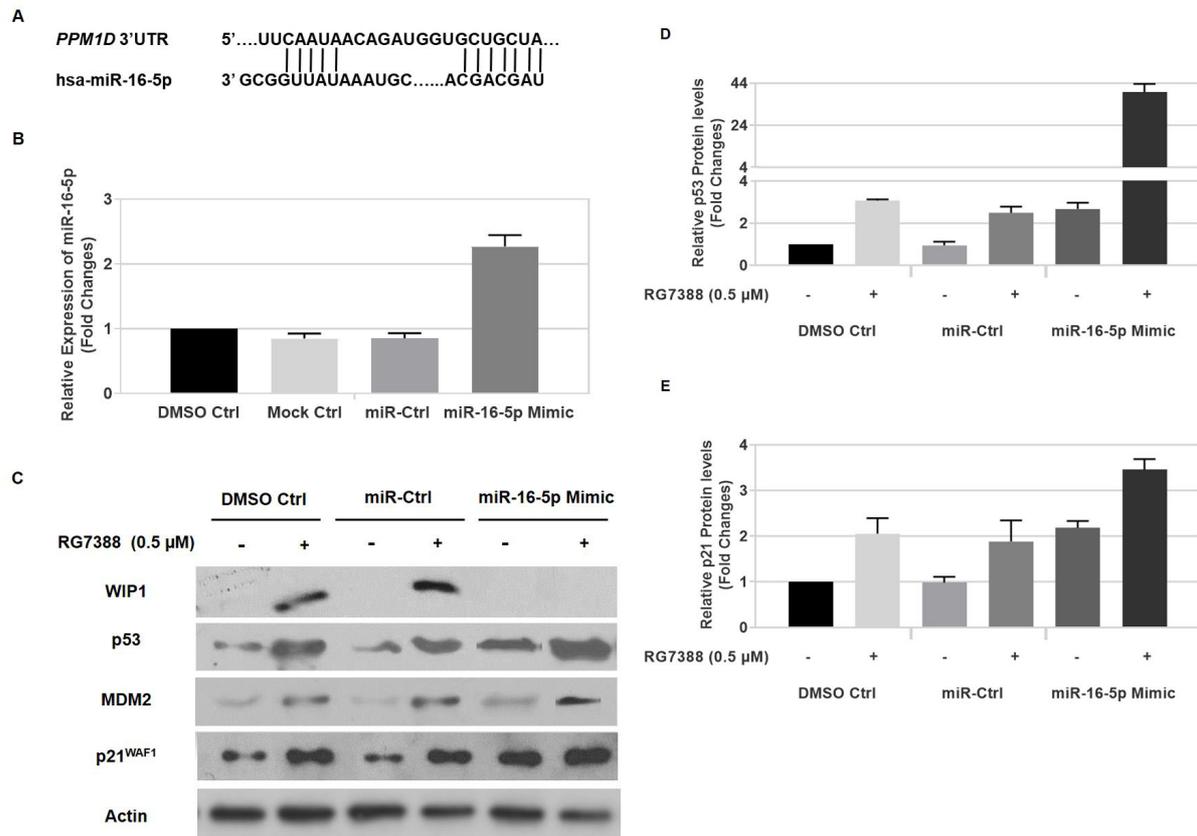

Figure 4. miR-16-5p suppresses WIP1 expression, affects p53 stabilization and its activity, and enhances sensitivity to RG7388. (A) miR-16-5p sequences and its putative binding sites in the 3'-UTR of PPM1D; (B) Nalm6 cells were transfected with negative control miRNA and miR-16-5p mimic (200nM). Total RNA was extracted from DMSO (0.5%) treated Nalm6, mock control, and those transfected with negative control miRNA or miR-16-5p mimic at 48 h after transfection. miR-16-5p levels were measured by quantitative RT-PCR shown significant ectopic overexpression of miR-16-5p in transfected cells with miR-16-5p compared to DMSO control, mock control and negative control miRNA; (C) ectopic overexpression of miR-16-5p suppresses WIP1 expression, enhances p53 stabilization and upregulates expression of p53 target genes, p21^{WAF1} and MDM2 in wild-type *TP53* Nalm6 treated with RG7388. Nalm6 cells were transfected with miR-16-5p (200nM) or scrambled miRNA. Cells were treated with RG7388 (0.5 μM) at 48 h after transfection and their protein levels analyzed at 6 h after RG7388 treatment. The intensity of p53 blots ($P < 0.05$ or $P < 0.1$) (D) and p21^{WAF1} blots ($P < 0.05$) (E) was quantified by Image J software and normalized with the DMSO control. Data shown are the average of three independent experiments and error bars represent SEM. Ctrl, Control. * $P < 0.05$, ** $P < 0.01$

cell viability of wild-type *TP53* ALL cell lines following treatment with Mdm2 inhibitor Nutlin-3a^[36,37].

Within a panel of primary cultures, RG7388 significantly decreased the viability of most ALL cells (6 out of 7, 86%) isolated from *de novo* patients. Conversely, primary cultures derived from relapsed patients were resistant to the cytotoxicity effect of RG7388 at the delivered dose. Given the fact that response to RG7388 is dependent on wild-type p53, resistance to RG7388 could be related to *TP53* mutations that are infrequent in childhood ALL patients at diagnosis, but they increase at relapse. Since the genomic status of *TP53* gene is the major determinant of response to Mdm2 inhibitors, DNA sequencing of *TP53*, as the gold standard method, is highly recommended for identification of *TP53* mutations in primary cells, particularly in the personalized directed use of inhibitors such as RG7388^[38]. It is also possible that amplification/overexpression of WIP1 in different types of cancer including hematological tumors^[10] results in dysfunctional wild-type *TP53* and resistance to p53-dependent treatments comprising Mdm2 inhibitors^[11].

In accord with the action mechanism of Mdm2 inhibitors, RG7388 treatment resulted in more stabilization of p53 and increased expression of its downstream targets, p21^{WAF1} and Mdm2 in wild-type *TP53* Nalm6, in a concentration-dependent manner, and functional p53 primary cultures at the delivered dose of RG7388. In contrast, no significant enhancement of p53 downstream target genes was observed in mutant *TP53* CCRF-CEM and non-functional p53 ALL samples following treatment with RG7388. These outcomes are consistent with other studies that reported induction of the p53 pathway in wild-type *TP53* ALL cell lines after treatment with Nutlin-3a^[36,37], CLL patients treated with RG7388^[28], and Acute myeloid leukemia patients' clinical response to RG7388^[39].

Given the promising phase 1 results observed in blood cancer patients treated with Mdm2 inhibitors RG73122^[40], RG7388^[8,39], and AMG-32^[5], and the prognostic value of miR-16 expression in childhood ALL^[41] and CLL^[15], we evaluated the impact of miR-16-5p expression on the induction of p53 pathway and response to Mdm2 inhibitor RG7388.

Wip1 protein levels were measured at the basal level and following treatment with RG7388 in both Nalm6 and CCRF-CEM cell lines. In comparison with CCRF-CEM, in which WIP1 is highly expressed at the basal levels, WIP1 is not detectable at its basal levels in Nalm6. As expected, RG7388 treatment led to more stabilization of p53 and its target, WIP1, in a concentration-dependent manner in wild-type *TP53* Nalm6. However, there was no stabilization of p53 and no upregulation of WIP1 in *TP53* mutant CCRF-CEM cell line, demonstrating that the effect is p53-dependent. Notably, CCRF-CEM harbors a heterozygous *PPM1D* mutation (c.1327A>G; p.N443D) reported by the COSMIC (Catalogue of Somatic Mutations in Cancer)^[42].

It was also shown that upregulation of miR-16-5p (by ~ 2.5-fold) significantly induced p53 stabilization (by ~ 3-fold) and upregulated its downstream target p21^{WAF1} (by ~ 2.5-fold). p53 is considered as a representative haploinsufficient tumor suppressor gene in which a small change in its protein levels and/or its activity could immensely affect tumorigenesis in both mice and humans^[43]. Interestingly, ectopic overexpression of miR-16-5p dramatically suppressed WIP1 expression after treatment with RG7388, followed by a significant rise in the p53 stabilization (by ~ 15.5-fold) and p21^{WAF1} upregulation (by ~ 2-fold). These results were in accord with several studies indicating the therapeutic impact of combined treatment between Wip1 inhibitor, GSK2830371, and Mdm2 inhibitors for increasing sensitivity to p53-Mdm2 antagonists in wild-type *TP53* cell lines^[11,31,44-46]. Mdm2 inhibitors release p53 from its negative regulator, Mdm2, which results in more stabilization of p53. Inhibition of Wip1 leads to increased phosphorylated p53 at serine 15 which activates the p53 pathway playing a critical role in cell cycle arrest mostly via upregulating of p21^{WAF1}, and apoptosis through upregulating proapoptotic genes including *PUMA*^[11,31,46], and downregulating antiapoptotic genes particularly, *BCL2* and *BIRC5* (survivin)^[46,47]. Furthermore, miR-16-5p targets multiple cell cycle genes simultaneously, which leads to the accumulation of cells in G0/G1^[47-49] and directly targets the antiapoptotic *BCL2* gene which results in enhancing apoptosis^[50,51] and modulating multidrug resistance. Therefore, in addition to genomic status of *TP53* and its downstream target genes involved in apoptosis and cell cycle arrest, the expression levels of miR-16-5p might be considered as a marker to predict the sensitivity to Mdm2 inhibitors like RG7388 and other drugs working through the p53 pathway^[52]. It is of note that local delivery, which is limited to the localized primary tumors, systemic route, viral delivery, and non-viral administration of miRNAs, are choices in delivering miRNAs^[53].

In conclusion, the current study indicated the cytotoxic effect of the Mdm2 inhibitor, RG7388, on ALL patients' primary cells in a p53-dependent manner. Moreover, it was shown that ectopic overexpression of miR-16-5p increases sensitivity to RG7388 in ALL cells by suppressing WIP1 expression and inducing p53 stabilization. These data indicated, for the first time, the mechanistic importance of miR-16-5p in the

pathophysiology of ALL, sensitivity to RG7388, and suggested its combination with RG7388 as a novel strategy for therapeutic targeting of non-mutant p53 pediatric ALL patients.

DECLARATIONS

Acknowledgments

The authors would like to acknowledge Mrs. Saideh Rahmani (University of Isfahan) for purifying mononuclear cells from the collected specimens and all patients and their parents who took part in this study.

Authors' contributions

Study design: Zanjirband M

Acquisition of data: Zanjirband M, Aberuyi N

Analysis and interpretation of data: Zanjirband M, Rahgozar S, Aberuyi N

Manuscript preparation: Zanjirband M, Rahgozar S, Aberuyi N

Statistical analysis: Zanjirband M, Aberuyi N

Availability of data and materials

All data generated or analyzed during the current study are available from the corresponding author upon reasonable request.

Financial support and sponsorship

This work was supported by the University of Isfahan (96/100000/4000).

Conflicts of interest

All authors declared that there are no conflicts of interest.

Ethical approval and consent to participate

This study has been approved by the University of Isfahan review board and ethics committee under ethics agreement number IR.UI.1397.145. The patients' parents were clearly informed regarding the aim of the study, the method and any possible complications related to the bone marrow/blood sampling in written format and verbal explanation. Informed written consent was obtained from every patient's parent before the start of the study by trained medical staff. Participants were assured that they had the right to leave the study at their convenience. Patients' samples were identified through a code number. Clinicopathological data of patients were confidentially kept, and the electronic information was stored on a password-protected computer.

Consent for publication

Consents for publication were obtained.

Abstract

The emergence of chemoresistant disease during chemotherapy with 5-Fluorouracil-based (5-FU-based) regimens is an important factor in the mortality of metastatic CRC (mCRC). The causes of 5-FU resistance are multifactorial, and besides DNA mismatch repair deficiency (MMR-D), there are no widely accepted criteria for determining which CRC patients are not likely to be responsive to 5-FU-based therapy. Thus, there is a need to systematically understand the mechanistic basis for 5-FU treatment failure and an urgent need to develop new approaches for circumventing the major causes of 5-FU resistance. In this manuscript, we review mechanisms of 5-FU resistance with an emphasis on: (1) altered anabolic metabolism limiting the formation of the primary active metabolite Fluorodeoxyuridylate (5-Fluoro-2'-deoxyuridine-5'-O-monophosphate; FdUMP); (2) elevated expression or activity of the primary enzymatic target thymidylate synthase (TS); and (3) dysregulated programmed cell death as important causes of 5-FU resistance. Importantly, these causes of 5-FU resistance can potentially be overcome through the use of next-generation fluoropyrimidine (FP) polymers (e.g., CF10) that display reduced dependence on anabolic metabolism and more potent TS inhibitory activity.

INTRODUCTION

It is estimated that 1.93 million colorectal cancer (CRC) cases will be newly diagnosed in 2022 worldwide, with 0.94 million CRC-caused deaths. According to the American Cancer Society (ACS), CRC is the 2nd most common cause of cancer-related mortality in the United States, accounting for ~51,000 deaths annually^[1,2]. Surgical approaches are the primary treatment modality for limited-stage CRC when there is no evidence of distant metastasis. However, in elderly patients that constitute most new CRC diagnoses, there is an increased risk of post-operative complications^[3]. Adjuvant chemotherapy with 5-Fluorouracil-based (5-FU-based) combinations reduces the risk of disease recurrence in stage III and high-risk stage II CRC. Chemotherapy with 5-FU-based combinations together with biologics (e.g., bevacizumab or cetuximab) and immunotherapy in some instances are also used to treat metastatic CRC (mCRC)^[4,5], which often occurs in liver and is frequently not amenable to surgical resection.

The chemotherapeutic molecule most widely used for CRC treatment is 5-fluorouracil (5-FU), a synthetic fluorinated pyrimidine (FP) analog of uracil that is used to treat > 2 million cancer patients each year worldwide^[6,7]. In addition to its widespread use for CRC treatment, 5-FU is also widely used to treat pancreatic, stomach, esophageal, breast, and head-and-neck cancer. 5-FU belongs to the antimetabolite class of anti-cancer drugs^[8,9], {Chen, 2019 #42}{Chen, 2019 #42}{Chen, 2019 #42}{Chen, 2019 #42} and its activity results from intracellular conversion into active metabolites that interfere in thymidine biosynthesis and affect DNA- and RNA-mediated processes^[10,11]{Chen, 2019 #42}{Chen, 2019 #43}. The primary molecular target of 5-FU's anti-cancer activity is thymidylate synthase (TS), which is required for *de novo* thymidylate (thymidine 5'-O-monophosphate) biosynthesis^[12]. TS is a well-validated target for cancer chemotherapy^[13] and aggressive malignant cells are relatively more reliant on *de novo* thymidylate biosynthesis than non-malignant cells that utilize the alternative salvage pathway^[14]. The importance of targeting TS for 5-FU's anti-cancer activity is underscored by its invariant clinical use in combination with folinic acid (Leucovorin; LV), a reduced folate co-factor that binds TS in a ternary complex with 5-Fluoro-2'-deoxyuridine-5'-O-monophosphate (FdUMP), the 5-FU metabolite that irreversibly inhibits TS enzymatic activity. TS inhibition depletes cellular stores of thymidylate, resulting in increased misincorporation of 2'-deoxyuridine-5'-triphosphate (dUTP) in DNA. In cells treated with FP drugs, 5-fluoro-2'-deoxyuridine-5'-triphosphate (FdUTP) is also misincorporated into DNA, and this causes Topoisomerase 1 (Top1)-mediated DNA damage^[15]. The Gmeiner lab has developed FP polymers (e.g., CF10) that directly release FdUMP without a requirement for anabolic metabolism. CF10 inhibits TS at 100-1,000-fold lower concentrations than 5-FU in CRC cells^[16-18] and causes extensive Top1-mediated DNA damage to generate increased replication stress, a point of therapeutic vulnerability in CRC cells.

While the anti-cancer activities of 5-FU and other FP drugs are considered to primarily result from TS inhibition and DNA damage, only a relatively small percentage of 5-FU administered to humans is converted to FdUMP and DNA-directed metabolites (< 5%^[19]). Most 5-FU (~80%) is either degraded in the liver or excreted intact in the urine^[20]. Among anabolic metabolites, ribonucleotides are produced at approximately 10-fold greater levels than deoxyribonucleotides^[20,21]. The importance of RNA-directed metabolites for 5-FU's anti-cancer activity remains an active area of investigation^[22]; however, the systemic toxicities associated with RNA-directed metabolites are established and include gastrointestinal tract toxicity^[23,24] and immunosuppression^[23,25], both of which are alleviated by uridine administration^[26] to dilute

5-FU's effects on RNA-mediated processes. Patients that are deficient in 5-FU catabolism are highly vulnerable to serious systemic toxicities if treated with 5-FU^[27]. Approximately 5% of the human population display polymorphisms in the gene encoding dihydropyrimidine dehydrogenase (*DPYD*) that catalyzes the initial step in 5-FU degradation and 5-FU use at standard levels is contraindicated in these patients^[28].

5-FU remains a central component of CRC treatment both in the adjuvant setting and in the treatment of mCRC^[4,5], which is the cause of cancer-related lethality. While 5-FU is just one component in combination therapy regimens such as FOLFOX and FOLFIRI that combine folinic acid, 5-FU, and either oxaliplatin (FOLFOX) or irinotecan (FOLFIRI), understanding the mechanistic basis for 5-FU resistance can help guide the development of new and more effective therapeutic approaches. FOLFOX or FOLFIRI are frequently used in frontline treatment of mCRC, often in combination with a biologic, such as bevacizumab^[29]. While current 5-FU-based chemotherapy regimens have contributed to significantly improved survival for mCRC patients (~20 months;^[30]), 5-year survival remains rare, < 14%, indicating a critical need to understand the mechanistic basis of resistance and develop new strategies to more completely eradicate metastatic disease^[31]. Innate or acquired resistance remains a prominent cause of treatment failure for patients with metastatic cancer. 5-FU resistance can result from multiple causes; however, a critical review of the literature indicates cancer cells adapt to 5-FU's cytotoxic effects through: (1) decreasing intracellular FdUMP levels [Figure 1]; (2) elevating activity of the target enzyme, TS; and (3) dysregulating the balance between autophagy and apoptosis to favor cell survival. These endpoints are achieved via multiple mechanisms making overcoming resistance a challenging endeavor. This review focuses on addressing the causes of clinical resistance to 5-FU, considering both clinical data and cellular models of CRC. We review mechanisms by which 5-FU-based therapy fails, intending to provide insight into novel strategies to overcome resistance and improve outcomes beyond the incremental gains achieved in recent years^[32].

CLINICAL DETERMINANTS OF 5-FU RESPONSE IN CRC TREATMENT

The applicability of 5-FU-based chemotherapy for CRC treatment depends upon several factors. For patients with stage III CRC or diagnosed with stage II CRC with risk factors consistent with an elevated likelihood for relapse, 5-FU-based adjuvant chemotherapy is recommended unless tumor biopsy demonstrates high microsatellite instability (MSI-H) or deficiency in DNA mismatch repair (MMR-D). For patients with MSI-High or MMR-D primary CRC tumors, which include familial syndromes such as Lynch syndrome, 5-FU-based regimens are ineffective and testing for MMR-D status prior to treatment is standard care. Testing for MMR-D status is also required for establishing responsiveness to immune checkpoint blockade immunotherapy, which is relatively more effective in CRC patients with high tumor mutational burden associated with MMR-D^[33]. MSI testing by polymerase chain reaction (PCR) and immunohistochemistry (IHC) is used to establish MMR-D^[34]. Two antibody IHC testing for MSH6 and PMS2 is used to identify MMR-proficient CRC patients, and if deficiency is suspected, IHC for mutS homolog 2 (MSH2) and mutL homolog 1 (MLH1) are undertaken to establish MMR-D^[35]. MLH1 promoter methylation testing is done for cases with MLH1-IHC loss.

Relevance of MMR-D for CRC chemotherapy is that, in general, MSI-High and MMR-D in early-stage primary colon cancer confer a good prognosis and NCCN does not recommend adjuvant 5-FU for stage II CRC that is MSI-high. However, the FOLFOX regimen is beneficial in MSI-high stage III^[36], and patients with Transforming growth factor- β_{RII} ($TGF-\beta_{RII}$) mutations in particular may be responsive to 5-FU-based therapy^[37]. The $TGF-\beta$ pathway also is implicated in drug resistance in pre-clinical studies and specific inhibition of $TGF-\beta_1$ restored the sensitivity of resistant CRC cells to 5-FU^[38]. Similarly, for patients with mCRC that is MSI-H or MMR-D, alternative frontline therapy to 5-FU-based therapy is implemented,

central and well-established chemotherapy target^[13]. The structural basis for TS inhibition by FPs was shown to result from nucleophilic attack by Cys195 at C6 of FdUMP, resulting in irreversible enzyme inhibition via a ternary complex that also includes a reduced folate co-factor^[49].

The relationship between TS levels and response to 5-FU, other FPs, or TS inhibitors is complex, in part because while elevated TS levels contribute to resistance (since more FdUMP is required for TS inhibition), but very low TS levels slow cell proliferation, which is necessary for replication-dependent DNA damage. Further, establishing elevated TS as a cause of resistance to 5-FU or other TS-targeted therapeutics is challenging because TS is regulated at multiple levels including through gene amplification, polymorphisms in the promoter, and upregulation of transcription factors that regulate its intratumor expression [Figure 2]. TS levels and activity^[52] significantly correlate with response to 5-FU-based treatment and LV enhanced TS inhibition. However, incorporation of 5-FU into either DNA or RNA does not correlate with response to 5-FU^[53].

Transcriptional regulation of TYMS

Transcriptionally, *TYMS* (encoding TS) is regulated by E2F family transcription factors^[54] in an S-phase-dependent manner^[55]. *TYMS* expression is also sensitive to Myc levels and silencing *TYMS* decreases the oncogenic properties of elevated MYC in some cell contexts^[56]. Recently, an analysis from the Cancer Genome Atlas (TCGA) database revealed lower *TYMS* was associated with better response to FOLFOX/FOLFIRI therapy in mCRC patients and MYC was identified as an upstream controller of genes that regulate response to 5-FU+folate therapy^[57]. The forkhead transcription factor forkhead box M1 (FOXO1) is regulated by E2F1 and directly upregulates *TYMS* and is responsive to DNA damage. Elevated FOXO1 is a cause of 5-FU resistance through the upregulation of *TYMS*^[58], and recent studies indicate targeting FOXO1 can overcome 5-FU resistance^[59]. Other signaling pathways may upregulate *TYMS* and cause 5-FU resistance, including HSP90/Src^[60]. Further, *TYMS* is regulated by the MALAT1-miRNA network^[61] and other miRNAs that regulate drug resistance^[62] and can be used as biomarkers^[63].

Gene amplification of TYMS

The importance of TS gene and protein expression for 5-FU resistance was established in CRC tumors. Responsive patients had significantly lower mean TS protein and gene levels relative to non-responsive patients^[64]. Further, CRC cells selected for acquired 5-FU resistance displayed elevated TS, which occurred through gene amplification^[65]. Elevated TS is associated with clinical resistance to 5-FU^[66], consistent with TS being the primary molecular target of FPs. Several studies^[67,68], including a meta-analysis of 13 studies^[69], demonstrated that elevated TS was associated with poor outcomes. However, multiple studies indicate the relationship between TS expression and 5-FU response is complex and may depend on the extent of TS nuclear localization or the expression of other genes, particularly those regulating 5-FU metabolism including dihydropyrimidine dehydrogenase deficiency (DPD) and TP^[66]. TS undergoes reversible SUMOylation^[70] and localizes to the nucleus (nTS) as part of a multi-protein complex that enables efficient *de novo* dTP biosynthesis during S-phase^[71]. Clinical studies indicate that increased intratumor nuclear localization of TS may be a better indicator of disease aggressiveness than overall TS levels^[72]. *TYMS* gene amplification is detected in mCRC from patients pre-treated with 5-FU-based chemotherapy and was associated with shorter median survival for patients treated with chemotherapy following surgical resection^[73]. A summary of studies in which TS gene amplification was implicated with 5-FU resistance is included in Table 1.

TSER and alternative causes of elevated TS

In addition to *TYMS* gene amplification and increased transcription, at least three other processes are potential factors that could increase TS levels and contribute to 5-FU resistance [Figure 2]: i) TS enhancer

Table 1. TS Gene Amplification in 5-FU Resistance

Tissue/cells	Frequency/treatment	Site	Reference
mCRC	18%	Liver metastases	[73]
mCRC	23%	Liver metastases	[74]
CRC	Increased progression	Colon cancer	[75]
CRC cells	FdU treatment	Colon cancer cells	[76]
CRC cells	5-FU treatment	Colon cancer cells	[65]

TS: thymidylate synthase; mCRC: metastatic colorectal cancer; CRC: colorectal cancer.

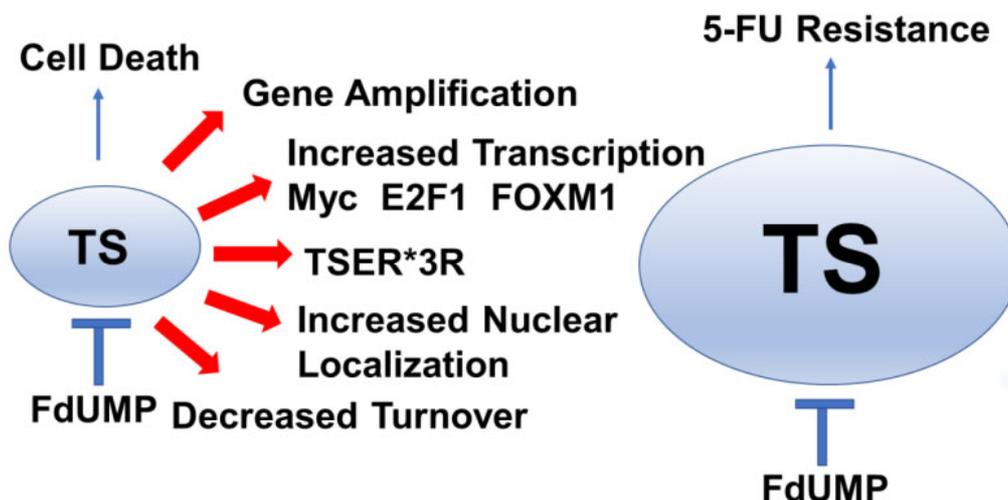

Figure 2. 5-FU Resistance develops from processes that increase thymidylate synthase (TS) activity in cancer cells. Increased TS activity can result from multiple processes including gene amplification, increased transcription, TSER*3R polymorphism, increased TS nuclear localization, and decreased TS protein degradation, which are indicated by red arrows. Increased TS activity renders cells 5-FU-resistant because FdUMP levels are insufficient to inhibit all the TS available. 5-FU: 5-Fluorouracil; FdUMP: 5-Fluoro-2'-deoxyuridine-5'-O-monophosphate; FOXM1: forkhead box M1.

region (TSER) polymorphisms; ii) TS translational autoregulation; iii) TS proteasomal degradation. Polymorphisms in the 5'-UTR of *TYMS* contribute to elevated *TYMS* expression in some contexts^[77,78]. A triple tandem repeat (TSER*3)^[79] in the 5'-UTR of the TS gene^[80] resulted in elevated *TYMS* expression and 5-FU resistance^[81]. The clinical significance of TSER genotypes remains largely unproven in CRC; however, prospective selection of patients with gastric cancer have at least one TSER*2 allele favoring lower *TYMS* expression therapy resulted in an encouraging disease control rate for treatment with FOLFOX^[82]. Further, *TYMS* polymorphisms, together with *KRAS* and *BRAF* mutation status, retrospectively, were associated with reduced relapse in CRC^[83]. TS also poses a negative autoregulatory function at the translational level by binding to its own mRNA; thus, it prevents the synthesis of functional TS enzyme^[73]. Autoinhibition of TS protein expression is countered by FdUMP binding and ternary complex formation. At present, there is no evidence that autoregulation of TS by this mechanism contributes to 5-FU resistance. However, another aspect of translation is affected by 5-FU, which is the efficiency and selection of proteins translated by the ribosome^[84]. TS also undergoes proteasomal degradation and TS levels reflect a dynamic balance of new protein synthesis, dependent upon gene expression and translational efficiency, that is countered by the rate of degradation for expressed protein. A recent study showed that decreased O-GlcNAc transferase (OGT), an enzyme responsible for post-translational modification of multiple proteins including TS, affected TS proteasomal degradation in 5-FU-resistant cells^[85].

Increased TS and intrinsic 5-FU resistance

The elevated expression of TS is commonly accepted as a primary molecular mechanism for acquired 5-FU resistance^[86], but it also is important for intrinsic resistance. The stability of the ternary complex is highly dependent on 5,10-methylenetetrahydrofolate (CH₂THF) levels^[78], and lack of CH₂THF creates an unstable TS: FdUMP binary complex resulting in poor inhibition^[81,86,87]. Increased TS level prior to 5-FU-based treatments is associated with perturbed folate pools, which cause intrinsic resistance compared to acquired resistance associated with upregulated *TYMS* expression and gene amplification^[73,86]. These findings suggest that patients with tumors showing TS amplification prior to treatment should not be treated with 5-FU to avoid systemic toxicity without the likelihood of clinical benefit^[73,74].

GENES MODULATING 5-FU METABOLISM

Acquired drug resistance is a principal cause of treatment failure and significantly contributes to cancer-related mortality. In the case of 5-FU, elevated TS is clinically established as a significant cause of drug resistance^[69]. Still, other reasons have been identified, and prominent among them are alterations in genes that modulate 5-FU metabolism, affecting both its degradation and its conversion to FdUMP, the TS inhibitory metabolite^[88] [Figure 1]. A key aspect of 5-FU activity, toxicity, and resistance is mediated by *DPYD*, the gene encoding DPD, the first and rate-limiting step in 5-FU degradation. Atypical 5-FU degradation in liver is associated with serious systemic toxicities^[89]. In many countries, genetic screening is used to identify CRC patients with *DPYD* polymorphisms associated with decreased DPD activity that result in serious 5-FU toxicities unless the administered dose is reduced from standard dosing^[90]. Since DPD is not the only potential cause of altered 5-FU toxicity or sub-optimal therapeutic response, alternative procedures such as therapeutic drug monitoring^[91] are used to quantify patient response on an individualized basis and to customize 5-FU treatment to account for individual variations in drug metabolism.

Intratumor 5-FU catabolism

In addition to the role of *DPYD* polymorphisms in modulating 5-FU toxicity and therapeutic response by affecting systemic drug degradation, intra-tumoral *DPYD* expression is an important factor in modulating therapeutic response. For example, elevated intra-tumoral *DPYD* expression, together with elevated *TYMS*, is associated with poor outcomes in CRC patients treated with 5-FU-based chemotherapy^[66]. A third gene, thymidine phosphorylase (TP; encoded by *TYMP*), was implicated together with *DPYD* and *TYMS* in this study. TP catalyzes a reversible reaction that may produce thymidine or 2'-deoxyuridine, or analogs such as 5-fluoro-2'-deoxyuridine (FdU), from their respective nucleobases (e.g., 5-FU), together with 2'-deoxyribose 1-phosphate. Alternatively, TP degrades thymidine analogs such as FdU to the nucleobase after dephosphorylation by ecto-5'-nucleotidase (NT5E)^[92]. The directionality of TP catalysis depends on intra-tumor substrate/product ratios; however, levels of 2'-deoxyribose 1-phosphate in plasma were also found to be predictive of chemotherapy sensitivity in gastric cancer that included a fluoropyrimidine^[93]. Findings from this study^[66] that elevated *TYMP* levels together with *TYMS* and *DPYD* are associated with decreased response to 5-FU are consistent with TP primarily catalyzing FdU degradation in CRC tumors and resistance to 5-FU is associated with elevated *TYMP* expression. Further, TP-mediated degradation of trifluorothymidine (TFT), the FP component of TAS-102, limits activity resulting in the inclusion of a TP inhibitor, Tipiracil^[94]. TP is also known as platelet-derived endothelial cell growth factor (PDEC GF), a growth factor promoting angiogenesis, and increased PDEC GF/TP is a prognostic factor for poor survival in CRC^[95] that acts through the production of 2'-deoxyribose 1-phosphate from thymidine to promote chemotaxis of vascular endothelial cells^[96].

Anabolic 5-FU metabolism and resistance

The anabolic biosynthesis of FdUMP from 5-FU can occur via either of two major pathways: (1) TP/thymidine kinase (TK) in which FdUMP is produced by 5-FU in two steps; or (2) via a multi-step biosynthetic pathway (UMPS/RNR) that involves UMP synthase (UMPS), uridine kinase (UK), and UMP kinase (UMPK) to produce FUDP. FUDP is a substrate for ribonucleotide reductase (RNR) to produce FdUDP, which can be converted to 5-fluoro-2'-deoxyuridine-5'-diphosphate (FdUDP) through conversion to FdUTP followed by dUTPase cleavage. Enzymes important for the *de novo* biosynthesis of pyrimidines are upregulated in CRC relative to non-malignant tissue^[97], and reduced activities of these enzymes which may occur via altered splicing^[88,98] are associated with 5-FU resistance^[99]. The importance of FdUMP biosynthesis via the UMPS/RNR pathway is demonstrated by studies that identify reduced expression and activity of enzymes in this pathway in 5-FU-resistant cells. Studies in KM12C xenograft tumors showed resistance to 5-FU was associated with decreased RNR activity^[100], while analysis of clinical samples indicated 5-FU resistance was associated with high TS mRNA and low RNR activity^[101].

Collectively, the preponderance of evidence indicates that altered *de novo* thymidine biosynthesis, either by affecting TS expression [Figure 2] or modulating genes important for 5-FU anabolic metabolism to FdUMP [Figure 1], is central to 5-FU resistance. In a few instances, 5-FU resistance is mediated by changes affecting RNA-directed processes including tRNA modifications^[102,103] and rRNA^[22]. However, the clinical significance of RNA-directed activities for 5-FU anti-tumor activity is not yet proven. Further evidence for anabolic metabolism of 5-FU to FdUMP being important for 5-FU resistance comes from studies demonstrating elevated expression of ABCC10^[104] and ABCC5^[105], two ATP binding cassette proteins^[106] that mediate FdUMP efflux from 5-FU-treated cells, cause of 5-FU resistance as does elevated FOXM1, a major transcriptional regulator of ABCC10^[104] [Figure 1].

CELL DEATH SIGNALING IN 5-FU RESISTANCE

The cytotoxicity of multiple anti-cancer drugs, including 5-FU, depends on the activation of programmed cell death that irreversibly commits drug-treated cells to destruction^[107,108]. p53 is considered to be the most highly mutated gene in cancer and it plays a central role in determining if drug-treated cells undergo cell cycle arrest mediated by p53's downstream effector p21, or initiate apoptosis mediated by Bax and other p53-dependent pro-apoptotic genes^[109] [Figure 3]. In the case of established DNA-damaging drugs such as Adriamycin, either p53 or p21 deficiency leads to loss of the G1/S checkpoint and efficient apoptosis^[110]. However, 5-FU deletion of p53 in HCT-116 cells resulted in resistance to apoptosis and 5-FU was less effective towards p53^{-/-} HCT-116 xenografts relative to isogenic tumors that were p53^{+/-}. Furthermore, 5-FU-induced apoptosis both required p53 and was inhibited by exogenous uridine, but not thymidine, consistent with apoptosis induction in response to an RNA-directed process under these treatment conditions^[110]. Studies from our laboratory confirm that p53 deletion causes 5-FU resistance in HCT-116 cells with expression of the R248W gain of function p53 mutation causing greater resistance, while the DNA-directed FP polymer CF10 showed reduced resistance indices relative to 5-FU^[1].

However, even in cell models of CRC, there is variability in the extent that p53 is required for 5-FU-induced apoptosis. Studies report that 5-FU-induced apoptosis occurs in both wild-type and mutant p53 CRC cells with increased expression of the pro-apoptotic Bcl-2 family proteins Bax and Bak identified as being particularly important for 5-FU-induced apoptosis^[111] [Figure 3]. The importance of p53 for regulating 5-FU-induced apoptosis has also been shown to occur via altered chromatin accessibility upon 5-FU treatment that affects the transcription of genes important for apoptosis^[112]. The clinical significance of p53 mutations for 5-FU resistance is not established, although some clinical data indicate *TP53* mutations confer a worse prognosis^[113], while p53 together with Rb and the anti-apoptotic bcl-family member Mcl-1

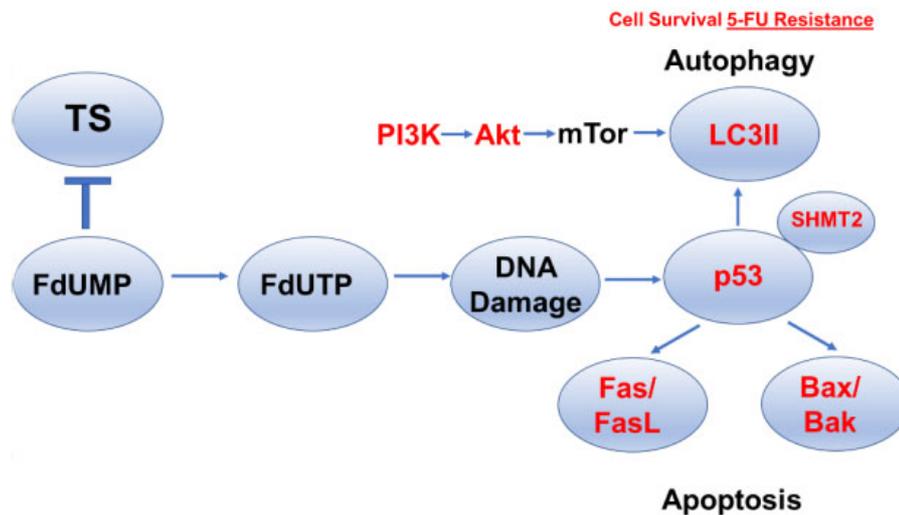

Figure 3. 5-FU Resistance develops from an altered balance between autophagy, which favors cell survival and apoptosis in 5-FU-treated cells. p53 is a key regulator of autophagy/apoptosis balance in 5-FU-treated cells and is modulated by SHMT2. Increased signaling through the PI3K/Akt/mTOR pathway stimulates LC3II and upregulates autophagy to promote cell survival and 5-FU resistance. Induction of apoptosis involves upregulation of the death receptor pathway or mitochondrial pathway for programmed cell death, and downregulation of Fas/FasL or Bax/Bak decreases 5-FU-induced apoptosis and promotes cell survival and 5-FU resistance. 5-FU: 5-Fluorouracil; TS: thymidylate synthase; FdUMP: 5-Fluoro-2'-deoxyuridine-5'-O-monophosphate; FdUTP: 5-fluoro-2'-deoxyuridine-5'-triphosphate; SHMT2: serine hydroxymethyl transferase.

correlated with clinical outcomes in patients with colorectal liver metastases^[114]. Factors other than p53 that are important for activating apoptosis in response to 5-FU treatment include Fas, which was shown to be induced in response to 5-FU treatment in a p53-dependent manner and to regulate apoptosis^[115] [Figure 3]. Houghton and co-workers showed that different CRC cell lines varied in the efficiency of Fas upregulation in response to 5-FU/LV treatment and this correlated with the efficiency of thymidine reversal, indicating 5-FU's DNA-directed effects were cell line dependent and correlated with Fas upregulation and activation of extrinsic apoptosis^[116]. Resistance to 5-FU-induced Fas upregulation and apoptosis can occur via methylation of the Fas promoter, silencing its expression, which can be reversed by 5-Aza deoxycytidine^[117]. Clinical significance for Fas upregulation in 5-FU response was shown by increased Fas expression in biopsy specimens following 5-FU treatment^[118].

AUTOPHAGY IN 5-FU RESISTANCE

Autophagy plays an important role in tumorigenesis and modulating drug response and can either be complementary to apoptosis by promoting drug lethality or protective of the cytotoxic effects of drug treatment^[119]. Activation of the PI3K/Akt/mTOR signaling pathway upregulates autophagosome formation and inhibitors of this pathway modulate drug response, in part, through downregulating autophagy. Treatment of CRC cells with 5-FU was shown to increase LC3-II levels consistent with autophagy activation and co-treatment with 3-methyl adenine (3-MA), a PI3K inhibitor, blocked autophagosome formation and promoted 5-FU-induced apoptosis implicating a protective role for autophagy in 5-FU treatment^[120] [Figure 3]. However, reduced autophagy has also been reported in 5-FU-resistant CRC cells^[121]. Overactivation of the Akt pathway is also associated with 5-FU resistance and Akt inhibition may overcome resistance in some CRC cells^[122], in part by modulating autophagy, while miRNA regulation of Akt deactivation by the PP2A phosphatase complex also regulates 5-FU resistance^[123]. The autophagy inhibitor chloroquine also enhanced the lethality of 5-FU to CRC cells, and in these studies, a serine hydroxymethyl transferase (SHMT2) was shown to regulate 5-FU resistance by binding p53 and inhibiting its degradation [Figure 3]. Overall, SHMT2 was upregulated in CRC tissue compared to non-malignant tissue; however,

patients with low SHMT2 had worse outcomes and this correlated with elevated LC3-II and p62 consistent with autophagy activation in SHMT2-low, 5-FU-resistant CRC^[124]. Interestingly, trifluorothymidine (TFT), the FP used in TAS-102, differed from 5-FU in the extent of activating autophagic survival^[125]. Activation of the p38MAPK pathway is also a determinant in autophagy activation and modulates cellular responses to 5-FU. Inhibition of the p38MAPK pathway correlated with attenuation in 5-FU-mediated apoptosis and promoted CRC cell resistance^[126]. Thus, the p38MAPK signaling pathway modulates 5-FU resistance by regulating the pivot between autophagy and apoptosis^[126]. The autophagy-regulated gene HSPB8 was found to be key in regulating interactions with the tumor microenvironment that regulate 5-FU resistance^[127]. Autophagosome formation is also regulated by Rho kinases^[128], which are implicated in 5-FU resistance^[129]. Curcumin has been studied to inhibit AMPK/ULK1-dependent autophagy with the potential to overcome 5-FU resistance through autophagy activation^[130], and studies from our laboratory indicate curcumin enhances the cytotoxicity of DNA-directed polymeric fluoropyrimidines^[131,132].

CONCLUSION

5-FU remains central to the management of colorectal cancer and it is widely used both in the adjuvant setting to treat CRC patients with limited-stage disease and in combination with chemotherapy regimens to treat mCRC^[4]. The evasion of 5-FU cytotoxicity through intrinsic or acquired resistance in patient tumors contributes to poor outcomes manifest either as a high rate of relapse despite adjuvant chemotherapy or limited survival in the metastatic setting despite multiple lines of chemotherapy that include 5-FU or other FP drugs^[5]. Lack of response to 5-FU chemotherapy is predictable in patients with deficiencies in DNA MMR, or high microsatellite instability, and therapy with 5-FU is contra-indicated in these patients. 5-FU therapy is also predictably toxic in patients with polymorphisms in *DPYD* that limit 5-FU degradation in the liver^[89], and these patients require special management^[90]. Beyond these limited exclusions, there are currently no defined criteria for determining which CRC patients are not likely to be responsive to 5-FU-based therapy. Thus, there is a need to systematically understand the mechanistic basis for 5-FU treatment failure, and an urgent need to develop new approaches for circumventing major causes of 5-FU resistance.

In this review, we have summarized major mechanisms that contribute to 5-FU resistance with an emphasis on those for which available data support clinical significance and that affect the on-target activity of 5-FU (TS inhibition). The causes of colorectal cancer are multi-factorial and involve both lifestyle choice and personalized genetic susceptibility^[133]. Further, response to treatment also depends on multiple factors^[134]. Collectively, the reviewed literature consistently implicates resistance as developing from processes that limit the anabolic metabolism of 5-FU to FdUMP, the TS inhibitory metabolite [Figure 1], and from mechanisms that result in elevated TS activity that results from gene amplification, polymorphisms in the TS promoter, elevated levels of transcription factors that regulate *TYMS* expression, and/or altered nuclear localization of TS [Figure 2]. Dysregulation in the balance between cell survival and programmed cell death is also important in the development of 5-FU resistance [Figure 3]. We have not attempted to review miRNA regulation of *TYMS*^[61] or other epigenetic causes of 5-FU resistance^[135], and these have recently been reviewed^[136-138]. We also have not directed the reader to literature focused on cellular changes that promote quiescence and stemness to escape the cytotoxic effects of 5-FU^[139,140], although these are likely to be of clinical significance. Further, it is clear that the tumor microenvironment modulates therapy response by processes independent of on-target effects on cancer cells and these processes are not reviewed in this manuscript.

The focus of this review is on acquired resistance to 5-FU with decreased anabolic metabolism and elevated TS activity^[49] as clinically relevant causes. In principle, these causes of 5-FU can be addressed through the translation of next-generation FP drugs that retain the anti-tumor activity associated with targeting TS in

CRC, but that do not require multiple steps of anabolic metabolism required by 5-FU. TAS-102, a combination of the FP trifluorothymidine and a TP inhibitor Tiperacil, shows efficacy in 5-FU-resistant models and activity in refractory metastatic CRC^[141]. TAS-102 activation requires thymidine kinase and it is not a substrate for DPD^[94]. Our laboratory has pioneered the development of DNA-based FP polymers to deliver Fluorodeoxyuridylate, the TS-inhibitory metabolite of 5-FU, without a requirement for metabolic activation. We showed that the prototype FP polymer F10 was, on average, 338-fold more potent than 5-FU across the NCI60 cell line screen^[15,135], but it was still very well tolerated *in vivo*^[142], indicating 5-FU toxicities do not necessarily arise predominantly from on-target effects. The 2nd generation FP polymer CF10 is even more potent and shows promising activity in pre-clinical models of CRC and pancreatic cancer^[16,17]. Further, the cytotoxic mechanism of CF10 results from both inhibiting TS and poisoning of DNA topoisomerase 1 (Top1)^[41,143], which results from a distinct mechanism distinct from current Top1 poisons in clinical use^[144]. In summary, the next generation of FPs has the potential to overcome the established mechanism of resistance for 5-FU reviewed herein that has limited clinical response to FPs to date.

DECLARATIONS

Abstract

Colorectal cancer (CRC) is the third most diagnosed cancer and the second most deadly type of cancer worldwide. In late diagnosis, CRC can resist therapy regimens in which cancer stem cells (CSCs) are intimately related. CSCs are a subpopulation of tumor cells responsible for tumor initiation and maintenance, metastasis, and resistance to conventional treatments. In this scenario, colorectal cancer stem cells (CCSCs) are considered an important key for therapeutic failure and resistance. In its turn, mitochondria is an organelle involved in many mechanisms in cancer, including chemoresistance of cytotoxic drugs due to alterations in mitochondrial metabolism, apoptosis, dynamics, and mitophagy. Therefore, it is crucial to understand the mitochondrial role in CCSCs regarding CRC drug resistance. It has been shown that enhanced anti-apoptotic protein expression, mitophagy rate, and addiction to oxidative phosphorylation are the major strategies developed by CCSCs to avoid drug insults. Thus, new mitochondria-targeted drug approaches must be explored to mitigate CRC chemoresistance via the ablation of CCSCs.

Keywords: Cancer stem cells, mitochondria, colorectal cancer, drug resistance, mitophagy

INTRODUCTION

Colorectal cancer (CRC) is the third most diagnosed cancer worldwide, the second leading cause of cancer death in women, and the third in men^[1]. Currently, the chemotherapy regimens for CRC consist of 5-fluorouracil (5-FU) plus leucovorin for early stages (stages 0, I, and II), and 5-FU plus oxaliplatin (FOLFOX) or 5-FU plus irinotecan (FOLFIRI), which may be accompanied by targeted therapies (e.g., bevacizumab or cetuximab), as a first-line treatment for more advanced stages (stages III and IV)^[2]. FOLFOX and FOLFIRI chemotherapy regimens achieve objective response rates of approximately 50% and the overall CRC patients present 5-year survival rates of 60%. Although there are tools for genetic screening of CRC for defective DNA mismatch repair (MMR) using immunohistochemistry and/or microsatellite instability test^[3], diagnosis of disease at a late stage (stage IV) is frequent in CRC, which reduces the overall 5-year survival rate to approximately 18%^[1]. In addition, nowadays, it is known that miRNAs play an important role in resistance to the chemotherapy regimens mentioned above, which makes them a relevant target for major studies^[4].

Regarding therapy resistance, researchers have sought new strategies, such as using CRC patient-derived organoids (PDOs), to understand this challenging problem. Recent studies suggest that PDOs can prevent patients from undergoing ineffective chemotherapy and can help to develop effective and personalized therapies against CRC^[5,6]. However, drug resistance is still a problem to be fought, with cancer stem cells (CSCs) emerging as an important factor in the process^[7]. CSCs are a subset of tumor cells defined by their ability to self-renewal and differentiate into distinct progenies, being also responsible for invasion and migration, leading to metastasis, and a slow-cycling cellular turnover, making them resistant to therapies^[8,9]. CSCs have been described in many types of cancer, and colorectal cancer stem cells (CCSCs) are considered the major cause of therapeutic failure and resistance to CRC treatments, leading to tumor progression, recurrence, and, eventually, patient death^[10].

The mechanisms underlying CCSCs chemoresistant phenotype include reversible quiescent state, high expression of drug efflux pumps, activation of protumoral signaling pathways, such as Hedgehog, Notch, Wnt/ β -catenin, Hippo, PI3K/Akt, and TGF- β , avoidance of chemotherapeutic-induced DNA damage, dysregulation of microRNAs, hypoxia microenvironment, metabolic switch for oxidative phosphorylation (OXPHOS), among others^[2].

Since conventional anticancer therapies act on highly proliferating cells, it does not affect quiescent cancer stem cells, as they are restrained in the G₀ phase from the cell cycle, a non-proliferative state. Additionally, these cells can re-enter the cell cycle after undergoing chemotherapy, leading to cell proliferation and tumor regeneration^[11]. Francescangeli *et al.*^[12] showed a high proportion of quiescent and chemoresistant CCSCs in response to treatment with oxaliplatin and 5-fluorouracil in a xenograft model.

Several studies have shown that mitochondria are involved in the mechanisms of chemoresistance of cytotoxic drugs or radiotherapy due to the many metabolic pathways conferring tumor cells' resistant phenotype and, specifically, CSCs^[13-15]. Therefore, it is important to understand the mitochondrial role in CRC drug resistance mediated by cancer stem cells.

MITOCHONDRIAL ROLE IN DRUG RESISTANCE: AN OVERVIEW

Beyond the powerhouse of the cell, mitochondria have been shown to act in many different frontlines, such as cell survival, proliferation, autophagy, and calcium homeostasis^[16]. In cancer, these double-membrane organelles play a pivotal role in establishing and progressing the disease, ranging from mitochondrial dynamics, biogenesis metabolism, and cell death regulation. Reactive oxygen species (ROS) balance

mitochondria DNA (mtDNA) mutations^[17], drug resistance, and mitochondria work like stress sensors, mediating adaptations in the face of an adverse environment caused by chemo or radiotherapies^[18,19].

Some major mechanisms for drug resistance include alterations in drug transport and metabolism, enhanced DNA damage repair machinery, and inhibition of apoptosis^[20]. Most chemoresistant tumors present a high expression of drug efflux membrane transporters, wherein the ATP-binding cassette (ABC) transporter family is the most important, highlighting ABCB1 and ABCG2, which are key players in cancer chemoresistance as they are capable of transporting the majority of conventional chemotherapeutic agents^[21]. Since ABC transporters depend on ATP hydrolysis to pump chemotherapeutics, mitochondria have their importance heightened as they are major producers of ATP via OXPHOS. A recent study using chemoresistant ovarian cancer cells showed that electron transport chain inhibitors increased drug retention and reverted the chemoresistant phenotype *in vitro* and *in vivo*^[22].

Mitochondria morphology is also an important feature of drug resistance. It is a dynamic organelle and can vary in size and copies inside cells due to fusion and fission, which are regulated by a GTPase family of proteins. Mitochondrial fusion, which usually occurs in nutrient deprivation and increased OXPHOS cases, implicates long interconnected tubules, forming networks. Oppositely, mitochondrial fission appears as small and fragmented mitochondria, commonly associated with cellular and mitochondrial dysfunction, severe stress, and increased proliferation^[23]. A study using cisplatin-resistant cervical and ovarian cancer cell lines exhibited a prevalence of elongated mitochondria, similar to tubular shapes, suggesting that mitochondria fusion is required to resist the drug treatment^[24]. Nevertheless, studies in breast cancer and acute lymphoblastic leukemia cellular lineages have demonstrated that mitochondria fission is required for metabolic adaptation favorable for protecting cells from chemotherapy agents^[25,26]. In addition, mitochondrial fission factor (MFF) is upregulated in prostate cancer stem cells compared to the primary tumor and normal prostate cells^[27]. A novel study with metastatic breast cancer cells shows that changes in mitochondrial dynamics, tending to a fission increase, lead to increased production of mitochondrial ROS, which retrograde response endows cells with resistance to oxidative stress and reactive oxygen species-dependent chemotherapy drugs^[28]. Therefore, the role of mitochondrial dynamics on drug resistance is an important area for further study.

Considering that mitochondria act as a metabolic hub, these organelles are expected to have great importance in modulating therapy sensitivity, especially by controlling redox metabolism^[29]. Resistant cancer cells usually exhibit great mitochondrial functionality, with high rates of OXPHOS. For instance, many studies have shown that OXPHOS inhibitors suppress resistance to anticancer drugs in lung adenocarcinoma, prostate cancer, melanoma, pancreatic cancer, and colon cancer^[30]. A study showed that treating ovarian cancer cells with cisplatin might induce oxidative phosphorylation and stem cell enrichment, which can be overcome using OXPHOS inhibitors^[31]. Fatty acids oxidation (FAO), which depends on mitochondrial enzymes, is also considered an accomplice of therapeutic resistance^[32], as a study demonstrated that FAO inhibition promotes chemosensitivity in breast CSCs^[33]. Lee *et al.*^[34] showed that liver cancer stem cell chemoresistance depends on glutamine metabolism by mitochondria since mitochondrial ATP used in drug efflux is provided by glutamine, and its inhibition reduces efflux, decreasing chemoresistance. Increased expression of MTHFD2, a mitochondrial enzyme involved in the one-carbon metabolic pathway, was observed in gefitinib-resistant lung cancer cells with stem cell features. MTHFD2 knockdown decreased stem cell phenotype and promoted gefitinib sensitization, highlighting the MTHFD2 importance and potential as a target for anticancer therapy^[35]. Another important pathway in which mitochondria participate in is folate metabolism, also known as 1C metabolism^[36]. This metabolic process involves the activation and transference of one carbon-molecules to support nitrogenous bases

biosynthesis, antioxidant agents' regeneration, and amino acid balance. In this scenario, mitochondria can be responsible for chemoresistance fueling 1C metabolism, then enhancing OXPHOS. Lucas *et al.*^[37] observed that the activity of SHMT2, a mitochondrial enzyme involved in serine and tetrahydrofolate metabolism, ensures complex I assembly and function, thus increasing the electron transport chain activity and developing resistance.

Resistance to apoptosis is described as one hallmark of cancer, and its contribution to resistant cancer cells is remarkably relevant^[38]. Indeed, the correct functioning of mitochondria is fundamental for cellular health. It also has an essential role in programmed cell death, and its morphology is critically important for apoptosis commitment^[39]. Changes in the permeability of the inner mitochondrial membrane lead to the loss of the mitochondrial membrane potential allowing the release of pro-apoptotic proteins, such as B-cell lymphoma 2 (Bcl-2) family proteins (Bcl-2, Bcl-xl, Bcl-W, MCL-1, A1, and Bcl-B)^[40,41]. Xu *et al.*^[42] showed that overexpression of Bcl-2 blocked apoptosis in human ovarian cancer cells. In addition, other pro-apoptotic proteins, such as apoptosis-inducing factor (AIF) and endonuclease G (Endo G), are released from a late event in apoptosis, which occurs once the cells are committed to dying^[40]. AIF and Endo G act in a caspase-independent manner to execute cell death^[43]. Alvero *et al.*^[44] were shown that Endo G mediates caspase-independent cell death in response to chemotherapeutic agents in an ovarian cancer model. One of the aims of chemotherapy is to induce apoptosis by targeting these pro-apoptotic proteins, mainly the Bcl-2 family, creating mitochondrial outer membrane permeabilization, which results in the irreversible release of cytochrome c, caspase activation and then apoptosis^[45]. For instance, docetaxel, a common chemotherapeutic agent whose primary mechanism of action is inhibition of microtubule disassembly, can also bind to Bcl-2, inducing apoptosis^[46]. Furthermore, a cutting-edge contribution of mitochondria in cancer drug resistance is the exchange of this organelle mediated by tunneling nanotubes, a transient cytoplasmic connection between non-adjacent cells^[47]. Several studies have described mitochondrial transfer from important stromal cells of the tumor microenvironment, such as endothelial cells and mesenchymal stem cells, to cancer cells in many types of cancer, such as breast cancer^[48], acute myeloid leukemia^[49] and glioblastoma^[50]. This mechanism promotes tumor survival and chemoresistance by improving OXPHOS or increasing anti-apoptotic proteins.

Mitochondria-targeted drugs for cancer - current status

Since mitochondria are a central organelle for cell survival, including cancer cells, several researchers have dedicated time and effort in recent years to develop new anticancer drugs and strategies that could target mitochondria. This group of compounds, proposed to impair mitochondria, are designated as mitochondria-targeted drugs (MTDs). Their mechanism of action can range from targeting tricarboxylic (TCA) cycle enzymes to electron transport chain (ETC) complexes and Bcl-2 anti-apoptotic family proteins^[51]. Some MTDs studied comprise Mito-carboxy proxyl (Mito-CP), Mito-metformin, and Mito-methyl coumarin.

Mito-CP, a lipophilic cationic nitroxide conjugated to an alkyl triphenylphosphonium cation (TPP), showed to accumulate in mitochondria, combined with 2-deoxyglucose (2-DG), a glycolysis inhibitor, in hepatocellular carcinoma and breast cancer cells, inducing apoptosis via caspase 3/7 activation and a significant decrease in intracellular ATP. Notwithstanding, Mito-CP did not affect primary hepatocytes cells or non-tumoral fibrocystic breast cell line (MCF10A), highlighting a possible selectivity of this compound^[52,53]. Concerning colorectal cancer, Boyle *et al.*^[54] demonstrated for the first time that MTDs induce mitophagy in cancer cells. In the study, Mito-CP and Mito-Metformin, a TPP-conjugated derivative of a common type 2 diabetes drug metformin which acts inhibiting complex I of mitochondrial respiratory chain, released Unc-51-like autophagy-activating kinase 1 (ULK1) from mTOR-mediated inhibition, affecting mitochondrial morphology, and decreasing mitochondrial membrane potential, which are

indicators of mitophagy. Another MTDs is Mito-methyl coumarin, a compound synthesized using the coumarin backbone, which exhibited anticancer proprieties in Hela cells by increasing ROS generation, reducing mitochondrial mass and membrane potential, and inducing programmed cell death^[55].

Regarding cancer chemotherapy resistance, Chan *et al.*^[56] showed that drug molecules carried by multifunctional nanodiamonds could be effectively delivered to mitochondria and induce remarkable cytotoxicity and cell death in doxorubicin-resistant MCF-7 breast cancer cells. In addition, Li *et al.*^[57] synthesized mitochondria-targeted polydopamine nanoparticles loaded with doxorubicin and demonstrated that this system could potentially overcome drug resistance with a short-term treatment plan toward breast cancer cell lines (MDA-MB-231).

Focusing on cancer stem cells (CSCs), MTDs are considerably more effective in triggering apoptosis of CSCs, when compared to other agents, via mitochondrial dysfunction by regulating Bcl-2 family proteins, and ROS production^[58]. Thus, specific mitochondrial-targeted compounds can induce cell death in chemoresistant CSCs. For example, Hirsch *et al.*^[59] showed that metformin, an inhibitor of the complex I mitochondrial respiratory chain, selectively kills CSCs in breast cancer cell lines. Alvero *et al.*^[60] demonstrated that the novel isoflavone derivative NV-128 significantly decreased mitochondrial function and induced cell death in ovarian CSCs.

Although only one MTD has been approved for cancer treatment (BH3 mimetic Venetoclax) so far, other drugs have shown beneficial and promising effects in phase I/Ib and phase I clinical trials, such as MitoTam (EudraCT 2017-004441-25)^[61] and IACS-01075917 (NCT03291938)^[62], respectively. Given the importance of mitochondria for cancer cells, especially cancer stem cells, further research on agents that target mitochondria and combining these drugs with other chemotherapeutics are encouraged to increase the efficiency of anticancer therapies.

CANCER STEM CELLS AND MITOCHONDRIA: A STRONG PAIR IN DRUG RESISTANCE IN CRC

As already described, mitochondria are involved in many metabolic pathways, and alterations in this metabolism have been found in CSCs^[24]. Huang *et al.*^[63] discovered that suppressing mitochondrial ROS production drives glioma stem-like cell progression and facilitates radiotherapeutic resistance. In addition, Ren *et al.*^[64] observed alterations in mitochondrial function, such as the low amount of mtDNA and oxygen/glucose consumption and low intracellular ROS and ATP concentrations in thyroid cancer stem cells, which contribute to radioresistance. Kuntz *et al.*^[65] indicate that alterations in essential mitochondrial functions, such as oxidative phosphorylation, contribute to therapy-resistant chronic myeloid leukemia stem cells.

The damage of mtDNA, or even its loss, causes a reduction in the proliferation rate of CSCs^[27]. Huang *et al.*^[66] show that mtDNA deficiency may induce ovarian cancer stem cell-like properties and reveal the downregulation of mitochondria-related genes and upregulation of genes related to cell proliferation, anti-apoptosis, and drug resistance. Although these data indicate mitochondrial dysfunction and OXPHOS reduction, it has been reported the coexistence of a CSCs subpopulation that produces ATP via an anaerobic glycolytic pathway and feeds the OXPHOS of the OXPHOS-addicted subpopulation. This metabolic shift, known as the Warburg effect, usually occurs in regions of tumor hypoxia^[67]. Genetic and epigenetic alterations were found in the mtDNA of cisplatin-resistant oral squamous cancer cells. Further study of these changes may help to elucidate their role in chemoresistance^[68].

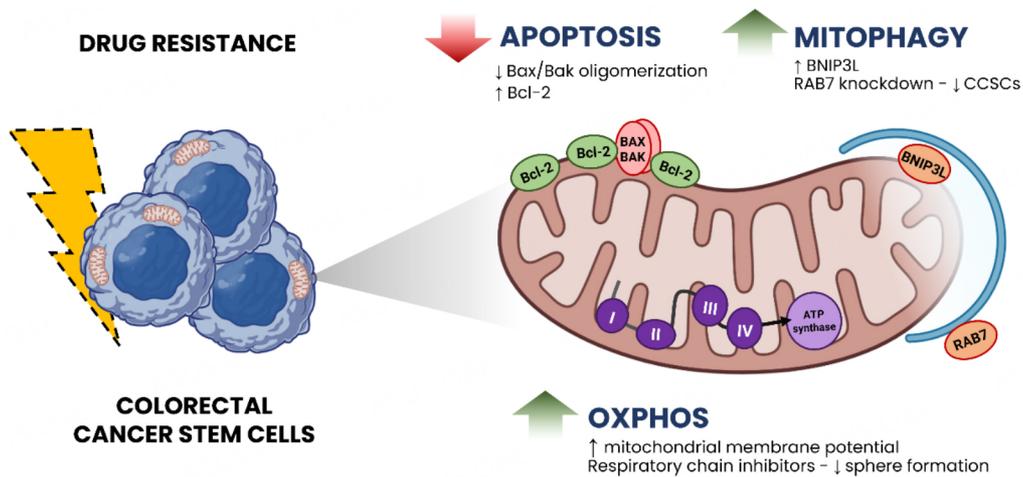

Figure 1. Mitochondria involvement in colorectal cancer stem cells and drug resistance. (1) Reduced apoptosis due to lower Bax/Bak oligomerization and higher Bcl-2 expression. (2) Enhanced mitophagy with the participation of RAB7 and higher BNIP3L expression. (3) Addition to OXPHOS with high mitochondrial membrane potential. The vectors used in the figure are from BioRender©. BNIP3L: BCL2 Interacting Protein 3 Like; CCSCs: colorectal cancer stem cells; OXPHOS: oxidative phosphorylation; RAB7: Ras-related protein 7.

Concerning apoptosis, CSCs survival depends on the dysregulation of apoptosis pathways and the overexpression of anti-apoptotic proteins^[69]. The anti-apoptotic proteins include the cellular FLICE-inhibitory protein (c-FLIP), the Bcl-2 family of proteins, and the inhibitor of apoptosis proteins (IAPs). Piggott *et al.*^[70] showed that the overexpression of c-FLIP plays a crucial role in resistance to TNF-related apoptosis-inducing ligand (TRAIL)-induced apoptosis, an anticancer agent, in breast cancer stem cells. Guo *et al.*^[71] indicated that survivin/BRIC5, a member of the IAPs family, is promising to be an excellent candidate for recombinant anti-cancer protein by promoting apoptosis of cancer cells and their stem cells through sensitizing cells to chemotherapeutic drugs.

Furthermore, CSCs and mitochondrial dynamics are valuable partners for overcoming drug resistance^[72]. Brain CSCs derived from tumor xenografts and primary tumor samples showed higher fragmented mitochondria and activation phosphorylation of dynamin-related protein 1 (DRP1) compared to non-CSCs^[73]. Notwithstanding, in a breast cancer model, mitochondrial fusion promoted by upregulation of MCL-1 showed to maintain CSCs properties in cooperation with MYC, facilitating mitochondrial respiration, thus inducing chemotherapy resistance^[74].

Apoptotic proteins expression

In CRC, there is an intimate relationship between CSCs and mitochondria in drug resistance scope [Figure 1]. Regarding the apoptosis mitochondrial pathway, recent data ensure that anti-apoptotic protein overexpression is vital for CCSCs chemoresistance. Purushothaman *et al.*^[75] showed that untreated CD133⁺ CCSCs (HCT116) expressed lower Bax/Bak oligomerization and higher Bcl-2 in comparison to Ruthenium(II) complex 1-treated group. In agreement with these findings, Colak *et al.*^[76] observed that CCSCs have decreased mitochondrial priming, accumulating anti-apoptotic proteins and inducing chemoresistance instead of differentiated CRC cells. In contrast, CCSCs incubated with WEHI-539, a specific inhibitor of Bcl-xl, were more sensitive to oxaliplatin, indicating that the mitochondrial apoptosis pathway is a great potential target for drug-resistant CCSCs. Ramesh *et al.*^[77] demonstrated that treatment with a BCL-XL inhibitor (A-1155463) increased the percentage of cells with active caspase-3 in Wnt-high CCSCs, indicating cell death, while BCL-2 (ABT-199) and MCL-1 (AZD5991) inhibitors did not promote this effect. These data suggest that CCSCs may depend only on BCL-XL and not on BCL-2 and MCL-1,

indicating the therapeutic potential of inhibiting BCL-XL activity.

Mitophagy rates

Mitophagy has also been assessed in CCSCs as it is another important mechanism for therapy resistance in cancer. Takeda *et al.*^[78] demonstrated that mitophagy was enhanced among CCSCs compared to non-CCSCs, and the knockdown of RAS-Associated proteins (RAB5 and RAB7) diminished the CD44v9⁺/CD133⁺ CCSCs population. Yan *et al.*^[79] showed that CD44⁺/CD133⁺ CCSCs (HCT8 cell lineage) were more resistant to doxorubicin treatment and expressed higher levels of BNIP3L, a mitophagy-related protein concerning parental cells. Instead, when CCSCs were treated with siRNA for BNIP3L, they became more sensitive to doxorubicin, suggesting that mitophagy is a major strategy of CCSCs to escape from death.

Oxidative phosphorylation addiction

Regarding metabolism, Denise *et al.*^[80] showed that 5-FU resistant colorectal HT29 cancer cells are addicted to OXPHOS while expressing more CD133 and forming more spheres, a 3D cell culture, *in vitro*. The coadministration of 5-FU and respiratory chain complex inhibitors led to a shrinkage of spheres. Corroborating to these findings, Song *et al.*^[81] demonstrated that CD133⁺/CD44⁺/Lgr5⁺ CCSCs were highly dependent on OXPHOS and presented high mitochondrial membrane potential. Besides, it was observed that the incubation with 5-FU did not alter ATP levels of CD133⁺ CCSCs compared to non-CCSCs. Combine treatment of 5-FU and antimycin A, an inhibitor of complex III from the respiratory chain, promoted cell death along with high expression of cleaved caspase 3. Thus, the addiction to OXPHOS appears to support CCSCs phenotype.

CONCLUSION

Colorectal cancer remains a disease of great concern as therapy resistance remains a remarkable challenge. In this scenario, cancer stem cells are well-known contributors, and their mitochondria exhibited a valuable role in providing it. A major mechanism for chemotherapeutic avoidance in CRC is an enhancement in anti-apoptotic protein expression among CSCs, a higher mitophagy rate and a reliance on OXPHOS.

In this concern, studies involving approaches such as patient-derived xenografts and organoids should be conducted to expand the understanding of the correlation of CCSCs and their mitochondria, regarding energetic metabolism, apoptosis pathway, especially mitophagy, providing a better picture of the heterogeneity intrinsic to CRC and its chemoresistance. The literature also lacks studies about mitochondria morphology in CCSCs in drug resistance context, which is a potential topic for new remarks. Moreover, new chemotherapy strategies targeting mitochondria must be studied and developed aiming at the elimination of CCSCs and their great contribution to CRC chemotherapy resistance.

Abstract

Pancreatic ductal adenocarcinoma (PDAC) is one of the most lethal cancers in humans due to late diagnosis and poor response to treatments. The tumor microenvironment (TME) of PDAC is characterized by a distinctive, suppressive immune profile, which inhibits the protective functions of anti-tumor immunity and thereby contributes to PDAC progression. Recently, the study of Alam *et al.* discovered for the first time that the intratumoral fungal mycobiome could contribute to the recruitment and activation of type 2 immune cells in the TME of PDAC via enhancing the secretion of a chemoattractant, interleukin (IL-) 33. In this article, we reviewed the important findings of this study. Together with our findings, we synthetically discussed the role of the fungal mycobiome in orchestrating the immune response and thereby modulating tumor progression.

Keywords: Mycobiome, pancreatic cancer, chemoresistance, interleukin 33, type 2 immune cells

MAIN TEXT

The recent development of various -omics approaches has greatly expanded our knowledge of the diverse fungal species colonizing different body sites, which constitute an important component of the human microbiome, termed the “mycobiome”^[1,2]. Traditionally, members of the human mycobiome, such as the well-known *Candida* spp., are known as opportunistic pathogens which reside in most healthy individuals and cause local or systemic infectious diseases only under certain circumstances. However, a growing body of evidence has suggested that the mycobiome plays a critical role in the onset and progression of cancers^[3]. A noteworthy example is the implication of the mycobiome in the carcinogenesis of pancreatic ductal adenocarcinoma (PDAC).

PDAC is a highly aggressive malignancy with a 5-year overall survival (OS) rate of around 10%, ranking the fourth leading cause of cancer-related deaths in the Western world^[4]. The dismal prognosis mainly results from a lack of specific symptoms for early diagnosis, the early metastatic spread and the poor response to available treatments^[5]. Previously, a seminal study discovered that PDAC harbors a distinct mycobiome profile as compared to that of the normal pancreas, while fungal ablation with antifungal treatments showed protective effects against oncogenic progression^[6]. These results suggested the potential of the mycobiome in PDAC as a new target for the development of novel biomarkers and therapeutic strategies^[7].

The tumor microenvironment (TME) of PDAC is characterized by a distinctive immune profile dominated by immune-suppressive cells including T_H2 cells and innate lymphoid cells 2 (ILC2), which can inhibit the functions of anti-tumor T cell immunity and thereby contribute to PDAC progression^[8]. In addition, these infiltrated T_H2 cells have also been found to fuel PDAC progression in the early stage of tumorigenesis via the secreted type 2 pro-tumorigenic cytokines, such as interleukin (IL-) 4 and IL-13^[9].

Most recently, Alam and collaborators^[10] revealed for the first time that the intratumoral mycobiome could enhance the secretion of the chemoattracting cytokine IL-33 from cancer cells, which subsequently recruited and activated T_H2 and ILC2 cells in the TME of PDAC, thus promoting pancreatic oncogenesis. This study was the first to show that TME of PDAC has an increased infiltration of T_H2 and ILC2 cells as compared to the normal pancreas both in a PDAC mouse model and in human PDAC samples^[10]. In order to determine the chemotactic factors secreted by cancer cells that may recruit and activate these immune cells, the authors also conducted a transcriptomic analysis of multiple PDAC cell lines and identified a 30-fold upregulation of IL-33, which was mediated by oncogenic *Kras*^{G12D} signaling. Immunohistochemistry staining showed that IL-33 expression was indeed relatively high in human PDAC tissues, while it was undetectable or below 25% nuclear staining in exocrine cells in normal pancreas specimens in the Human Protein Atlas database (<https://www.proteinatlas.org>, Figure 1A). IL-33 is known as a potent activator of T_H2 and ILC2 cells^[11]. In order to elucidate the requirement of IL-33 expression by cancer cells to recruit type 2 immunocytes, the authors depleted IL-33 in cancer cells by lentivirus transduction of small hairpin RNA in a syngeneic orthotopic model of PDAC. The IL-33 depletion reduced both T_H2 and ILC2 infiltration in the TME and functionally inactivated the resident ILC2 cells that were already present within the TME. The decreased IL-33 expression in cancer cells also resulted in reduced tumor burden and increased survival. Taken together, these results indicated that cancer-cell-derived IL-33 recruits and activates type 2 immune cells into the TME of PDAC.

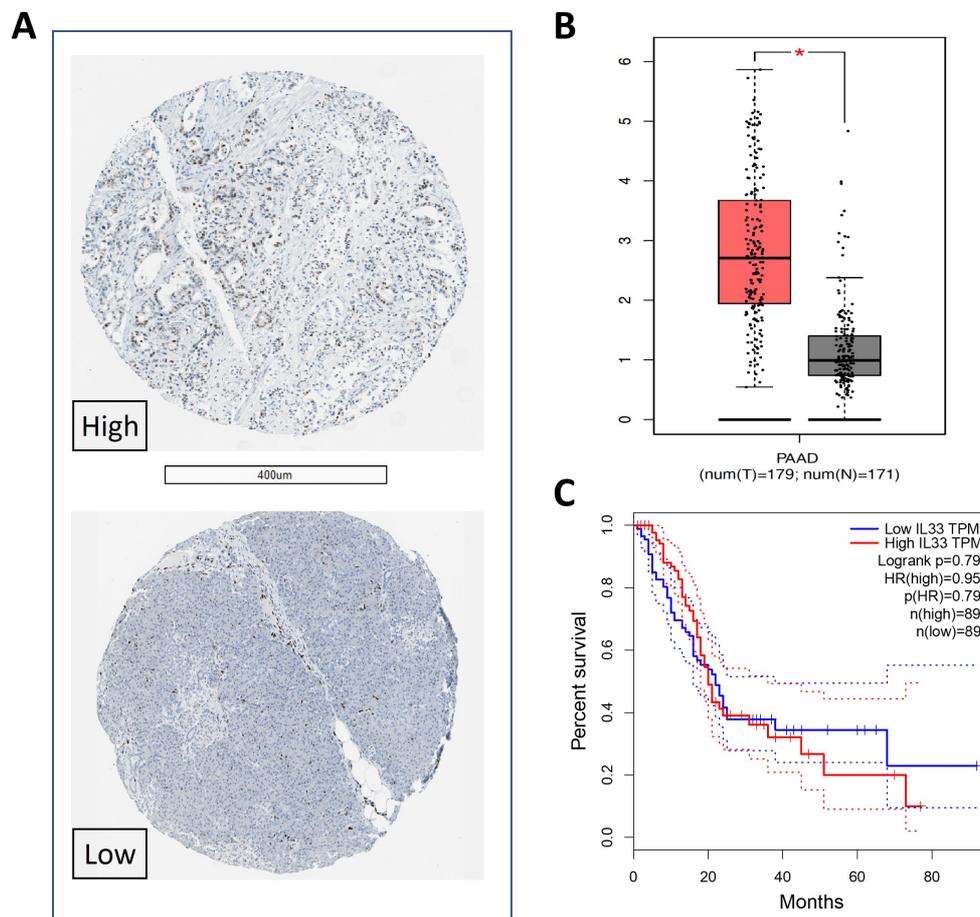

Figure 1. IL-33 expression and outcome in PDAC. (A) Representative images showing differential expression (high vs. low) of IL-33 in cores of tissue microarrays including specimens from two PDAC patients^[24]. The immunohistochemical staining was performed using the IL-33 antibody AF3626 (R&D systems), as reported by Alam *et al*^[10]; (B) the mRNA expression of IL-33 in PDAC was evaluated using the web-based genomics analysis and visualization platform GEPIA, analyzing the RNA sequencing expression data of 9,736 tumors and 8,587 normal samples from the TCGA and the GTEx projects, including 179 PDAC and 117 normal pancreatic tissues; (C) the levels of IL-33 mRNA expression did not correlate with overall survival in the TCGA-PAAD database.

Other experiments focused on the role of the mycobiome in PDAC on IL-33 secretion as well as in PDAC tumorigenesis^[10]. Using both 18S internal transcribed spacer (ITS) sequencing and fluorescence *in situ* hybridization, a higher load of fungi was found in the PDAC specimens as compared to the normal pancreas, with *Malassezia* being the most abundant genus, in accordance with previous findings^[6]. In addition, in both studies, the fungal depletion or repopulation was shown to retard or accelerate PDAC tumor growth, respectively. However, various mechanisms may be responsible. *M. globosa* was shown to promote tumor progress^[6] via mannose-binding lectin that can recognize fungal pathogens and the subsequent activation of C3 complement cascade which belongs to innate immunity^[12]. Interestingly, *M. globosa* was also shown to be involved in regulating the adaptive immune response to promote tumor growth by facilitating the extracellular expression of IL-33 and consequently enhancing the infiltration of T_H2 and ILC2 cells^[10].

However, IL-33 is a member of the IL-1 cytokine family^[13] and it is well known for its dichotomous functions, acting both as a traditional extracellular cytokine and as a nuclear transcription factor^[14]. Unlike the traditional inducible cytokines, IL-33 is constitutively expressed by several cells including human

endothelial and epithelial cells. The full-length IL-33 can translocate to the nucleus upon synthesis and be stored there^[15,16]. This nuclear IL-33 might function as a transcriptional repressor to decrease inflammation^[17]. Once released or secreted, the extracellular IL-33 can be cleaved to its more active form and induce the type 2 immune response^[11,18]. Interestingly, there are different opinions on the function of type 2 immune response in intestinal immunity and in the development of pancreatitis and PDAC. Some studies showed that IL-33 deficient mice were highly susceptible to colitis, colorectal cancer and pancreatitis^[19,20], which suggest a protective function of IL-33. However, other studies showed increased IL-33 levels in biopsies obtained from patients with active inflammatory bowel disease^[21], while elevated serum IL-33 was found in patients with severe acute pancreatitis^[22]. Opposite findings described that the IL-33-induced ILC2 infiltration in PDAC cells correlated positively with long-time survival in patients^[23]. In The Cancer Genome Atlas (TCGA) database, the mRNA expression of IL-33 is significantly higher in PDAC tissues compared to normal pancreatic tissues but was not associated with a significantly different OS [Figure 1B and 1C].

However, in many human cancers including PDAC, it was found that the fragile X mental retardation protein (FMRP) repressed immune attack by up-regulating IL-33 together with tumor-secreted protein S and extracellular vesicles (EVs), which promote M2-like tumor-associated macrophages, while down-regulating the chemoattractant C-C motif chemokine ligand 7^[25]. Of note, FMRP mRNA and protein expression levels were not associated with clinical outcomes in several cohorts of cancer patients, but a gene signature reflecting FMRP's cancer regulatory activity (with 156 genes, including IL-33) was prognostic for reduced OS across multiple human cancers. These discrepancies underline the importance of understanding the role of IL-33, its induced type 2 immune response and the network of genes and cells in the TME that contribute to the capability of PDAC to evade immune destruction and resist chemotherapy. Elucidation of the processes is essential before designing novel treatment strategies.

Since the mycobiome is living in symbiosis with bacteria as commensals in the human body, it is very likely that the mycobiome exerts an important influence on the microbiome. The involvement of microbiome in the development of PDAC and its chemoresistance has been convincingly demonstrated by several studies^[26-29]. Bacterial taxa, Proteobacteria (*Pseudoxanthomonas*) and Actinobacteria (*Saccharopolyspora* and *Streptomyces*), are positively correlated to the short-term survival of PDAC patients^[29]. The 18S ITS sequencing can only detect the presence of fungal mycobiome but not the presence of microbiome. It is therefore unclear whether microbiome could function similarly to the mycobiome, inducing the secretion of extracellular IL-33 and thus activating the type 2 immune response. The factors which can trigger the release or secretion of extracellular IL-33 are not fully identified. Besides fungi or fungal components^[10], it has been shown that cellular injury or death is one of the mechanisms by which IL-33 reaches the extracellular environment^[30]. Hence IL-33 will also act as an alarm when there is a breach in the primary defenses of intestinal epithelium against pathogens and other threats^[18]. Other factors, such as extracellular ATP concentrations, mechanical stress or oxidative stress, can also enhance the secretion of IL-33. Extracellular ATP concentrations are regulated by ectonucleotidases CD39 and CD73, which are known to play a role in immune function as well^[31,32]. Multiple bacterial species, such as *Klebsiella pneumoniae* (for autoimmune pancreatitis)^[33], *Helicobacter pylori* (for gastric ulcers)^[34], *Staphylococcus aureus* (for lung infection)^[35], have been shown to enhance the secretion of IL-33, indicating the involvement of tumoral microbiome, possibly together with mycobiome, in orchestrating the innate and adaptive immunity and modulate tumor progression.

Furthermore, mycobiome may also play a role in chemoresistance. Aykut *et al.*^[6] have shown that fungal ablation via antifungal treatment enhanced the efficacy of gemcitabine-based chemotherapy in PDAC-

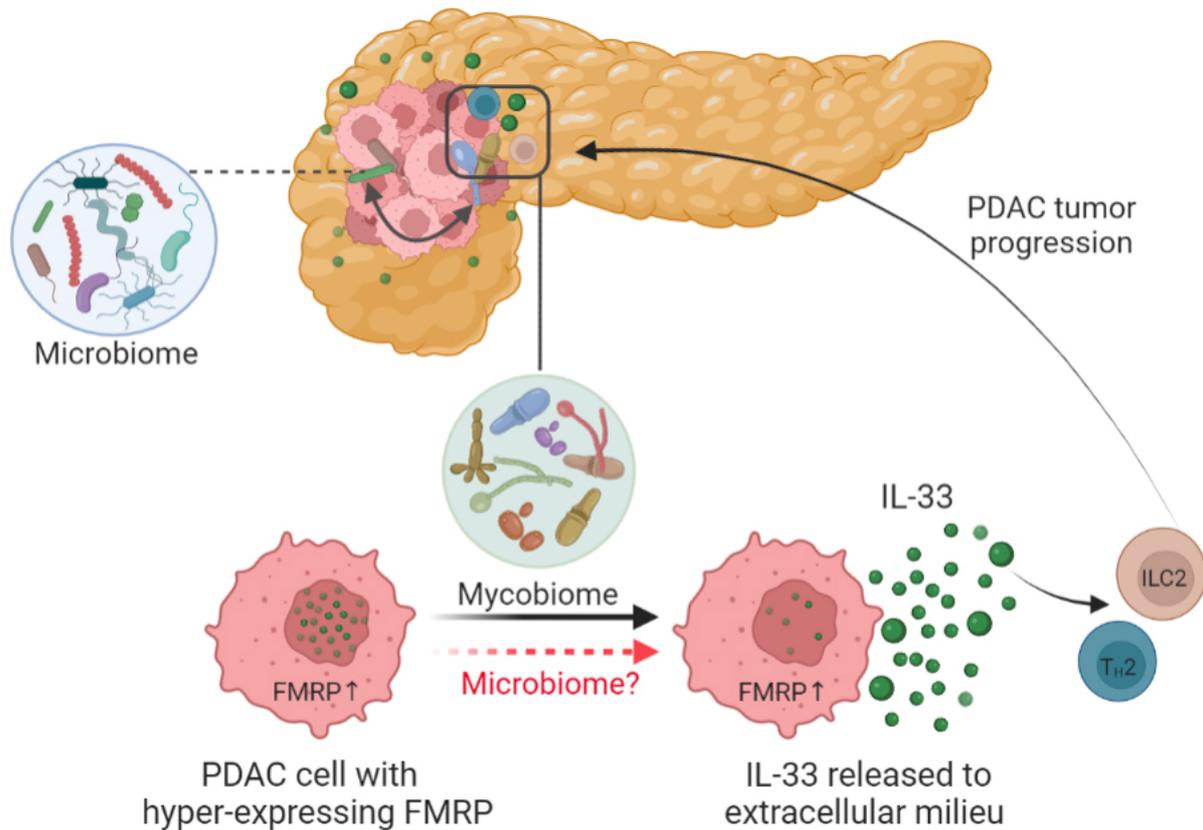

Figure 2. Intratumoral mycobiome can facilitate the extracellular secretion of interleukin (IL-) 33 from the nuclear of pancreatic ductal adenocarcinoma (PDAC) cells, which recruit the pro-tumorigenic immune cells such as T_H2 and ILC2 cells to the tumor microenvironment and thus accelerate PDAC tumor progression. Notably, bacteria species have been shown to be able to enhance the secretion of IL-33, and possibly together with mycobiome, intratumoral microbiome may also exert a role in orchestrating the host immune response and modulating tumor progression. FMRP, fragile X mental retardation protein. (Created with BioRender.com).

bearing mice. In humans, it was suggested that the gut mycobiome might modulate the response to preoperative chemotherapy (gemcitabine-cisplatin) in patients with bladder cancer^[36]. Compared to the non-responders, the responders had a distinct mycobiome featured by a higher diversity and lower abundance of *Agaricomycetes* and *Sacchaaromycetes*. However, the mechanisms underlying mycobiome-induced chemoresistance are still unclear. There are several hypotheses: (1) mycobiome may confer chemoresistance through metabolism and enzymatic degradation of chemotherapeutic drugs, similar to the previously reported intratumoral bacteria-mediated chemoresistance^[27]; (2) studies on breast cancer have identified IL-33 as a key driver of chemoresistance of tumor cells. IL-33 overexpression transformed tumor cells into polyploid giant cancer cells that are highly resistant to chemotherapy due to their dormancy or abnormal cell cycle^[37,38]. Thus, the fungal mycobiome may also elicit chemoresistance of cancer cells via the enhanced secretion of IL-33, as shown in the current evaluated study of Alam *et al.*^[10].

In summary, recent data revealed that the intratumoral fungal mycobiome can contribute to PDAC pathogenesis by stimulating the extracellular secretion of IL-33 from cancer cells, thus driving the recruitment and activation of T_H2 and ILC2 cells in TME of PDAC and promoting tumor progression [Figure 2]. Recent studies suggest that additional mechanisms, including modulation of FMRP and interaction with other fungi and bacteria, play a pivotal role in the impact of IL-33 as “friend or foe” in PDAC [Figure 2]. These findings may provide new insights for the development of novel therapeutic

strategies for overcoming PDAC chemoresistance by targeting the intratumoral mycobiome and correlated factors. Nevertheless, research on fungal mycobiome in PDAC is still at the infant stage. More studies are needed to illustrate how fungal mycobiome and its interaction with intratumoral bacteria can influence the oncogenesis and chemoresistance of PDAC. Furthermore, clinical studies should also be conducted to understand the prevalence of fungal infection in PDACs, the heterogeneity of IL-33 expression and the tumor-stage associated IL-33 expression, which may assist in the discovery of novel biomarkers for monitoring disease progression.

Abstract

Despite intensive efforts and refined techniques, overall survival in HPV-negative head and neck cancer remains poor. Robust immune priming is required to elicit a strong and durable antitumor immune response in immunologically cold and excluded tumors like HPV-negative head and neck cancer. This review highlights how the tumor microenvironment could be affected by different immune and stromal cell types, weighs the need to integrate metabolic regulation of the tumor microenvironment into cancer treatment strategies and summarizes the emerging clinical applicability of personalized immunotherapeutic strategies in HPV-negative head and neck cancer.

Keywords: Tumor microenvironments, head and neck cancer, SBRT, immunotherapy, metabolic reprogramming, radiotherapy, HPV-negative

INTRODUCTION

Head and neck squamous cell carcinomas (HNSCC) develop in close proximity to the anatomical structures responsible for breathing, speaking, chewing, and swallowing. These structures include the pharynx, larynx and oral cavity. HNSCC are common worldwide, with approximately 880,000 new cases and 445,000 deaths (excluding salivary glands) in 2020^[1], and are expected to increase by 42% by 2040^[2]. Up to 60% of patients

with HNSCC present with locoregionally advanced disease^[3] and usually receive multimodal treatment combining surgery, radiation therapy (RT), and chemotherapy. Even following vigorous treatment, recurrences in the same area or elsewhere have a poor prognosis^[3]. As a result, there is a great deal of morbidity associated with the treatment for HNSCC, whether it is intended to slow the disease's course or to cure it entirely. More importantly, HNSCC survivors experience one of the highest rates of suicide likely influenced by the accompanying psychosocial distress and reduced quality of life^[4]. Multidisciplinarity is a cornerstone of HNSCC management^[5] that incorporates diagnostic, therapeutic, prognostic, and patient care collaborative reasoning in the decision-making process. Consensus guidelines are a valuable resource in challenging situations and ensure the quality of tumor board decisions^[6]. Finally, emergent strategies like the impact of the microbiome in HNSCC can be readily incorporated into multidisciplinary treatment planning^[7].

The current treatment strategy is based on tumor location and disease stage, making tumor burden a strong determinant for the treatment decision and outcome, though HPV-positive tumors are associated with a better prognosis^[8]. Despite recent technological advances aimed at reducing treatment-related toxicities^[9-11], local control and overall survival rates in locally advanced disease are rather low, ranging from 40% to 50% at 5 years, especially in HPV-negative cancer^[12]. Recent developments in immunotherapy have revealed the importance of the tumor microenvironment (TME) in participating in effective immune responses. In recurrent/metastatic HNSCC (R/M-HNSCC), immunotherapy is now a mainstay of treatment, with objective response rates of 13%-17% in an unselected R/M-HNSCC population and 2-year overall survival rates of 17%-27%^[13-15], but immunotherapy has failed in the curative setting^[12]. Equally relevant, genetic and epigenetic events define treatment response. In that regard, it has been shown that HPV-positive tumors with excellent antitumor response harbor a defective DNA repair^[16]. However, not all HPV-positive tumors hold a better prognosis^[17]. It is well known that outcomes are poorer for HPV-negative cancers, including those in early stages. In summary, even within histology, tumors may have markedly differing sensitivities.

Hypoxia, which is a hallmark of HNSCC, is a significant impediment to the effectiveness of radiation therapy (RT). Hypoxia, which reduces the induction of DNA double-strand breaks in low oxygen conditions^[18] and induces tumor cells to enter a state of quiescence^[19], is the cause of radiation resistance. This is essentially the result of aberrant tumor vasculature as well as the high oxygen consumption of a tumor cell population that is expanding at a rapid rate. Both the failure of the treatment and the development of tumor resistance have been connected to hypoxia-induced changes in cellular redox as well as the utilization of alternative metabolic pathways in the TME. Future efforts should focus on differentiating between patients with severely and/or non-correctable hypoxic tumors and those with milder hypoxic characteristics.

Neck nodal disease is common and a well-established adverse prognostic factor in HNSCC^[20]. Occult metastases in the cervical lymph nodes may be present in patients even if their primary tumors were not particularly large. This has traditionally resulted in the inclusion of elective treatment of the neck as part of the curative therapeutic strategy, being regarded as a factor contributing to survival^[21]. However, de-escalation strategies suggest that treatment intensity can be modulated. For example, unilateral neck treatment for lateralized oral cavity and oropharyngeal tumors^[22] or reduction of RT dose and/or volume to the elective neck in HNSCC^[23,24]. In the 30 ROC trial, treatment volume and radiation dose were reduced by 60% (i.e., to 30 Gy) in HPV-positive oropharyngeal tumors obtaining excellent results in non-hypoxic tumors^[16]. Furthermore, recent preclinical models suggest that elective nodal irradiation reduces the efficacy of combined stereotactic radiotherapy and immunotherapy^[25]. Cumulative evidence suggests that functional

lymphatics promote an effective immune response. In contrast, lymphatic remodeling promotes tumor proliferation, indicating that tumor lymphangiogenesis is a causal factor in tumor immune surveillance by the host^[26]. Preclinical studies have shown that lymph node tumor cells have the ability to reach other organs via high endothelial venules^[27,28], which is an intriguing fact to take into consideration. As a result, the development of novel treatments is made possible thanks to a deeper comprehension of the dynamic relationship that exists between lymphatics, tumor cells, and the TME.

This review explores how immune and stromal cells in the TME influence immunosuppression and proposes targeting strategies to promote immunomodulation, weighs the integration of metabolic regulation of the TME into treatment strategies, and summarizes the emerging clinical applicability of personalized immune therapies in HPV-negative HNSCC.

KNOWLEDGE GAPS IN THE CURRENT THERAPEUTIC LANDSCAPE IN HPV-NEGATIVE HNSCC

A high tumor mutational burden is characteristic of HNSCC, and this has been identified as a critical factor in immune response in other malignancies. Furthermore, HNSCC tends to exhibit tumor-infiltrating immune cells, which are a recognized prognostic factor in a subset of HNSCC subtypes. However, the impact of immunotherapy on HNSCC has been rather low, with HNSCC falling into certain subtypes and that have a high level of resistance^[29,30]. Reevaluating the treatment for these tumors, which are not immunogenic, is one way to improve the standard of care for these cancers.

Prognosis

The stage and HPV status are recognized as the major determinants of HNSCC prognosis. However, it is becoming clear that not all HPV-positive HNSCC share the same good prognosis^[17] and that not all HPV-negative HNSCC are the same^[31].

Anatomical location, patterns of lymphatic drainage and patient preference, in combination with technical/technological requirements/skills and foreseen toxicities delineate curative treatment strategies in HNSCC. Nevertheless, hypoxia and the TME strongly affect the efficacy of immunotherapy^[32]. An understanding of the relative variations in the different anatomical sites of HNSCC might assist in the planning of new and more effective treatment strategies. A recent evaluation of the TCGA dataset concludes that HPV-negative sites are molecularly different, especially between tumors of the oral cavity and larynx^[31]. In this study, larynx cancer had a higher mutational burden, and was enriched for neuronal and glycosylation pathways, with a greater abundance of B cells and endothelial cells; while oral cavity cancer was enriched in extracellular matrix (ECM) pathways, with a greater abundance of monocytes and greater methylation of Hox genes; oropharyngeal cancer was the most hypoxic, and oral tongue cancer had a higher abundance of dendritic cells (DCs).

The immune system's decreased recognition of the tumor or inhibition of its response may explain why some HNSCC respond to immunotherapy, but many others behave as resistant and are regarded as poor immunogens (see excellent review in ref.^[33]).

Landscape of the immunosuppressive TME in HPV-negative HNSCC

The TME is heterogeneous and can be envisioned as a core of specialized microenvironments disposed as intersecting paths that can reprogram cancer biology and serve as potential targets of cancer therapy [Figure 1].

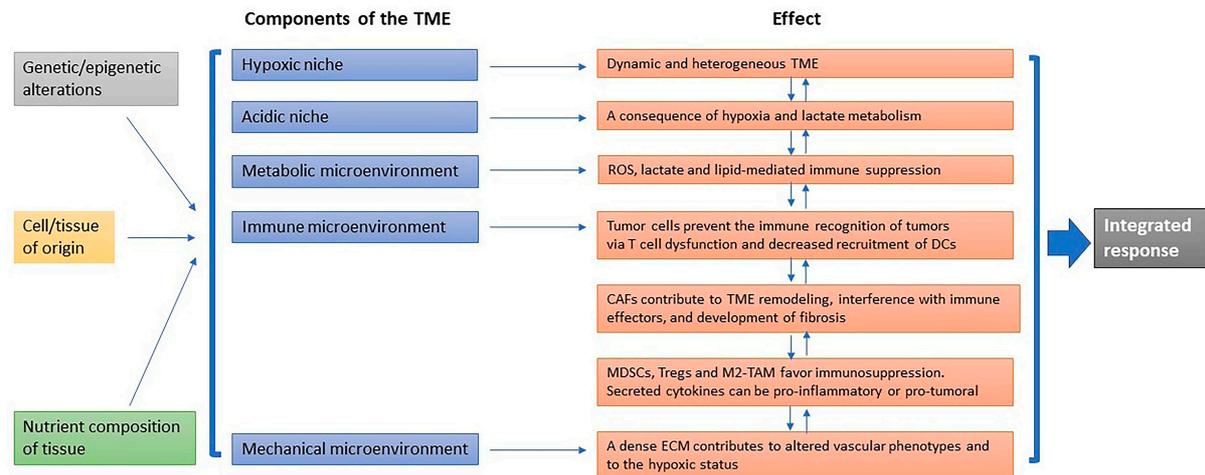

Figure 1. Dynamic composition of the TME. Specialized microenvironments that can be influenced by the genetic/epigenetic background, the tissue of origin, and the components of the tissue, and promote specific effects that are dynamically interconnected. The final outcome results from an integrated response.

Spatial architecture of the tumor versus immune evasion

A global hypoxic state is facilitated by a dense ECM, which limits immune cell infiltration and prevents their antitumor effect. Increased angiogenesis, the recruitment of additional immunosuppressive cells, tumor progression and enhanced metastatic ability are all factors that contribute to a global hypoxic state. Tissue microarrays of human HNSCC confirmed the vascular heterogeneity observed in patient-derived xenograft (PDX) models of HNSCC. These models showed three distinct vascular phenotypes, including a tumor vessel (TV) phenotype in which the majority of the blood vessels were distributed throughout the tumor; a stromal vessel (SV) phenotype in which the majority of the vessels were restricted to the infiltrating stroma next to the tumor cells; and a mixed vessel phenotype. In HPV-negative HNSCC, a heterogeneous distribution of vascular phenotypes was seen, with 60% of the tumors belonging to the SV phenotype, 25% of the tumors belonging to the mixed vessel phenotype, and 15% of the tumors belonging to the TV phenotype. A better response to antivascular agents was seen in the TV phenotype, but not in the SV phenotype^[34]. Understanding the physical barriers involved in HNSCC opens up the possibility for localized drug delivery, which could limit the systemic effects of different immunotherapies.

Tumor cells versus immune recognition of tumors

Conditions that prevent the proper priming, activation and infiltration of T cells are known to compromise the immune response. Thus, the T cells that are present in poorly immunogenic tumors are dysfunctional, exhausted or excluded from the TME. T cell exhaustion (TEX) is considered a major limitation to the long-term efficacy of immunotherapy. The complex immunosuppressive network in the TME facilitates the majority of CD8⁺ T cells evolving into the exhausted T cell subtype^[35]. TEX is not a static process with only one conceivable end; rather, it comprises a large variety of transitional phases. Instead, the pool of exhausted CD8⁺ T cells that are found in the TME should be considered as a population of CD8⁺ T cell subsets that have varying degrees of TEX, and each has its own unique set of functional capabilities^[36]. In this regard, a pan-cancer analysis of the heterogeneous TEX subset landscape using a five-stage trajectory as measured using TEX-specific hierarchical developmental signaling pathway signatures reveals the interdependencies of the TEX subgroups in various types of tumors, as well as among the same types of tumors. TEX patterns in HNSCC TCGA molecular subgroups revealed that the highly immunogenic progenitor TEX (TEX^{prog}) subset was particularly enriched in the HNSCC basal type, while the three

remaining molecular types (atypical, mesenchymal and classical) demonstrated intermediate distribution of transcriptional factors T cell factor 1 (TCF1, marks a downstream population of stem-like precursors of CD8⁺ T cells characterized by high self-renewal capacity, proliferation, and polyfunctionality^[37]), T-box expressed in T cells (T-bet; involved in effector, memory and exhausted CD8⁺ T cell differentiation^[38]), and thymocyte selection-associated high mobility group box (TOX, essential role in the induction of TEX by mediating transcriptional and epigenetic changes) known to coordinate the dynamics underlying TEX subset transitions^[39].

Decreased recruitment of DCs, required for tumor antigen presentation, can also contribute to immune escape by preventing adequate T cell priming and trafficking into the TME. Both classical DC (cDC1, cDC2) and plasmacytoid DC (pDC) are distinct subsets of the DC compartment. Batf3-driven CD8 α ⁺/CD103⁺ cDC1 are thought to be the major mediators of antigen transport and cross-priming since they are the most common cross-presenting DC subgroup. While cDC2/moDC and pDC have been shown to have stimulatory roles in some contexts, these cells' roles are often more tolerant in the TME^[40]. Tissue-specific DCs and tumor-associated macrophages (TAMs) can be generated in the environment of the tumor, inhibiting the anticancer immune response. The relevance of tissue-derived APCs to anticancer immune responses is highlighted by the plasticity of the myeloid compartment in response to the microenvironment. Learning how tissue-specific APCs differ in their function will aid in the discovery of cutting-edge cancer immunotherapies^[41].

It is common knowledge that various other cell types are also capable of carrying out the process of exogenous antigen presentation. These cell types are grouped together and referred to as “amateur” APCs^[42]. There is accumulating evidence to suggest that the expression of HLA class II antigens on tumor cells has a major impact on immunogenicity^[43]. There is a correlation between favorable outcomes and high levels of constitutive HLA class II antigen expression in oropharynx cancers^[44]. It is possible that the favorable effect of HLA class II antigen expression is due to the presence of high amounts of interferon gamma (IFN γ) in tumors that have substantial infiltration by T cells.

Immunosuppressive cells in the TME vs. immune effectors

Cancer-associated fibroblasts

Cancer-associated fibroblasts (CAFs) participate very actively in the TME remodeling and interfere with immune cell effectors, rendering them ineffective. High CAF density is correlated with disease stage and poor prognosis in HNSCC^[33]. CAF-induced recruitment of regulatory T cells (Tregs) through transforming growth factor beta (TGF- β) and interleukin 6 (IL-6) inhibits the proliferation of CD8⁺ T cells in HNSCC^[45].

CAFs-TME remodeling. CAFs are the most common type of cell to be seen in the stroma of a tumor. These CAFs secrete cytokines, which can either act on many immune cells at the same time or affect the TME in some other way to influence immune cell infiltration. CAFs are responsible for the release of soluble molecules, such as IL-6, which have an effect on T cells, NK cells, DCs, TAMs, and neutrophils. Single-cell RNA sequencing has previously been used to identify three distinct CAF types in HNSCC; these types include myCAF and two undefined CAF subtypes (CAF1 and CAF2). Despite this, the functional significance of these subtypes and their relationship to the immunotherapy response are still unknown^[46]. A study that used protein activity patterns, as determined by the VIPER algorithm analysis of a longitudinal single-cell transcriptomics HNSCC dataset^[47], indicated that there are five CAF subtypes that are distinct from one another on a molecular level. The HNCAF-0 and HNCAF-3 subtypes were predictive of favorable clinical responses to PD-1 immune checkpoint blockade (ICB), and they were connected to improved CD8⁺

T cell cytotoxicity (pro-inflammatory CAFs). Tissue-resident memory (Trm) phenotype CD8⁺ T cells were created by co-culturing HNCAF-0/3 with CD8⁺ T cells. These cells co-expressed CD94/NKG2A group 2 member A (NKG2A, CD159), an inhibitory receptor that is substantially abundant in tumor-infiltrating Trm⁺ CD8⁺ T cells in HNSCC^[48]. As activating NKG2A with its ligand HLA-E reduces cytotoxicity and effector function, this protein has the potential to be used as a new target for immunotherapy^[49]. In clinical trials involving HNSCC, the use of a combination of NKG2A inhibition and other checkpoint inhibitors has been shown to have a positive effect on the patients^[50]. Additional evidence has been reported in bladder cancer, suggesting that bladder tumors having both high levels of HLA-E and NKG2A-positive CD8⁺ T cells could benefit the most^[49], and in radioresistant tumors that do not respond to combined RT and ICB^[51]. High-resolution single-cell sequencing CAF analyses constitute an excellent framework to develop strategies to reprogram CAFs towards the pro-inflammatory phenotype, identify novel combinations with immunotherapy, and the potential to establish HNCAF subtypes as biomarkers of response and resistance in future clinical trials^[47].

The proliferation of CAFs is a critical step in the development of fibrosis in the tumor stroma^[52]. Multiple studies have pinpointed a critical function for the anti-apoptotic protein Bcl-2-associated athanogene 3 (BAG3) in tumor cell signaling in the TME^[53] and in the progression of fibrosis in tumor tissues^[54]. BAG3 causes TAM activation and IL-6 production in pancreatic tumor cells. The close link of BAG3 expression with cancer fibrotic phenotypes^[55] suggests that anti-BAG3 therapy dramatically down-modulated the expression of α -SMA, an activation hallmark of CAFs, with a marked reduction of collagen buildup. HNSCC has been identified as a fibrotic tumor phenotype that is more likely to respond to anti-BAG3 therapy, as determined by an analysis of three distinct databases including high-throughput RNA sequencing information from PDXs^[56].

Myeloid-derived suppressor cells

Myeloid-derived suppressor cells (MDSC) trafficking-metabolism. Monocytic (M-MDSC), granulocytic polymorphonuclear (PMN-MDSC), and early stage (e-MDSC) are the three subsets of MDSCs recognized; e-MDSCs lack the myeloid lineage markers found in the first two groups^[57]. It has been found that both PMN-MDSCs and M-MDSCs are linked to T cell suppression^[58]. The presence of PMN-MDSCs also in the bloodstream^[59] has been linked to poor survival^[60] and TEX^[61].

It has been observed repeatedly that RT induces MDSC expansion coupled to PD-L1 upregulation on the surface of MDSCs. This appears to occur approximately 2 weeks after RT and correlates with high levels of IL-6 and arginase activity^[62,63]. In addition, the production of reactive oxygen species (ROS) is caused by RT, which dramatically activates the hypoxia-inducible factor 1 subunit alpha (HIF1 α) in cancer cells^[64]. As HIF1 α signaling in malignant cells has been consistently associated with MDSC accumulation in the TME and enhanced immunosuppression^[65], and ROS control MDSC functions^[66,67], research is required to translate targeting strategies of MDSC-dependent immunosuppression into appropriate clinical scenarios, such as in patients with marked MDSC expansion/activity^[68].

Regulatory T cells

Regulatory T cells (Tregs) constitute a unique subpopulation of CD4⁺ T cells characterized by expression of the forkhead box P3 (FOXP3) transcription factor and high levels of CD25, a component of the IL-2 receptor. Tregs play a major role in restraining tumor-associated antigen-specific immune responses. It has been demonstrated that some markers, such as CTLA4, TIM3 and STAT3, play a part in the process of

mediating resistance to RT and ICB. The suppressive effects of several immune populations, including Tregs, are known to be increased by these markers^[69]. It seems that activated Tregs can suppress effector cells with inhibitory cytokines, metabolic competition, or direct inhibitory action on effector T cells (Teff) and DCs by secreting inhibitory cytokines, engaging in metabolic competition or taking direct inhibitory action [Figure 2]. Such findings have been documented in HNSCC patients treated with cisplatin-based chemoradiation, where > 20% elevations in circulating MDSCs were detected and correlated with an increase in Tregs and with suppressed T cell responses^[70].

Treg-APC axis. In immunologically cold HNSCC, characterized by limited T cell infiltration and poor responsiveness to RT plus anti-PD-L1 combination, antitumor immunity produced by RT can be improved through regulation of the APC-Treg axis. Treg depletion alone appears to be insufficient in tumors poorly infiltrated by Teff, which likely explains that Treg depletion combined with immunotherapy will not work. Conversely, RT is an excellent strategy to transform poorly immunogenic tumors owing to its immune-boosting properties^[71]. RT plus anti-CD25 seems to be effective only in tumor models unable to induce infiltration of MDSCs, suggesting that multiple immune-suppressive populations may need to be targeted to induce a robust antitumor immune response by RT^[72]. Preclinical HNSCC models have shown that treatment with anti-TIM3 plus anti-PD-L1 combined with RT^[73] and anti-STAT3 plus RT^[72] are potent therapeutic strategies against Tregs in appropriate tumor models. The activation of DCs and stimulation of their ability to mature and move to the lymph node have been important for eliciting a Teff response in this highly resistant HNSCC, even though this combination can effectively eliminate several tumors in animal models. In preclinical models, tumor eradication occurs when RT is coupled with anti-CD25 (Treg depletion) and anti-CD137 (DC agonism) treatment^[74]. Previous studies have demonstrated that tumor necrosis factor receptor superfamily member 9 (CD137,4-1BB) can enhance DCs and reprogram Tregs^[75]. Reprogramming Tregs into Foxp3⁺ CD4⁺ T cells with cytolytic activity was significantly aided by modulating the interaction of CD137 with its ligand. To emphasize the significance of increased antigen release for tumor eradication, it is important to note that these results were only accomplished with hypofractionated RT^[74].

Cytokine responses vs immunometabolic reprogramming

Cytokines are small molecular messengers that affect immune cell proliferation, differentiation and activation, hence regulating lymphoid tissue development, immunity and inflammatory responses by controlling immune cell growth, differentiation and activation. The HNSCC TMEs are abundant in immunosuppressive phenotypes (Tregs, TAMs, MDSCs, pDCs, CAFs) which cause immune effector cells to be either excluded from the tumor or to become dysfunctional. These stromal cells not only supply the tumor cells with intermediary metabolites and nutrients, but also produce a large quantity of pro-inflammatory and proangiogenic cytokines, which together create a pro-tumorigenic environment and aid in the evasion of the antitumor immune response (see review in ref.^[76]).

It is possible for tumor cells to directly secrete immunosuppressive and anti-inflammatory cytokines, such as interleukin 10 (IL-10) and TGF- β , which negatively affect APCs and T cells; other cytokines can polarize immune effector cells toward adopting an anti-inflammatory phenotype that leads to tumor progression. Expression of anti-inflammatory cytokines (IL-10, IL-6, and TGF- β) is favored in HPV-negative HNSCC. Mediating communication between tumor cells and CAFs^[77] and playing a crucial role in hypoxia-induced MDSC accumulation, elevated serum IL-6 levels are linked to increased tumor burden and aggressiveness^[78]. IL-10 affects the functional capacity of tumor-infiltrating pDCs, promoting the expansion of Tregs^[79], and is a potential predictor of a poor clinical outcome for the treatment of HNSCCs of laryngeal origin^[80]. TGF- β suppresses Teff cells and promotes Tregs^[81]. Recent research suggests that a myeloid PD-L1

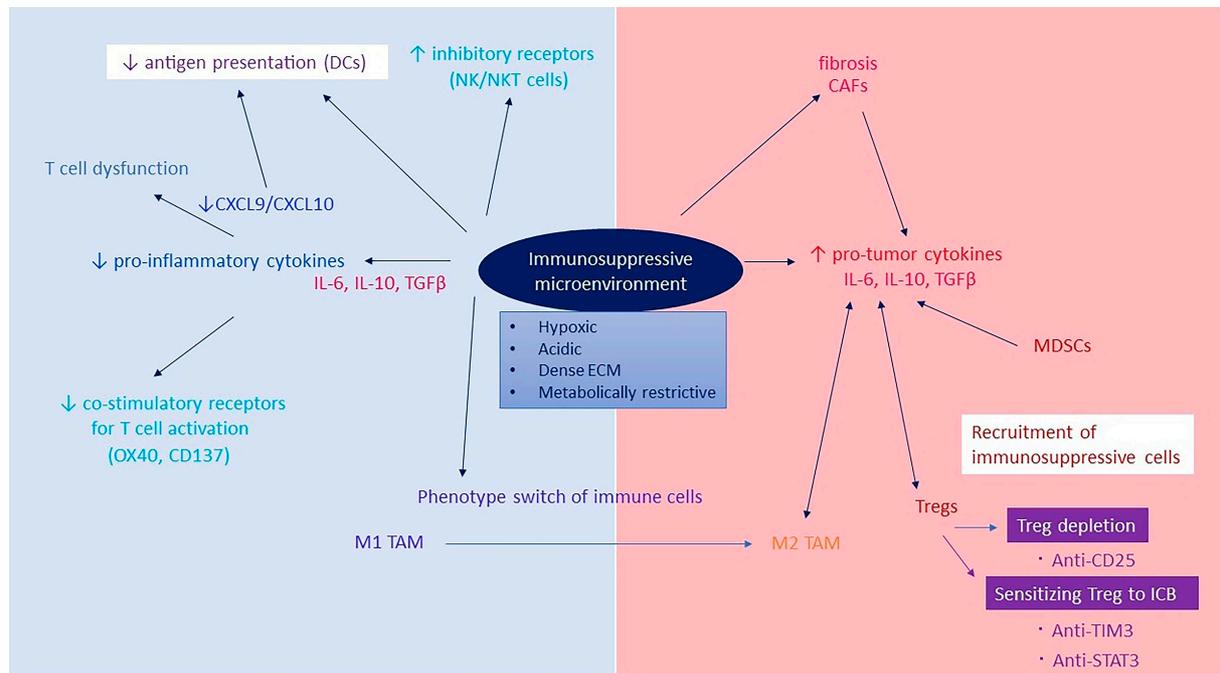

Figure 2. Immunosuppressive tumor microenvironment. Direct and indirect alterations in the TME suppress the immune response. Pro-tumor cytokines recruit immunosuppressive cells that prevent antigen presentation, which could be addressed by targeting Tregs. Reduction of pro-inflammatory cytokines generates T cell dysfunction and reduced antigen presentation. CAFs: cancer-associated fibroblasts; DCs: dendritic cells; ICB: immune checkpoint blockade; IL-6: interleukin 6; IL-10: interleukin 10; MDSC: myeloid-derived suppressor cells; TAM: tumor-associated macrophage; TGF- β : transforming growth factor beta; TME: tumor microenvironment.

blockade combined with TGF- β depletion in HPV-negative HNSCC can increase CD8⁺ T cell infiltration in responders showing a more permissive TME for Teff function^[82,83]. Thus, TME cytokine milieu-targeted therapies can either increase the production of pro-inflammatory cytokines or decrease the production of pro-tumor cytokines. More research is needed to establish the best way to manipulate local cytokines in order to modify the TME, especially in conjunction with other medications.

Chemokines are chemotactic cytokines capable of moving receptor-expressing cells along chemical gradients. The role of chemokines in cancer is conflicting in that they may facilitate the migration of tumor cells as well as attract tumor-infiltrating immune cells^[84]. Patterns of chemokine/ligand-receptor expression are emerging. Growing data indicate that the CXCR3 ligands CXCL9 and CXCL10, induced by IFN γ , play an important role in immune-inflamed tumors. In contrast, even if CXCL9 and CXCL10 are present in immune-excluded tumors, the spatial exclusion of Teff cells may represent the abundance of MDSCs, which stimulate the formation of a dense stroma that restricts the T cell entry^[85].

Studies of chromosome somatic copy-number alteration (SCNA, or aneuploidy) profiles have mapped the chromosomal alterations driving tumors to show reduced expression of cytotoxic infiltrating immune cells that predict response to ICB, being the strongest signals for HNSCC and pancreatic cancer^[86]. In HPV-negative HNSCC, 9p21.3 loss was associated with depletion of cytotoxic T cell infiltration in *TP53* mutant tumors; and in oral cancer, 9p-arm level loss was the strongest driver of cytotoxic T cell depletion (mainly of CD8⁺ T cells), promoting profound decreases of IFN γ -related chemokines (CXCL9, CXCL10). In addition, 9p arm-level loss and *JAK2-CD274* codeletion (at 9p24) were predictive markers of poor survival in recurrent HPV-negative HNSCC after anti-PD-1 therapy. As a consequence of the profound decrease in the chemokines CXCL9 and CXCL10, tumor-antigen cross-presentation and T cell priming and activation are

most affected since these IFN γ -inducible chemokines are known to be secreted by dendritic cDC1 cells^[87,88]. Further dissection of the 9p21 and 9p24 loci credits 9p21.4 loss as the key somatic alteration to shape the immune TME response. Conversely, 9p24.1 gain may act as a driver of immune activation and ICB response in HPV-negative HNSCC^[89]. Together, 9p loss promotes T cell depletion and defective IFN γ -related pathways (CXCL9, JAK2 signaling), with enrichment of suppressive cells (Tregs, MDSCs)^[87,88,90]. Hence, 9p loss has been proposed as a biomarker that could better predict the clinical benefit of ICB.

The proliferation and accumulation of oncometabolites in the TME give evidence for the metabolic state in cancer. This evidence is related to the requirement to maintain aerobic glycolysis, glutaminolysis, or one-carbon metabolism.

CHANGES TO MAJOR METABOLIC PATHWAYS AND TREATMENT RESISTANCE IN HPV-NEGATIVE HNSCC

As tumors grow, metabolism in the TME switches from oxidative phosphorylation to a glycolytic pathway favoring TME acidification. According to recent research^[91], metabolic plasticity in cancer cells has been demonstrated to improve antioxidant defenses and DNA repair activities, both of which can limit the efficacy of anticancer treatments [Figure 3]. In addition, the metabolic activity of cancer cells is highly plastic in response to a wide variety of environmental stresses, such as hypoxia and cytotoxic treatments, such as chemotherapy and RT. Finding new therapeutic targets for treating HNSCC could be the result of research into how ionizing radiation and other therapies affect the metabolism of cancer cells.

Oxidative stress

Radiation induces oxidative stress that damages macromolecules, and when the excess of ROS that is generated after radiation exposure remains unrepaired, the oxidative stress can be lethal. Cancer cells with strong metabolic flexibility benefit from antioxidant effects and the DNA repair metabolites provided by metabolic rewiring. So, strong antioxidant defenses are crucial to minimizing radiation susceptibility. Tumor redox metabolism was discovered as a strong predictor for radiation sensitivity in TCGA patient tumors, including HNSCC^[92], showing a reliance on metabolic routes that accelerate the clearance of ROS and sustain antioxidant mechanisms as a driver of radiosensitivity. It is possible that metabolically focused therapies could modulate radiation sensitivity in this context. Numerous metabolic processes, such as glycolysis, the pentose-phosphate pathway (PPP), glutaminolysis, and one-carbon metabolism, play a role in antioxidant defenses and DNA repair. Metabolic reprogramming in cancer cells has been extensively reviewed in other publications^[91,93,94].

Glycolysis and the pentose phosphate pathway

One of the main nutrients that aid in the development and survival of cancer cells is glucose. Despite the fact that glycolysis is a highly inefficient process for producing ATP, rapidly proliferating tumor cells, which require large amounts of ATP molecules due to their unsustainable rate of replication, may use glycolytic intermediaries as precursors for the anabolic pathways and biomolecules necessary for cancer cells to survive^[95]. The mechanisms of glucose metabolic reprogramming vary by cancer type and sometimes even within tumors of the same origin^[96].

Elevated levels of lactate and pyruvate in cancer cells drive the Warburg effect thanks to the overexpression and activation of glycolytic regulatory enzymes such as hexokinase (HK), phosphofructokinase (PFK) and pyruvate kinase (PK). In addition, the enhanced cellular transportation of metabolites through glucose transporters (GLUTs) maintains the Warburg effect. As a result of radiation, glucose metabolism is increased, which improves antioxidant activity and nucleic acid synthesis. The expression of GLUT1 has

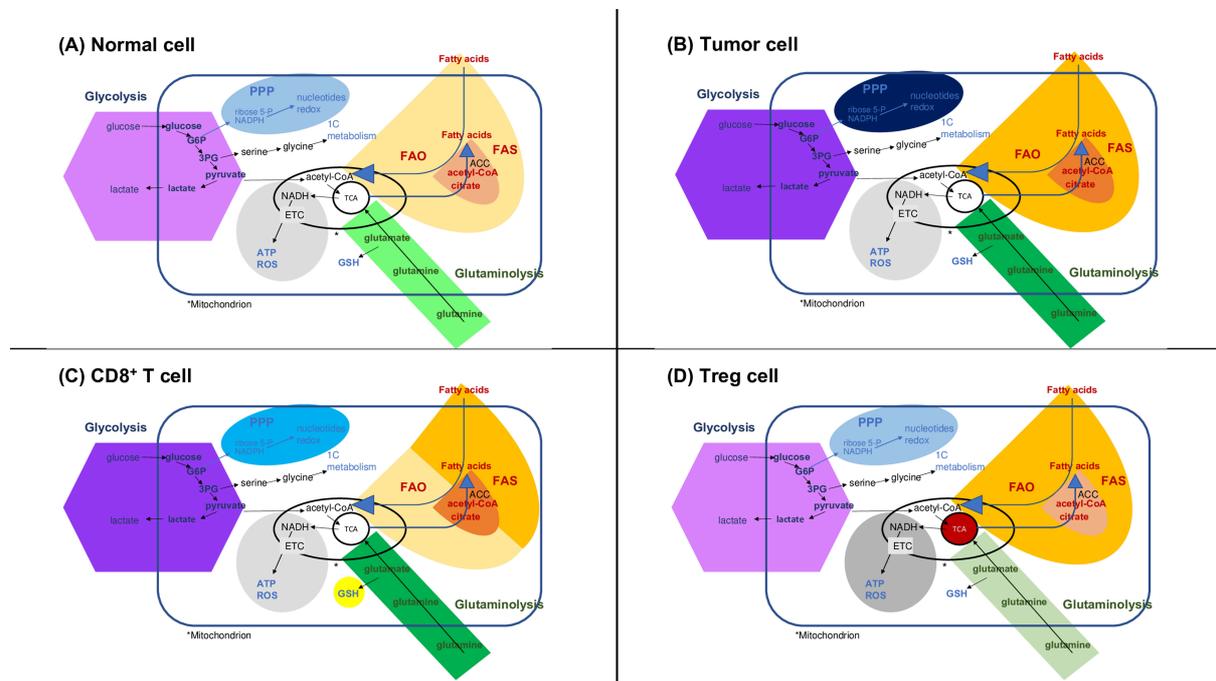

Figure 3. Metabolic pathways in (A) normal cells, (B) cancer cells, (C) CD8⁺ T cell, and (D) Treg cell. (A): Glycolysis, the conversion of glucose to pyruvate, and the pentose phosphate pathway (PPP), that generates ribose-5-phosphate and NADPH (required for nucleotide synthesis, redox balance, and fatty acid synthesis). Pyruvate can be converted to lactate and secreted or enter the tricarboxylic (TCA) acid cycle in the mitochondria. Fatty acids can undergo fatty acid oxidation and glutamine glutaminolysis, and enter the TCA. The TCA generates NADH and FADH that can enter the electron transport chain (ETC) and contribute to the synthesis of ATP and reactive oxygen species (ROS). Citrate from the TCA can enter the cytoplasm to participate in fatty acid synthesis (FAS). Glutamine metabolism can also synthesize glutathione (GSH); (B): cancer cells increase glycolysis, lactate production, PPP, FAO, FAS, and glutaminolysis. Cancer cells also maintain certain levels of the TCA cycle and oxidative phosphorylation (OXPHOS); (C): CD8⁺ T cells increase glycolysis, fatty acid uptake, FAS, glutamine uptake, glutaminolysis, and glutathione synthesis. The limited entry of pyruvate to the TCA favors the expression of IFN γ ; (D): Tregs increase FAO, the TCA cycle, and OXPHOS; maintain PPP and glycolysis to obtain pyruvate, which feeds the increased flux of the TCA cycle and OXPHOS, while the conversion of pyruvate to lactate is restricted. Tregs limit FAS and glutamine metabolism. Increased fluxes are indicated by higher color tones.

been associated with resistance to radiation in HNSCC^[97,98]. Activation of glycolysis (via HK2) and HIF1 in HPV-negative HNSCC cells has been shown to induce radioresistance^[99]. The activity of glycolytic intermediates that respond to oxidative stress increases after radiation. Namely, the activity of the PPP is mediated through the activation of the transcription factor nuclear factor erythroid 2-related factor 2 (NRF2), a master regulator of enzymes involved in ROS detoxification and elimination, via inactivation of its negative regulator Kelch-like ECH-associated protein 1 (KEAP1), which facilitates the transcription of NRF2 target genes (including metabolic genes that drive the PPP) to generate NADPH that fuels the antioxidant systems. Preclinical models have identified NRF2 as predictive of radioresistance in oral cavity SCC^[100]. Moreover, the PPP can be activated via ataxia telangiectasia mutated (ATM), a redox-sensitive kinase activated in response to radiation-induced DNA damage, by inducing the activity of glucose 6-phosphate dehydrogenase (G6PDH).

Pyruvate and lactate

NAD⁺ is provided by the conversion of pyruvate to lactate in a highly glycolytic phenotype. Lactate production results in a requirement for lactate transport, both to prevent lactate accumulation and to provide a respiratory substrate. The temporal dynamics of the lactate-to-pyruvate ratio after radiation show a decrease shortly after radiation and increased levels over time, suggesting that redox modulation after

radiation evolves over time^[91]. Monocarboxylate transporters (MCTs) are the major players in the context of lactate exchange in tumor tissue. MCT1 strongly influences lactate levels and has been suggested as a potential biomarker of chemoradiation response in HNSCC, regardless of HPV status^[101]. Further studies addressing the temporal dynamics of the altered lactate synthesis and transport following radiation are required for a better understanding of associated pathways and proposal of new targets^[91].

Lactate is used as a fuel^[102], but it also promotes tumor growth^[103]. In addition, recent findings suggest that blocking the effects of intratumoral acidity while keeping CD8⁺ T cells' lactate metabolism at a normal level can enhance antitumor immunity^[104]. For T cell function specifically, lactate appears to represent a fundamental carbon source^[105] and further promotes the stemness of CD8⁺ T cells associated with the inhibition of histone deacetylase activity^[106]. A fraction of highly glycolytic HNSCC stem cells is driven by epigenetic alterations that have been found. Antioxidant defense and nucleotide synthesis are both bolstered by a gene profile associated with glutathione (GSH) metabolism and stemness in this SIRT6 loss model^[107]. SIRT6 is a member of the sirtuins, a family of negative regulators of HIF1-dependent glycolysis. There is mounting evidence that increased glycolysis is a hallmark of HNSCC.

Amino acids and one-carbon metabolism

Cancer cells require amino acids as a source of energy. Next to glucose, glutamine is the most important nutrient for cancer cells since it is used in the creation of proteins and nucleic acids. It is becoming increasingly clear that glutamine is essential for metabolic remodeling in cancer under oxidative stress. One main cause for the enhanced GSH production is glutaminolysis, which is a primary source for tricarboxylic acid cycle (TCA)-derived biosynthesis^[108]. This makes glutamine very necessary for ROS scavenging and anabolic needs.

One of the limiting steps in glutaminolysis is the activity of glutaminases. An emerging strategy for interfering with cancer metabolism and tumor progression is targeting glutaminolysis by inhibiting glutaminases^[109]. Studies imply that targeting a specific glutaminase metabolic route is unlikely to become a successful anticancer strategy due to the TME's heterogeneity, the interconnected nature of cellular metabolism, and the plasticity of intracellular metabolic pathways. Having a better idea of which cells are using glutamine and in what pathways could help narrow down the possibilities^[110,111].

The increased need for glutamine in cancer cells is met by the solute carrier (SLC) family of membrane transporters, which includes the SLC1, SLC1-6, SLC1-7 and SLC1-38 families. Emerging evidence indicates that extracellular glutamine promotes ferroptosis, an iron-dependent cell death mechanism characterized by excessive generation of lipid peroxidation, which has been shown to induce cell death through ROS accumulation in cells. Of interest, it has been recently found that radiotherapy leads to lipid oxidation and ferroptosis via repression of SLC7A11^[112]. It is noteworthy that lipid membrane composition regulates radiation sensitivity, indicating that lipid metabolism may be therapeutically addressed to enhance RT efficacy. Radiation resistance and decreased RT induction of ferroptosis and lipid peroxidation are related to high NRF2 and SLC7A11 expression^[113].

Nucleotide metabolism

The synthesis of nucleotides is highly required for DNA repair of double-strand breaks after radiation damage, especially in less radiosensitive cell types^[94]. Consequently, an efficient DNA damage response (DDR) is linked to radiation resistance in cancer cells. Alkylating agents, such as cisplatin and lipid peroxidation resulting from ROS accumulation, can generate DNA adducts that also result in metabolic reprogramming through all major pathways (reviewed in ref.^[114]). *De novo* synthesis of nucleotides, which

affects DNA replication and repair, requires certain metabolites, such as glutamine and aspartate. The DDR's activity is affected by cellular metabolism because of changes in substrate availability. The DDR is capable of regulating metabolic pathways that cause or protect against DNA damage, as well as those that rearrange chromatin and are necessary for DNA repair^[115].

Signaling via purine nucleotides and nucleosides, such as adenosine and adenosine 5'-triphosphate (ATP), is increased in HNSCC^[116]. The balance between ATP (pro-inflammatory) and its catabolite, adenosine (anti-inflammatory), is tightly controlled in immune microenvironments at multiple levels. Adenosine signals in DCs upregulate IL-10, TGF- β , and arginase-2, promoting tumor growth. In TAMs, adenosine induces pro-tumor M2 macrophage polarization by reducing the expression of interleukin 2 (IL-2), tumor necrosis alpha (TNF α), and nitric oxide but upregulating arginase-1, IL-10, and vascular endothelial growth factor (VEGF)^[117]. However, the balance is shifted to increased adenosine production in tumors, rendering a deeply immunosuppressed TME^[118]. Moreover, ATP is rapidly converted into adenosine in the TME by the ectonucleotidases CD39 and CD73, which are particularly expressed in CD25⁺ or FoxP3⁺ Tregs. Hypoxia, via HIF1 α , upregulates CD39 and CD73, further enhancing the adenosine pathway via adenosine receptor A2A (A2AR) in HNSCC^[119,120]. Cancer cell death induced by RT releases ATP dose-dependently, which activates DCs and triggers an antitumor immune response. Conversion of ATP to adenosine can be generated directly by RT, via production of ROS, which activates TGF- β and promotes the M2 TAM phenotype^[121]. Therapeutic targeting of A2AR, CD73, and TGF- β may shift the TME to a pro-ATP environment and reduce resistance to immunotherapy in the setting of RT. Purinergic signaling stands out as a particularly promising target for the development of novel anticancer agents, for the most part in combination with standard-of-care therapeutics or ICB^[122,123].

Fatty acids and lipids

Lipid metabolism is an area of cancer metabolic reprogramming that has received less attention. The need for metabolic intermediaries in macromolecule production is particularly great in cancer cells. In order to produce membrane-forming, energy-storing, signaling-molecule-generating and ATP-generating molecules, lipid metabolism is a crucial route. Alterations in lipid availability are associated with altered cancer cell motility, angiogenesis development, metabolic symbiosis, immune surveillance evasion, and treatment resistance. The reprogramming of fatty acid (FA) metabolism in tumor tissues has gained considerable interest as a potential cancer treatment target^[93]. This suggests that FAs may be another environmental resource that CD8⁺ Teff cells need to compete with tumor cells in the TME^[124], given that CD8⁺ Teff cells also take up FAs at high rates.

The first stage in FA metabolism is for FA transporters (CD36/FAT, FABPpm, and FATPs) to bring FAs into the cell. In order to power keratinogenesis and the TCA cycle, mitochondria convert imported FAs into fatty acyl-CoA before transporting it for oxidation. Lipogenesis enzyme overexpression, FA trafficking, and FA oxidation (FAO) are among the ways in which FA metabolism can be influenced. Key regulators of lipogenesis include stearoyl-CoA desaturase 1 (SCD1), fatty acid synthase (FASN), acetyl-CoA carboxylase (ACC), and the sterol regulatory element-binding proteins (SREBPs). There is a class of proteins called FA binding proteins (FABPs) that play a role in the transport of FAs within cells. Cancer cells rely heavily on FAO reprogramming. FAO generates cytosolic NADPH to assist biosynthesis and can produce twice as much ATP as carbohydrates.

Studies on FAs in patients with HNSCC are limited. Abnormal elevation of the FA transporter CD36 in oral HNSCC promotes tumor metastasis. In contrast, its inhibition leads to complete remission or elimination of lymph node and lung metastases in *in vivo* models^[125]. In fact, acidosis-induced TGF- β 2 activation

stimulates both partial epithelial-to-mesenchymal transition and FA uptake via CD36 that are stored in lipid droplets (LD). LDs represent energy stores for cancer invasion and dissemination^[126]. The lipogenesis enzyme FASN was shown to promote radiation resistance in preclinical HNSCC models^[98].

There is a correlation between radiation, lipid redox, and ferroptosis that has recently been established in the literature. Liposomes undergo peroxidation and lipid fragmentation after radiation, while radiolysis generates oxygen radicals that cause lipid peroxidation of polyunsaturated FA (PUFA), in a radiation dose-dependent manner^[127]. The excess of lipid oxidation leads to ferroptosis. Ferroptosis is a form of cell death induced by iron-dependent lipid peroxidation. Ferroptosis induction is dictated by the proportion of PUFA in the lipid membrane^[128]. Thus, targeting lipid metabolism may accentuate the effect of radiation. Upregulation of SLC family members that regulate cystine import (critical for GSH biosynthesis and maintenance of the antioxidant pool within the cell) has been related to acquired RT resistance. The suppression of SLC7A11 by RT-activated ATM results in decreased cystine absorption, enhanced tumor lipid oxidation and ferroptosis, and improved tumor control^[112]. Additionally, low levels of RT-induced ferroptosis and lipid oxidation are associated with high levels of NRF2 and SLC7A11 expression, which is linked to resistance to RT^[113]. In HNSCC, preclinical models suggest that NRF2 inhibition could restore cisplatin sensitivity^[129]. In another model, the inhibition of the glutamine transporter SLC1A5, expressed at high levels in the CD44 variant-cancer stem-like cells (SLC1A5⁺/CD44^{v^{high}}), triggered oxidative damage^[130]. Taken together, these findings show that cystine transporters represent an original and targetable mechanism to improve RT efficiency.

It has been hypothesized that PMN-MDSCs in the TME of HNSCC use ferroptosis as an immunosuppressive mechanism. Even though ferroptosis reduces PMN-MDSC numbers in the TME, it inhibits T cell function by increasing the release of immunosuppressive chemicals. It has been postulated that ferroptotic PMN-MDSCs exert suppression by soluble substances, possibly including prostaglandin E2, and is favored under hypoxic settings, in contrast to their main mechanism in peripheral lymphoid organs, which is direct interaction between PMN-MDSCs and T cells^[131]. Additional work is required to understand how to integrate ferroptosis into the clinical setting.

Role of hypoxia

Rapid tumor cell proliferation in the TME creates low-oxygen regions with uneven concentrations of oxygen, leading to hypoxic stress. Extreme low oxygen levels stimulate a tolerant TME that allows evasion of immune surveillance^[132]. In particular, the hypoxic TME encourages the formation and production of immunosuppressive cells and secretion of substances (e.g., VEGF and TGF- β), and upregulation of immune checkpoint molecules on cancer cells to limit the capacity of effector immune cells to eradicate cancer cells. Under hypoxic conditions, the tumor ECM stimulates collagen synthesis and maturation, thereby generating a highly dense ECM^[133]. The stabilization of HIF-signaling by hypoxic cells alters cellular redox and increases the use of glycolysis and alternate metabolizing pathways, which in turn increases resistance in the surrounding cells^[134].

In contrast, hypoxic signaling may trigger angiogenesis, which will cause reoxygenation of tumor tissue, and enhanced radiosensitivity. In spite of this, there has been evidence that radioresistance persists after reoxygenation of hypoxic cells caused by G1 arrest/quiescence. These findings may suggest that tumor cells in chronic hypoxic regions, which are often located near necrotic zones due to an inadequate oxygen supply^[135], acquire a quiescent state^[136] and that reoxygenation alone is not sufficient to re-sensitize previously hypoxic cells. Notably, in cases of HPV-positive HNSCC, this condition disappears entirely. This would suggest that hypofractionation may maximize cancer cell death, while the interfraction interval

should be tuned to provide optimal re-entry of previously hypoxic cells into the cell cycle^[139].

It has been shown that HNSCC patients with persistent tumor-associated hypoxia during chemoradiation had a worse outcome^[137] linked to high levels of tumor-infiltrating lymphocytes^[138], highlighting the clinical relevance of persistent hypoxia in HNSCC.

BRIDGING THE GAP

The local TME of the tumor and T cell priming in the lymph nodes greatly define the potency of the cytotoxic immune response^[139]. DCs play an essential role in CD8⁺ T cell differentiation and antitumor activity^[140]. Preclinical research to exploit these traits^[25,74,141] has been clinically translated recently, offering new strategic opportunities in HPV-negative HNSCC. In addition, considering the more active role of tumor-draining lymph nodes merits consideration.

Innovative preclinical models to evaluate the TME in HNSCC

Apart from animal models, other tools have been incorporated to account for the effect of immune infiltration in the TME. In the context of personalizing treatment options, major efforts are being directed towards the development of reliable three-dimensional experimental models to study the microenvironment and treatment-resistance mechanisms.

Amongst them, organotypic co-culture models to culture fresh HNSCC tumor explants allow cultivation of cancer slices for up to 21 days in their original tumor microenvironment and investigation of the clonal expansion of resistant cancer cells upon treatment^[142]. A lymphatic organotypic microfluidic model has been proposed to study lymphangiogenesis, consisting of a lymphatic vessel surrounded by primary tumor-derived fibroblasts, which offers the potential to evaluate HNSCC metastasis to lymph nodes via lymphatic vessels accounting for the heterogeneity of the individual TME^[143]. An alternative system is a biomimetic collagen-based scaffold, which has been used to study the impact on the phenotype and genotype of oropharyngeal cancer cells. The 3D architecture in this model enables the study of the induction of migration properties and of the expression of epithelial-mesenchymal transition markers^[144].

One emerging field uses microfluidic platforms to study the TME and how immune cells and tumor cells interact with it. Organs-On-Chip are innovative tools that have boosted the research on cell-cell interactions and migratory behaviors. In the oncoimmunology field, these platforms are called OncoImmuno chips, and in their most ambitious objective aspire to become a Human-On-Chip (HOC, a multicellular chip module that contains all the key cellular components and extracellular factors derived from a specific human donor's immune cells)^[145]. In this regard, a HOC recapitulating the systemic metastatic spread has been proposed, composed of different modules that in the near future could be connected to generate a working metastasis HOC^[146].

Clinical translation

Because immunological dysfunction can develop over time and while treatment is being received^[147], the optimal timing of immunotherapeutic intervention, such as neoadjuvant therapy^[148], window of opportunity trials^[149] for surgically resectable HNSCC, concurrently with standard definitive treatment, or as adjuvant or salvage therapy, has yet to be determined.

Patients with HPV-negative HNSCC who participated in a recent phase I/Ib trial and were treated with neoadjuvant hypofractionated stereotactic body radiotherapy (SBRT) with a single dose of durvalumab had an overall survival of 80.1% (95% CI, 62%-100%), locoregional control/progression-free survival of 75.8%

(95% CI, 57.5%-99.8%), and major/complete pathological response of 75% (95% CI, 51.6%-100%)^[150]. It has been demonstrated that combining immunotherapies with RT can boost the infiltration of immune cells into the TME, and immunological priming is the intended outcome of this research. It has been demonstrated that SBRT is able to increase antitumor immune function by increasing the abundance of T cells in the TME and activating those T cells. A single dosage of the neoadjuvant durvalumab is administered to patients anywhere from three to six weeks prior to the scheduled standard operation. This dose was provided concurrently with neoadjuvant SBRT to regions that exhibited clear signs of disease. This was escalated using a 3 + 3 model. Initially, adjuvant therapy based on pathology was used, but in the expansion cohort, none of the patients who achieved pathological major or complete response received adjuvant treatment^[74]. All of the patients received adjuvant durvalumab between 6 and 12 weeks after their surgeries, with a maximum of 6 doses per patient. It was concluded that a total of 24 Gy, split up into three doses, is the maximum dose of SBRT that can be safely given. The maximal pathological response was not seen until at least 5 weeks after radioimmunotherapy was finished. This likely indicates the amount of time required to create systemic immunological memory. Specifically, a biological correlation research study found that patients who had a positive response to treatment had higher levels of Teff cells, lower levels of immunosuppressive cells, and improved antigen presentation. The changes that occurred in the draining lymph nodes (DLNs) of responders provided evidence for enhanced antigen presentation and T cell priming in the DLNs. This was demonstrated by an indication of a shorter distance between DCs and T cells. It has been observed that when CD8⁺ T cells were located closer to cancer cells in the TME, outcomes were much better than using the overall number of CD8⁺ T cells^[151]. The findings of this research suggest that the two patterns are related.

In a different trial, a phase Ib/IIa study testing neoadjuvant combined checkpoint blockade prior to surgery in HNSCC, two doses of nivolumab plus one dose of ipilimumab were administered 4 weeks before conventional surgery, and resulted in 35% of major pathological response^[152]. Notably, the response was discordant between primary HNSCC and its lymph node metastases. As it might be a matter of time to surgery, other potential explanations might apply.

A role for tumor-draining lymph nodes in immunotherapy

A lymph node has been found to have a lipid-rich milieu that tumor cells may preferentially utilize as an energy source^[153]. Moreover, new evidence suggests that FAO can aid in the settling of circulating tumor cells (CTCs) in lymph nodes^[154]. This lymph node pre-metastatic niche (PMN) requires lymphangiogenesis, recruitment of immunosuppressive cells, upregulation of chemokines and cytokines and vascular remodeling^[155]. Proliferation and differentiation of lymphatic endothelial cells cause lymphangiogenesis, which has been demonstrated to be regulated by FAO^[156]. Tregs, MDSCs, TAMs and pDCs within the PMN potentially suppress antitumor immune responses. However, Teff cells, being at a disadvantage in competing for glucose with tumor cells, redirect their metabolism towards FAs. Furthermore, Tregs may augment FAs, thus influencing effector cell development. FAO dominates in M2 TAMs, favoring interleukin 1 beta (IL-1 β) secretion and tumor cell migration^[157]. MDSCs activate FAO enhancing the ability to suppress T cell function. Recent studies show that stromal and immune cells in the PMN secrete substances in concert with FAO, including TGF- β and vascular endothelial growth factor-C (VEGF-C)^[158]. Vascular remodeling, also known as tumor cell-induced microvascular expansion, may increase angiogenesis and vascular permeability to promote metastasis^[159]. As a result of an increase in HIF1 and hypoxia-induced proangiogenic factors, CTCs from the vasculature and lymph vessels may reach the PMN and recruit more tumor cells. Modifications to the microenvironment of the lymph node, such as lymphangiogenesis, an increase in the expression of immunosuppressive cytokines, and an increase in the number of immunosuppressive cells, make it possible for tumor cells to thrive and remain dormant until stimuli drive their progression into a micrometastasis.

The potential role of the lymphatic system in driving immune evasion and metastasis has become highly relevant in cancer research^[26]. The state of the TME may become functionally altered depending on lymphatic activation states. In support of the hypothesis that lymph node metastasis is a functional driver of disease, a recent publication finds that metastatic lymph nodes display Treg expansion that generates tolerance to tumor cells and enhanced metastatic potential^[160]. The effect of increasing tumor burden remains to be determined. There is evidence of a progressive loss of T cell proliferation accompanied by the proliferation of Tregs^[27]. Whether this hypothetical setting can influence the established role of complete lymphadenectomy, which has shown limited survival impact, or provide an opportunity for neoadjuvant immunotherapy to target and remodel regional lymph nodes, remains to be seen. An improved understanding of lymphatic adaptation in tumor progression and response to immunotherapy could lead to more effective treatment strategies.

CONCLUDING REMARKS

The multiplicity of immune evasion mechanisms that immune-cold tumors can adopt is a major barrier to benefit from immune therapy strategies. The impact of immunotherapy in HPV-negative HNSCC has been rather low, indicating that a better understanding of the immune escape mechanisms in these tumors can definitively enhance their immunogenicity and treatment response. This review proposes that modulation of the TME to relieve immunosuppression, creation of a metabolically permissive TME, and priming the immune system are promising strategies to remodel the TME to overcome treatment resistance in HPV-negative HNSCC [Figure 4]. However, the concepts that have been discussed have yet to be implemented in the clinic, reflecting the preliminary stage of this information. Nonetheless, a few salient points can be summarized.

Evidence that an efficient antigen presentation machinery elicits a potent immune response in HNSCC has been studied in two phase I-II trials^[150,152] with strong accompanying correlative studies. Major or complete pathological responses of 75% were shown after neoadjuvant SBRT to gross disease and a single dose of durvalumab, followed by adjuvant durvalumab of up to 6 doses^[150]. The biological correlates indicated that response was related to higher levels of T_H1 cells, lower levels of immunosuppressive cells, and improved antigen presentation and T cell priming in the draining lymph nodes. Of note, when DCs and T cells were closer in the draining nodes, and CD8⁺ T cells and tumor cells were closer in the TME, outcomes were better^[151]. In preclinical models, Treg depletion or reprogramming strategies in combination with radiation have proven to activate DCs^[72-74]. A central tenet of this strategy is the use of SBRT only on gross disease, which optimizes the presence of neoantigens and allows a better coordinated immunologic response in the draining lymph nodes. Additional data confirmation and a refined consideration of the different contributions of the immunosuppressive cells that compose the heterogeneous TME will further guide the strategic scope of this treatment approach.

Robust data exist that indicates that the functionality of the IFN γ -inducible chemokines CXCL9 and CXCL10, essential for the recruitment of CD8⁺ T cells and NK cells, favors T cell trafficking and infiltration. Multiomic analyses of HPV-negative HNSCC cohorts have identified that losses at genomic regions on the chromosome 9p containing IFN γ -pathway genes result in CD8⁺ T cell depletion and CXCL9/CXCL10 suppression, and predict immune-cold, ICB-resistant tumors^[87-89]. Pan-cancer studies suggest that this mechanism is prominent in HNSCC and pancreatic cancer^[86], and has become a biomarker that synergizes with PD-L1/TMB for patient stratification. Further genomic/non-genomic dissection of these alterations can provide new strategies to target these tumors.

Remodeling the tumor microenvironment

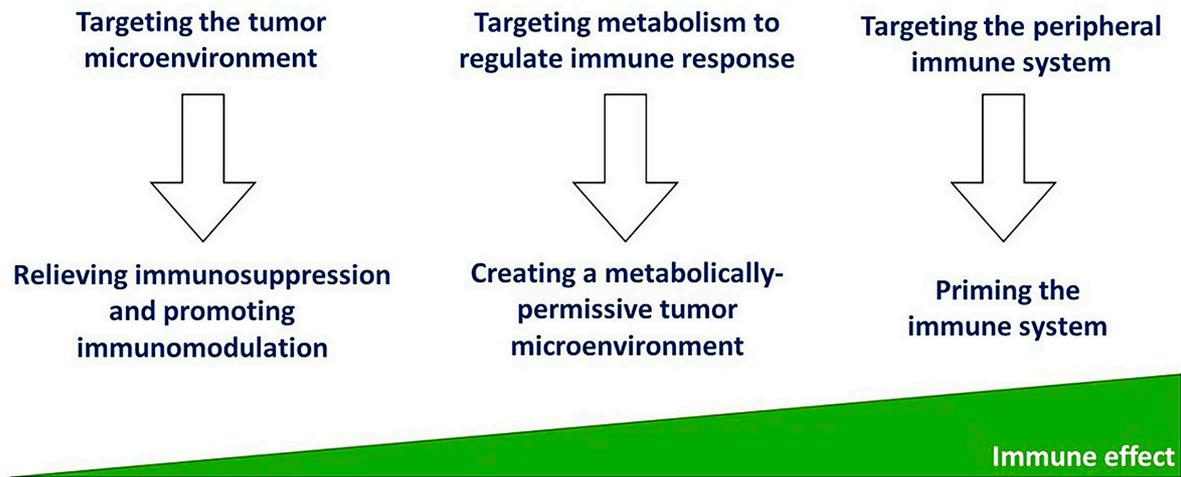

Figure 4. Immunomodulation, creating a metabolically permissive microenvironment, and priming the immune system to remodel the tumor microenvironment and elicit a strong immune response.

Studies evaluating the metabolic alterations that occur in the TME have uncovered potential treatment targets, like the transcription factor NRF2 which supports the PPP^[100]. Preliminary data suggest that the amino acid cysteine may play an important role in mediating CD8⁺ T cell-induced ferroptosis^[161], a recently identified form of regulated cell death. Ferroptosis, the mechanism by which abnormal intratumoral lipid metabolism induces cell death, has attracted great attention as a potential novel target in oncology^[162]. The discovery that radiotherapy induces ferroptosis in cancer cells as a result of an ATM-mediated downregulation of SLC7A11, and that this effect is enhanced in combination with ICB in animal models, has evolved into an ongoing active area of investigation^[112].

In conclusion, while additional research is needed, confidence exists that well-designed preclinical and clinical studies to assess neoadjuvant SBRT schedules in combination with immunotherapy, the clinical applicability of 9p loss, and the role of ferroptosis in cancer will elucidate which patient subgroups benefit the most. A better definition of contributing factors of an immunogenic microenvironment constitutes a significant step forward, which could be further exploited by incorporating emerging factors like genomics or the influence of the microbiome^[163].

Abstract

Renal-cell carcinoma (RCC) remains a leading cause of cancer-related mortality worldwide. Though newer therapeutic combinations of immune checkpoint inhibitors and targeted therapies have greatly improved outcomes, resistance to these therapies is becoming a challenge for long-term control. Mechanisms of resistance have been explored in a variety of solid tumors, including RCC. Based upon our review of the current literature on the mechanisms of resistance to immunotherapies for the management of metastatic clear-cell renal cell carcinomas (mccRCC), the ensuing conclusions have been made:

The management of mccRCC has progressed substantially with the advent of checkpoint inhibitors and targeted oral therapies, alone and/or in combination.

Nevertheless, innate or developed resistance to these therapies remains an ongoing challenge, particularly to immune checkpoint inhibitors (ICIs).

Several of the known mechanisms of resistance have been well defined, but recent progression in cellular therapies helps to expand the armamentarium of potential combination options that may overcome these modes of resistance and improve long-term disease control and survival for an otherwise dismal disease.

In the ensuing review and update of the literature on the mechanisms of resistance to immunotherapies in mcrRCC, we have revisited the known resistance mechanisms of immunotherapies in metastatic clear-cell RCC and explored ongoing and future strategies to overcome them.

Keywords: Metastatic clear-cell renal-cell carcinoma, immune therapy, checkpoint inhibitor resistance, chimeric antigen receptor T-cell therapy

INTRODUCTION

Renal-cell carcinoma (RCC) remains a common cause of morbidity and mortality worldwide. It is the eighth most common cancer diagnosed in the United States, and in 2022 there were an estimated 79,000 new cases diagnosed, accounting for 4% of new cancer diagnoses in the country^[1]. Though the relative 5-year survival is nearly 77%, the prognosis of advanced RCC remains dismal with an estimated 5-year survival of 15%^[1]. Clear-cell renal-cell carcinoma (ccRCC) still accounts for the majority of RCC, with non-clear-cell histologies making up about 25%^[2].

Historically, standard chemotherapy and radiation have been ineffective for ccRCC. Clinical studies suggested an immunologic role in the growth and control of RCC, particularly the presence of tumor-infiltrating lymphocytes (TILs) within the tumor and the process of immune evasion^[3-5]. Immune therapies were then explored as potential therapeutic options, particularly immune cytokines such as interferons and interleukin-2 (IL-2) and later immune checkpoint inhibitors (ICIs). A better understanding of the role of programmed death 1 (PD-1), programmed death ligand 1 (PDL1), and cytotoxic T-lymphocyte-associated protein 4 (CTLA4) led to the eventual use of ICIs in metastatic renal-cell carcinoma (mRCC).

The discovery of a defective von Hippel-Lindau (VHL) gene as a major molecular alteration in the pathogenesis of ccRCC was another leap forward. VHL alterations resulted in upregulation of several growth factors involved in angiogenesis (platelet-derived growth factor receptor-beta, vascular endothelial growth factor [VEGF], and transforming growth factor alpha) using the hypoxia-inducible factor (HIF) pathway. This led to the development of newer therapies specifically targeting these factors^[6]. VEGF-receptor tyrosine-kinase inhibitors, such as sunitinib, pazopanib, and sorafenib, quickly became the standard of care given their improved response rates, more convenient administration, and manageable toxicity profiles^[7-9].

Single-agent use of tyrosine-kinase inhibitors and ICIs was effective but with limited responses and long-term control. Resistance, particularly to ICIs, remains a barrier to achieving and maintaining a durable response to these therapies. It is also important to note that ICIs have several potential adverse effects which must be taken into consideration, especially with long-term use^[10]. Efforts have been made to combine immunotherapies and anti-angiogenic agents with each other and with other drugs. Other therapies include chemotherapy and radiation for potential synergistic and immunomodulatory effects and to overcome this resistance. Recent reviews summarized potential mechanisms but primarily focused on anti-angiogenic drug resistance^[11]. In a prior review by Moreira *et al.* published in this journal, resistance mechanisms to immunotherapies in the management of metastatic RCC were explored^[12]. Here, we revisit these mechanisms and discuss updated ongoing and future strategies for overcoming resistance, particularly adoptive cellular therapies.

Aim

To review and update the literature on mechanisms of resistance to immunotherapies in mcrCC.

Methods

Various internet databases were searched, including: PUBMED, Yahoo, Google, and Google Scholar. The search words that were used included: metastatic clear-cell renal-cell carcinoma, immune therapy, immune checkpoint inhibitor, immune checkpoint inhibitor resistance, and chimeric antigen receptor T-cell therapy. One hundred and six (106) references were identified, which were used to write the review and update the literature on the mechanisms of resistance to immunotherapies in mcrCC.

CURRENT THERAPEUTIC LANDSCAPE

The current treatment landscape for ccRCC in the first and second lines reflects the efficacy seen with immune and anti-angiogenic agents, both alone and in combination, over previously standard cytokine therapies. Choice of treatment is in part led by risk as determined by the International mRCC Database Consortium and Memorial Sloan Kettering Cancer Center/Motzer risk-stratification criteria^[13,14]. Individual patient factors, including comorbid conditions, concomitant medications, and socioeconomics, also play a large role in the choice of therapy.

Current preferred first-line treatments for favorable risk metastatic ccRCC include: pembrolizumab/axitinib, nivolumab/cabozantinib, and pembrolizumab/lenvatinib, with response rates ranging from 55% to 71%^[15-17]. Current preferred first-line treatment options for intermediate/poor-risk disease include: pembrolizumab/axitinib, nivolumab/cabozantinib, nivolumab/ipilimumab, pembrolizumab/lenvatinib, and cabozantinib^[18].

Second-line treatments vary and include anti-angiogenic and immune-therapy agents that the patient may not have previously received. Inhibitors of the PI3K/AKT/mTOR pathway, such as everolimus and temsirolimus, currently have a role in later lines of therapy^[19,20].

MECHANISMS OF RESISTANCE

ICIs have now become essential in the therapeutic armamentarium for several malignancies, including urothelial carcinoma, melanoma, and non-small-cell lung cancer. In addition to approved combinations for metastatic ccRCC, ICI was recently integrated into the adjuvant treatment of ccRCC with the approval of pembrolizumab post-nephrectomy for high-risk disease, based on results from KEYNOTE-564, noting a disease-free survival benefit of nearly 10% at 24 months, and 30 months disease-free survival HR of 0.63^[21,22]. Though ICIs have been very effective, we now see evidence of resistance to these therapies, which limits the durability of response.

The complex and intricate interaction between the immune system and the cancer cell has been described by the various host- and tumor-specific characteristics that have an impact on this interaction and are visually depicted by Blank *et al.*, where potential and confirmed biomarkers at these levels are also noted [Figure 1]^[23]. However, this interface is complex, and many parts of this interaction remain undiscovered. In general, immune resistance can be innate, acquired, intrinsic, or extrinsic^[24]. Innate or primary resistance is an immediate lack of response caused by the presence of resistant clones before starting treatment. Acquired or secondary resistance occurs while on active therapy after an initial response to treatment. Intrinsic resistance occurs when the tumor cells interfere with internal processes, such as cell signaling, gene expression, DNA damage response, and immune recognition, whereas extrinsic resistance occurs through T-cell activation and other processes outside the cell^[24]. Moreira *et al.* divided potential factors contributing

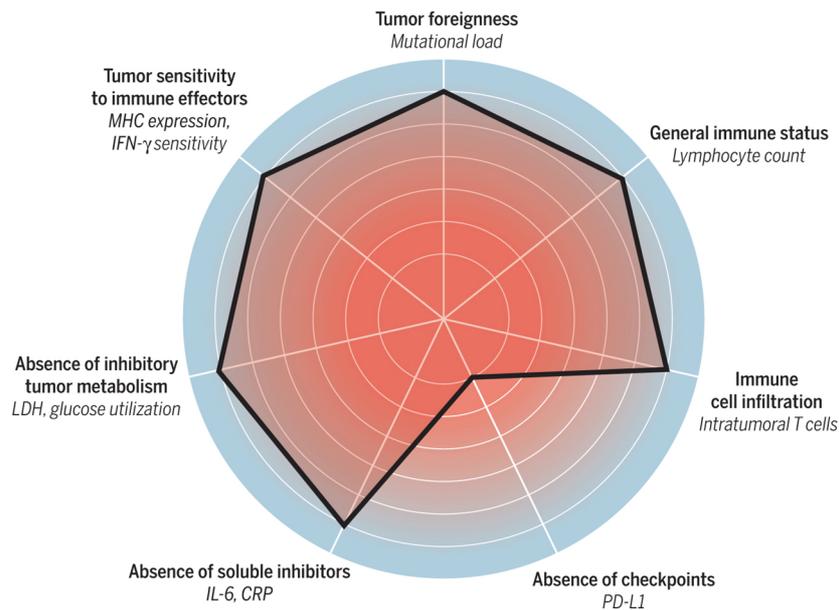

Figure 1. The cancer immunogram - parameters that characterize aspects of cancer-immune interactions where biomarkers have been or may be identified^[23]. Reprinted with permission from the American Association for the Advancement of Science.

to resistance into three major groups - patient, tumor cell, and tumor microenvironment (TME)^[12].

Patient-associated factors of resistance

Patient-related factors include sex/gender, HLA genotype, sarcopenia, gut microbiome, and antibiotic and corticosteroid use. Recent data have continued to show trends toward sex-related differences in response to ICI, favoring males over females^[25-27]. Over recent years, there has been tremendous interest in the relationship between the gut microbiome and ICI response. Several studies in melanoma and renal-cell carcinoma have shown that increased diversity in intestinal bacteria is associated with better responses to checkpoint blockade and that certain species may improve or diminish response^[28,29]. Mouse-model studies exhibited that the microbiome may alter the amount of tumor dendritic cells, antigen-presenting cells, and cytokines^[30]. Species associated with improved response in mRCC include *Akkermansia* spp. and *Bifidobacterium* spp^[28]. In a recent phase I study, Dizman *et al.* investigated the use of nivolumab and ipilimumab with or without CBM588, a bifidogenic live bacterial product, in mRCC and found enhanced outcomes among patients receiving combination therapy with the probiotic agent^[31]. Moreover, antibiotic therapy may alter ICI response because it dysregulates the microbiome. Studies found poor ICI response associated with antibiotic use among patients with mRCC on immunotherapy^[32]. This was also evaluated in a recent meta-analysis of 10 studies which found decreased progression-free survival (PFS), overall survival (OS), and objective response rate (ORR)^[33]. In a recent population-based study of patients over 65 years of age, antibiotic use within 1 year of ICI therapy, in particular fluoroquinolones, was associated with worse OS^[34]. Additionally, steroid use while receiving ICIs has been associated with poor outcomes (PFS and OS). In a recent meta-analysis of 16 studies including non-small cell lung cancer and melanoma, steroid use for supportive care or brain metastases was associated with reduced OS rather than use for adverse effects from ICIs^[35]. Ongoing studies are evaluating ways of modifying the gut microbiome and factors of antibiotics and steroid use that may be modifiable and affect response to therapy.

Tumor cell-associated factors of resistance

Tumor cell-related factors for immune evasion and resistance include altered methods of antigen presentation and T-cell exhaustion. By reducing the expression of tumor antigens and downregulating MHC class I, tumor cells may avoid immune surveillance and destruction^[36]. Alternatively, chronic exposure to an antigen may lead to upregulation of PD-1 or the expression of other inhibitory receptors, such as TIM3, LAG3, BTLA, TIGIT, and VISTA^[24,37,38].

This interaction between tumor antigens and immune response led to the theory of combining immunotherapies and stereotactic body radiation therapy (SBRT) as a therapeutic option. Radiation causes tumor necrosis and may release more tumor antigens, which in turn may allow ICIs to work more effectively both locally and potentially beyond what is irradiated. Several studies evaluated the efficacy of this approach, including NIVES, RADVAX RCC, and a high-dose IL2 + SBRT study. NIVES was a phase II study evaluating the role of nivolumab and SBRT in a pretreated patient with mRCC. Sixty-nine patients were enrolled with ORR of 17%, disease control rate of 55%, and OS of 20 months. However, the authors concluded that this combination did not result in improved outcomes among pretreated patients but could be studied further and considered in an oligometastatic population^[39]. RADVAX RCC evaluated dual-checkpoint blockade with ipilimumab and nivolumab and SBRT. Twenty-five patients were enrolled and initial analysis noted an ORR of 56%^[40]. Interleukin-2 with SBRT has been studied in metastatic melanoma and mRCC with promising antitumor activity^[41,42].

TME-associated factors of resistance

The TME includes factors extrinsic to the cancer cell and plays a substantial role in regulating T-lymphocytes. The balance between Tregs and Teff cells is an important factor in the response or resistance to ICI, with greater Tregs resulting in a diminished response. Moreover, myeloid-derived suppressor cells are another regulatory mechanism that allows for continued tumor growth through immune regulation^[24]. Tumor-associated macrophages, TGF-beta, VEGF, and cytokines are all involved in these regulatory processes and may alter the response to ICI therapy.

Chronic antigen exposure can result in upregulation of PD-1 expression and ultimately T-cell exhaustion, a hypofunctional state associated with decreased Teff function^[43,44]. Exhausted T cells in cancer are similar to those in chronic viral infections, and upregulation of immune checkpoints is a hallmark feature^[45]. This exhaustion in turn may alter antigen presentation and can be a potential mechanism of resistance to checkpoint blockade in multiple tumor types, including mRCC^[46-48].

TILs are strong tumor-defense mechanisms regulating growth and spread. In most malignancies, higher amounts of TILs have been associated with better prognosis and response to ICIs^[49-51]. However, there are some tumor types in which more TILs are not necessarily better. Though RCC is a heavily T-cell - enriched tumor with high numbers of CD8+ TILs, these are mostly dysfunctional or exhausted^[52-55]. They also express more inhibitory receptors, such as LAG3 and Tim-3, co-expressed with PD-1, which have been associated with more aggressive phenotypes exhibited by higher TNM staging and a higher Fuhrman grade^[49,56].

Hypoxia is a major feature in the TME of RCC that may contribute to immune dysregulation and tumor progression through several different mechanisms, as was previously described by Moreira *et al.* and others^[12,38,57,58]. Hypoxia results in the release of hypoxia-inducible factors 1 and 2 (HIF-1a and HIF-2a), which stimulate the expression of inhibitory signals, such as VEGF, CTLA4, and LAG3, and suppress T-cell activation and function^[12]. Belzutifan, a selective HIF-2a inhibitor, was studied in a phase I trial with promising antitumor activity in heavily pretreated patients with mRCC^[59]. It is currently FDA-approved for VHL disease - associated tumors, including RCC, CNS hemangioblastomas, and pancreatic

neuroendocrine tumors^[60]. The use of belzutifan in other settings of RCC and in combination with other therapies, including ICI, is under investigation. Tumor-intrinsic factors and the TME and their interplay are illustrated in [Figure 2](#) as originally developed by Ballesteros *et al.*^[61].

FUTURE DIRECTIONS

Proposed strategies to overcome resistance to ICIs include novel combination approaches, including checkpoint inhibitors with cytokine or chemokine therapy, adoptive cellular therapies, or oncolytic viruses. Biomarkers remain elusive in mRCC as most, including PD-L1, have failed to predict therapeutic response^[62-64]. Cell-free circulating tumor DNA (ctDNA) may have some utility in mRCC but is limited by lower levels in RCC compared to other solid tumors^[65,66]. Those with higher tumor volume appear to shed more ctDNA^[67]. Tumor mutation burden may also be a useful predictor of response to ICIs because a higher tumor mutation burden is associated with a favorable response, though this does not appear to hold for combined checkpoint inhibitors^[68]. Recently, transcriptomics, metabolomics, and metabolic profiling of RCC cells have allowed for a potential avenue of tumor and resistance detection based on common metabolic features of the cancer cell. Lower OS and greater ICI resistance have been noted in tumor cells with an altered kynurenine/tryptophan ratio and higher hypoxia and Wnt/beta-catenin signaling^[69-72].

Revisiting cytokine therapy

The success of ICIs is limited by resistance reinvigorated interest in cytokine therapy, which had originally been effective in RCC, though without robust responses (around 20%) and their use was limited by challenges in administration and potential toxicities^[73-75]. In a retrospective analysis, Buchbinder *et al.* evaluated response among patients with metastatic melanoma and mRCC who had received HD IL-2 after prior treatment with PD-1/PD-L1 therapies through the PROCLAIM database. Of the 57 total patients, 17 had mRCC and ORR was 24% with two complete responses^[76]. In the PIVOT-02 phase I/II study, bempegaldesleukin, a pegylated form of IL-2, was tested with nivolumab as the first line in mRCC. Initial tumor activity was noted with an ORR of 35% and a complete response of 6%^[77]. This is being evaluated further in PIVOT-09, the phase III study, though enrollment was recently terminated as of November 2022^[78,79]. Another recent early-phase trial studied pembrolizumab with HD IL-2 in mRCC and noted an ORR of 70% and no worsening toxicities suggesting further exploration^[80].

Chimeric antigen receptor T-cell (CAR-T) therapy

CAR-T therapy is an adoptive cellular treatment that has revolutionized the management of refractory hematologic malignancies. In essence, a patient's T cells are removed and modified against a specific cellular target and then infused back into the patient (autologous therapy)^[81]. This began with the FDA approval of axicabtagene ciloleucel (axi-cel), an autologous anti-CD-19 CAR-T, in October 2017 for relapsed/refractory (R/R) large B-cell lymphoma after two or more prior lines of therapy based on results of the phase I Zuma-1 study^[82,83]. Since then, axi-cel has been approved for second-line management of large B-cell lymphoma based on results from Zuma-9^[84]. Other agents and indications have received approval - brexucabtagene autoleucel (brexu-cel) for R/R B-cell precursor acute lymphoblastic leukemia (ZUMA-3); tisagenlecleucel (tisa-cel) for R/R B-ALL (NCT02435849) and R/R large B-cell lymphoma (JULIET); idecabtagene vicleucel (ide-cel) for R/R multiple myeloma (KarMMA); abi-cel for R/R follicular lymphoma (FL) (ZUMA-5); and lisocabtagene maraleucel (liso-cel) for R/R large B-cell lymphomas (TRANSCEND). However, axi-cel's utility in solid tumors remains under investigation with modest results to date, partly because of tumor-suppressing molecules in the TME and tumor heterogeneity^[85-91].

Several preclinical studies assessed potential targets for CAR-T in RCC, with CD70 as a promising site because it appears highly expressed in clear-cell and sarcomatoid tumors^[92-94]. Early findings from the

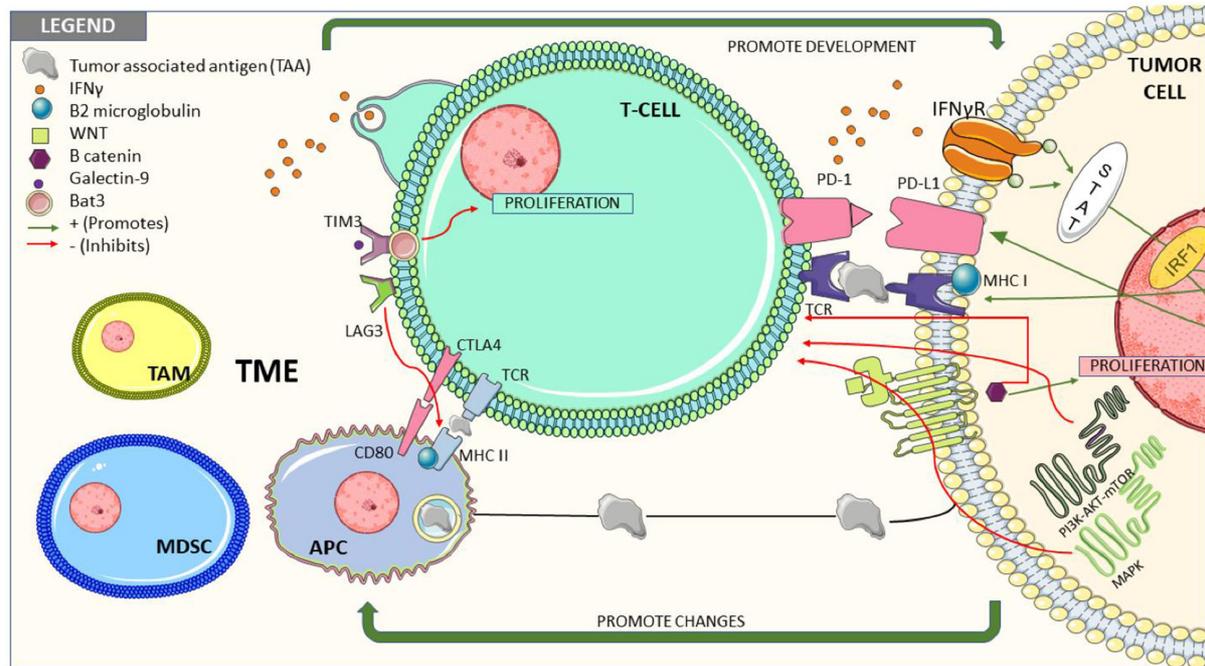

Figure 2. Tumor-intrinsic factors and the TME to describe potential mechanisms of resistance to immune therapies^[61]. Reprinted with permission from Multidisciplinary Digital Publishing Institute. Abbreviation: TME, tumor microenvironment. Reproduced from^[60] under the Creative Commons Agreement License.

COBALT-RCC trial (NCT04438083) were recently presented at the 2022 Society for Immunotherapy of Cancer Annual Meeting with safety and clinical activity for CTX130, an allogeneic anti-CD70 CAR-T that has been CRISP/Cas9 gene-edited, in the 13 evaluable patients so far. The ORR was 8% and the disease control rate 77%, with 1 partial response resulting in a CR maintained at 18 months^[95]. TRAVERSE is an ongoing clinical trial studying the safety and efficacy of ALLO-360, an allogeneic CAR targeting CD70, in mRCC with preliminary data pending (NCT04696731). Another CAR-T product directed against carboxy-anhydrase-IX (CAIX) was promising in preclinical studies, though in an early phase trial, anti-CAR-T antibodies developed with immune responses, and no clinical benefit was noted, and the study was terminated^[96]. This agent has again been evaluated now in combination with sunitinib, though in mouse models, with some synergistic response seen^[97]. Ongoing studies are investigating other potential targets and methods of overcoming resistance and suppressive mechanisms of CAR-T by potentially combining it with other agents.

TIL therapy

TIL therapy has been investigated in mRCC for decades but with limited success, often because of suppressive features of the TME limiting retrieval of large amounts of tumor-reactive TILs^[98-100]. Figlan *et al.* studied radical nephrectomy with IL-2 and TIL therapy among patients with mRCC with favorable results^[101]. In a recent commentary, Andersen *et al.* highlighted several prior TIL studies in RCC with variable ORR ranging from 0% to 35%^[99]. Ongoing studies for TIL therapy are limited though may benefit from combination-based strategies as previously considered, particularly with ICIs to help overcome TME-suppression coinhibitory signals^[102]. Newer methods of TIL retrieval and expansion are also being explored to help overcome these limiting features^[99,103]. Table 1 summarizes ongoing cellular therapy trials in mRCC.

Table 1. Summary of ongoing cellular therapy clinical trials in metastatic/advanced RCC. Information obtained from clinicaltrials.gov

Name	Identifier	Modality	Primary Site	Status
Clinical study of CAIX-targeted CAR-T Cells in the Treatment of Advanced Renal Cell Carcinoma	NCT04969354	CAR-T	Affiliated Hospital of Xuzhou Medical University	Recruiting (last updated June 2021)
Clinical study of CD-70 targeted CAR-T therapy in advanced renal cancer	NCT05420519	CAR-T	The Second People's Hospital of Shandong Province	Recruiting (updated June 2022)
Aldesleukin and pembrolizumab in treating patients with advanced or metastatic renal cell carcinoma	NCT03260504	CAR-T	Fred Hutch/ University of Washington Cancer Consortium	Recruiting (updated October 2022)
TIL Therapy for Metastatic Renal Cell Carcinoma	NCT02926053	TIL	Center for Cancer Immune Therapy, Denmark	Recruiting/ unknown (updated December 2019)
Safety and efficacy of ALLO-316 in subjects with advanced or metastatic clear-cell renal cell carcinoma (TRAVERSE)	NCT04696731	CAR-T	City of Hope, UCLA Medical Center, Moffitt Cancer Center, Memorial Sloan Kettering Cancer Center, Providence Portland Medical Center, MD Anderson Cancer Center	Recruiting (updated March 2022)
P-MUC1C-ALLO1 Allogeneic CAR-T cells in the treatment of subjects with advanced or metastatic solid tumors	NCT05239143	CAR-T	University of California San Francisco, Sarah Cannon Research Institute at HealthOne, University of Kansas Cancer Center, MD Anderson Cancer Center, NEXT Oncology	Recruiting (updated October 2022)
A clinical research about CD70-positive advanced/ metastatic solid tumors treated by CD70-targeted CAR-T	NCT05468190	CAR-T	Henan Cancer Hospital	Recruiting (updated September 2022)
A clinical study of CD70-targeted CAR-T in the treatment of CD70-positive advanced/ metastatic solid tumors	NCT05518253	CAR-T	First Affiliated Hospital, Zhejiang University	Recruiting (updated September 2022)
Safety and Efficacy of CCT301 CAR-T in adult subjects with recurrent or refractory stage IV renal cell carcinoma	NCT03393936	CAR-T	Shanghai Public Health Clinical Center	Active, not recruiting (updated October 2021)
A safety and efficacy study evaluating CTX130 in subjects with relapse or refractory renal cell carcinoma (COBALT-RCC)	NCT04438083	CAR-T	Multiple sites including the United States, Australia, Canada, and the Netherlands	Recruiting (updated May 2022)
HERV-E TCR Transduced Autologous T cells in People with Metastatic Clear-Cell RCC	NCT03354390	TCR	National Institutes of Health Clinical Center	Recruiting (updated December 2022)
Administering Peripheral Blood Lymphocytes Transduced with a CD70-Binding Chimeric Antigen Receptor to People with CD70 Expressing Cancers	NCT02830724	CAR-T	National Institutes of Health Clinical Center	Recruiting (updated January 2023)

Oncolytic virus-based therapy

Another avenue to overcome resistance is the combination of ICIs with oncolytic viruses, which elicit antitumor immunity^[104]. Their use seems limited when used alone but may be more beneficial when combined with other agents targeting specific tumor-suppressive signals in the TME. In a phase II open-label study, patients with metastatic melanoma received either talimogene laherparepvec with ipilimumab or ipilimumab alone, and higher antitumor activity with a greater response rate was seen in the combination without increased toxicities (ORR 39%)^[105]. Recently, a phase I study evaluating NeoVax, a neo-antigen cancer vaccine, with ipilimumab in RCC is actively recruiting (NCT02950766).

Other targeted approaches

As discussed previously, HIF-2a inhibitors are now being investigated in mRCC, and favorable outcomes led to the approval of belzutifan for VHL-associated tumors, including RCC. The role of HIF-2a inhibitors is being expanded and its use in combination with other agents, including ICIs, is being tested. Preclinical studies for belzutifan used in mouse models without HIF-2a expression found no efficacy for single-agent use, but there was potential synergy with checkpoint inhibitors^[106].

Cyclin-dependent kinase 4/6 (CDK4/6) are signaling molecules that promote the progression of the cell cycle by overcoming the tumor suppressor activity of retinoblastoma. Inhibitors of CDK4/6 are currently FDA-approved in the management of breast and ovarian cancers with favorable response rates. Recent preclinical data show promise for CDK4/6 inhibition in RCC to potentiate response with ICIs and chemotherapy^[107].

CONCLUSIONS

The management of mcrRCC has progressed substantially with the advent of checkpoint inhibitors and targeted oral therapies, alone and/or in combination. However, innate or developed resistance to these therapies remains an ongoing challenge, particularly to ICIs. Several of the known mechanisms of resistance have been well defined, but recent progression in cellular therapies helps to expand the armamentarium of potential combination options that may overcome these modes of resistance and improve long-term disease control and survival for an otherwise dismal disease.

DECLARATIONS

Acknowledgment

Editorial assistance was provided by Moffitt Cancer Center's Office of Scientific Publishing by Daley Drucker and Gerard Hebert; no compensation was given beyond their regular salaries. We would like to thank the American Association for the Advancement of Science (AAAS) and Multidisciplinary Digital Publishing Institute (MDPI) for granting us permission to reprint the included figures.

Author's contributions

Conceived and organized the design of the manuscript, performed the literature review and evaluation, and wrote the body of the manuscript: Chatwal MS

Provided administrative, technical, and material support and assisted in editing and reviewing the manuscript: Spiess PE

Performed the literature review, provided material and technical support, and helped to review and edit the manuscript: Chahoud J

Availability of data and materials

Not applicable.

Financial support and sponsorship

None.

Conflicts of interest

Monica Chatwal has no conflicts of interest to report. Jad Chahoud reports advisory board consultation for Pfizer, Aveo, and Exelixis. Philippe Spiess has no conflicts of interest to report.

Ethical approval and consent to participate

Not applicable.

Consent for publication

Not applicable.

Abstract

In 2030, pancreatic ductal adenocarcinoma (PDAC) will become the second leading cause of cancer-related mortality in the world. Unfortunately, neither conventional chemotherapy nor novel immunotherapeutic strategies can provide durable responses and the survival prognosis remains very low. PDAC is notorious for its immune-resistant features and unique genomic landscape facilitating tumor escape from immunosurveillance. Novel immune-checkpoint inhibitors (ICI) failed to show promising efficacy and other multi-modal approaches are currently being validated in multiple clinical trials. In this paper, we provide our opinion on the major mechanisms responsible for PDAC resistance to ICI therapy and provide our view on future strategies which may overcome those barriers.

Keywords: Pancreatic cancer, immune-checkpoint inhibitors, tumor resistance, microenvironment

Pancreatic ductal adenocarcinoma (PDAC) represents a major challenge in modern oncology^[1]. It is predicted that by 2030 PDAC will become the second leading cause of cancer-related death^[2]. Surgery is curative at earlier stages, whereas advanced or metastatic stages are almost impossible to treat^[3].

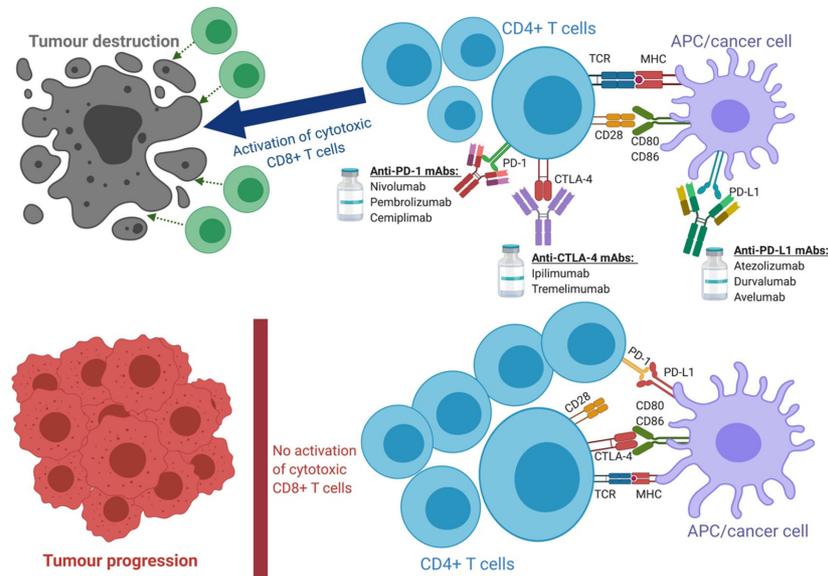

Figure 1. Mechanisms of immune-checkpoint inhibitors. ICIs target unique inhibitory checkpoint molecules expressed by T- and antigen-presenting cells. By blocking those receptors, ICIs promote the proper induction and differentiation of T cell-mediated immunity. In contrast, the absence of ICIs results in successful priming of checkpoint receptors with their ligands, thus inhibiting TCR activation overall, leading to cancer escape from immunosurveillance. APC: antigen-presenting cell; CD: cluster of differentiation; CTLA-4: cytotoxic T-lymphocyte associated antigen 4; mAb: monoclonal antibody; MHC: major histocompatibility complex; PD-1: programmed cell death protein 1; PD-L1: programmed cell death protein 1 ligand 1; TCR: T cell receptor.

Conventional chemotherapy can only provide a short partial remission with 5-year overall survival (OS) of less than 9% in patients with advanced PDAC^[4]. Recent discoveries in cancer immunology have led to the successful use of immune-checkpoint inhibitors (ICIs) in treating advanced solid malignancies. ICIs are monoclonal antibodies that target immune checkpoints such as cytotoxic T-lymphocyte associated antigen 4 (CTLA-4), programmed cell death protein 1 (PD-1) with its ligands PD-L1/L2 and other expressed by antigen-presenting cells (APCs) and T cells [Figure 1]^[5]. ICIs have shifted treatment paradigms for melanoma, non-small cell lung cancer (NSCLC), and hepatocellular carcinoma^[6,7]. Unfortunately, PDAC has shown incredible resistance to immunotherapy^[8]. To date, US Food and Drug Administration (FDA) has only approved PD-1 inhibitor *pembrolizumab*, albeit only for patients with high microsatellite instability (MSI-H)^[9]. Unfortunately, the majority of patients (~ 97%) with microsatellite stable status (MSS) are not benefited from ICIs and their outcomes remain critically poor^[10]. Early trials combining chemotherapy with ICIs also fail to show any superior efficacy in MSS patients^[9]. This paper provides an opinion on factors responsible for PDAC resistance to ICIs and potential strategies to overcome this issue.

Classically, PDAC has an immunologically “cold” tumor microenvironment^[11] characterized by abundant infiltration of myeloid cells and a small number of infiltrating T- and NK (natural killer) cells [Figure 2]. A few studies suggested that focal adhesion kinases (FAK) can regulate the fibrotic features of cold tumors, including the immunosuppressive microenvironment^[12,13]. The data from *in vitro* studies on the synergistic efficacy of FAK + PD-1 inhibitors showed promising responses and resulted in further testing of this regimen in clinical trials. Other factors of resistance are low mutational burden and complex immunosuppressive features able to inhibit T cell priming and trafficking, resulting in lower efficacy of immunotherapy^[14].

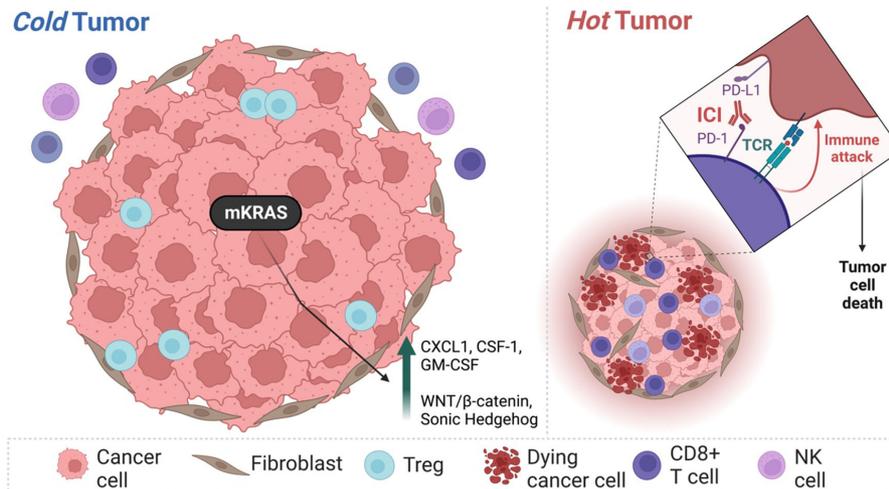

Figure 2. Mechanisms of pancreatic cancer resistance to immune-checkpoint inhibitor therapy. Pancreatic ductal adenocarcinoma is known as a tumor with a "cold" microenvironment characterized by a small number of CD8+ T- and NK cells, an abundance of regulatory T (immunosuppressive) cells, and poor response to ICI therapy. Mutation in *KRAS* gene (mKRAS) allows pancreatic cancer cells to induce expression of granulocyte-macrophage colony-stimulating factor (GM-CSF), chemokine C-X-C motif ligand 1 (CXCL1) and C-C motif chemokine ligand 4 (CCL4) playing a crucial role in immunosuppression. Moreover, mKRAS leads to upregulation of WNT/ β -catenin pathway and Sonic Hedgehog pro-inflammatory pathways overall, inhibiting the ICI therapy.

Stromnes *et al.* reported that analysis of tumor samples revealed that PDAC has a lower number of effector T cells and lower clonality of T cell receptors as compared to other solid tumors that can be successfully managed by ICIs^[15]. Genome studies have established that PDAC almost ubiquitously has activating *KRAS* (Kirsten ras oncogene) mutations^[16]. Conventionally, mKRAS is known to be associated with tumor proliferation and metastasis; however, recent results of high-throughput studies have established that mKRAS may orchestrate downstream signaling responsible for immunosuppression^[17]. A few *in vitro* studies established that mKRAS inhibits the expression of MHC-I, CD47, and PD-L1^[18,19]. It is known that PD-L1 is a crucial marker for ICI efficacy in non-small cell lung cancer^[20]. Perhaps the lower expression of checkpoint proteins (targets) negatively impacts ICI therapy and explains its lower effectiveness in PDAC patients. Secondly, mKRAS can upregulate the expression of GM-CSF and CXCL1, which are involved in the recruitment of myeloid-derived suppressor cells known for their immunosuppressive features^[21,22]. Furthermore, mKRAS can downregulate the expression of CCL4 via WNT/ β -catenin pathway^[23]. CCL4 is an important factor for recruiting dendritic cells; major APCs require FOR priming T cell response and activating the cytotoxic cascade^[24,25]. A lower number of APCs impacts the tumor escape from immunosurveillance. Additionally, mKRAS promotes signaling via the Sonic Hedgehog pathway and can induce expression of matrix metalloproteinase 7 (MMP-7)^[26] as well as selectively target lysosomal degradation of MHC-I molecules through an autophagy-dependent mechanism, thus negatively impacting ICI therapy^[19]. Overall, it results in chronic inflammation and proliferation of the fibrotic stroma, thus complicating T cell trafficking^[27]. The development of mKRAS-directed strategies may one day overcome this critical resistance mechanism and result in higher effectiveness of ICIs in PDAC.

In summary, PDAC is among the most immune-resistant tumors. Recent discoveries in understanding key elements of PDAC resistance to ICI therapy, including FAK^[28], mKRAS and other novel molecules^[29], have reshaped our view on future approaches for PDAC treatment. To effectively treat PDAC, it is crucial to elucidate the rational combinatorial approach(es) targeting both checkpoint proteins and non-redundant mechanisms of PDAC resistance, such as mKRAS. Moreover, novel therapeutic strategies should be selected based on patient's individual genotype, which is responsible for high phenotypic heterogeneity observed

across PDAC patients. Finally, mKRAS remains the bull's eye for PDAC immunologic resistance; thus, the combinatorial approach of ICI + MEK (mitogen-activated protein kinase) inhibitors should be thoroughly studied in randomized trials. The synergistic effect of both drugs may improve clinical outcomes for PDAC patients in the near future.

Abstract

Targeted therapy has become one of the standards of care for advanced lung cancer. More than 10 genetic aberrations have been discovered that are actionable and several tyrosine kinase inhibitors (TKIs) have been approved to target each of them. Among several genetic aberrations that are actionable in non-small cell lung cancer (NSCLC), *ROS1* translocations also known as gene fusion proteins, are found in only 1%-2% of the patient population. *ROS1* mutations can usually be detected using a combination of techniques such as immunohistochemistry (IHC), Fluorescence in-situ testing (FISH), polymerase chain reaction (PCR), and next-generation sequencing (NGS). However, RNA NGS and ctDNA NGS (liquid biopsies) also contribute to the diagnosis. There are currently numerous FDA-approved agents for these tumors, including crizotinib and entrectinib; however, there is in-vitro sensitivity data and clinical data documenting responses to ceritinib and lorlatinib. Clinical responses and survival rates with these agents are frequently among the best compared to other TKIs with genetic aberrations; however, intrinsic or extrinsic mechanisms of resistance may develop, necessitating research for alternative treatment modalities. To combat the mechanisms of resistance, novel agents such as repotrectenib, cabozantinib, talotrectinib, and others are being developed. In this article, we examine the literature pertaining to patients with *ROS1* tumors, including epidemiology, clinical outcomes, resistance mechanisms, and treatment options.

Keywords: *ROS1*, targeted therapy, non-small cell lung cancer

INTRODUCTION

Cancer is one of the leading causes of death in the United States. Over 1.8 million people are newly diagnosed with cancer every year, and 606,520 people lose their lives as a direct result of the disease. Three most common types of cancer are breast cancer, lung cancer, and prostate cancer^[1]. There were 236,740 new cases of lung cancer, and over 130,180 people lost their lives to the disease^[2]. Lung cancer is the most common cause of death resulting from any form of cancer, including breast, colorectal, prostate, and brain cancers.

Cancer of the lung is a disease that originates in the pulmonary parenchyma or the airways of the lungs. Non-small cell lung cancer (NSCLC) and small cell lung cancer (SCLC), which together account for 95% of all cases of lung cancer, are the two types of lung cancer that can be classified based on the histology. NSCLC includes adenocarcinoma, squamous cell carcinoma, adenosquamous carcinoma, large cell carcinoma and sarcomatoid.

Previously, the treatment for lung cancer was only systemic chemotherapy that would target all cells that were proliferating or dividing which would prolong survival but would cause burden on quality of life of patients due to the toxic effects of treatment. Most recently, there has been a substantial amount of research on molecular pathways which allowed for target therapies to be developed to combat the pathways. Common molecular targets in lung cancer include EGFR, ALK, KRAS, ROS1, BRAF V600E, NTRK 1/2/3, METexon14, RET, ERBB2 and PD-L1. Molecular testing can be done with DNA sequencing, next generation sequencing (NGS), Fluorescence in-situ testing (FISH), immunohistochemistry (IHC) and liquid biopsies.

The availability of molecular testing, the identification of mutational drivers, and the introduction of targeted therapies have all changed the landscape of lung cancer therapy in recent years^[1]. Epidermal Growth Factor Receptor (EGFR) mutations, for example, are known to contribute to the maintenance and functioning of cancer stem cells, including metabolism, immunomodulatory activity, dormancy, and therapeutic resistance^[1]. While the *ALK* gene, located on the short arm of chromosome 2, is a transmembrane tyrosine kinase receptor which activates downstream signaling pathways resulting in uncontrolled cell proliferation and survival have been studied previously and are good therapeutic targets in the treatment of NSCLC^[3,4]. The effectiveness of targeted therapy in treating EGFR^[2-6] and ALK^[7-11] mutations has increased interest in identifying additional oncogenic drivers with potential for clinical use.

The proto-oncogene *ROS1* on chromosome 6 encodes a tyrosine kinase receptor, limited to distinct epithelial cells during embryonic development^[5] but with unknown functionality afterwards. It was originally identified in 1986 as the cellular homolog of the transforming *v-ros* sequence from the UR2 avian sarcoma virus^[6] and later identified in glioblastoma-derived cells^[7]. Further research has demonstrated ROS1's ability to cause cancer using in vitro and in vivo animal models^[12]. The discovery of *ROS1* gene fusions in NSCLC has important clinical implications because it allows for the treatment of a subset of patients with a targeted therapy that can significantly improve their outcomes. It emphasizes the significance of extensive molecular profiling in NSCLC for identifying targetable mutations and guiding treatment decisions. Additionally, TKIs are effective on multiple targets including targeting the ALK rearrangement position, ROS1 fusions and NTRK rearrangements using agents such as ceritinib, crizotinib, lorlatinib and entrectinib^[8].

Therapy options for NSCLC includes chemotherapy, immunotherapy and targeted therapy. Common chemotherapy options includes platinum agents (cisplatin, carboplatin) in combinations with taxanes (paclitaxel, albumin bound paclitaxel) or pemetrexed. Immunotherapy may be incorporated also using pembrolizumab, atezolizumab or even ipilimumab and nivolumab.

Molecular testing

Molecular testing is constantly evolving field and there is no single standard modality for detection of abnormalities. Different modalities of testing include DNA sequencing, NGS, FISH, IHC and liquid biopsies. DNA sequencing is the one of the oldest forms of testing for mutations which looks at an entire length of a single gene for mutation. The sensitivity is the lowest amongst all tests and may cause false negatives. The test requires the tumor cellularity to be high in the tissue sample to detect an abnormality. DNA and RNA NGS allows for testing of multiple genes at the same time or whole genomes with high sensitivity even if the tumor cellularity is low. The sensitivity is so high that it may detect even molecular alterations in the blood via circulating tumor DNA. FISH helps to examine gene rearrangements such as translocations, amplifications or deletions using DNA probes of various colors that move apart when gene has separated. IHC is both sensitive and specific. The turnaround time for results is rapid and it is the only test available to test for PD-L1 expression. Lastly, liquid biopsies allow for non-invasive and inexpensive means to test even when there is minimal tumor samples available for testing. It allows to monitor for disease response during treatment or even relapse in the future^[9]. Liquid biopsies allow for detection of cell-free ctDNA in the blood of lung cancer patients. The negative aspects of the test is that there is a high false negative rate compared to standard tests due to small and variable amounts of circulating DNA that may be present. The sensitivity of liquid biopsies is 60% to 80% and sometimes cannot detect tumors that do not secrete DNA into the blood.

NSCLC GENOTYPES

ROS1 gene fusions

ROS1 gene fusions are genetic alterations that have been associated with the development and progression of multiple cancers, including NSCLC. The *ROS1* gene located on chromosome 6 (region 6q22.1) is responsible for the generation of two main splice variants of *ROS1* that are encoded by either exon 43 or exon 44 and codes for a receptor tyrosine kinase that is essential for cell growth and differentiation. *ROS1* gene fusions occur when a portion of the gene joins with another gene, resulting in the production of a new, chimeric protein that promotes the growth of cancerous cells. *ROS1* fusion genes have been linked to a wide range of cancers ever since their discovery in the glioblastoma cell line U118MG in 1987^[10-12]. *ROS1* is a proto-oncogene that encodes a receptor tyrosine kinase in humans, but its physiological function is not known. The somatic chromosomal fusions that involve *ROS1* produce chimeric oncoproteins that are the driving force behind a wide variety of cancers, and a significant amount of interpatient partner-gene heterogeneity has been observed in various types of cancer. While *ROS1* rearrangements are only present in approximately 1%-2% of patients with lung cancer, a significant number of people are affected by this mutation given high prevalence of lung cancer.

ROS1 fusions are most common in patients with NSCLC who are younger (median age of 50 years) and who have never smoked (80%)^[12-15]. The CD74-*ROS1* fusion is the most prevalent type of *ROS1* fusion (44%), followed by the EZR-*ROS1* fusion (16%), SDC4-*ROS1* fusion (14%), and SLC34A2-*ROS1* fusion (10%). Interchromosomal translocations are the major cause of recurrent *ROS1* fusions in NSCLCs^[12,15]. In model systems, *ROS1* fusions on their own are sufficient to induce tumorigenesis; however, *ROS1* fusions working in conjunction with other aberrant oncogenes or tumor suppressor pathways can promote a significantly more aggressive form of disease. In some instances, *ROS1* fusions have been discovered to coincide with the presence of other oncogenic alterations. Other driver mutations, such as RET, NTRK, and

ALK fusions in NSCLCs, IMTs, and Spitzoid neoplasms, as well as FGFR2 and IDH alterations in cholangiocarcinoma^[13,14], are likely to be mutually exclusive with the ROS1 fusions. In clinical practice, ROS1 fusion can be evaluated on a tissue biopsy and fluid cytology with ROS1 IHC. However, similar to the ALK IHC, the ROS1 IHC can report false positive results and thus, requires confirmation with NGS, ROS1 FISH, or with a multiplex reverse transcriptase-polymerase chain reaction (RT-PCR) panel.

ROS1 gene fusions in NSCLC are typically detected via molecular testing, such as FISH or RT-PCR. These techniques enable the identification of the precise fusion partner and the development of therapies that inhibit the activity of the chimeric protein and plasma samples, the NGS can be used to analyze ROS1 rearrangement^[13,14,16]. *ROS1* gene fusions in NSCLC have a significant potential therapeutic application. ROS1 inhibitors have shown remarkable efficacy in patients with ROS1-positive NSCLC, with response rates ranging from 60% to 80% and a median progression-free survival (PFS) of 12-19 months. This suggests that ROS1 inhibitors are highly effective. This is a significant improvement over conventional chemotherapy, which only has a moderate impact on NSCLC. Certain minority groups, including African-Americans, are disproportionately affected by lung cancer and may be more likely to have *ROS1* gene fusions. Understanding the epidemiology of ROS1 mutations in lung cancer, particularly in minority populations, is critical for improving cancer prevention, diagnosis, and treatment outcomes; similarly, understanding the prevalence, types, and characteristics of ROS1 fusion-positive mutations in NSCLC is critical for developing effective, patient-beneficial targeted therapies^[13,16]. The use of appropriate diagnostic techniques to identify ROS1 fusion-positive patients, as well as the use of ROS1 inhibitors, has shown tremendous promise in the treatment of NSCLC.

EGFR mutations

Epidermal growth factor receptor (EGFR) mutations compromise 15% of NSCLC adenocarcinomas and occur often in non-smokers and Asian populations^[17]. Common mutations in EGFR include exon 19 deletions or exon 21 L858R mutations which are very responsive to TKIs for treatment. Previously, first-generation TKI (gefitinib, erlotinib) and second-generation (afatinib) TKIs have been used for treatment but recently there has been improvement in survival with third-generation agents such as Osimertinib. Osimertinib is approved for first-line treatment in patients with EGFR exon 19 deletions or exon 21 L858R mutations. In the FLAURA study, a phase III trial, patients with treatment naïve EGFR-mutated NSCLC were randomized to receive Osimertinib versus the standard of care TKI (gefitinib or erlotinib). Osimertinib showed improvement in PFS 18.9 months versus 10.2 months, increased duration of response (DOR) (17.2 months versus 8.5 months) and overall survival (OS) 38.6 months versus 31.8 months^[18]. Common adverse reactions include QTc prolongation and decreased left ventricular ejection fraction.

ALK mutations

Anaplastic lymphoma kinase (ALK) is a tyrosine kinase that is often found to have chromosomal rearrangements involving *ALK* gene on chromosome 2 and compromise 3%-5% of NSCLCs^[19,20]. The rearrangement involves the 5' end of the echinoderm microtubule-associated protein-like (*EML4*) gene with the 3' end of the *ALK* gene, creating a fusion oncogene *EML4-ALK*^[21]. ALK mutations are often found in never or light smokers and younger populations. Common ALK inhibitors include alectinib, brigatinib, certinib, lorlatinib and crizotinib. In the ALEX study, 303 patients were randomly selected to receive alectinib versus crizotinib. Alectinib showed a decreased risk of progression or death in 53% of patients, PFS was 35 months versus 11 months in the crizotinib arm and OS was not reached^[22]. Common side effects included anemia, myalgia, hyperbilirubinemia, weight gain and photosensitivity.

MET mutations

MET is a tyrosine kinase receptor for hepatocyte growth factors. MET mutations include MET exon-14 skipping mutations (3% of NSCLC) and *MET* gene amplification (2%-4% of NSCLC). MET exon-14 skipping mutations decreases the degradation of MET which causes it to become a oncogenic driver. Capmatinib, crizotinib and tepotinib have been both approved for treatment of MET exon-14 skipping mutations. In the GEOMETRY-mono-1 trial included 97 patients with MET exon-14 skipping mutations and capmatinib showed a 68 percent overall response rate and the PFS was 12.4 months. Common adverse reactions included peripheral edema, nausea, vomiting and increased creatinine^[23]. Lastly, in *MET* gene amplifications capmatinib or crizotinib is often used.

RET rearrangements

The rearranged during transfection gene (*RET*) translates a cell surface tyrosine kinase receptor kinase that is mutated. RET rearrangements are present in 1%-2% of NSCLC, often in non-smokers and younger patients. First line therapy include treatment with selpercatinib, pralsetinib and cabozantinib. Common side effects include hypertension, fatigue, diarrhea, transaminitis and pneumonia^[24-26].

BRAF mutations

BRAF is involved with downstream signaling of Kristen rat sarcoma viral oncogene homolog (KRAS) and activates the mitogen-activated protein kinase (MAPK) pathway. BRAF mutations are present in 1%-3% of NSCLC and are present in patients with a smoking history. BRAF mutations can occur in the V600 position of exon 15 or outside of the domain. First line therapy options include dabrafenib, dabrafenib/trametinib and vemurafenib.

NTRK fusions

NTRK fusions are very rare (< 1% of NSCLC) and involve one of three tropomyosin receptor kinases (TRK). Therapy options for NTRK fusions include Larotrectinib and Entrectinib. Larotrectinib was analyzed in several phase I/II trials which showed an ORR 79%. Most common adverse effects included elevated transaminases, anemia and neutropenia^[27]. Entrectinib showed a ORR 57% in several trials^[28]. Entrectinib and Larotrectinib have not been compared with each other.

KRAS mutations

The Kristen rat sarcoma viral oncogene homolog (KRAS) occurs in 20% to 25% of NSCLC and is often associated with smoking^[29]. In NSCLC, the G12C mutation is targeted by sotorasib and adagrasib as subsequent therapy after patients have received 1 prior therapy. The most common adverse reactions include elevated transaminases and diarrhea.

Mechanisms of resistance

As was mentioned before, systemic or central nervous system resistance often develops after good clinical responses and survival. Mechanisms of resistance to ROS1 can be categorized as on-target or off-target. After a tumor has been treated with a TKI, on-target resistance mechanisms can emerge, such as ROS1 mutations^[30-32]. There are several mutations described, the most commonly recognized of which is G2032R, followed by D2033N, and both of them are solvent-front mutations. Other acquired resistance mutations included gate keeper mutations and among them S1986F/Y, L2000V, F2004V, L2026M, and G2032K^[33-36]. L2086F is an important and very dangerous resistance mutation because it is resistant to all TKIs (crizotinib, lorlatinib, taletrectinib) [Figure 1]^[30,31,34].

TKIs have varying efficacy against resistant mutations, sensitivity must be confirmed prior to initiating therapy. For example, lorlatinib has efficacy against the K1991E or S1986F resistant mutations, but has

ROS1 Inhibitor

ROS1 Receptor

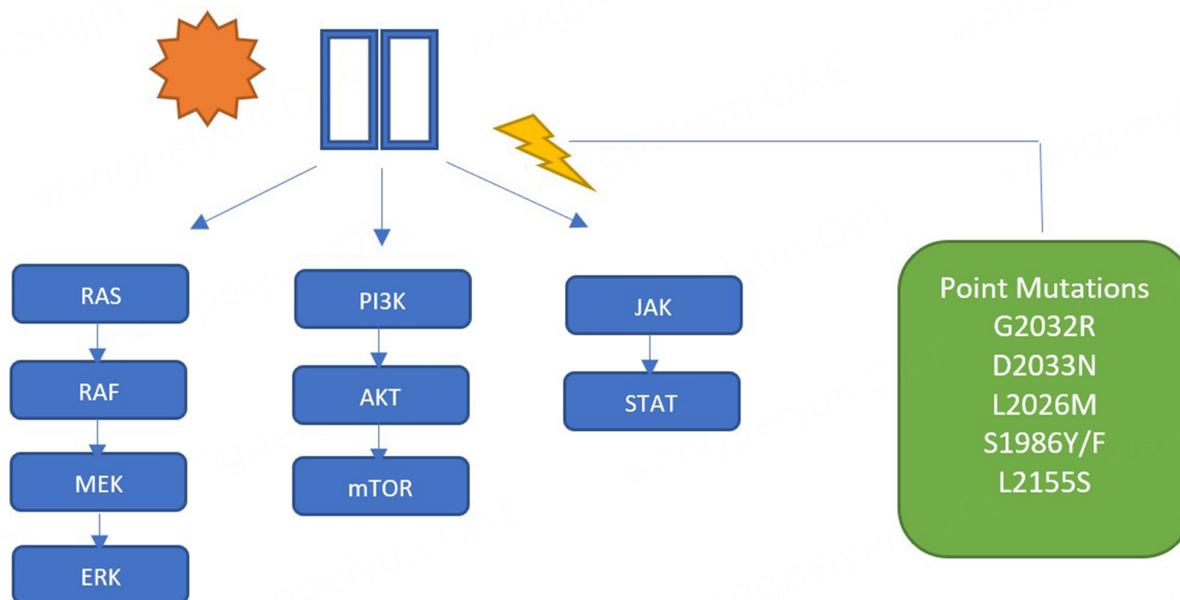

Figure 1. ROS1 pathway and resistance mechanism. Molecular mechanisms of ROS1 Inhibitors in ROS-1 rearranged lung cancer patients. Molecular pathways to resistance include an activated ROS1 kinase which activates the SHP-2 phosphatase and increases the JAK/STAT3, PI3K/AKT/mTOR, RAS/RAF/MEK/ERK signaling pathways to promote growth and survival of the cell.

limited therapeutic potential against the G2032R mutation^[35,36], and may be used after failure on entrectinib^[37]. Sequential use of crizotinib and lorlatinib has led to the formation of a compound mutation of G2032R/L2086F but cabozantinib has potential to overcome this compound mutation^[30,31,34]. Cabozantinib is frequently used to treat thyroid cancer as well as other tumors that it can selectively target, including MET, VEGFR-2, RET, ROS-1, and AXL, with good penetration of blood brain barrier. Despite the presence of resistance mutations such as D2033N or G2032R^[38-40], resistance to crizotinib, ceritinib, and entrectinib can be overcome with cabozantinib. Brigatinib, an additional ROS1 inhibitor, has demonstrated antitumor activity against a number of crizotinib-resistance mechanisms^[41], including the L2026M mutation, but not the G2032R mutation^[41-43]. Talectrectinib, ROS1 and NTRK inhibitor with activity against G2032R, L1951R, S1986F and L2026M mutations, but minimal activity against D2033N mutation. A clinical trial with 46 patients on previous multiple lines of therapy had a 33% ORR and another trial with 15 patients, reported 58.3% ORR in previously exposed patients and 66.7% in treatment naïve patients^[30,44]. There have been additional intrinsic mutations discovered in addition to the ones described and shown in [Table 1](#).

Additionally, there are important off-target resistance mechanisms that involve the presence of other genomic aberrations like: *MET* amplification (3%), *KRAS* mutations (20%-25%) or small cell transformation (3%-10%)^[45-47]. Lastly, the molecular pathways to resistance includes an activated ROS1 kinase activates the SHP-2 phosphatase and increases the JAK/STAT3, PI3K/AKT/mTOR, RAS and MAP/ERK signaling pathways to promote growth and survival of the cell^[48] and HER2 mediated bypass signaling [[Figure 1](#)].

ROS1 TARGETED THERAPIES

Numerous tyrosine kinase inhibitors (TKIs) have been developed, such as crizotinib, ceritinib, entrectinib,

Table 1. Intrinsic mutations in ROS1 resulting in resistance

and lorlatinib. Both crizotinib and entrectinib have been approved for use in the first-line setting. According to [Table 2](#), the use of a ROS1 TKI in the first-line setting improves OS, response rate (RR), and progression-free survival (PFS) in comparison to standard chemotherapy^[24]. [Table 3](#) depicts the most prevalent adverse events associated with each targeted therapy.

Crizotinib

Crizotinib was the first TKI to be approved for management of ROS1 mutated NSCLC. In 2014, the PROFILE 1001 study showed significant activity against ROS1-rearranged NSCLC^[49]. PROFILE 1001 was a multicenter, single-arm phase I study that included patients with metastatic ROS1 positive NSCLC that depicted an ORR 72%, PFS 9.2 months and median DOR 17.6 months^[49]. An updated analysis of the PROFILE 1001 in 2019, median OS was 51.4 months, median PFS 19.3 months and median DOR 24.7 months^[50].

In a prospective phase II OxOnc study, crizotinib demonstrated an ORR 91%, DOR 19.7 months, PFS 15.9 months and OS 32.5 months^[51]. In comparison to the PROFILE 1001 study, the OxOnc study included patients with brain metastases (BM) both symptomatic and asymptomatic comprising 18% of study population. The study showed a PFS of 10.2 months (patients with BM) vs. 18.8 months (patients without BM)^[51]. Additionally, another phase II multicenter study, evaluated not only ROS1 rearrangement but also co-mutations with TP53. The results of the phase II study showed ORR 70% with median PFS 20 months, while those with TP53 co-mutations had a shorter median of PFS of 7 months^[52].

Failure to respond to crizotinib frequently results from CNS progression and mutations. G2032R/K, D2033N, S1986Y/F, L2026M, and L1951R are common mutations that cause crizotinib to fail, with G2032R being the most common^[53]. Lorlatinib is a potential agent that can be used in patients that have progression on crizotinib as it is able to overcome resistance mutations.

Table 2. Clinical activity and toxicity profiles of ROS1 tyrosine kinase inhibitors in treatment naïve patients

TKI	RR (%)	PFS (months)	OS (months)/(1 yr)
Crizotinib ^[49,50]	72	19.3	51.4/79
Ceritinib ^[56]	67	19.3	24/56
Entrectinib ^[62]	53	19	NR/85
Lorlatinib ^[64]	21	21	NR

OS: Overall survival; PFS: progressive free survival; RR: response rate; TKI: Tyrosine Kinase Inhibitor.

Table 3. Summary of adverse events from ROS1 tyrosine kinase inhibitors

Tyrosine Kinase Inhibitor	Common TRAE	Grade 3-4 TRAE (%)
Crizotinib ^[49,50]	Visual impairment, diarrhea, constipation, peripheral edema, nausea, elevated AST, dizziness	36
Ceritinib ^[56]	Diarrhea, nausea, anorexia, vomiting, cough, elevated creatinine, elevated transaminases	37
Entrectinib ^[62]	Dysgeusia, fatigue, dizziness, constipation, nausea, weight gain, paresthesia	34
Lorlatinib ^[64]	Hypercholesterolemia, hypertriglyceridemia, edema, peripheral neuropathy, AMS, weight gain, dizziness	49

AMS: Altered mental status; AST: aspartate aminotransferase; TRAE: treatment related adverse events.

In a phase I/II trial with ROS1-positive patients who have received crizotinib previously led to an ORR of 35%^[54]. Additionally, cabozantinib is a potential agent that be used to overcome crizotinib resistance^[38]. Crizotinib also has very poor blood-brain barrier penetration and is often limited for use in patients with CNS progression^[53]. Lastly, common side effects of crizotinib include vision disorder, diarrhea, nausea, vomiting and peripheral edema^[49].

Ceritinib

Ceritinib is a second-generation TKI approved to treat NSCLC patients with ROS1 rearrangement. Ceritinib is a highly potent TKI with a potency 20 greater than crizotinib^[55]. Ceritinib efficacy was evaluated in a multicenter, phase II study of 32 patients with ROS1 rearrangement and the results showed a ORR of 67%, median PFS 19.3 months and median OS 24 months^[56]. Most common side effects included diarrhea, nausea and anorexia^[56]. In 2017, the ASCEND-8 trial evaluated if a decreased dosage of ceritinib had similar efficacy with less adverse risk. Certinib 450 mg was compared to the standard 750 mg dosage and similar efficacy but more tolerable side effects were seen using the lower dosage^[57]. Although ceritinib is a highly effective TKI in the treatment of ROS1-mutated NSCLC, it has limited applications in crizotinib-resistant patients because it is resistant to the common mutations seen with crizotinib, such as G2032R, D2033N, L1951R, and S1986Y/F^[55].

Entrectinib

Entrectinib is a ROS1 inhibitor with profound penetration in the CNS allowing it to exert its anti-tumor activity^[58]. In the STARTRK-1, STARTRK-2 and ALKA-372-001 trials, 53 ROS1 mutated treatment naïve patients were given entrectinib 600 mg daily and followed for at least 12 months. The patients were evaluated for ORR and DOR as co-primary endpoints while OS, PFS, intracranial DOR (IC-DOR), intracranial ORR (IC-ORR) and safety effect profile were secondary endpoints. In the studies, most patients were white (59%), female (64%) and never smokers (59%) with baseline CNS disease present in over 43% of patients^[59-61]. Forty-one patients were found to have a response, 6% of patients had a complete response (CR), 72% had a partial response (PR) and 2% had an objective response (OR). The median DOR was 24.6 months, ORR 77% and median PFS 19 months in patients without CNS disease. Median OS was not met at 15.5 months during follow-up. While on the contrary, patients with CNS disease had a median DOR 12.6

months, ORR 74%, median PFS 13.6 months, IC-DOR 12.9 months and IC-ORR was 55%. The study showed that entrectinib was not only active systemically but also had good CNS penetration. The most common side effects included nervous system disorders (3%) and cardiac disorders (2%)^[62].

Lorlatinib

Lorlatinib is a selective third-generation ALK and ROS1 TKI that has both systemic and CNS activity via reduction of P-glycoprotein 1-mediated efflux^[63]. In a phase I study, Lorlatinib was given to ROS1-positive NSCLC patients with ECOG status 0-1. The primary endpoint was dose-limiting toxicities and the secondary endpoints were pharmacokinetics, safety, and overall response. Lorlatinib has good penetration in the CNS with a response of 60%. Common adverse effects were weight gain, peripheral edema and constipation.

In a phase II trial, 69 patients were enrolled with ROS-1 positive NSCLC with 30% being TKI naïve and 70% having previous TKI exposure (58% were pretreated with crizotinib and 12% with other TKIs) to evaluate for an overall and intracranial response. The RR was 62% in the TKI naïve patients and 35% in the TKI exposed patients, while the PFS was 21 months vs. 8.5 months. Intracranial responses were seen in 64% of TKI naïve and 50% in those pre-treated with crizotinib. The most common side effects included hypertriglyceridemia and hypercholesteremia^[64].

In the PFROST study, predictive molecular events for response were evaluated. All patients in study were ROS1 mutated and had been previously treated with crizotinib. Prior to initiation of therapy with lorlatinib, the patients had a tissue or blood sample taken. Patients with a G2032R mutation progressed rapidly and continued to have this mutation at the time of treatment failure, showing the importance of early testing to predict response to therapy^[35].

Lastly, the efficacy of lorlatinib was tested in the French LORLATU and Asian GLASS studies, which revealed significant RR both extracranial and intracranial, confirming lorlatinib's potency as a good therapeutic option in the treatment of ROS1 mutated NSCLC^[65,66].

Novel agents

First-generation TKIs are effective in treating ROS1+ NSCLC until resistance mutations develop, presenting a clinical challenge. Chemotherapy is still used as a last resort after disease progression occurs as a result of resistance mutations. Chemotherapy is not as effective as TKIs, with a median PFS of 7 months^[44]. Studies for potential newer second-line regimens are ongoing.

Cabozantinib

Cabozantinib is a tyrosine kinase inhibitor that is currently approved for treatment of renal cell carcinoma, hepatocellular carcinoma and medullary thyroid cancer^[39]. In a recent study, four patients were evaluated that developed resistance to first line TKIs, crizotinib and ceritinib, and were subsequently treated with cabozantinib. In the study, an OR 25 percent and PFS from 4.9 to 13.8 months was achieved. Study limitations included no pre-therapy tissue samples to identify resistance mutations and no clear understanding whether the effects were due to ROS1 inhibition or direct drug effects^[67]. Cabozantinib is very effective against most mutations including G2032R and D2033N but has significant toxicity that limits research on the medication for ROS1+ patients^[58].

Taletrectinib (DS-6051b)

Taletrectinib is a TKI that has activity against both NTRK and ROS1. Recently, it was found that Taletrectinib can be used in ROS1 positive patients that harbor CD74, S1986F, L2026M, L1951R and

G2032R mutations^[39]. In a phase I study, 15 Japanese patients were enrolled with 12 having measurable lesions and 9 were treatment naïve. In treatment naïve patients, the ORR was 66.7 percent, while those that were pre-treated with TKIs the ORR was 33.3 percent^[44]. Most recently, two phase I studies in the United States and Japan evaluated an ORR, PFS and safety. Twenty-two patients with ROS1 positive NSCLC were evaluated and given Talrectinib in dose escalation. The ORR for ROS1 TKI naïve patients was 66.7 percent, while for previously treated patients it was 33.3 percent. The PFS for TKI naïve patients was 29.1 months, in contrary to pre-treated TKI patients it was 14.2 months^[68]. Talrectinib was found to have good systemic activity in patients with ROS1 positive NSCLC regardless of TKI pretreatment. Most common side effects include elevated transaminases (27%) and GI toxicity (4.5%).

Repotrectinib (TPX-0005)

Repotrectinib is a selective tyrosine kinase inhibitor that not only inhibits NTRK and ALK but also ROS1 with a potency level of > 90 folds of crizotinib and is able to overcome G2032R and D2033N mutations^[69]. Repotrectinib has both systemic and CNS activity^[70]. Recently, in the TRIDENT-1 trial, 33 ROS1 positive patients were evaluated that included both TKI naïve and pre-treated TKI patients. The patients received dose escalations of repotrectinib with a ORR 82 percent (regardless of dose) in TKI naïve patients and 39 percent in pre-treated TKI patients. The ORR increased to 55 percent in pre-treated TKI patients with dosages of 160 mg. The intracranial-ORR was 100 percent in treatment naïve patients and 75 percent in those previously treated with TKI. The median DOR was 23.1 months, while the PFS was 24.6 months^[71]. The study demonstrates that repotrectinib is a potent TKI that can be used in both treatment naïve and previously treated TKI patients with ROS1 positivity. More research is required, and it is currently underway in phase II of the Trident study, which is scheduled to conclude in 2023. The TRIDENT study's Phase II is enrolling 190 ROS1 positive patients and evaluating response based on the number of TKIs previously used. Dizziness, fatigue, constipation, and dyspnea are the most common side effects.

CONCLUSIONS

ROS1 fusions are not very common and only represent around 2% of NSCLC, however due to the high incidence of lung cancer in the US, this genetic aberration is present in several thousand patients.

Thanks to DNA NGS and other diagnostic methods in tissue or blood we are able to detect these genetic aberrations and offer our patient's front-line therapy with very good clinical outcomes, significant survival prolongation and good quality of life.

Currently, crizotinib and entrectinib are approved for ROS1 tumors, however ceritinib and lolartinib have already showed good clinical efficacy too. Repotrectinib, talotrectinib and cabzantinib are in development to fight on-target mechanisms of resistance as future therapeutics in the combat against ROS1 fusions.

Abstract

Epithelial ovarian cancer (EOC) is treated in the first-line setting with combined platinum and taxane chemotherapy, often followed by a maintenance poly (ADP-ribose) polymerase inhibitor (PARPi). Responses to first-line treatment are frequent. For many patients, however, responses are suboptimal or short-lived. Over the last several years, multiple new classes of agents targeting DNA damage response (DDR) mechanisms have advanced through clinical development. In this review, we explore the preclinical rationale for the use of ATR inhibitors, CHK1 inhibitors, and WEE1 inhibitors, emphasizing their application to chemotherapy-resistant and PARPi-resistant ovarian cancer. We also present an overview of the clinical development of the leading drugs in each of these classes, emphasizing the rationale for monotherapy and combination therapy approaches.

Keywords: Ovarian cancer, platinum resistance, PARPi resistance, DDR

OVARIAN CANCER AND PLATINUM-BASED CHEMOTHERAPY

Ovarian cancer is the deadliest gynecologic malignancy, estimated to account for 12,810 deaths in 2022^[1]. Epithelial ovarian cancer (EOC) is treated in the first-line setting with combined platinum and taxane chemotherapy^[2]. Over 80% of high-grade serous ovarian cancers (HGSOC), the most common ovarian cancer subtype, will exhibit an initial response to platinum-based chemotherapy^[3]. Defects in homologous recombination repair (HRR) are present in about 50% of EOC, and the initial sensitivity of EOC to platinum-based therapy has been attributed to the high prevalence of homologous recombination deficiency (HRD) in this cancer type^[4]. Only a minority (10%-15%) of HGSOC will not demonstrate a meaningful initial response to first-line platinum-based chemotherapy^[3]. Regardless of the initial response to platinum-based chemotherapy, the majority of patients with EOC will go on to develop disease recurrence. Most recurrent EOC will eventually exhibit platinum resistance following treatment with one or more lines of chemotherapy^[2]. In this regard, ovarian cancer exhibits both intrinsic and acquired resistance to platinum-based chemotherapy.

Multiple mechanisms of inherent and acquired resistance to platinum-based chemotherapy have been described. One of these is the alteration of volume-regulated anion channels (VRACs) which regulate the influx of platinum compounds into cells^[5,6]. Additional mechanisms of platinum resistance include altered intracellular sequestration of platinum, changes to the tumor microenvironment, and altered recognition and repair of DNA damage^[4,5]. Alterations in the DNA damage response (DDR) are being studied as a potential vulnerability that can be exploited for the treatment of EOC. It has been demonstrated that acquired alterations in key DDR genes following PARPi therapy, like reversion mutations in *BRCA*, *RAD51C*, and *RAD51D*, resulting in restoration of homologous recombination, are associated with the development of post-treatment resistance^[7]. In this review, we will focus on the role of DDR in the current landscape of treatment for recurrent EOC.

PARP INHIBITION IN OVARIAN CANCER

PARP inhibitors were the first drug class to exploit synthetic lethality for the treatment of ovarian cancer^[8]. Synthetic lethality is the concept whereby an inactivating mutation in one gene (or inhibition of its protein product) is innocuous, but inactivating mutations in two genes (and/or inhibition of their protein products) results in cell death^[8]. The proteins encoded by the *BRCA1* and *BRCA2* genes are critical for homologous recombination, a DNA damage repair pathway for double-strand break repair. The PARP1 protein is involved in single-strand break repair via base excision repair^[9]. A PARPi is lethal only to cells with a predisposing defect in homologous recombination^[8]. PARPi therapy has been most effective in patients with germline *BRCA1* or *BRCA2* mutations, whose tumors likely exhibit deficient homologous recombination. Maintenance therapy with the PARPi olaparib after first-line chemotherapy in patients with *BRCA*-mutated advanced ovarian cancer showed dramatic improvements in progression-free survival (PFS) compared to placebo^[10]. Patients with germline *BRCA1* or *BRCA2* mutations account for about only 15% of all patients with ovarian cancer, but approximately 50% of epithelial ovarian cancers harbor defects in HRR^[11,12]. PARP inhibitors have shown some activity in patients who do not carry *BRCA* mutations but whose tumors exhibit HRD based on the result of a somatic profiling assay (ex. Myriad MyChoice CDx HRD)^[10,13,14]. On April 29, 2020, the FDA approved niraparib as first-line maintenance for all advanced EOC following first-line platinum-based chemotherapy, regardless of *BRCA* status or HRD status. The EMA made a similar approval on October 29, 2020.

The majority of patients treated with PARP inhibitors in the first-line setting will go on to experience disease recurrence^[10,14]. Multiple mechanisms of PARPi resistance have been described. These include reversion mutations in *BRCA1* or *BRCA2*, which restore HRD^[15], downregulation of non-homologous end-

joining (NHEJ), loss of 53BP1^[16], and enhanced replication fork protection^[17,18]. Cells that exhibit HRD, such as *BRCA* deficient cells, can also defer to a more error-prone polymerase theta-mediated end-joining (TMEJ, a.k.a. alt-NHEJ or microhomology-mediated end-joining, MMEJ) as a backup pathway to repair double-strand breaks. TMEJ-mediated repair involves PARP1, DNA ligase III, and DNA polymerase theta (Polθ)^[19].

Polθ is encoded by the gene *POLQ*. Polθ has become a therapeutic target of interest in cancers due to evidence of synthetic lethality when there is a loss of *POLQ* and dysregulation or loss of other DNA repair-related tumor suppressor genes that control double-strand break repair or HRR^[20]. Some recent studies suggest that secondary mutations restoring *BRCA1/2* function are caused by the activity of TMEJ with Polθ facilitation. Ceccaldi *et al.* provided *in vitro* evidence that HRR-deficient ovarian cancer cells were dependent on Polθ^[21]. ART558, a small molecule inhibitor of Polθ, elicited DNA damage in *BRCA1*- and *BRCA2*-mutant tumor cells and was shown to enhance the effects of a PARPi in *in vitro* and *in vivo* models^[22]. ART 558 is expected to move forward in Phase I trials. It has also been proposed that cancer stem cells (CSCs) might display an inherent or acquired resistance to PARPi. Using *in vitro* and *in vivo* preclinical models of ovarian cancer, it was shown that PARP inhibition primarily targeted the non-cancer stem cell populations. While the CSCs showed increased evidence of DNA damage in response to PARP inhibition, the CSCs were able to repair their damaged DNA more efficiently than their non-cancer stem cell populations^[23]. DMC1, a meiotic-specific recombinase, which has been shown to be expressed in cancers, was proposed as a possible mediator of this purported resistance. Interestingly, recent research shows that diverse mechanisms of resistance can emerge within a *BRCA1* mutant cell line, and multiple mechanisms of resistance may emerge within even a single clone. For example, a single clone has been shown to demonstrate restoration of RAD51 foci formation and decreased levels of PARylation, suggesting downregulation of PARP1^[17]. Given the multiple described mechanisms of acquired resistance to targeted small molecule inhibitors, overcoming therapeutic resistance is an ongoing challenge to investigators and clinicians alike^[24,25]. Other combination strategies designed to target the CSCs as well as the more differentiated tumors cells have been investigated in preclinical ovarian cancer models, including those targeting the metabolic pathway, aldehyde dehydrogenase activity, and long non-coding RNAs in combination with either a cytotoxic or another biologic agent^[26-28]. Others have shown that metformin could reduce CSC populations and increase sensitivity to cisplatin^[29]. The diversity in the CSC populations from patient to patient is likely to have some impact on their success in the clinic.

TARGETING DDR PROTEINS IN THE PARPI-RESISTANT OR PLATINUM-RESISTANT SETTING

The current treatment paradigm for PARPi-resistant and platinum-resistant HGSOE does not address specific mechanisms of resistance. Instead, treatment typically shifts away from therapies dependent on deficient HRR^[30]. To this effect, PARP inhibitors have shown very poor efficacy in the heavily pretreated setting^[31]. These findings suggest the need for an alternative approach to treatment for EOC that is resistant to both platinum-based chemotherapy and PARP inhibitors.

It is well understood that the cancer genome is less stable than that of healthy cells^[32], and tumor cells demonstrate high rates of DNA replication and division. HGSOE has a high incidence of inactivating *TP53* mutations^[33]. *TP53* encodes p53, a critical tumor suppressor that protects cells from proceeding through the cell cycle in the setting of DNA damage^[34]. The cooccurrence of inactivating *TP53* mutations and mutations in *BRCA1* and *BRCA2* has been suggested to be a critical element in the development of *BRCA* null tumors^[35,36]. As such, PARPi resistance almost always occurs in the setting of deficient p53. In the setting of DNA damage, p53-deficient cells will be preferentially dependent on alternative cell cycle checkpoints. This

selective dependence is being explored as a potential target for EOC treatment^[37,38].

While many mechanisms are likely at play, cancer cells ultimately attempt to replicate damaged DNA, leading to “replicative stress”. Genomic instability, resulting from an accumulation of DNA damage, is a hallmark of many cancers, including ovarian cancer. Accumulation of DNA damage can result in replication stress. ATM and ATR are kinases that the cells rely on to alleviate replication stress. Specifically, ATM/ATR signaling arrests the cell cycle via phosphorylation of downstream kinases such as CHK2 and CHK1, respectively. If ATM/ATR fails, the replication fork becomes unstable and can collapse^[39,40]. To this end, these proteins critical to DDR (ATR, ATM, CHK1, CHK2) are being studied as potential therapeutic targets. This strategy relies on the hypothesis that inhibition of various DDR pathways may confer a therapeutic effect in heavily pretreated EOC that is resistant to either platinum-based chemotherapy, PARP inhibitors, or both. Inhibitors of ATR, ATM, CHK1, CHK2, and WEE1 are in clinical trials. Here we discuss inhibitors of ATR, CHK1, and WEE1 in more detail, as they have progressed the furthest in clinical development.

ATR

The serine/threonine kinase ATR functions as one of the cell’s master regulators of genotoxic stress. Some forms of DNA damage can result in tracts of single-stranded DNA. In addition, segments of single-stranded DNA may be formed at stalled replication forks when the activities of the replication helicase and DNA polymerase are uncoupled^[41]. Replication protein A (RPA) is recruited to regions of single-stranded DNA (ssDNA). ATR then localizes to regions of single-stranded DNA (ssDNA) via its binding partner ATRIP (ATR interacting protein), a process dependent on RPA [Figure 1]^[42]. Following ATR localization to RPA, multiple activator proteins, including TopBP1 and ETAA1, are required for ATR activation^[41]. When active, ATR phosphorylates its immediate downstream effector CHK1. Moreover, ATR plays a key role in preventing replication fork collapse by limiting CDK (cyclin-dependent kinase) signaling, which restrains replication fork firing^[43]. ATR also directly targets helicases, preventing unstable replication fork configurations, and ATR regulates deoxyribonucleotide availability in response to DNA damage. It has been proposed that replications forks may be more prone to collapse without these interventions^[41].

The high burden of replication stress in cancer cells suggests that malignant cells may be especially sensitive to ATR inhibition. To this end, ATR inhibitors have proven effective in slowing the proliferation of *BRCA2*-mutant HGSOC cell lines and tumors^[44], with synergistic effects following co-treatment with platinum-based chemotherapy or PARP inhibition. Using organoid models of HGSOC, recent studies have leveraged the ability to monitor homologous recombination defects to predict sensitivity to ATR inhibition^[45,46].

ATR inhibition has been studied in ovarian cancer as a mechanism for overcoming PARPi resistance^[47]. Supporting this hypothesis, PARPi-resistant, *BRCA1*-null cells have been shown to increase dependence on ATR^[48]. Two trials investigating combined ATR and PARP inhibition among patients with PARPi-resistant recurrent ovarian cancer are ongoing. CAPRI is a phase II clinical trial of olaparib in combination with the ATR inhibitor ceralasertib (AZD6738) in patients with recurrent ovarian cancer; data on the platinum-resistant ovarian cancer cohort of this trial has been published^[49]. Among the 12 PARPi-naïve patients who were evaluated, the best response was stable disease in nine patients and progressive disease in three [Table 1]. This combination was well tolerated in the trial with a side effect profile similar to PARP inhibition alone. NCT04149145 is a phase I trial of niraparib in combination with the ATR inhibitor M4344 among patients with PARPi-resistant, recurrent ovarian cancer and was anticipated to begin enrollment in December 2022 (NCT04149145).

Table 1. Summary of key trials targeting ATR, CHK1, and WEE1 for the treatment of recurrent ovarian cancer

Target	Inhibitor	Trial Identifier	Trial Overview	Key Findings	Reference
ATR	Ceralasertib	NCT03462342	Phase II study of olaparib in combination with ceralasertib in platinum-resistant ovarian cancer	Among the 12 PARPi-naïve patients who were evaluable for response, the best response was stable disease in 9 patients.	[49]
CHK1	Prexasertib	NCT02203513	Phase II trial of prexasertib for recurrent ovarian cancer in patients without germline <i>BRCA</i>	Partial response rate of 29% (95% CI 13%-49%)	[64]
CHK1	Prexasertib	NCT02124148	Phase Ib study of prexasertib in combination with multiple chemotherapeutic agents in advanced cancer	No ovarian cancer-specific response data available Objective response rate of 12.7% in combination with cisplatin arm Hematologic toxicities were dose-limiting.	[65]
CHK1	Prexasertib	NCT03057145	Phase I study of prexasertib in combination with the PARPi olaparib in HGSOc and other solid tumors	Identified a schedule with acceptable tolerability Partial response rate of 22% in PARPi-resistant HGSOc	[66]
WEE1	Adavosertib	NCT01164995	Phase II study of adavosertib plus carboplatin in patients with <i>TP53</i> -mutant advanced ovarian cancer, platinum-resistant or -refractory	ORR of 43% Median PFS of 5.3 months Median OS of 12.6 months	[77]
WEE1	Adavosertib	NCT01357161	Phase II study of adavosertib versus placebo plus carboplatin and paclitaxel in patients with advanced, <i>TP53</i> -mutated platinum-sensitive ovarian cancer	Modest PFS prolongation in the combination arm: PFS (7.9 months vs. 7.3 months), HR 0.63 (0.38-1.06), $P = 0.080$ No significant change in ORR (74.6% vs. 69.4%, $P = 0.52$) or OS (HR 1.0 (0.53-1.88), $P = 0.898$) Increased adverse events in experimental arm	[78]
WEE1	Adavosertib	NCT02101775	Phase II randomized trial of adavosertib versus placebo with gemcitabine chemotherapy in patients with platinum-resistant or refractory HGSOc	Improved PFS in experimental arm (4.6 months vs. 3.0 months, HR 0.55 (0.35-0.90), $P = 0.015$) Improved OS in experimental arm (11.4 months vs. 7.2 months, HR 0.56 (0.35-0.91), $P = 0.017$) Improved partial response rate in experimental arm (23% vs. 6%, $P = 0.038$) Increased adverse events in experimental arm	[79]
WEE1	Adavosertib	NCT02272790	Adavosertib with chemotherapy in patients with primary platinum-resistant ovarian, fallopian tube, or peritoneal cancer: an open-label, four-arm, phase II study	The best ORR was 66.7%, with a disease control rate of 100%. Toxicity was notable. 100% of patients had grade 3 or higher adverse events.	[80]

ATR: Ataxia telangiectasia and Rad3 related; BRCA: breast cancer gene; CHK1: checkpoint kinase 1; CI: confidence interval; HGSOc: high-grade serous ovarian cancer; HR: hazard ratio; PARPi: poly (ADP-ribose) polymerase inhibitor; PFS: progression-free survival; ORR: overall response rate; OS: overall survival ratio.

CHK1

The serine/threonine kinase CHK1 plays an integral role in the cellular response to genotoxic stress, functioning as the principal effector for ATR. CHK1 has been described in multiple organisms to regulate cell cycle transition during basal states^[50] and in response to DNA damage^[51-53]. In addition, CHK1 regulates other proteins involved in DNA replication, including PCNA (proliferating cell nuclear antigen)^[54] and Pol- α (holding cells at the G2 phase) [Figure 1]^[55]. Thus, activated CHK1 slows down DNA replication, allowing the cell to begin DNA repair, which is further enforced by CHK1 through its phosphorylation of Rad51, which is important in regulating HRR^[56]. Given its role in cell cycle progression, CHK1 is heavily regulated, with phosphorylated CHK1 undergoing a transition from the nucleus to the cytoplasm and proteasome-mediated degradation^[57].

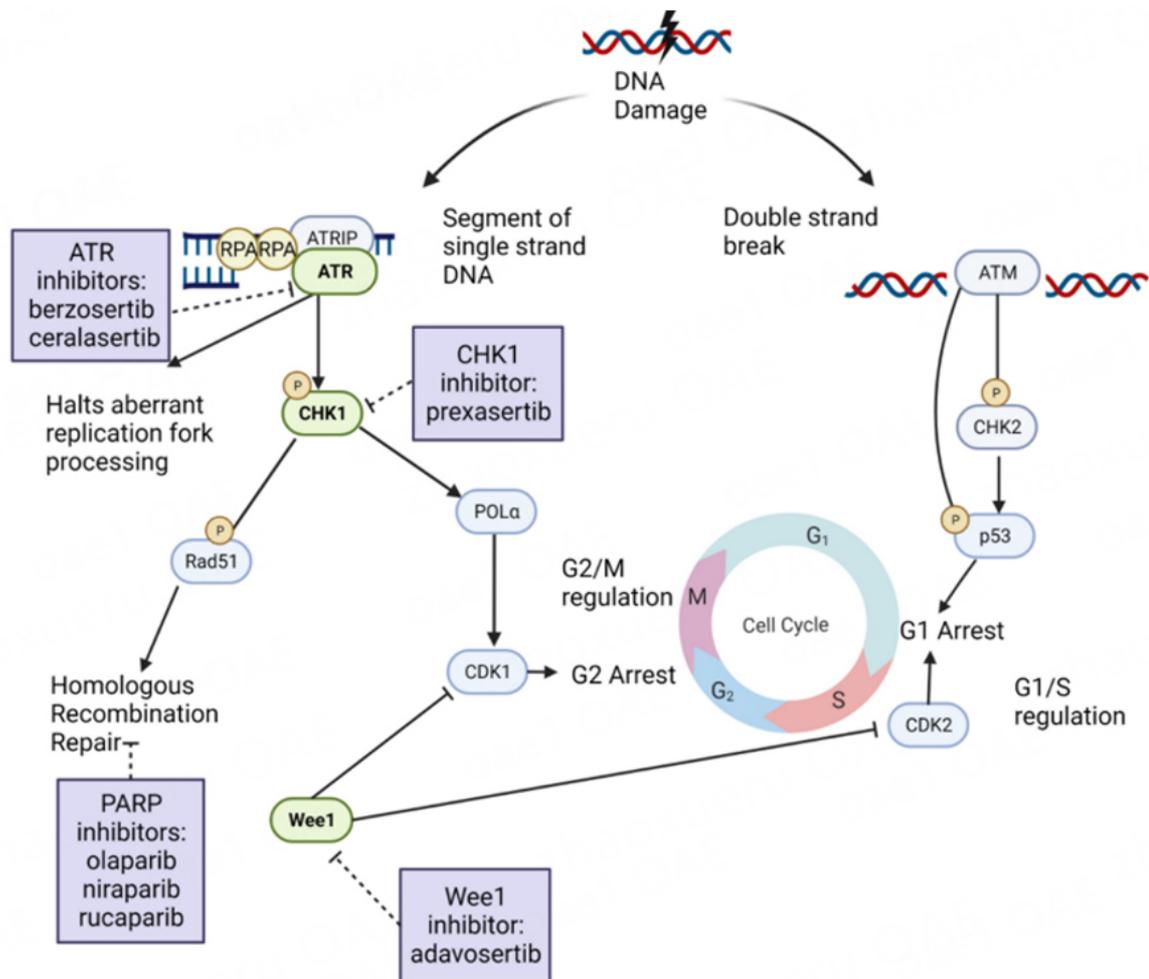

Figure 1. A schematic representation of the DNA damage response and its interaction with cell cycle regulation. RPA binds to sites of ssDNA and co-localizes with ATR and its binding partner ATRIP. CHK1 is the effector of ATR and regulates cell cycle progression via induction of G2 arrest. Ovarian cancer cells with deficient p53 function have aberrant G1/S regulation and rely more heavily on G2/M regulation. Wee1 activates the G2/M checkpoint through phosphorylation of CDK1, a critical regulator for cells with deficient p53 function.

The underlying hypothesis for targeting CHK1 stipulates that blocking CHK1 activity will promote cell cycle progression in the presence of DNA damage, resulting in an accumulation of double-stranded breaks in rapidly dividing cancer cells. This accumulated damage will ultimately lead to collapse of genomic integrity and cell death. HGSOC is a particularly good candidate for CHK1 inhibition because p53-deficient cells will be preferentially dependent on the G2-M checkpoint which may render them further susceptible to CHK1 inhibition^[37,38].

To date, a majority of CHK1 inhibitors are ATP (adenosine triphosphate)-competitive and have been designed to have good selectivity over CHK1's highly homologous cousin CHK2 (checkpoint kinase 2)^[58]. Multiple first-generation CHK1 inhibitors did not advance through early phase clinical trials due to unfavorable pharmacokinetic and pharmacodynamic profiles, as well as excess toxicity. However, a second-generation CHK1 inhibitor (CHK1i), prexasertib (LY2606368), has emerged as a prioritized compound for further development^[59]. Prexasertib is a selective small molecule inhibitor of CHK1 and CHK2^[60]. Prexasertib^[61] showed efficacy as a monotherapy in HGSOC patient-derived PDX models which were

BRCA1-mutant or resistant to olaparib, with further synergy observed between a PARPi and CHK1i^[62].

Prexasertib is currently advancing through clinical trials. It demonstrated favorable tolerability in a phase I clinical trial^[63]. A phase II trial of prexasertib monotherapy for the treatment of recurrent HGSOC in patients without germline *BRCA* mutations demonstrated a partial response rate of 29% (95%CI: 13-49)^[64], with an encouraging response rate in the platinum-resistant or platinum-refractory patient subgroup of 32%. Common treatment-emergent adverse events included neutropenia, leukopenia, thrombocytopenia, and anemia [Table 1]^[64]. These results are notable in this difficult-to-treat patient population and warrant further clinical investigation.

As described above, CHK1 is hypothesized to synergize with other agents that either induce DNA damage or inhibit its repair, such as chemotherapeutics and PARP inhibitors. A phase Ib study of prexasertib in combination with multiple chemotherapeutic agents (cisplatin, cetuximab, pemetrexed, or 5-fluorouracil) in patients with advanced or metastatic cancers reported an objective response rate of 12.7% in the cisplatin arm, with frequent and dose-limiting hematologic toxicities^[65]. This approach has not been studied specifically in the platinum-resistant HGSOC population. A phase I study of prexasertib in combination with the PARPi olaparib in HGSOC and other solid tumors identified a schedule with acceptable tolerability and demonstrated preliminary activity in patients with *BRCA* mutations who had experienced prior progression on a PARPi [Table 1]^[66].

WEE1

WEE1 is a tyrosine kinase that activates the G2/M cellular checkpoint through phosphorylation and subsequent inhibition of CDK1 (cyclin-dependent kinase 1) and CDK2 (cyclin-dependent kinase 2), which regulate cell cycle progression in the presence of damaged DNA [Figure 1]^[67,68]. While normal cells repair damaged DNA during G1 arrest, malignant cells with deficient p53 and defects in the G1 checkpoint depend more on a functional G2–M checkpoint for DNA repair. Thus, inhibition of WEE1 can increase genomic instability and replication stress leading to mitotic catastrophe in cells with an overreliance on the G2/M checkpoint. Moreover, WEE1 levels are elevated in ovarian cancer^[69]. Inhibition of WEE1 has also been shown to force cells arrested in S-phase into mitosis^[70]. As such, WEE1 inhibitors have been hypothesized to synergize with DNA-damaging agents. This effect may be particularly relevant for p53-deficient cells, which are more dependent on the intra-S-phase checkpoint following DNA damage^[70].

In 2009, Hirai *et al.* reported on the development of adavosertib (MK-1775, AZD1775), a potent and selective small molecule inhibitor of WEE1^[71]. Treatment with adavosertib sensitized cells to the antitumor effects of chemotherapy, with the largest effects noted, as would be expected, in p53 deficient cell lines^[71]. Additional preclinical studies confirmed the sensitivity of *TP53*-mutant cells to the combined effects of chemotherapy plus adavosertib^[72-74] in non-ovarian cancer models, thus forming the basis for early phase I studies. Adavosertib was shown to negatively impact cell viability in both *in vitro* and *in vivo* models of ovarian cancer^[75].

In clinical trials, adavosertib has been studied as a monotherapy or in combination with chemotherapy in advanced solid tumors^[76]. Encouraging responses were noted in tumors with mutant *TP53*, leading to a follow-up phase II study in HGSOC, which harbors high rates of inactivating *TP53* mutations^[33]. A phase II study of adavosertib plus carboplatin in patients with *TP53*-mutant advanced ovarian cancer, either resistant or refractory to first-line platinum-based chemotherapy, demonstrated an encouraging overall response rate (ORR) of 43% [Table 1]^[77]. Significant toxicities were noted, including frequent grade 3 or 4 thrombocytopenia and neutropenia.

A double-blind, randomized, phase II trial of the combination of adavosertib versus placebo plus standard platinum-based chemotherapy in patients with advanced, *TP53*-mutated platinum-sensitive ovarian cancer^[78] failed to demonstrate a significant difference in objective response rate (74.6% *vs.* 69.4%, $P = 0.52$). A randomized phase II trial of adavosertib versus placebo with gemcitabine chemotherapy in patients with platinum-resistant or platinum-refractory HGSOc showed a modest improvement in PFS (4.6 months *vs.* 3.0 months, HR 0.55 (0.35-0.90), $P = 0.015$) but with increased toxicity in the combination arm [Table 1]^[79].

Most recently, Moore *et al.* reported on the results of an open-label four-arm phase II trial of adavosertib in combination with chemotherapy in patients with primary platinum-resistant ovarian, fallopian tube or primary peritoneal cancer^[80]. The best ORR was 66.7% (disease control rate 100%), but toxicity was considerable in this arm, with 100% of patients experiencing grade 3 or higher adverse events [Table 1]. In addition to these studies demonstrating a promising role of WEE1 inhibitors in combination with chemotherapy, a number of trials [NCT02576444 (OLAPCO), NCT03579316] have been planned or are ongoing to investigate adavosertib in combination with PARP inhibitors due to the role of WEE1 in stabilization of replication forks^[67]. This combination has shown synergy in preclinical models; however, toxicity concerns persist^[81].

MORE SELECTIVE AND POTENT EXPLOITATION OF HRD

The first generation of PARP inhibitors (olaparib, niraparib, rucaparib, and talazoparib) inhibit both PARP1 and PARP2. It has been proposed that PARP1 inhibition is required to induce DNA damage^[82]. Moreover, inhibition of PARP2 has been linked to suppression of erythropoiesis^[83], and has been suggested to be a driver of the hematologic toxicity associated with the currently approved PARP inhibitors^[84]. The first next-generation PARPi to enter clinical trials AZD5305 is a highly potent and selective PARP1 inhibitor^[84]. AZD5305 is being studied in the ongoing PETRA study (NCT04644068), a phase I/II study of AZD5305 in patients with tumors harboring mutations in key DDR genes. Preliminary data demonstrated a favorable toxicity profile and encouraging clinical activity; publication of final results is highly anticipated. A PARP inhibitor with a superior therapeutic index may confer improved clinical activity as monotherapy. Moreover, an improved hematologic toxicity profile may allow for more effective and better tolerated combinations with other DNA damage repair inhibitors. Further clinical data are needed to evaluate these hypotheses.

BIOMARKERS PREDICTIVE OF RESPONSE

Konstantinopoulos *et al.* reported a post-hoc retrospective study investigating patients with HGSOc receiving gemcitabine with berzosertib (an ATR inhibitor) *vs.* placebo. They observed that the benefit from the addition of berzosertib was only seen in patients with a platinum-free interval of 3 months or less. They proposed that tumors with low replication stress (defined as the absence of *CCNE1* amplification, *RB1* two-copy loss, *CDKN2A* two-copy loss, *KRAS* amplification, *NF1* mutations, *ERBB2* amplification, *MYC* amplification, and *MYCL1* amplification) preferentially benefit from the addition of ATR inhibition to chemotherapy^[85]. Further validation of this proposed biomarker approach is still needed.

CCNE1 (cyclin E1) amplification may be another potential predictive biomarker. *CCNE1* forms a complex with *CDK2*, and when activated, this complex is an important regulator of the initiation of DNA replication. *CCNE1* amplification has been associated with an acceleration of progression through the G1/S restriction point in the cell cycle, ultimately leading to an increase in mutations in genes that control cell survival and proliferation^[86]. *CCNE1* amplification has been proposed as a biomarker of intrinsic resistance to platinum-based chemotherapy in ovarian cancer^[86]. More recently, *CCNE1* amplification has been proposed as a potential biomarker indicative of response to combined WEE1 inhibition and ATR inhibition in preclinical

ovarian cancer and endometrial cancer models. It has been proposed that *CCNE1*-overexpressing cells are preferentially dependent on the G2/M checkpoint. Both WEE1 and ATR are key regulators of the G2/M checkpoint, and as such, their inhibition may exploit a vulnerability in *CCNE1*-overexpressing cells that chemotherapy does not^[87]. These results will require clinical validation, and perhaps more importantly, a combined WEE1-ATR inhibition strategy must demonstrate acceptable tolerability.

CONCLUSION

In this review, we have explored several approaches to overcome platinum-based chemotherapy resistance and PARPi resistance, focusing on the role of DNA damage repair inhibitors. Several DNA damage repair inhibitors have demonstrated activity, but efficacy in the platinum-resistant setting has been relatively modest. Moreover, considerable hematologic toxicity has been a recurring limitation of this approach. Work is being done to identify patients most likely to benefit from this treatment approach, and the possibility of combination treatment strategies with a next-generation PARPi holds some promise. Based on the available data, it is almost certain that additional treatment strategies will be needed to overcome resistance to first-line treatment more effectively.

Combination treatment strategies might be most effective if employed as part of first-line treatment to address intrinsic rather than acquired resistance to platinum chemotherapy and PARP inhibition. Moreover, we emphasize that the identified resistance mechanisms to both platinum-based chemotherapy and PARP inhibition rely on much more than the roles of ATR, CHK1 and WEE1 in the DNA damage response. For example, a recent study identifies a druggable nucleus-to-mitochondria reactive oxygen species (ROS) sensing pathway, which appears to mediate resistance to platinum-based chemotherapy in ovarian cancers^[88]. The identification of a novel mechanism of resistance holds promise, but further research to identify its best clinical application is needed. Multimodal combination approaches incorporating newer classes of medications, including antibody-drug conjugates and novel immunotherapy constructs, hold promise as well.

Abstract

Epithelial ovarian cancer (EOC) is the most lethal gynaecological malignancy, and despite advancements in therapeutics, most women unfortunately still succumb to their disease. Immunotherapies, in particular immune checkpoint inhibitors (ICI), have been therapeutically transformative in many tumour types, including gynaecological malignancies such as cervical and endometrial cancer. Unfortunately, these therapeutic successes have not been mirrored in ovarian cancer clinical studies. This review provides an overview of the ovarian tumour microenvironment (TME), particularly factors associated with survival, and explores current research into immunotherapeutic strategies in EOC, with an exploratory focus on novel therapeutics in navigating drug resistance.

Keywords: Ovarian cancer, immunotherapy, tumour microenvironment, drug development

INTRODUCTION

Ovarian cancer is one of the most lethal cancers worldwide, with over 200,000 deaths in 2020^[1]. Epithelial

ovarian cancer (EOC) is the most common subtype (90%), with germ cell tumours, sex cord-stromal tumours and other rare subtypes, including small cell carcinoma, accounting for the remaining 10%^[2]. EOC (including fallopian tube and primary peritoneal cancer) is a complex disease as it encompasses a heterogeneous group of inherently different histological subtypes with differing underlying genomic and molecular drivers resulting in different clinical behaviours and outcomes^[3,4]. High-grade serous ovarian carcinoma (HGSOC) is the most common, followed by endometrioid carcinoma, clear cell carcinoma, low-grade serous carcinoma, and mucinous carcinoma^[2].

Most women with EOC are diagnosed at advanced stage and more than 70% will recur within the first three years. *BRCA1/2* germline mutations are the strongest known genetic risk factors, with an estimated frequency of 13%-16% in women diagnosed with EOC^[5,6,7], most of which are HGSOC histological subtype^[7]. Germline *BRCA1/2* mutations are associated with greater sensitivity to platinum-based chemotherapy and poly(adenosine diphosphate[ADP]-ribose) polymerase inhibitors (PARPi), and carriers have generally been reported to have improved survival compared to non-mutation carriers with high-grade serous EOC^[8,9].

The majority of EOC patients will eventually succumb to the disease, with 10-year survival being only 17%^[10,11]. Cytoreductive surgery with chemotherapy remains the standard of care in the treatment of EOC^[12]. Doublet-platinum chemotherapy can be administered as adjuvant treatment or as a neoadjuvant regime (usually three cycles prior to interval debulking surgery, followed by the remaining three cycles). Neoadjuvant chemotherapy provides an opportunity to assess chemosensitivity and assists with prognostication^[13,14]. Other drug classes such as vascular endothelial growth factor (VEGF) inhibitors have shown survival benefits, and thus bevacizumab is routinely used in combination with chemotherapy as a maintenance strategy^[15-17]. Most recently international, phase 3 studies have proven the effectiveness of PARPi in improving both progression and overall survival as well as the quality of life outcomes in both front-line and recurrent maintenance settings for certain subsets of advanced EOC, particularly those with *BRCA* mutations^[8,9,18,19]. However, not all benefit from PARPi use, particularly those who are platinum-resistant, those without *BRCA* gene mutations and/or with intact homologous recombination repair (HRR) pathway, which comprises approximately 50% of the most common EOC histological subtype, HGSOC^[3]. Unfortunately, even with PARPi, many patients will develop resistance and thus chemotherapy remains important in the treatment of recurrent ovarian cancer. With successive lines of treatment, most EOC will become resistant to chemotherapy, in particular to platinum-containing agents. Other subtypes such as low-grade serous, mucinous carcinoma and clear cell carcinoma are largely resistant to chemotherapy as a result of molecular and genetic profile and alterations^[20]. Studies in preclinical models have suggested a number of mechanisms underlying acquired platinum resistance in EOC, including drug accumulation, drug efflux, cellular response to DNA damage and impaired apoptosis; however, evidence for clinical relevance for most of these mechanisms is lacking^[21]. Limitations include using cell line models that are not representative of the common EOC subtypes seen clinically^[22], and using non-physiological drug exposures to induce drug resistance phenotypes *in vitro*. More compelling studies investigating patient samples following the development of clinical resistance *in vivo* have implicated restoration of DNA repair pathways, including reversion of *BRCA* mutations and methylation, as significant mechanisms of acquired platinum resistance^[23-25]. As the outlook for platinum-resistant EOC remains extremely guarded, with a median survival of only 12 months^[26], there has been a strong focus on identifying mechanisms of resistance against platinum chemotherapy and PARPi, to address this urgent unmet therapeutic need. As such, many clinical trials are now standardly incorporating exploratory correlative studies with emerging and innovative technologies to further clarify molecular signalling events and proteomic characterisation of ovarian cancer to gain a deeper understanding of the disease, with the ultimate goal of developing and incorporating novel

therapeutics to avoid and/or bypass mechanisms of intrinsic and acquired resistance in EOC.

Immunotherapy has been transformative in the oncology therapeutic landscape. Immune checkpoint inhibitors (ICIs) counter several major immune-evasion mechanisms of cancer to induce killing of tumour cells by CD8⁺ T cells. Dramatic effects of improved progression-free and overall survival with utilisation of ICI have been demonstrated in a number of cancers, including melanoma, lung and colorectal cancers^[27-29]. The durability and sustained benefit of ICI in other tumours make it an attractive therapy in ovarian cancer, particularly when there is evidence that ovarian cancer is immunogenic with the presence of tumour-infiltrating lymphocytes (TILs), regulatory T cells (Tregs), natural killer cells and tumour-associated macrophages (TAMs) detected in peripheral blood, ovarian cancer tissue and ascites^[30-33]. Specific immune cell signatures, combined with multiple co-occurring DNA repair gene alterations and increased predicted neo-antigen load, have been associated with response to treatment and exceptionally long survival in patients with HGSOC, providing further evidence for tumour immune activity, at least in a proportion of cases^[34].

However, disappointingly, durable responses to single-agent ICI in platinum-resistant EOC remain modest^[35-37] and published studies to date have returned negative results with the addition of programmed cell death receptor-1 (PD1/L1) targeted ICI to standard adjuvant chemotherapy with or without bevacizumab^[38,39]. Intriguingly, more encouraging clinical trial results from early phase studies exploring combination ICI with other agents such as PARPi, and VEGF inhibitors to act as immunomodulators have emerged.

In this article, the authors will describe the interplay between the immune system and tumour microenvironment (TME) including its interaction with the DNA damage repair (DDR) pathway, summarise the clinical trial landscape of immunotherapy in EOC, and discuss novel therapeutic pathways under investigation to overcome ICI therapy resistance.

ROLE OF THE TUMOUR MICROENVIRONMENT IN EPITHELIAL OVARIAN CANCER

As previously mentioned, ovarian cancer encapsulates a heterogeneous group with subtypes that differ histologically, genomically and molecularly^[3]. A dualistic model categorising EOC into two groups, Type I and Type II EOC, has been described^[3]. According to this classification, Type I includes low-grade subtypes, typically arising from a recognisable precursor lesion such as borderline tumours with low malignant potential, whereas Type II EOC includes HGSOC, the most common subtype, with frequent *TP53* mutations and HRR pathway gene alterations^[40]. Immune-cell infiltrates differ markedly between the histological subtypes, with the high-grade serous showing the most TIL infiltration, and the other subtypes being largely “cold” with respect to immune cell infiltrates, although there is wide variability between individual patients^[41,42].

The defining genomic features of HGSOC are profound structural variation, including gene copy number alterations and genomic rearrangements, on a background of near-ubiquitous *TP53* mutation, with the most common somatic and germline alterations found in HRR pathway genes, mainly *BRCA1* and *BRCA2*^[23]. When lacking HRR function, as in *BRCA*-mutant cells, DNA double-strand breaks will be processed by alternative but error-prone repair pathways, such as the non-homologous end joining repair (NHEJ), which lead to the accumulation of genomic instability and ultimately cancer cell death. NHEJ is faster than homologous recombination and mainly occurs in the G1 phase. Nevertheless, there is recent evidence that NHEJ functions throughout the cell cycle. Beyond the already-known proteins, such as Ku70/80, DNA-PKcs, Artemis, DNA pol λ/μ , DNA ligase IV-XRCC4, and XLF, new proteins are involved in the

NHEJ, namely PAXX, MRI/CYREN, TARDBP of TDP-43, IFFO1, ERCC6L2, and RNase H2. Among them, MRI/CYREN has a dual role, as it stimulates NHEJ in the G1 phase of the cell cycle and inhibits the pathway in the S and G2 phases^[43]. In addition to this genomic complexity, a challenging clinical feature of HGSOc is the presence of widespread intraperitoneal disease at the time of diagnosis. Distinct spatial immunostimulatory and immunosuppressive mechanisms have been identified within individual patients depending on the anatomical site, with a relative paucity of immune cells in primary adnexal disease sites, in contrast with metastatic sites^[44].

The impact of the heterogeneity of the tumour microenvironment on response to immunotherapy between and within ovarian cancer patients is not yet fully understood.

The immune system plays an integral and extensive role in tumour formation and growth in all tumours, including ovarian cancer [Figure 1]. Tumour growth is facilitated by the critical interplay between TME and immune cells, including natural killer (NK) cells, CD8+ T cells and CD4+ helper T (Th) cells together with pro-inflammatory macrophages (M1) and dendritic cells. When a tumour is formed, it is recognised and eliminated by the immune system (elimination phase). The tumour cells which survive this process enter a phase called equilibrium phase, during which the tumour can continue to grow despite ongoing destruction from the immune system. Eventually, tumour cells evade the immune recognition and destruction, termed the escape phase, leading to continual tumour growth and progression and finally metastasis. TME is a collective term that encapsulates a dynamic interplay between tumour cells and components of the immune system and plays an important role in tumour differentiation, dissemination, and immune evasion. It consists of extracellular matrix consisting of matrix metalloproteinases (MMPs) and stromal cells including tumour-infiltrating lymphocytes (TILs), fibroblasts, and endothelial cells, amongst others.

Tumour-infiltrating lymphocytes

TILs are white blood cells including T cells, B cells, macrophages and natural killer cells, which are localised to tumour or tumour stroma in response to molecular signals. CD3+, CD4+, and CD8+ TILs have long been known to exist in ovarian cancer, and an association between the presence of TILs and improved overall survival (OS) in ovarian cancer has been demonstrated in multiple studies. A meta-analysis to evaluate the prognostic value of TILs in ovarian cancer has found a significant association between TILs and survival, with a hazard ratio of 2.24 for those without TILs^[45]. A study of 5577 EOC tissue samples identified that CD8+ TILs were associated with longer OS for those with multiple histological subtypes, particularly those with high-grade serous ovarian carcinomas. The median OS survival was 2.8 years for those with no CD8+ TILs compared to 5.1 years in those with high levels regardless of the extent of residual disease post cytoreductive surgery, standard treatment, and germline *BRCA1* mutation^[41]. It also demonstrated prognostic value in other histological subtypes including endometrioid and mucinous carcinomas. Overall, CD8+ TILs have become the standard for prognostic evaluation for TILs in ovarian cancer.

CD8+ T lymphocytes

When naïve T cells are activated, they differentiate into CD8+ cytotoxic T cells and are migrated into TME via a number of signalling proteins called chemokines (including CCL5, CXCL9, CXCL10)^[46]. CD8+ cytotoxic T cells target tumour cells via T cell receptor interaction with MHC Class I, facilitating tumour apoptosis via several mechanisms including perforin and granzyme B secretion. Tumour cells adopted numerous mechanisms to evade apoptosis, such as downregulation of MHC Class I, dysregulated expression of death receptors, or modification of antigen processing and thus reduced presentation capacity^[47]. Additionally, CD8+ cytotoxic T cells upregulate checkpoint receptors such as PD-1, CTLA-4, LAG-3 and TIM3, which makes them susceptible to inhibitory signalling since binding of checkpoint receptors induces cytotoxic T cell exhaustion and anergy^[47,48].

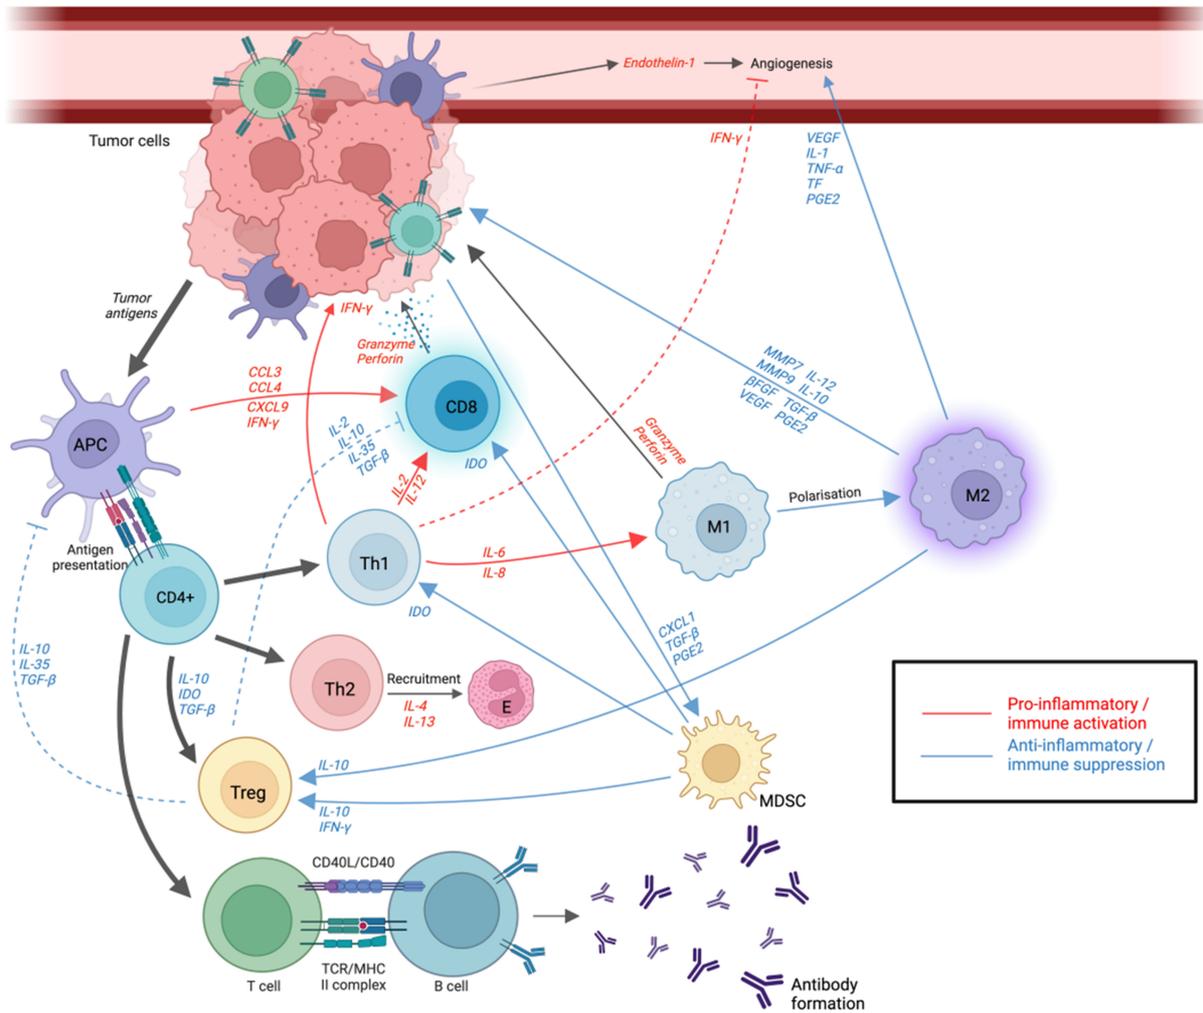

Figure 1. Schematic diagram outlining complex pro- and anti-inflammatory interplay within epithelial ovarian cancer microenvironment. Created with Biorender.com. Tumour cells recognised by APC, from which tumour antigens are presented to naïve CD4+ T cells, triggering T cell differentiation into Th1, Th2, Treg cell subclones (and other Th subsets – not pictured). Cytotoxic CD8+ T cells are recruited to TME via chemokines such as CCL3 and CXCL9 and are activated. Once activated, it releases granzyme and perforin to lyse cells directly. Th1 cells have dual action by secreting cytokines including IL-2 and IL-12, further activating CD8+ T cells to directly kill tumour cells as well as secreting IFN-gamma to suppress angiogenesis. Th2 assists eosinophil recruitment via IL-4 and IL-13 cytokine release, which assist in antitumour response. Treg cells suppress DC maturation and mute CD8+ T cell response by secreting inhibitory cytokines IL-10, IL-35, and TGF-β in response to regulate inflammatory response. M1 TAM, a pro-inflammatory type, is involved in tumour destruction, while M2 TAM exhibits immunosuppressive effects allowing tumour migration and invasion by releasing factors including endothelin-1, VEGF and TNF-alpha to induce tumour angiogenesis. CD4+ T cells bind to B cells via major histocompatibility II complex to induce antibody formation via the adaptive immune system. APC: antigen-presenting cell; MDSC: Myeloid-derived suppressor cells; IL: Interleukin; TGF-β: transforming growth factor-beta; TNF: Tumour necrosis factor; CCL: Chemokine (C-C Motif); CXCL: Chemokine (C-X-C Motif); IDO: Indoleamine 2,3-dioxygenase; Th: T-Helper; M1 and M2 TAM: Tumour-associated macrophages; MMP: matrix metalloproteinase; E: eosinophil; VEGF: vascular endothelial growth factor; TF: tissue factor; PGE2: prostaglandin E2; IFN: interferon; β-FGF: beta-fibroblast growth factor.

CD4+ T lymphocytes

Naïve CD4+ T cells are activated by tumour antigens, and they differentiate into different subsets, including Th1, Th2, Th9, Th17, Th22, and Tregs. While the majority of CD4+ lymphocyte subsets further assist the activation of CD8+ T lymphocytes, thus facilitating the killing of the tumour, some have dual roles in promoting tumour growth via increasing angiogenesis.

T regulatory cells

T regulatory cells (Tregs) play an important role in suppressing immune responses and maintaining self-tolerance. Tregs in ovarian cancer are identified by several marker expressions, CD4 and CD35, which are present extracellularly, or forkhead box P3 (FOXP3) located intracellularly. When activated, Tregs release inhibitor cytokines such as TGF- β and IL-10 facilitating immunosuppressive effects on TME^[49]. Increased Treg presence has been identified in tumours that are able to evade immune destruction, and it has been demonstrated that increased recruitment of Treg cells is associated with reduced survival with a high death hazard ratio in ovarian cancer^[45,48]. Those who have undergone primary debulking surgery for ovarian cancer were identified to have decreased Tregs and increased TILs compared to those with suboptimal debulking surgery had the opposite trend^[50,51]. Additionally, those undergoing neoadjuvant chemotherapy had lower FOXP3+ Treg infiltration and demonstrated higher survival compared to those with higher FOXP3 Treg counts^[52]. Although Treg is not recognised as a prognostic factor, it seems clear that Tregs in TME have immunosuppressive effects, thus hampering the immune system to destroy cancer cells.

Myeloid-derived suppressor cells

Myeloid-Derived suppressor cells (MDSCs) consist of a heterogenous population of myeloid cells expressing GR-1 and CD11b myeloid surface markers. MDSCs mostly act to suppress the immune system via T cells in multiple ways, eventually promoting tumour progression. MDSCs reduce essential amino acids such as L-arginine and L-cystine required for T cell activation and function^[53], and also inhibit the recruitment of T cells and promote T cell apoptosis. MDSCs also promote Treg cell activation and stimulate oxidative stress as well as facilitate neovascularisation, therefore priming and promoting tumour progression^[53,54].

Dendritic cells

Dendritic cells (DCs) play a critical role in bridging the innate and adaptive immune systems and are essential in precipitating T cell immune response. As antigen-presenting cells, DCs facilitate tumour antigen recognition and presentation, thus triggering appropriate T-cell response. DCs also play an important role in activating and manipulating cytotoxic T-lymphocyte population in the TME mostly mediated by appropriate DC maturation. When DC maturation process becomes faulty due to various mechanisms, it can result in a more tumour-tolerant TME, thereby promoting tumour progression.

Programmed cell death ligand-1

Up to 60% of EOC express PD-L1, which has been identified as a poor prognostic factor for both PFS and OS^[37-39,55,56]. In a study by Hamanishi *et al.*, five-year survival rates were found to be 80.2% vs. 52.6% for high and low PD-L1 expressing EOC, respectively^[56]. Furthermore, CD8+ TILs appear to be inversely correlated to PD-L1 expression^[56]. PD-1 is a surface molecule commonly expressed on CD8+ T cells and is a negative regulator of T cell activation. Its expression blocks entry into the cell cycle and production of cytokines such as IFN- γ and TNF- α involved in activating inflammatory and immune responses^[57]. Upregulation of PD-L1, which is exclusively expressed on the surface of tumour cells and a common ligand for PD-1, causes impaired tumour destruction and apoptosis of T cells. PD-1 pathway activation also escalates Treg function^[58]. Thus, collectively activation of the PD-1/L1 pathway collectively results in the ability of cancer cells to evade the immune system and facilitating ongoing tumour growth. Harnessing and manipulating this pathway has been the rationale for therapeutic use for PD-1/L1 targeted ICIs. Despite the tremendous efficacy and clinical benefit of anti-PD-1/L1 ICI in other tumour types, it has been largely disappointing in ovarian cancer.

IMMUNE CHECKPOINT INHIBITORS: A WORK IN PROGRESS

Current understanding of immune-mediated response in relation to malignancy and tumour microenvironment has exponentially increased over the last two decades, especially with the development of immune checkpoint inhibitors. ICIs are now being commonly utilised in the treatment of both non-solid and solid malignancies, with efficacy rates ranging from 70% in lymphoma^[59] and 39%-60% well-selected solid tumour groups, including those with high microsatellite instability (MSI-H)^[60,61]. Impressively, in some cohorts, such as metastatic melanoma, 22% and 19% were able to achieve complete response with doublet and single-agent ICI, respectively^[27]. Additionally, the durability of ICI makes it an attractive therapeutic, with overall survival of 44%-52% in metastatic melanoma cohorts at five-year follow-up noted^[27]. Unfortunately, these drugs are not without their side effects. While reasonably well tolerated, grade ≥ 3 treatment-related adverse events occur in approximately 20%-25% of cases, and this rate can increase to 59% with the use of doublet ICIs^[27,28]. While most immune-related toxicities are easily manageable, they are often life-long issues that require constant monitoring and management; thus, careful selection of patients for immunotherapy is paramount^[27]. Additionally, the cost of ICI is problematic, as most Western and first world countries can fund it via government-subsidised programs or medical insurance; generalisability and utility of ICI worldwide realistically will be challenging. Particularly in low-middle-income countries, financial toxicity is a real issue affecting the quality of life for many patients affected by cancer.

Despite the significant advances in the understanding of the role of TME in EOC, the efficacy of single-agent and combination ICI therapy has been somewhat disappointing, as demonstrated through numerous international randomised trials. Amongst tumour types where immunotherapy is typically effective, there have been therapeutic strategies posited to transform “cold” tumours to “hot”, that is, by increasing T-cell infiltration to predispose tumour cells to immune therapy anti-cancer effects^[62]. Given the current therapeutic landscape of ovarian cancer and the limited role of immunotherapy, ongoing clinical trials are focused generally on three mechanisms: overcoming resistance by administering ICI therapy in synergism with other drug classes, enhancing immune responses through utilising other immune pathways, or bypassing resistance through exploring alternative therapeutic pathways [Figure 2]. Biomarker studies will provide further crucial information in determining which patients will benefit from particular treatment strategies. This section outlines the state of evidence for ICI therapies in EOC and discusses combination trials in progress looking to overcome resistance.

Single-agent ICI therapy

Several PD-1/L1 targeted ICI monotherapy trials exist in advanced or recurrent EOC, most of which demonstrated modest efficacy. KEYNOTE-100 study, a phase II trial which included a total of 376 advanced recurrent EOC patients administered 200 mg of pembrolizumab, 3-weekly^[63]. It demonstrated only a modest ORR of 9.9% with a suggestion of the trend of increased responses for those with higher PD-L1 expression measured by combined positive score (CPS). The median PFS was 2.1 months, while the median OS was 18.7 months. Aside from CPS, no other clinical features such as histology or platinum-sensitivity display a correlation with higher response.

Numerous other studies investigating different single-agent anti-PD-1/L1 ICI agents such as avelumab and nivolumab in recurrent and platinum-resistant disease have demonstrated similarly disappointing modest responses with ORR^[64-66]. Despite the initial suggestion of higher response for clear cell carcinomas, this has been largely disappointing, with no clinically meaningful ORR or survival benefit in the recently presented MOCCA trial^[67]. Additionally, JAVELIN Ovarian 100^[38] and IMagyn050^[39] incorporating ICI with standard chemotherapy in the upfront setting have demonstrated no significant benefits, without improvement in PFS or OS, despite PD-L1 stratification^[38,39].

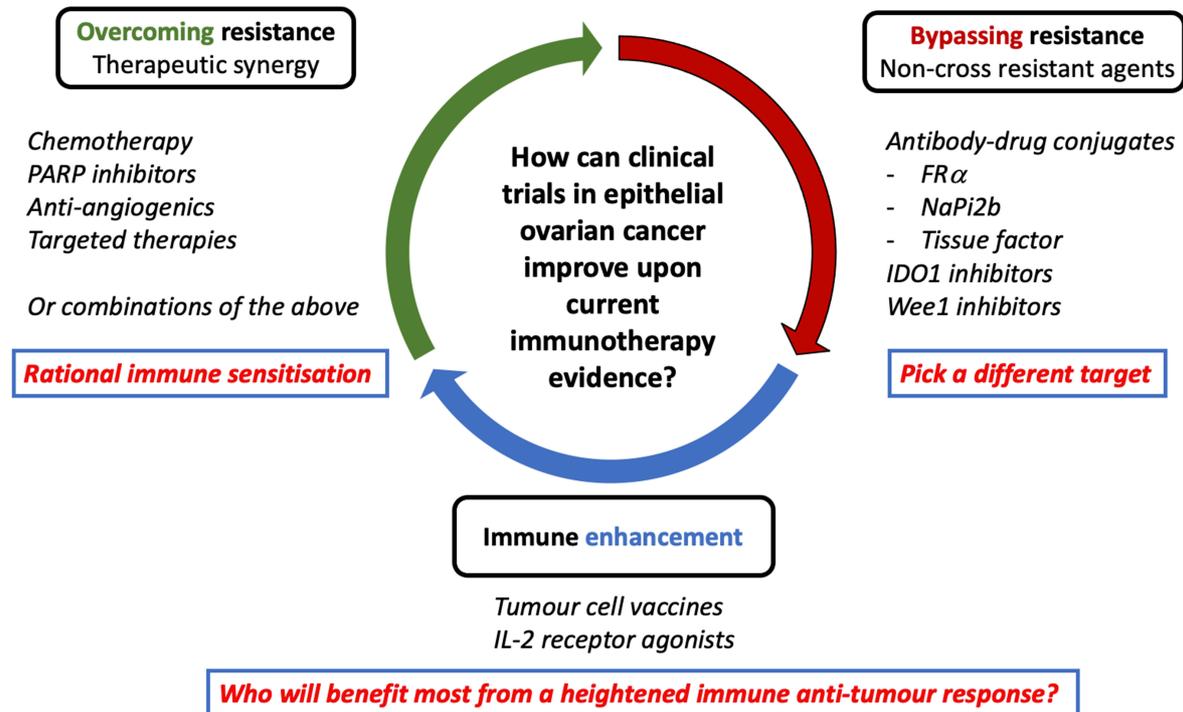

Figure 2. Schema outlining biomarker-driven strategies to improve upon current evidence for immunotherapy in ovarian cancer. Current trials are focused on improving clinical outcomes by either overcoming resistance through synergistic therapeutics (rational immune sensitisation) or bypassing resistance mechanisms (choosing different therapeutic targets). FR α : folate receptor-alpha; IDO1: Indoleamine 2, 3-dioxygenase 1; PARP: Poly-ADP ribose polymerase.

Despite disheartening single-agent anti-PD-1/L1 ICI results across the board of different EOC subtypes, a number of different studies examining different therapeutic combinations with ICI have been undertaken to investigate whether drug synergism of ICI can be enhanced for advanced EOC.

Dual-agent ICI therapy

Ipilimumab is a monoclonal antibody targeting cytotoxic T-lymphocyte associated protein-4 (CTLA-4), another immune checkpoint surface protein involved in negatively regulating T-cell function in priming immune response. Combining anti-CTLA4/anti-PD1 inhibitors have demonstrated significant treatment effects in other solid cancers, although this efficacy is limited in EOC. Zamarin *et al.* demonstrated that from the 100 recurrent EOC patients, those who had doublet-ICI demonstrated higher ORR at 6 months (31.4% vs. 12.2%) and PFS improvement (HR 0.528, 95%CI: 0.339-0.821; $P = 0.04$)^[68]. Again, there was no association between the magnitude of PD-L1 staining and other clinical outcomes, which suggests the need for better predictive biomarkers to assist with ICI usage guidance. As expected, grade 3 adverse events were higher in the combination group (49% vs. 33%), although this did not reach statistical significance.

Combination studies with antiangiogenic agents

Angiogenesis is a hallmark of cancer growth and metastasis, and VEGF plays an integral role in this process. It binds to a number of VEGF receptor tyrosine kinases, namely VEGF-A, VEGF-B, VEGFR-C/D, VEGFR-1/2, and VEGFR-2/3. Amongst solid cancers, EOC is known to have high VEGF expression^[69] and the use of bevacizumab, a VEGF-A inhibitor, is commonplace with proven clinical benefit in both platinum-sensitive and platinum-resistant settings^[17,70]. Furthermore, there is strong evidence demonstrating the immunomodulatory effects of VEGF; preclinical data demonstrate that signalling through VEGFR-1

mediated by VEGFR-A can suppress maturation of dendritic cells, increase Treg population via VEGFR-2 signal and stimulate the growth of myeloid-derived suppressor cells, leading to further suppression of TME^[71,72]. VEGF blockade leads to increased cytotoxic T cell recruitment and migration to tumour cells with a reduction in CD4⁺ Treg in TME^[50,73,74]. Therefore, the potential synergistic activity of ICI therapy with antiangiogenic therapy has been hypothesised.

In addition to the previously discussed IMagyn050 in the upfront setting, nivolumab and atezolizumab combined with bevacizumab have been investigated in the recurrent setting^[68,75]. Liu *et al.* recruited 38 women with recurrent, pre-treated EOC in a phase II study in which the ORR was higher than single-agent ICI with 28.9%; however, disappointingly, the majority of the benefit appeared to lie within the platinum-sensitive cohort with a median PFS of 12.1 months versus 7.7 months in the platinum-resistant cohort^[76]. These findings again highlight the importance of patient selection for these therapies, although at present, aside from platinum sensitivity, more accurate and pertinent biomarkers are yet to be discovered to guide therapy.

Other antiangiogenic therapies have also been explored in combination with ICI therapy including lenvatinib and sitravatinib. Lenvatinib is a multi-receptor tyrosine kinase inhibitor, which mainly targets VEGF 1-3, fibroblast growth factor (FGF) receptors 1-4, platelet-derived growth factor receptor α , KIT, and RET. LEAP-005^[77], an ongoing multi-cohort phase II study, includes 31 recurrent EOC patients with three or more prior lines of treatment including bevacizumab (ClinicalTrials.gov, NCT02501096). The results were more encouraging - ORR was 32% with a median PFS of 4.4 months, and nearly a quarter of responders were platinum resistant. Sitravatinib, an orally available multi-tyrosine receptor inhibitor that acts on VEGF2, KIT and TAM receptors, has also been identified to modulate immunosuppressive influences on TME. An early-phase study investigating tislelizumab, an anti-PD-1 monoclonal antibody, with sitravatinib in 60 platinum-resistant EOC demonstrated an ORR of 26% with a median PFS of 4.1 months and a median OS of 12.8 months^[78]. Unfortunately, these novel combination therapies report significant treatment-related adverse events requiring dose reductions or interruptions in significant proportions of patients. Although these combinations are promising in overcoming therapeutic resistance in recurrent EOC, issues of tolerance and quality of life remain important factors. Lastly, AK112, a novel anti-PD-1/VEGF-A bi-specific antibody, has been investigated in an ongoing Phase Ia/Ib study in platinum-resistant/refractory EOC^[79]. The ORR was higher at 29.4%, with two spectacular responders noted: one with clear cell histology with prior ICI exposure and one with HGSOE. The toxicity profile was similar to sitravatinib, but tolerability was much better with manageable adverse events in comparison.

In summary, trials so far investigating ICI and angiogenic combination approach have demonstrated preliminary efficacy, which appears to be clinically meaningful, but balancing this with the challenge of managing adverse events represents the true dilemma in moving forward, particularly in terms of patient selection for therapy, appropriateness of dose reductions, and ongoing biomarker discovery. As the role of combination angiogenesis and immunotherapy agents grows in EOC treatment, clear guidelines on practical aspects and real-world data will become increasingly relevant in informing clinicians of best practices.

Combination studies with PARP inhibitors

PARPi, namely olaparib, niraparib and rucaparib, have demonstrated breakthrough improvements in survival outcomes for individuals with EOC. Defects in the HRR pathway are strongly associated with the development of high-grade serous and endometrioid ovarian cancers, and it is in these patients with demonstrable HRR deficiencies or mutations that PARPi confer the greatest clinical benefit. Unfortunately,

a substantial proportion of individuals develop resistance to PARPi, and it is in this population that therapeutic direction remains unclear. Named resistance mechanisms to PARPi in the literature include drug efflux transporters, decreased PARP trapping, replication fork stabilisation and restoration of HR repair in multiple ways including alteration of PARP1, reversion mutation in HRR genes, and loss of *BRCA1* promoter methylation^[80]. Of these, HR reversion mutations and drug efflux transporters (such as *ABCB1* mutations) have been implicated most prominently in the literature^[81-87].

PARPi are inherently immunogenic by the mechanism of action, leading to a consequent increase in genomic instability and formation of neoantigens leading to immune detection via T cells^[88]. Additionally, there is evidence to suggest that *BRCA1* deficiency may induce STING-dependent immune response by inducing type I interferon and pro-inflammatory cytokine production, providing some interconnected relationship between the therapeutic effect of PARPi and the immune response^[89]. It has also been demonstrated that PARP inhibition inactivates GSK3 and upregulates PD-L1 in a dose-dependent manner in various cell lines, such as breast and pancreatic cells^[90,91]. Consequently, T-cell activation is suppressed, resulting in enhanced cancer cell apoptosis^[90]. While the complete immunomodulatory effect of PARPi on TME is not yet fully explained, several studies have shown promising synergistic effects. TOPACIO, a phase I/II study, examined niraparib with pembrolizumab in 62 patients with recurrent platinum-resistant or -refractory EOC^[92]. The ORR was 18%, with the most common treatment-related adverse events being grade 3 anaemia and thrombocytopenia. No correlation in efficacy with *BRCA* and HRD status, PD-L1 expression and prior bevacizumab was observed. While it did not meet its predefined endpoint, the combination showed meaningful activity compared with single agent-based therapy in the same population with resistant or refractory OC. Another study examined olaparib with durvalumab in 32 platinum-sensitive EOC patients with germline *BRCA1/2* mutations and 31 *BRCA* wild-type patients with the addition of bevacizumab^[93]. The ORR was 71.9% for olaparib and durvalumab in *BRCA* mutated cohort, 34.4% in *BRCA* wild-type patients, and 87.1% in the triplet arm *vs.* 34.4% with doublet therapy. Mean PFS was also longer with triplet therapy (14.7 *vs.* 5.5 months). Overall, both triple and doublet therapy was well tolerated, with adverse events reported consistent with those previously reported for single drugs, and discontinuation of one or more drugs as a result of adverse events was greater with triplet therapy (16% *vs.* 6%).

Currently, there are conflicting results seen in trials investigating triplet therapy consisting of PARPi, antiangiogenics, and ICI. Zimmer *et al.* conducted a trial of cediranib, an oral anti-VEGFR1-3 agent combined with durvalumab and Olaparib, in 35 recurrent EOC patients with promising preliminary results of an ORR of 44%^[94]. A phase II is currently underway, with results expected in 2025. Meanwhile, other two-phase II studies, OPAL and GINECO BOLD, demonstrated a lower-than expected-ORR of 17.9% and no benefit in PFS and OS in either platinum-resistant or platinum-sensitive cohort^[95,96]. Eventually, when results from larger combination studies (demonstrated in Table 1) become available, careful comparisons between triplet therapy studies will need to be considered, particularly in terms of patient selection, rates of toxicity and efficacy outcomes, especially as specific drug combinations can have varying synergistic effects. This is especially applicable to the trials in the first-line setting, where improvements in PFS and OS are expected to be highest in the chemotherapy-naïve setting.

The AMBITION study was the first biomarker-driven, targeted trial in heavily pre-treated platinum-resistant EOC, which included 70 patients^[97]. The patients were allocated to receive combination therapy based on HRD and PD-L1 status determined on archival tumour sample. The patients were randomised to either olaparib and cediranib arm or olaparib or durvalumab arm. For HRD-positive patients or for HRD-negative patients, they were allocated to either durvalumab and ChT (either pegylated liposomal doxorubicin or topotecan or weekly paclitaxel) or durvalumab and tremelimumab and ChT. PD-L1

Table 1. Summary of ongoing immune checkpoint inhibitor combination trials in epithelial ovarian cancer. Taken from clinicaltrials.gov. (Accessed on 9th of January, 2023)

Trial Identifier	Trial name	Phase	Setting	n	Treatment Arm	Endpoints	Expected completion
NCT04417192	Olaparib Monotherapy and Olaparib + Pembrolizumab combination Therapy in Ovarian Cancer (OLAPem)	II	Upfront HRD positive only	30	Cohort 1: Olaparib Cohort 2: Olaparib, Pembrolizumab	ORR* AE CRS PFS OS	December 2023
NCT03740165	Study of chemotherapy with pembrolizumab (MK-3475) followed by maintenance with Olaparib (MK-7339) for the first-line treatment of women with BRCA non-mutated advanced epithelial ovarian cancer (EOC) (MK-7339-001/ KEYLYNK-001/ ENGOT-ov43/GOG-3036)	III	Upfront	1367	Pembrolizumab, Olaparib + Chemotherapy (carboplatin/paclitaxel) + Bevacizumab	PFS* OS OS (PD-L1 CPS > 10) PFS2 AE QoL TTD pCR	May 2025
NCT03737643	Durvalumab treatment in combination with chemotherapy with bevacizumab, followed by maintenance durvalumab, bevacizumab and olaparib treatment in advanced ovarian cancer patients (DUO-O)	III	Upfront	1374	Durvalumab, Olaparib + chemotherapy (carboplatin/paclitaxel) + bevacizumab	PFS* OS PFS2 QoL pCR ORR DOR	May 2028
NCT03522246	A study in ovarian cancer patients evaluating Rucaparib and Nivolumab as Maintenance treatment following response to front-line platinum-based chemotherapy (ATHENA)	III	Upfront	1000	Rucaparib, Nivolumab	PFS* OS ORR DOR	December 2030
NCT03602859	A phase 3 comparison of Platinum-based therapy with TSR-042 and niraparib versus standard of care (SOC) platinum-based therapy as first-line treatment of stage III or IV non-mucinous Epithelial Ovarian Cancer (FIRST)	III	Upfront	1405	Dostarlimab, Niraparib +/- chemotherapy (carboplatin/paclitaxel)	PFS* OS AE QoL	June 2026
NCT04679064	Trial of Niraparib-TSR-042 (dostarlimab) vs. Physician's choice of Chemotherapy in recurrent, ovarian, fallopian tube or peritoneal cancer patients not candidates for platinum retreatment (NITCHE-MITO33)	III	Recurrent	427	Arm A: Dostarlimab, Niraparib Arm B: Chemotherapy (pegylated liposomal doxorubicin, paclitaxel, gemcitabine, topotecan, bevacizumab)	OS* PFS ORR AE PRO	January 2025
NCT03598270	Platinum-based chemotherapy with Atezolizumab and Niraparib in patients with recurrent ovarian cancer	III	Recurrent	414	Niraparib + chemotherapy (gemcitabine, carboplatin, paclitaxel, pegylated liposomal doxorubicin) +/- atezolizumab	OS* PFS PFS2 AE PROs ORR DOR	January 2025
NCT04742075	Olaparib, Durvalumab and UV1 in relapsed ovarian cancer (DOVACC)	II	Recurrent	184	Arm A: Olaparib	ORR*	June 2026

NCT05092360	Phase III study of Nemvaleukin alfa in combination with pembrolizumab in patients with platinum-resistant epithelial ovarian cancer (ARTISTRY-7)	III	Recurrent	376	Arm A: Nemvaleukin-alfa plus pembrolizumab Arm B: Nemavaleukin-alfa Arm C: Pembrolizumab Arm D: Physician's choice chemotherapy	PFS* ORROS DCR DOR TTR CA125 AE	December 2026

ORR: Objective response rate; CRS: chemotherapy response score; PFS: progression-free survival; OS: overall survival; PRO: patient-reported outcomes; TTD: time to deterioration; pCR: pathological complete response; DOR: Duration of Response; AE: adverse events; CA125: Cancer Antigen 125; QoL: quality of life; PFS2: progression-free survival to second therapy; PD-L1: programmed cell death ligand 1; CPS: combined positive score; TTR: time to response. *primary endpoint.

positivity was defined as 25% or more of expression via Ventana SP263 assay. The overall ORR was 37.1%, with the highest ORR of 50% observed in Olaparib-cediranib cohort, closely followed by olaparib-durvalumab cohort with an ORR of 42.9%, as expected for HRD-negative cohorts, which had a low ORR ranging between 20%-33%. All treatment groups were manageable, with no treatment-related adverse events leading to discontinuation.

Currently, there are many ongoing trials of ICI with different combinations in EOC. These are listed in [Table 1](#), although the list of trials included is not exhaustive.

NOVEL TARGETS AND IMMUNE ENHANCEMENT IN OVARIAN CANCER

Unfortunately, it remains unclear as to whether ICI therapies will prove successful in improving clinical outcomes in EOC, and investigation of several novel therapeutic targets is currently underway.

Antibody-drug conjugates

Structurally, antibody-drug conjugates (ADC) are comprised of a targeted monoclonal antibody attached to a cytotoxic payload through a linker molecule, where binding of the antibody to its target results in endocytosis and subsequent cytotoxic action in cancer cells^[98]. Several molecules have shown promise in the treatment of EOC, as discussed below, although they remain highly variable in efficacy and rates of toxicity. Trials remain in progress for certain therapeutic targets in ovarian cancer, including tissue factor (tisotumab vedotin, NCT03657043) and mesothelin (anetumab ravtansine, NCT03587311).

Mirvetuximab soravtansine

Folate receptor- α (FR α) is a cell surface protein frequently overexpressed in EOC in up to 81.5% of ovarian cancer tumours^[99]. Mirvetuximab soravtansine targets this receptor and is linked to a maytansinoid DM4, which is a tubulin targeting agent. In November 2022, the US Food and Drug Administration approved Mirvetuximab soravtansine, a novel antibody-drug conjugate, for platinum-resistant EOC with FR α -positive disease based on phase III SORAYA study^[100]. This study included 366 patients expressing FR α who received either mirvetuximab soravtansine or physician's choice chemotherapy^[100]. There was no PFS difference seen in either the overall population or FR α -high cohorts; however, the secondary outcomes (ORR, CA125 response, patient-reported outcomes) demonstrated significant improvement in FR α -high subgroups. The ORR was 24% compared to 10%, CA125 response was 53% compared to 25% and patient-reported outcome was superior with mirvetuximab soravtansine with 27% compared to 13%. There was no statistically significant difference in median OS in the overall population or in FR α -high subgroups. It also demonstrated a more manageable safety profile than chemotherapy, mainly resulting in low-grade, reversible ocular and gastrointestinal issues manageable with supportive interventions. Overall, there were fewer treatment-related grade 3 or higher adverse events (25.1% vs. 44%) and fewer treatment discontinuations (4.5% vs. 8.3%).

FR α as a therapeutic target has shown promise with reasonable adverse event rates, and it may be worthwhile looking for ways to increase the sensitivity of EOC cells to these molecules in future studies.

NaPi2b targeting ADCs

NaPi2b is a cell surface sodium-dependent phosphate transporter and is overexpressed in select cancers including ovarian cancer. Two ADC molecules, lifastuzumab vedotin and upifitamab rilsodotin, have demonstrated modest efficacy in early-phase trials^[101,102] and several other studies are underway (NCT03319628, NCT04907968, NCT05329545).

Epacadostat

Another investigational agent, Epacadostat, is a potential therapeutic in a number of tumour types, including ovarian cancer. Epacadostat is an Indoleamine 2,3-dioxygenase-1 (IDO1) inhibitor. IDO1 is a key regulator of immune tolerance in ovarian cancer, facilitating the breakdown of tryptophan and its mechanism, resulting in increased Tregs, myeloid-derived suppressor cells (MDSCs) with decreased tumour infiltration lymphocytes, and NK cells with upregulation of PD-1 in cytotoxic T cells overall leading to an immunosuppressive effect on TME. Overexpression of IDO1 has been associated with worse prognosis in

various cancers, and up to 56.7% of ovarian cancer has been identified to exhibit high IDO1 expression^[103]. With evidence of preclinical studies demonstrating synergistic effects of epacadostat and immune checkpoint blockade, many studies have been conducted in combination with ICI. So far, results have been largely disappointing, with only moderate efficacy seen in the melanoma and renal cell carcinoma cohort in phase III study^[104]. A phase II basket study examined the safety of epacadostat with pembrolizumab (NCT02178722) in 44 participants, including 37 with recurrent EOC. Unfortunately, a modest ORR of 8.1% was seen in this cohort. A further basket trial of epacadostat with nivolumab in solid tumours demonstrated a modest ORR of 14% and a disease control rate of 31% in a pre-treated ovarian cancer cohort of 29 patients^[105]. Currently, there is a phase I trial (NCT02042430) examining the safety and tolerability of epacadostat prior to cytoreductive surgery for newly diagnosed EOC.

Adavosertib

Adavosertib (AZD1775) is a Wee1 nuclear kinase inhibitor that has emerged as a potential compound able to regulate G2-M transition in the cell cycle and sensitise *TP53*-mutant cells to chemotherapy. Recent phase II trials in platinum-resistant or platinum-refractory settings demonstrated that when adavosertib was combined with gemcitabine, PFS was longer in the combination arm (median PFS 4.6 vs. 3 months)^[106]. Another single-arm phase II study examining adavosertib with carboplatin demonstrated an ORR of 38% with a median PFS of 5.6 months^[107]. Neither study demonstrated safety or toxicity issues, and side effects were reported to be manageable. Adavosertib is currently being examined with olaparib (NCT03579316) in recurrent EOC.

Gemogenovatumel-T

Gemogenovatumel-T (Vigil) is a novel autologous tumour cell immunotherapy with multiple functions, including granulocyte-macrophage colony-stimulating factor (*GM-CSF*) gene activation and TGF- β 1 and TGF- β 2 suppression through bi-functional short-hairpin RNA construct targeted to furin leading to generate a systemic immune response. Gemogenovatumel-T has been shown efficacy in phase IIb trial with a recurrence-free survival of 11.5 months (95% CI: 7.5-NR) compared to 8.4 months (95% CI: 7.9-15.5) in placebo arm with significant benefit in *BRCA*-wt patients with HR 0.69 (90% CI 0.44-1.07, one-sided $P = 0.078$)^[108]. Further post-hoc subgroup analysis demonstrated recurrent-free survival and OS benefit in *BRCA*-wt, homologous recombination proficient (HRP) patient population, an effect demonstrated out to up to 3 years^[109,110]. It remains unclear as to why this drug was particularly efficacious in the *BRCA*-wt population, but ongoing biomarker studies in EOC patients may reveal further answers in the future.

Gemogenovatumel-T and durvalumab combination were investigated in 5 *BRCA*-wild-type recurrent/refractory EOC in a pilot basket study alongside triple-negative breast cancer patients^[111]. Median PFS was 7.1 months with median OS not reached with greater benefit in PD-L1 expressing tumours ($n = 8$, HR 0.304, 95%CI: 0.0593-1.56, 1-sided $P = 0.4715$). There were three grade 3 treatment-related adverse events, all related to durvalumab, therefore demonstrating this combination is well-tolerated and has promising clinical activity in recurrent/refractory EOC cohort warranting further investigation.

Nemvaleukin-alfa

Nemvaleukin-alfa is an engineered cytokine binding selectively to intermediate affinity IL-2 receptors (IL-2R), leading to downstream activation of CD8-positive T-cells and NK cells and limited activation of regulatory T cells. Its preliminary activity was demonstrated through the ARTISTRY-1 study (NCT02799095), a phase I/II basket study that included an ovarian cancer cohort of 14 patients in combination with pembrolizumab (ORR 29%) with side effects most commonly being cytopenias^[112]. A four-arm, randomised, phase III study is currently underway (NCT05092360) with the same combination using physician's choice chemotherapy as the main comparator arm.

Nanoparticle-based combination immunotherapy

An active field of therapeutic development currently is in the development of nanotechnology with the development of nanoparticles (NP)^[113]. These act as drug delivery vehicles capable of providing localised and targeted therapeutic effects of immunotherapy with minimal toxicity when administered due to their targeted nature^[113]. The technology is currently in its early days and multiple trials are being undertaken to evaluate its therapeutic value, particularly in relation to NP-bound chemotherapy^[113].

Cancer vaccines

As referenced in [Table 1](#) (NCT0320047), cancer vaccines are currently being investigated in ovarian cancer to 'sensitise' the immune system to cancer antigens with the aim of inducing an immune response. Although there have been a plethora of studies investigating various formulations^[114], the clinical evidence remains very much in its infancy in treating ovarian cancer, although one recent phase II study in 10 heavily pre-treated, platinum-resistant EOC combining maveropepimut-S, a DPX-platform-delivered peptide cancer vaccine of the antigen survivin, with pembrolizumab and oral cyclophosphamide met its primary efficacy endpoint with 10% partial response and 20% stable disease for more than 12 weeks^[115].

CONCLUSION

Despite many advancements in understanding tumour biology and drug development within the last few decades, EOC remains a challenging disease to treat, with unacceptably high recurrence and mortality rates. Improved understanding of tumour biology and resistance mechanisms to current therapy, as well as the intricate interplay between tumour, TME and immune system, has paved the way for the development of immunotherapy. However, despite initial aspirations of transforming EOC from "cold" into "hot", immunogenic tumours with utilisation of ICI, this has been largely disappointing with modest clinical activity, suggesting that there are inherent resistance mechanisms at play within the EOC microenvironment. This review has attempted to highlight key players involved in the immune system and TME in the context of EOC; however, it is by no means a complete or exhaustive description of the myriad of key components and processes which make up the complex ecosystem.

Combining immunotherapies with other drug classes has shown early promise, but larger randomised trials are required to clearly define the role of ICI therapy in the EOC treatment landscape, if any. Importantly further studies in the mechanistic activity of immunomodulators and their interaction with ICI, TME and immune system to understand the enhanced efficacy of ICI combination therapy will be an important area of research in the future. Novel therapeutic classes such as antibody-drug conjugates and tumour-directed vaccines are of growing interest, and future studies involving biomarker strategies and robust research methods will be needed to determine which EOC patients will ultimately gain the most benefit from specific therapeutic combinations, with the ultimate goal of improving patient survival and quality of life.

Abstract

Aim: The nuclear pregnane X receptor (PXR) is a pivotal regulator of steroid and xenobiotics metabolism and plays an important role in shaping tumor cell responses to chemotherapy. Hypoxia within tumor tissue has multifaceted effects, including multiple drug resistance. The goal of this study was to determine whether PXR contributes to hypoxia-induced drug resistance.

Methods: Metastatic prostate cancer cells were used to study the interaction of PXR and hypoxia-inducible factor-1 (HIF-1) in drug resistance associated with hypoxia. The activities of PXR and HIF-1 were determined by assays for its reporter gene or target gene expression. Co-immunoprecipitation (Co-IP) was used to determine the interaction of PXR and HIF-1. Ablation or inhibition of PXR or HIF-1 was used to determine their roles in hypoxia-induced chemoresistance.

Results: PXR was activated by hypoxia, leading to increased expression of multidrug resistance protein 1 (MDR1). Inhibition of PXR by pharmacological compounds or depletion by shRNAs reduced the hypoxic induction of MDR1 and sensitized prostate cancer cells to chemotherapy under hypoxia. HIF-1 was required for PXR activation under hypoxia. Co-immunoprecipitation results showed that HIF-1 and PXR could physically interact with each other, leading to crosstalk between these two transcription factors.

Conclusion: PXR contributes to hypoxia-induced drug resistance in prostate cancer cells through its interaction with HIF-1.

Keywords: PXR, HIF-1, prostate cancer, chemoresistance, multidrug resistance, MDR1, hypoxia

INTRODUCTION

Hypoxia is a common occurrence in solid tumors as a result of the limited vasculature and the deregulated proliferation of cancer cells^[1]. Tumor hypoxia elicits profound changes in cellular behaviors that influence cellular metabolism, genetic stability, angiogenesis, and self-renewal^[2,3]. Tumor cells in the hypoxic regions are more resistant to chemotherapy than the cells in normoxic regions^[4]. Elucidation of the mechanism involved in hypoxia-induced drug resistance can lead to new approaches to improve the efficacy of chemotherapy.

Hypoxia-induced factors (HIFs), which belong to the basic-helix-loop-helix family of transcription factors, play a central role in cellular and systemic responses to oxygen deficiency^[5]. HIF-1, the hypoxia-inducible subunit of heterodimeric HIF-1, has been suggested as a promoter of tumorigenesis. The association between HIF-1 overexpression, treatment failure, and poor prognosis has been extensively reported^[6-8]. HIF-1 plays an important role in hypoxia-induced drug resistance and could be an interventional target for drug resistance^[9,10]. While the protective effects of HIF-1 against chemotherapy are attributed to its interference with cell cycle arrest and apoptosis and induction of multidrug resistant gene (MDR1) expression^[11,12], the molecular mechanisms underlying the HIF-1-mediated chemoresistance remain elusive.

Pregnane X receptor (PXR, NR1I2), a member of the nuclear receptor superfamily, is also known as steroid and xenobiotic receptor. PXR regulates cellular response to xenobiotics through the induction of drug-metabolic enzymes (DME) and transporters. Upon binding with ligands and activation, PXR translocates from the cytoplasm to the nucleus and regulates the transcription of target genes^[13]. The significance of PXR in cancer chemoresistance is underlined by its activation by commonly used agents of chemotherapy, and its putative role in the regulation of the expression of DMEs and efflux transporters. We have reported that activation of PXR with agonists led to increased resistance of prostate and breast cancer cells to Taxol, vinblastine and tamoxifen, indicating an important role of PXR in chemoresistance^[14,15].

Prostate cancer is one of the most common malignancies affecting men, and chemotherapy is part of the standard of care for metastatic castration-resistant prostate cancer. In this study, we tested the hypothesis that PXR is a determinant of hypoxia-induced drug resistance in prostate cancer. Here, we report that HIF-1 activated PXR under hypoxic conditions, leading to increased expression of MDR1 and increased resistance of prostate cancer cells towards chemotherapy. Interestingly, activated PXR and HIF-1 physically interacted with each other. These results suggest an intricate interaction between PXR and HIF-1 in shaping the hypoxic tumor response to chemotherapy.

METHODS

Materials

Phoenix Ampho and 293T packaging cell lines were purchased from Allele Biotechnology. The human prostate cancer cell lines LNCaP, DU145 and PC-3 were obtained from American Type Culture Collection. PXR (G-1) mouse monoclonal antibodies were purchased from Santa Cruz Biotechnology. HIF-1 rabbit monoclonal antibodies were purchased from Cell Signaling Technology. Myc-tag mouse monoclonal antibodies were purchased from Applied Biological Materials Inc. The real-time polymerase chain reaction

(PCR) reagents, dual luciferase reporter assay system, and 3-(4,5-dimethylthiazol-2-yl)-5-(3-carboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium (MTS)-based cell viability assay kits were obtained from Promega Corporation. DNAfectin liposome transfection reagents were purchased from Applied Biological Materials Inc. Apoptosis Assay kit was purchased from R & D Systems. Rifampicin was purchased from Tocris Bioscience. Ketoconazole, puromycin, and doxorubicin were obtained from Sigma. Taxol was obtained from Enzo Life Science. Doxycycline and cobalt chloride were obtained from Fisher Scientific. pGL3-HRE and pDNA3-HIF-1 were purchased from Addgene Company. PCDH (pCDH vector, purchased from System Bioscience)-myc-HIF-1, pGL3-PXRE, and pBabe-PXR were constructed in our lab. The pGIPZ lentiviral shRNA constructs against HIF-1 and pTRIPZ lentiviral shRNA constructs against human PXR were purchased from Open Biosystem.

Cell culture and stable transfection

Prostate cancer cells were grown in Roswell Park Memorial Institute (RPMI) 1,640 medium with 10% Fetal bovine serum (FBS) and 1% antibiotics under an atmosphere containing 5% CO₂ at 37 °C in a humidified incubator. Phoenix Ampho cells were grown in Dulbecco's Modified Eagle Medium (DMEM) with 10% FBS and 1% antibiotics. Regarding HIF-1 pGIPZ lentiviral shRNA and PXR pTRIPZ lentiviral shRNA viral preparations, 293T cells were transfected with the shRNA constructs in the presence of packaging plasmids (System Bioscience), according to the manufacturer's protocols. LNCaP cells with HIF-1 GIPZ lentiviral shRNA expression were marked by green fluorescent protein (GFP) and selected by fluorescence-activated cell sorting (FACS). LNCaP cells with PXR pTRIPZ lentiviral shRNA expression were regulated by a Tet-On system and marked by red fluorescent protein (RFP) in the presence of doxycycline treatment. For cell culture under hypoxia, hypoxia was induced by GasPak EZ Anaerobe Pouch System (Becton Dickinson and Company).

Immunocytochemistry

LNCaP cells were seeded into six-well plates containing cover glass and incubated under normoxic or hypoxic conditions for 24 h. Cells were fixed with 2% paraformaldehyde for 15 min, permeabilized with 0.1% Triton X-100 for 1 min, and blocked with 1% bovine serum albumin in PBS for 30 min. Cells were then incubated overnight at 4 °C with mouse monoclonal anti-PXR primary antibody at 1:100 dilution and sequentially incubated with Alexa Fluor 488 goat anti-mouse secondary antibody for 1 h at room temperature. The slides were then washed, mounted in Prolong Gold antifade reagent with 4',6-diamidino-2-phenylindole (Molecular Probe), and visualized with a BX41 system microscope (Olympus).

Cell viability assays

Cell viability and proliferation were MTS assay. Briefly, 5×10^4 cells were seeded onto 96-well plates with 200 μ L medium per well and incubated in standard cell culture conditions. After 24 to 72 h of incubation, 20 μ L MTS was added to each well and incubated at 37 °C for 2 h. The OD values at 490 nm wavelength were then obtained.

Anticancer drugs

To determine the sensitivity of tumor cell lines to anticancer drugs, the viabilities of cells after treatments were determined by MTS viability assay according to the manufacturer's instructions. Specifically, under normoxic or hypoxic conditions, 1×10^4 cells were incubated with different doses of anticancer drugs for 48 h. Hypoxia was induced by GasPak EZ Anaerobe Pouch System. After the treatments, the cells were incubated with the MTS solutions and the absorbances were measured at 490 nm.

Induction of apoptosis in tumor cells by Taxol was determined by two-color analysis using propidium iodide (PI) and FITC-conjugated annexin V based on the manufacturer's instructions. After incubations

with or without Taxol for 48 h under normoxic or hypoxic conditions, the cells were stained with PI and FITC-conjugated annexin V and analyzed with a flow cytometer.

Real-time PCR

Total RNA was isolated from the cultured cells using the PerfectPure RNA Purification System (5 Prime). The quantity and quality of different RNA samples were determined by the 260:280 nm absorbance ratios. The RNA samples were reverse transcribed with random hexanucleotide primers and ProtoScript Moloney Murine Leukemia Virus (M-MuLV) Taq RT-PCR kit (New England Biolabs). The cDNA samples were used by real-time PCR using an Applied Biosystems 7,500 real-time PCR system. Sequences for the primers are listed in [Table 1](#). The relative expression was calculated using the $\Delta\Delta C_t$ method and normalized to β -actin RNA levels.

Western blot

Cells were scraped off the plate and directly lysed with 2 × Sodium dodecyl-sulfate polyacrylamide gel electrophoresis (SDS-PAGE) electrophoresis sample buffer. The lysate was boiled, sonicated, and centrifuged. Supernatants were loaded into a 10% SDS-PAGE gel and transferred to a polyvinylidene difluoride PVDF membrane. The membrane was blocked for 1 hour and incubated with primary antibody overnight at 4 °C. After washing with Tris-buffered saline with 0.1% Tween® 20 detergent (TBS-T) three times for a total of 15 min, the membrane was incubated with fluorescently-labeled secondary antibody for 1 hour. After washing three times, the blots were scanned by an Odyssey infrared imaging system (LI-COR Biosciences).

Luciferase assay

Cells were seeded onto 12-well plates and transfected with luciferase reporter constructs pGL3-PXRE or vector controls in the presence of the control Renilla luciferase construct. The pGL3-PXRE was the PXR reporter construct containing two PXR-responsive fragments in *CYP3A4* promoters as previously described^[14,15]. Cells were harvested with the passive lysis buffer 48 h after transfection, and luciferase activity was determined by dual luciferase reporter assay system according to the manufacturer's protocol (Promega).

Co-immunoprecipitation assay

The 293T cells were transfected with pBabe-PXR or co-transfected with PCDH-myc-HIF-1 and pBabe-PXR. The transfected cells were lysed in a non-denaturing Radioimmunoprecipitation assay (RIPA) buffer (pH of 8.0) containing 20 mM Tris-HCl, 137 mM NaCl, 2 mM Ethylenediaminetetraacetic acid (EDTA), and 1% NP-40 containing protease inhibitors. The cellular lysates were agitated slowly at 4 °C for 20 min and clarified by centrifugation at 12,000 g at 4 °C for 20 min. To immunoprecipitate PXR, 1 mg supernatants were incubated overnight at 4 °C with 4 g mouse monoclonal anti-PXR antibody, followed by mixing of the cell lysates with 100 L protein G-coupled sepharose beads and agitation for 4 h at 4 °C. After washing 3 times with non-denaturing RIPA buffer, the beads were collected by centrifuging at 5,000 g at 4 °C for 1 min. The bound proteins were solubilized with SDS sample buffer and subjected to SDS-PAGE for Western Blot analyses.

Statistics

Two-tailed Student's t-tests with a significance level of 0.05 were used to analyze the differences between the two experimental groups. All results were expressed as mean ± SD.

RESULTS

PXR is activated by hypoxia and stimulates MDR1 expression

Previously, we reported that PXR activation was responsible for increased resistance towards chemotherapy in prostate and breast cancers^[14,15]. As a receptor for xenobiotics, PXR activation requires its translocation from the cytosol to the nucleus to regulate the expression of its target genes^[16]. First, we performed immunofluorescence analysis and found that PXR was localized to the nucleus when cultured under hypoxic conditions but was mostly localized to the cytosol under normoxic conditions [Figure 1A]. Next, we determined whether hypoxia can affect the transcriptional activity of PXR using luciferase reporter gene assay. As shown in Figure 1B, compared to normoxic conditions, the activity of PXR was significantly increased in LNCaP cells when cultured under hypoxic conditions. The results indicated that PXR was activated and translocated from the cytosol to the nucleus under hypoxic conditions in LNCaP cells.

PXR activation can stimulate the expression of DMEs and efflux transporters, such as MDR1(*ABCB1*)^[14]. To determine whether PXR activation by hypoxia can lead to altered expression of MDR1, we knocked down PXR expression in LNCaP cells using three independent shRNAs in LNCaP. As shown in Figure 1C and D, the shRNAs effectively suppressed mRNA expression and decreased the activity of PXR under hypoxic conditions. We then evaluated mRNA levels of MDR1 in LNCaP cells with PXR knockdown. In vector control cells, MDR1 expression had a 6.7-fold increase when cultured under hypoxic conditions compared to normoxic conditions [Figure 1E]. However, the hypoxia-stimulated 6.7-fold increase in MDR1 expression was reduced to only 2.7 to 3.8-fold in cells with PXR knocked down [Figure 1E], suggesting that PXR was at least partially responsible for MDR1 induction by hypoxia.

PXR activation contributes to hypoxia-induced chemoresistance

To model the effects of hypoxia on the drug sensitivity of prostate cancer cells, we plated out and cultured LNCaP cells in media with 10% FBS, subjected them to normoxic or hypoxic conditions, and determined their survival by MTS assays after treatment with Taxol for 48 h. LNCaP cells were more resistant to Taxol under hypoxic conditions than those under normoxic conditions [Figure 2A]. Next, we determined whether PXR activation is responsible for chemotherapy resistance under hypoxic conditions. We evaluated whether hypoxia-induced chemoresistance can be reduced by ketoconazole, an antagonist of PXR which suppresses PXR activation via disruption of the interaction of PXR with the co-activator steroid receptor co-activator-1^[17]. Results showed that treatment with ketoconazole restored the sensitivity of LNCaP cells to Taxol in hypoxic conditions [Figure 2B]. We further evaluated the effects of PXR knockdown on hypoxia-induced drug resistance. After treatment with Taxol in hypoxic conditions, the cell viability of these PXR knockdown cells was evaluated by MTS assays. Consistent with the results of antagonist experiments, knockdown of PXR by shRNAs restored the sensitivity to Taxol in one group (sh514 group) [Figure 2C]. However, in the other two groups (sh516 and sh546 groups), PXR knockdown reduced, but did not abolish, the hypoxia-induced drug resistance [Figure 2C].

Since cell viability can be multifactorial, we evaluated the apoptosis induced by Taxol via Annexin V staining in LNCaP cell lines under normoxic and hypoxic conditions. As shown in Figure 2D, the percentage of Taxol-induced apoptosis was reduced from 27% under normoxic conditions to 9% under hypoxic conditions. Taxol-induced apoptosis was also evaluated in PXR knockdown cells by Annexin V staining. Compared with the vector control, shRNA knockdown of PXR significantly increased the percentage of apoptotic cells under hypoxic conditions [Figure 2E]. These results suggest that PXR contributes to the increased resistance of hypoxic tumor cells to Taxol-induced apoptosis.

HIF-1 is required for PXR activation under hypoxic conditions

HIF-1 is a master regulator of adaptive responses to hypoxia and has been demonstrated to be related to hypoxia-induced chemoresistance. To test whether HIF-1 induction is required for PXR activation under hypoxic conditions, we determined the activities of PXR in LNCaP cells treated with chrysin, a natural

flavonoid that reduces the stability and inhibits protein synthesis of HIF-1^[18]. As shown in [Figure 3A](#), chrysin suppressed the induction of HIF-1 under hypoxic conditions in a dose-dependent manner. Concurrently, the activity of PXR was significantly reduced [[Figure 3B](#)].

We also knocked down HIF-1 expression in LNCaP cells with three different shRNAs against HIF-1. The induction of HIF-1 under hypoxic conditions was significantly suppressed in shRNA-expressed cells [[Figure 3C](#)]. The activity of PXR in HIF-1 knockdown cell lines was examined, and the results shown in [Figure 3D](#) suggest that PXR activity was significantly decreased in cells with HIF-1 knockdown compared with the control cell line.

Activation of PXR by HIF-1 and their interactions

Since the PXR activation by hypoxia was compromised by HIF-1 inhibition by chrysin or knockdown by shRNAs, we determined whether HIF-1 can directly activate PXR. We co-transfected 293T cells with pDNA3-HIF-1 and pGPL2-PXRE and determined the effects of HIF-1 on PXR activities. The results shown in [Figure 4A](#) indicate that HIF-1 significantly increased the transcriptional activity of PXR. We also examined the changes in PXR activity in 293T cells following the induction of HIF-1 with CoCl₂, a hypoxia-mimicking agent that stabilizes HIF-1^[19], and demonstrated that CoCl₂ also significantly increased the activity of PXR [[Figure 4B](#)].

The finding that PXR could be activated by HIF-1 led us to investigate whether there was direct interaction between these two transcriptional factors. The lysate of 293T cells co-transfected with PCDH-myc-HIF1 and pBabe-PXR was subjected to immunoprecipitation with anti-PXR antibody and subsequently to Western blot with anti-HIF-1, anti-myc tag, and anti-PXR antibody. Two specific bands with molecular weights of about 120 KDa and 110 KDa were detected [[Figure 4C](#)], indicating a protein-protein interaction between ectopically expressed HIF-1 and PXR under normoxic conditions.

We further confirmed the interaction of PXR with endogenous HIF-1. After transfection with pBabe-PXR, 293T cells were cultured under hypoxic conditions for 24 h, and co-immunoprecipitation was performed as described in the Methods. We found that PXR bound to endogenous HIF-1 (120KDa) isoform under

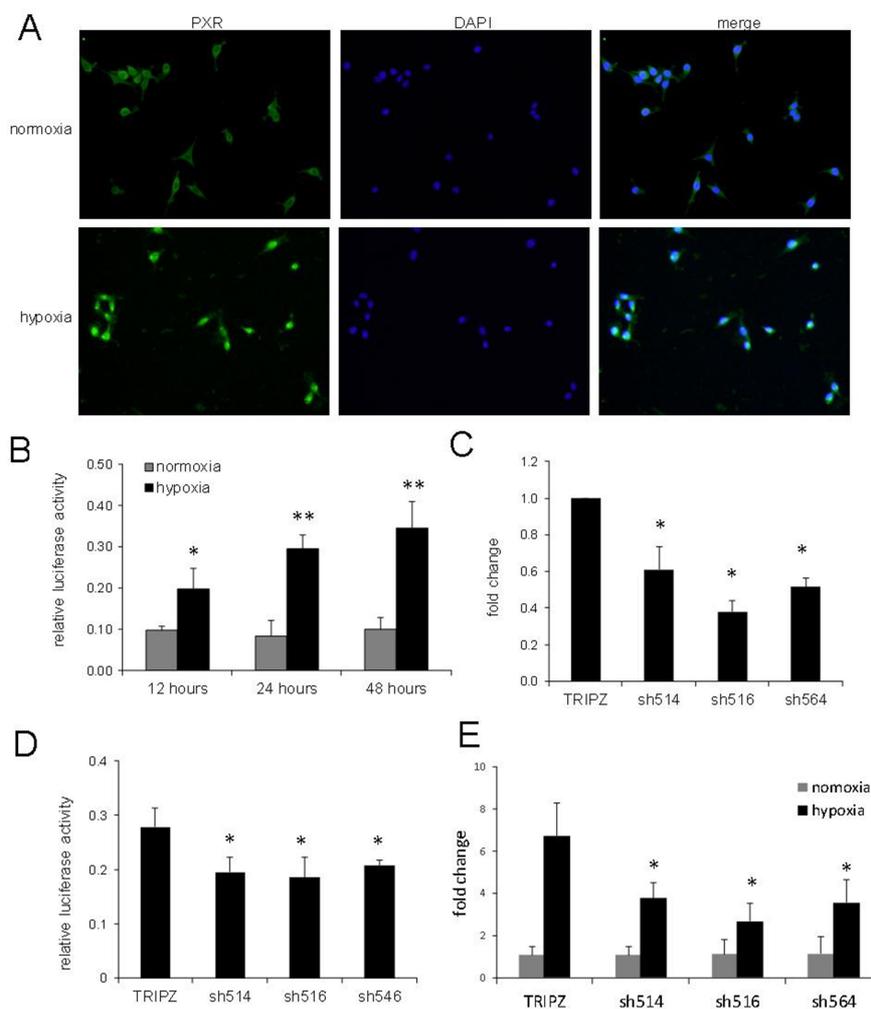

Figure 1. Activation of PXR by hypoxia. (A) Increased nuclear localization of PXR under hypoxia. hypoxia conditions [Figure 4D]. These results suggest a protein-protein interaction between PXR and HIF-1 under hypoxic conditions.

DISCUSSION

PXR has been reported to interact with other transcriptional factors including CAR, FXR, NF- κ B, and PPAR, suggesting its potential role in various non-canonical functions in addition to its role in metabolism of xenobiotics [20-22]. In the present study, we described the interaction and crosstalk between the nuclear receptor PXR and HIF-1, an important transcriptional factor that shapes cellular responses to changes in the availability of oxygen. Several lines of evidence suggest that the activation of PXR under hypoxic conditions

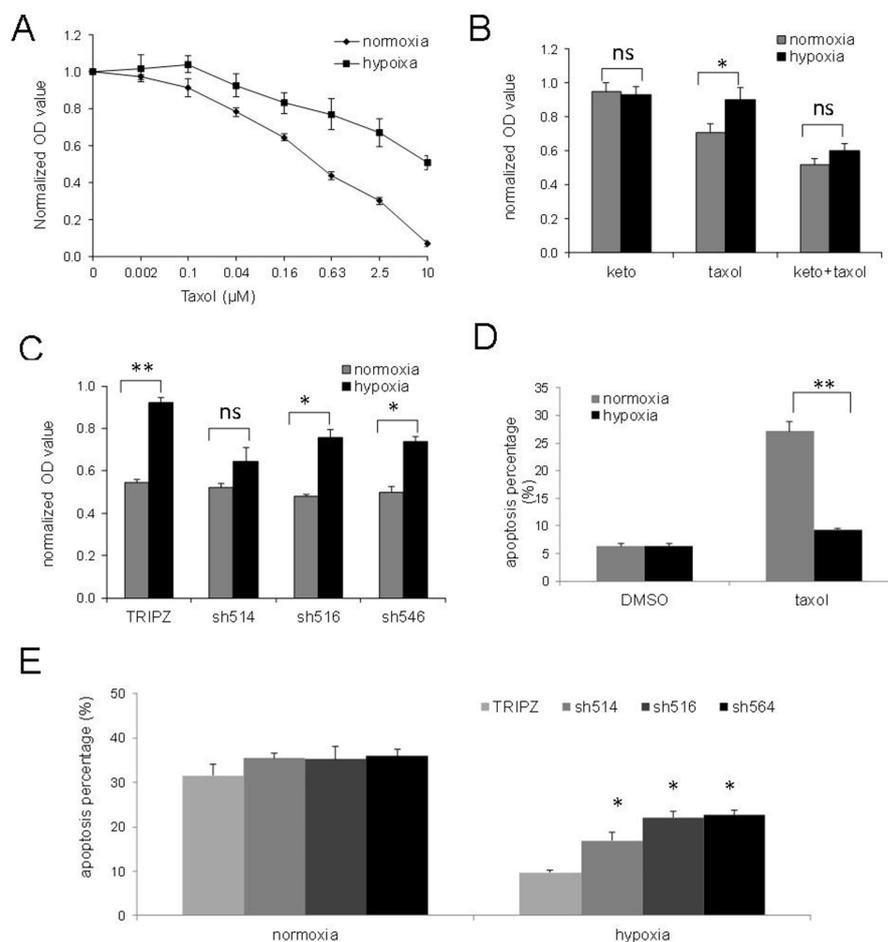

Figure 2. PXR's role in hypoxia-induced chemoresistance. (A) Hypoxia increased resistance of LNCaP cells to Taxol at different dosages; (B) Effects of ketoconazole (10 M) on the sensitivity of LNCaP cells to Taxol (1 μM) under normoxic or hypoxic conditions; (C) Sensitivity of LNCaP cells with PXR knockdown to Taxol (1 M); (D) Hypoxia reduced apoptosis induced by Taxol; (E) Sensitization of hypoxic LNCaP cells toward Taxol-induced apoptosis. LNCaP cells with PXR knockdown treated with Taxol 1 μM were incubated in hypoxic condition for 48 h, and the percentage of apoptosis was determined by PI and annexin V staining followed by flow cytometry assay. The results shown were from at least three independent experiments. Error bars represent standard deviation. * $P < 0.05$. ** $P < 0.01$. ns, not significant. was attributed to HIF-1: (1) forced or induced expression of HIF-1 increased PXR activity; (2) hypoxia-induced translocation of PXR from the cytoplasm to the nucleus; (3) HIF-1 inhibition by pharmacologic inhibition or shRNA knockdown abolished the activation of PXR under hypoxic conditions; (4) Co-IP analysis revealed a direct interaction between HIF-1 and PXR. These results strongly suggest that PXR activation by HIF-1 is one of the critical mechanisms underlying hypoxia-induced chemoresistance in prostate cancer cells.

Hypoxia-induced drug resistance poses challenges to effective cancer chemotherapy. Here, we confirmed that hypoxia caused drug resistance in prostate cancer cells. PXR is usually activated in response to xenobiotics, as well as many therapeutics, and plays a potential role in drug resistance during cancer treatment. In our previous study, we found that PXR was expressed in prostate cancer, and its activation led to the expression of MDR1 and *CYP3A4* and increased resistance to chemotherapeutics^[14,15]. In this study, we found that hypoxia increased PXR activity and nuclear translocation of PXR in LNCaP cells. PXR

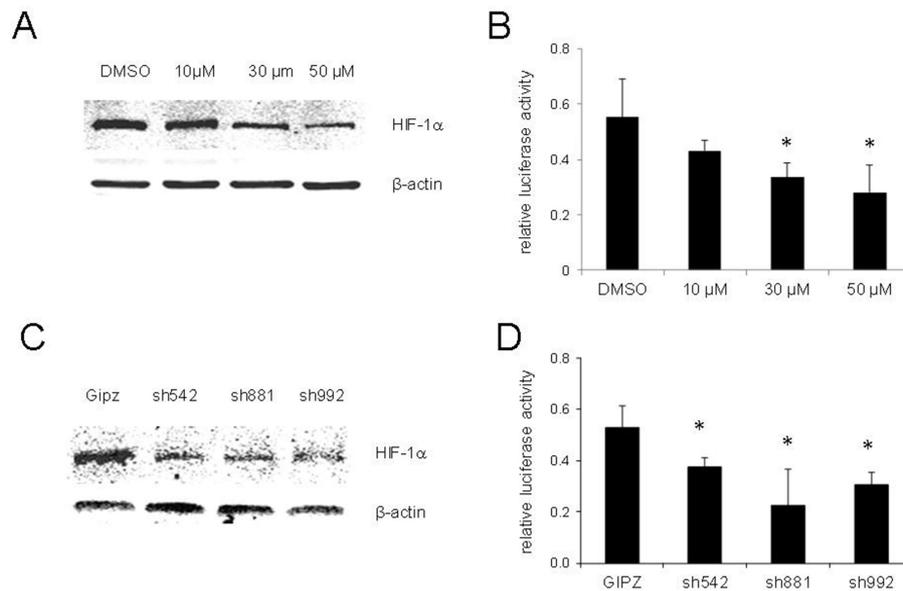

Figure 3. Inhibition or knockdown of HIF-1 suppressed the activity of PXR in hypoxia of LNCaP cells. (A) Expression of HIF-1 in LNCaP cells treatment with chrysin at the indicated concentrations and cultured under hypoxic conditions for 24 h. HIF-1 was detected by Western blot; (B) PXR activity of LNCaP cells treatment with chrysin at the indicated concentrations and cultured under hypoxic conditions for 24 h. PXR activity was determined by luciferase assay; (C) Expression of HIF-1 in LNCaP cells with stable expression shRNA against HIF-1 under hypoxic conditions. HIF-1 was detected by Western blot; (D) PXR activity of LNCaP cell lines with stable expression shRNA against HIF-1 under hypoxic conditions. The fold change was hypoxia/normoxia. The results shown are from three independent experiments. Error bars represent standard deviation. * $P < 0.05$. HIF-1: hypoxia-inducible factor-1; PXR: pregnane X receptor.

knockdown with shRNA or inhibition of PXR activation with the antagonist ketoconazole sensitized tumor cells to Taxol under hypoxic conditions. These results suggest a critical role of PXR in hypoxia-induced chemoresistance in prostate cancer.

While hypoxia-induced drug resistance can be multifactorial, efflux transporters such as MDR1 can contribute to tumor cell resistance to chemotherapy. MDR1 is an ATP-dependent efflux pump with broad substrate specificity. By maintaining reduced intracellular concentrations of antitumor drugs, MDR1 confers cancer cells with multidrug resistance phenotype. Consistent with a previous study^[11], MDR1 expression was induced at the transcriptional level under hypoxic conditions. The induction of MDR1 by hypoxia was compromised by either PXR or HIF-1 knockdown, suggesting that PXR activation by HIF-1 was responsible, at least partially, for the induction of MDR1.

The stability and activity of HIF-1 are tightly regulated, primarily through an oxygen-dependent pathway. Under normoxic conditions, HIF-1 α is hydroxylated at conserved proline residues by prolyl hydroxylases and ubiquitinated by a pVHL-containing E3 ubiquitin ligase, resulting in rapid degradation by proteasomes. Under hypoxic conditions, HIF-1 α is stabilized and regulates the expression of target genes^[23]. HIF-1 also has been reported to be regulated by cytokines, growth factors, environmental stimulators, and other signaling molecules in an oxygen-independent manner^[24]. We found that PXR binds to ectopically expressed HIF-1 under normoxic conditions and endogenous HIF-1 under hypoxic conditions. While the isoform (110 KDa) of HIF-1 was found to interact with PXR under normoxic conditions, it is the putative isoform HIF-1 (120 KDa) that interacts with PXR under hypoxic conditions. There are isoforms of HIF-1 that can suppress the activity and down-regulate mRNA expression of HIF-1^[25,26]. Further studies are

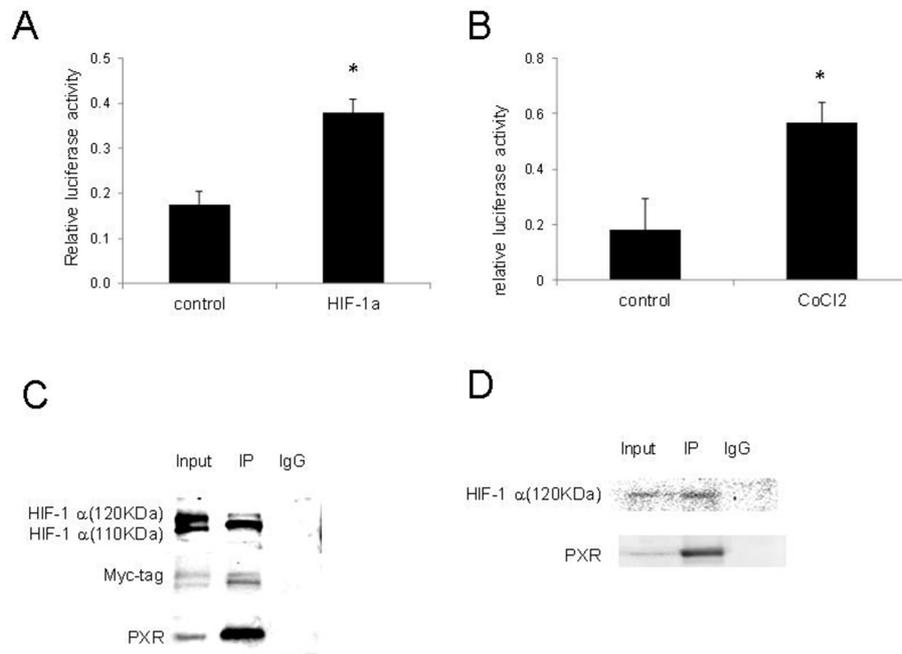

Figure 4. Activation of PXR by HIF-1 and their interactions. (A) HIF-1 increased PXR activity. 293T cells transiently co-transfected with pGL3-PXRE, PCDH-HIF-1, and pGL3-Renilla. PXR activity was determined by luciferase assay 48 h after transfection. The results shown are from three independent experiments. Error bars represent standard deviation. *Indicates significance ($P < 0.05$); (B) CoCl₂ increased PXR activity. 293T cells transiently co-transfected with pGL3-PXR and pGL3-Renilla and incubated with CoCl₂ 100 μM for 24 h. needed to determine whether and how PXR regulates the activities of HIF-1 during the tumor hypoxia response outside hypoxia-associated drug resistance.

In summary, our study identified a novel interaction between nuclear receptor PXR and transcriptional factor HIF-1. Under hypoxic conditions, HIF-1 increased the activity of PXR, leading to increased expression of MDR1 and increased resistance of prostate cancer cells to chemotherapy. PXR physically interacted with HIF-1 under hypoxic conditions. Our study highlights the pleiotropic effects of PXR on prostate cancer cells regarding the tumor hypoxia response and resistance to chemotherapy.

Abstract

Cancer is currently one of the most intractable diseases causing human death. Although the prognosis of tumor patients has been improved to a certain extent through various modern treatment methods, multidrug resistance (MDR) of tumor cells is still a major problem leading to clinical treatment failure. Chemotherapy resistance refers to the resistance of tumor cells and/or tissues to a drug, usually inherent or developed during treatment. Therefore, an urgent need to research the ideal drug delivery system to overcome the shortcoming of traditional chemotherapy. The rapid development of nanotechnology has brought us new enlightenments to solve this problem. The novel nanocarrier provides a considerably effective treatment to overcome the limitations of chemotherapy or other drugs resulting from systemic side effects such as resistance, high toxicity, lack of targeting, and off-target. Herein, we introduce several tumor MDR mechanisms and discuss novel nanoparticle technology applied to surmount cancer drug resistance. Nanomaterials contain liposomes, polymer conjugates, micelles, dendrimers, carbon-based, metal nanoparticles, and nucleotides which can be used to deliver chemotherapeutic

drugs, photosensitizers, and small interfering RNA (siRNA). This review aims to elucidate the advantages of nanomedicine in overcoming cancer drug resistance and discuss the latest developments.

Keywords: Cancer, nanomedicine, nanomaterials, drug delivery, multidrug resistance

INTRODUCTION

Physiologically, the formation of tumor cells is an uncontrolled and unnecessary growth of cells that require a large number of nutrients. According to the world health organization (WHO) report, cancer is the first or second leading cause of death in 112 out of 183 countries. One of the most common causes of death in cancer patients is the development of multidrug resistance (MDR)^[1,2]. The tendency of tumor cell drug resistance and its mortality rate is increasing yearly^[3]. Based on the development of the current medical level, chemotherapy is a conventional treatment for tumors. Although chemotherapy has made a great success, due to the lack of targeting and limited bioavailability, its efficacy is still facing severe challenges in clinical practice. More importantly, tumor cells will generate MDR, which can enhance the response threshold of other cytotoxic drugs after long-term administration of chemotherapy drugs^[4,5]. Novel molecular targeted therapy and immunotherapy have become methods to overcome the lack of specificity of traditional chemotherapy drugs^[6]. However, due to the development of drug resistance, cancer cells still can evade the cytotoxicity of newer molecular-targeted therapeutic drugs. Therefore, resistance to drugs is a common cause of death in cancer patients treated with conventional chemotherapy or novel targeted drugs. MDR is a highly heterogeneous disease state. When a tumor cell becomes resistant to a single anticancer drug, it may become cross-resistant to a range of drugs with different structures or mechanisms. It is one of the key factors for recurrence and metastasis of tumor patients^[7].

The decrease of drug accumulation in cells is the common cause of drug resistance in tumor cells. At present, it is generally believed that tumor cells develop tolerance to drug toxicity in two ways: one is to prevent drugs from reaching the target site through a series of self-regulation when drugs enter the cell from the outside; the other is to pump drugs into the cytoplasm directly outside the cell so that the concentration of drugs available inside the cell is reduced. Up to now, the mechanism of tumor drug resistance has not been fully understood^[8,9]. Cancer resistance is divided into two broad categories: primary resistance, with an early tumor progression, without prior tumor response, and secondary (acquired) resistance, which occurs after initial tumor responses^[10,11]. Among them, primary resistance may be mainly related to the lack of target dependence or the presence of other targets. The main mechanisms of acquired resistance include on-target resistance alterations, bypass alterations in the same pathway or connecting pathways, and changes in phenotypic transformation of tumor cells^[12,13].

The application of nanomaterials in the medical field is also called nanomedicine. This new treatment method can combine the delivery of drugs and improve the treatment effect while protecting normal tissues from side effects. In this paper, we start with the mechanism of tumor drug resistance and introduce the molecular mechanisms related to tumor drug resistance, such as the ATP-binding cassette (ABC) transporter family and MDR mediated by the enzyme system. Next, the research of a nano-drug delivery system in reversing tumor drug resistance was introduced, including the value of nanocarrier platforms in improving the solubility of chemotherapy drugs, improving drug targeting, multidrug delivery, and others. Finally, this paper expounds on the nano-drug delivery system reversal of tumor resistance to remedy the technical advantages and application prospects.

MECHANISMS OF RESISTANCE IN CANCER

More than half of cancer deaths are due to the generation of drug resistance^[2]. The drug resistance of tumor cells is involved in a variety of mechanisms, including the increase of MDR during long-term chemotherapy, DNA repair ability enhancement, genetic mutation, heterogeneous biological metabolism, blocked apoptosis pathway, microenvironment changes, and drug target alteration, among others^[14-16]. Any one or more of the above mechanisms will reduce the drug efficacy and increase the difficulty of tumor treatment. Therefore, from the perspective of molecular mechanisms, the study of molecular markers and molecular targets for reversing tumor resistance is the focus of tumor therapy [Figure 1]. Common MDR mechanisms that lead to drug resistance in tumor cells are briefly highlighted in the following sections.

Efflux of drugs mediated by ABC transporter family

The ABC transporter is a transmembrane protein that relies on the energy produced by the hydrolysis of ATP to shuttle the substrate through the channels of the cell membrane^[17,18]. It is mainly responsible for regulating the distribution, absorption, and excretion of various compounds. Among the ABC transporters that have been discovered, the primary proteins related to tumor cell drug resistance are p-glycoprotein (P-gp/MDR-1, or ABCB1)^[19], multidrug resistance-related protein (MRP-1/ABCC1)^[20], breast cancer resistance protein (BCRP/ABCG2)^[21]. In follow-up studies, scientists found that these proteins were up-regulated in various MDR cancer cells^[22-24]. Among them, the most typical cause of MDR is the overexpression of P-gp. P-gp has a self-protection mechanism, which can efflux most chemotherapeutic drugs out of the cell to reduce intracellular drug accumulation. The substrates of P-gp protein are widespread, including varieties of antitumor drugs, such as paclitaxel, cyclophosphamide, DOX, and emerging molecular targeted drugs^[25-28]. In brief, resistance is more likely to develop in P-gp overexpression tumor cells than that in naturally low P-gp expression ones. Huang^[29] clarified that the drug released by nanoparticles into the cytoplasm is susceptible to P-gp-mediated drug efflux. Based on the above facts, P-gp-induced drug efflux is considered one of the major reasons for drug resistance.

Tumor microenvironment and the enzyme system

The tumor microenvironment (TME) refers to the environment in the tumor cells, including mesenchymal cells and capillaries, the secretion of extracellular matrix, factors, and so on. TME contains a variety of stromal cells, which are mainly composed of tumor-associated macrophages (TAMs). As a heterogeneous population with plasticity, macrophages in TAMs exhibit two polarization states during maturation and differentiation through two different activation pathways, namely classical activation type (M1) and alternative activation type (M2), among which M2 TAMs are believed to play a key role in tumor resistance and disease progression^[30]. In short, TAMs can participate in the generation of drug resistance in tumor cells by releasing cytokines, regulating signaling pathways, intervening in angiogenesis, and interacting with tumor stem cells^[31].

Compared with normal tissue, the tumor microenvironment has abnormal physiological and biochemical characteristics, such as low extracellular pH, hypoxia, high intracellular glutathione (GSH) levels, and others. It affects the occurrence and development of tumors, including proliferation, angiogenesis, invasion, migration, drug resistance, and so forth^[32-36]. It is reported that Hypoxia-inducible factor-1 α (HIF-1 α) can significantly increase the expression of ABC transporters (MDR1, MRP1, BCRP) to induce cell resistance^[37,38]. In addition, HIF-1 α is found overexpressed in breast cancer and enhances the drug resistance of MCF-7 cells to tamoxifen by mediating tumor cell autophagy^[39]. GSH is a tripeptide, and glutathione transferase can catalyze glutathione. GSH plays a key role in protecting cells from oxidative stress. Importantly, it not only regulates the pH of the microenvironment in drug-resistant tumor cells, but also plays a key role in regulating cell resistance to drugs. GSH can indirectly enhance drug resistance by inhibiting the RAS-MAPK pathway and activating protein kinase^[40,41]. Topoisomerase II can form the Topo

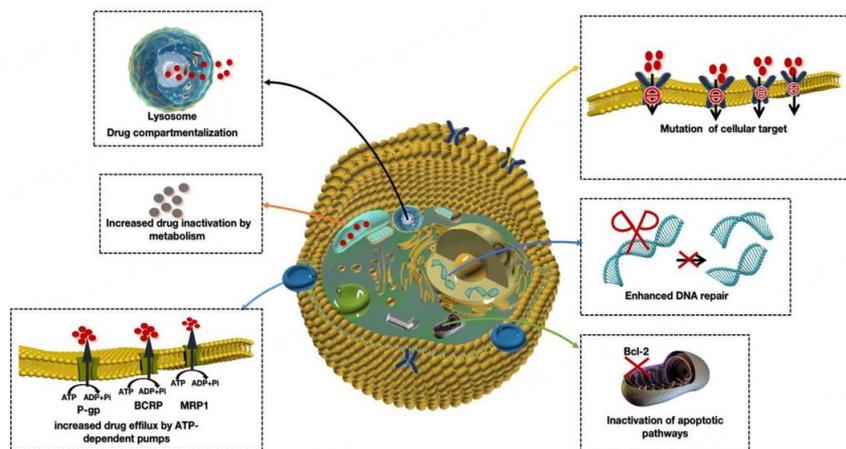

Figure 1. This diagram depicts the expulsion of cells by efflux transporters, including P-gp, BCRP, and MRP-1. Other mechanisms include drug inactivation by increasing the expression of enzymes that metabolize drugs and the development of resistance. Cells can develop resistance by changing the target of a drug, thus disabling the drug. Drug isolation into lysosomes can cause drug inactivation and cause cancer cells to acquire resistance. Drugs inhibit cell apoptosis and produce drug resistance by interfering with the genetic cycle of cells. BCRP: Breast cancer resistance protein; Bcl-2: B-cell leukemia protein 2; MRP: multidrug resistance-related protein; P-gp: p-glycoprotein.

DNA complex with drugs, and thus inhibit the expression of Topo or increase the phosphorylation level, reducing the enzyme content and activity, and leading to the reduction of drug action targets and drug resistance^[42]. The Ca^{2+} -dependent protein kinase system is also one of the enzyme systems that promote drug resistance in tumor cells. MAPK pathway is one of the important downstream targets regulated by calmodulin-dependent protein kinase II (CaMKII). CaMKII can regulate the survival and proliferation of MDR cancer cells by directly or indirectly up-regulating protein kinase C (PKC), extracellular signal-related kinases 1 and 2 (ERK1/2), AKT1, and other signaling pathways. PKC is widely distributed in various tissues and cells, which can mediate signal transduction and regulate gene expression and is related to tumorigenesis and drug resistance^[43-45].

In recent studies on some biomarkers overexpressed in the tumor microenvironment, many targeted nanoparticles have been developed for drug delivery. Excitingly, these studies also found that some nanoparticles can competitively bind to drug-resistant cytokines and enzymes, thereby blocking the proliferation of drug-resistant cells.

Transdifferentiation and tumor cell resistance

Under the effect of anticancer drugs, the tumor cell adopts distinct phenotypes to adapt to changes in their environment - This representation is commonly referred to as cell plasticity^[46]. This characteristic of transforming cells into tolerant or resistant cell states/phenotypes no longer relies on existing drug targets and pathways, thus escaping drug attacks^[47]. The earliest clinical evidence of cell plasticity came from patients with rare non-small cell lung cancer (NSCLC) who showed resistance to epidermal growth factor receptor (EGFR) inhibitors, and some of the patient's tumor tissue type transformed into small cell lung cancer (SCLC). Interestingly, Some patients regained sensitivity to EGFR inhibitors after discontinuation^[48]. Notably, there were differences in cell phenotypes after the transdifferentiation of resistant cells. In another case of a patient with non-small cell lung cancer, the drug-resistant cells metastasized into neuroendocrine cells^[49]. The most common phenomenon of drug-induced tumor cell plasticity is epithelial-mesenchymal cell transformation (EMT)^[50]. In addition, lineage transdifferentiation and proliferation-invasion phenotypic transformation are also manifestations of cell plasticity. EMT is regulated by transcription

factors mainly from SNAIL, TWIST, and ZEB families^[51-53]. TGF- β , FGF, EGF, HGF, IGF-1, and members of the Hedgehog, Notch and Wnt signaling pathway - can induce EMT^[54-56].

Regulation of cell metabolism in drug-resistant tumor cells

A common feature of tumor cell resistance is as much as possible to reduce glucose consumption by mitochondrial respiration. In many experiments, biological processes related to mitochondria were observed to be activated or enhanced in tumor-resistant cells. In addition, different types of tumors may differ in how they metabolize glucose. Superoxide produced by mitochondrial aerobic respiration can cause oxidative stress in tumor cells^[57-59]. Therefore, tumor-resistant cells require a potent antioxidant process in response to superoxide^[60,61]. One of its antioxidant pathways is that glutathione peroxidase 4 (GPX4) catalyzes the reduction of glutathione. GPX4 is used to reduce intracellular lipid peroxide to reduce oxidative stress^[44]. The other important antioxidant pathway is aldehyde dehydrogenase (ALDH) which protects drug-resistant cells from the toxic effects of reactive oxygen species^[62].

Cells spend more than half of their energy on protein synthesis, so tumor-resistant cells must minimize their protein synthesis^[63]. Whole-genome studies of different tumors have shown that the proliferation slowdown is deeply related to reduced protein synthesis. Posttranscriptional modification of N6-methyladenine (N6-methyladenosine, m6A) has been found to reduce the translation efficiency of drug-resistant tumor cells in leukemia and melanoma^[64].

Regulation of apoptosis in drug-resistant tumor cells

The eventual aim of most anticancer drugs is to promote tumor cell death. Consequently, the destruction of the apoptosis mechanism may give rise to the drug resistance of anticancer drugs. Defects in apoptosis occur when genes that control apoptosis are activated and are thought to complement the activation of proto-oncogenes^[65]. Thus, many unregulated oncoproteins, such as MYC, B-cell leukemia protein 2 (Bcl-2), and p53, have a weakened role in triggering apoptosis, which results in the drug resistance of cancer cells^[66].

In the apoptotic pathway, the changes of influential factors such as Bcl-2, nuclear factor NF-kappaB (NF- κ B), and tumor necrosis factor (TNF) reduce the sensitivity of tumor cells to drugs, and thus inhibit the apoptosis of tumor cells and lead to drug resistance in tumors^[67,68]. Among them, the molecular mechanism of the Bcl family inducing apoptosis is one of the few apoptosis pathways targeted by Food and Drug Administration (FDA) approved drugs^[69]. Recent studies have identified another anti-apoptotic protein, myeloid cell leukemia sequence 1 (MCL-1), as a compelling reason for adaptive drug resistance in tumor cells treated with a series of targeted therapies (including BRAF inhibition and EGFR inhibition)^[67]. Other anti-apoptotic mechanisms may also comprise the trigger of exogenous apoptotic pathways or autophagy^[70-72].

Multidrug resistance and autophagy

Autophagy is a highly conserved biological phenomenon, widely existing in eukaryotic cells^[73]. It is a way for cells to maintain homeostasis of the intracellular environment and genome stability by self-decomposing damaged organelles and cell components under extreme stress conditions, which is conducive to making cells gain survival advantages under stress and pressure conditions caused by growth or environmental changes^[74]. An increasing number of studies indicate that certain drugs can induce autophagy in tumor cells when they are stimulated. On the one hand, autophagy, as the executor of type II programmed death, can initiate the autophagy death mechanism and lead to cell death. On the other hand, autophagy, by protecting the survival of tumor cells, may activate the tolerance of tumor cells to chemotherapy drugs, resulting in reduced sensitivity of tumor cells to chemotherapy drugs and drug resistance^[75]. The up-regulation of autophagy function is a significant factor in drug resistance in drug therapy and radiotherapy. It has been

found that the P13K-AKT-mTOR signaling pathway is one of the main pathways mediating protective autophagy, which is mainly involved in the signal transduction of growth factors and hormones^[76]. In addition, Autophagy related genes (ATGs), p62, and IL-6 can also mediate autophagy to make some cancer cells acquire drug resistance^[77-79].

Enhanced DNA damage repair causes drug resistance in tumor cells

Another possibility for resistance to various anticancer drugs is the enhanced ability of tumor cells to repair DNA damage. Clinical use of cisplatin, DOX, and other chemotherapy drugs can cause DNA damage, which has a significant therapeutic effect. However, repeated DNA damage can induce the abnormal activity of the DNA repair system, leading to increased synthesis of enzyme proteins in tumor cells, weakening the effect of tumor drugs, and resulting in drug resistance^[80]. When the cell receives the stimulation after injury, it will activate the DNA damage response (DDR) way to reply. Currently, there are at least five major DNA repair pathways - base excision repair (BER), nucleotide excision repair (NER), mismatch repair (MMR), homologous recombination (HR), and non-homologous end joining (NHEJ). They are active at all stages of the cell cycle and enable cells to repair DNA damage^[81,82]. It is reported that DNA repair endonuclease xeroderma pigmentosum group F (XPF) and DNA repair protein excision repair cross-complementing 1 (ERCC1), which are involved in the nucleotide excision repair (NER) pathway, are crucial to effectively repair DNA damage induced by cross-linking agents and platinum-based reagents. Studies have shown that the overexpression of XPF and ERCC1 proteins is significantly related to the enhancement of cisplatin resistance of cancer cells^[83]. In many tumors, it was also found that the reduction of the DNA mismatch repair pathway can also lead to the increase of drug resistance, and the hypermethylation of the human MutL Homolog 1 (*hMLH1*) gene promoter leads to the decrease of MLH1 protein expression involved in the mismatch repair pathway. 5-fluoro-2-deoxycytidine and decitabine can reverse this hypermethylation and increase the sensitivity of cells to cisplatin^[84].

Drug target changes in drug-resistant tumor cells

Drug-resistant tumor cells can also acquire drug resistance through gene mutation in the condition of slow proliferation. Therein, mutations or aberrations of targets are one of the most common mechanisms. From the Cancer Genome Atlas (TCGA) database, people can accurately identify mutation types in thousands of tumors using sequencing methods^[85]. Among them, the activating mutations of oncogenes such as EGFR, RAS, RAF, and PI3K are the key driving factors for many cancers^[86-89]. With more in-depth research on this mutation generation, many approved drug molecules have been discovered. Many genetic changes lead to the inactivation of tumor suppressor genes in tumor cells, such as PTEN and p16INK4a^[90,91]. In addition, these mutated proteins may remain permanently “on” or more activated than wild-type (WT) proteins. These activated protein targets, further mutations of amino acids can also lead to drug resistance through numerous mechanisms. Although the mechanism of drug resistance is a highly concerning clinical problem, if we can grasp the off-target mechanism, it may provide a new choice for follow-up targeted drug therapy.

In conclusion, the important molecular mechanisms related to tumor resistance have been extensively investigated, including the ABC transporter superfamily, enzyme system in vivo, cell apoptosis, autophagy, embryonic stem cells, etc., which can lead to increased drug efflux, enhanced detoxification mechanism, increased DNA repair capacity, elevated metabolism of xenobiotics, and cell death inhibition. Due to the interaction of genes and signal regulatory pathways, these mechanisms can not clearly explain the MDR mechanism of tumors in a certain way. With the further advancement of the research on transcriptome and proteome, the regulatory mechanism of MDR can be explained in a multi-dimensional way, providing a reference for the research on the clinical reversal of tumor resistance.

Drug resistance of tumor cells can occur in any part of tumor cell growth. With the rapid development of modern medical technology, scientists continue to uncover the mystery of drug resistance in tumor cells. Subsequently, a new generation of antitumor drugs with targeting and high efficiency has been developed continuously. However, these chemotherapy drugs still have the shortcomings of cross-resistance, off-target, and damage to normal tissues. Due to the advantages of small particle size, large specific surface area, safety, enhanced permeability and retention effect (EPR effect), and promotion of drug enrichment, nanocrystals have been widely used^[92]. For the past few years, it has become a hot topic for scientists to effectively improve the therapeutic effect of antitumor drugs by using nanocarriers to load drugs and external tumor-specific identification of target molecules to establish targeted nano-delivery systems [Figure 2 and Table 1]. In the following, we will introduce some principles of drug resistance in tumor cells, as well as nano-drug delivery strategies targeting these resistance mechanisms.

Nanoparticles, as exogenous substances, will encounter various obstacles at all stages of transportation in vivo. After being injected intravenously into the blood, various proteins in the plasma will be attached to the surface of the nanoparticles and labeled. The reticuloendothelial system and mononuclear macrophages will recognize and remove the labeled nanoparticles and even form vascular embolism or organ infarction. By changing the characteristics of nanoparticles, such as stability, surface charge, surface functional groups, etc., we can improve the circulating ability of nanoparticles in vivo, increase the aggregation and targeting of drugs, and finally reverse the drug resistance of tumors.

NANO DRUG DELIVERY STRATEGY FOR MDR TREATMENT

The nanoparticle delivery platform can regulate drug release and change drug distribution in vivo. Currently, commonly used nanoparticle carriers include liposomes, solid lipids, polymers, mesoporous silica, and inorganic nanoparticles^[93,94]. It has been shown that nanoparticles can be designed with different sizes, multiple surface modifications, different shapes, and multiple loading modes^[95]. It can improve the solubility and bioavailability of insoluble drugs and enhance the targeting of drugs. At the same time, light, heat, sound, and other stimuli to trigger the release of drugs can reduce the toxic side effects of drugs^[96,97]. In the following, we detail the evolution of nanoparticles for overcoming chemoresistant tumors.

The tumors in the clinic are divided into solid tumors and liquid tumors. Solid tumors refer to a class of detectable tangible masses with high clinical incidence^[98]. However, non-solid tumors are mainly tumors of the hematopoietic system and lymphatic system, accounting for only 10% of all tumors, and can not be seen in imaging examinations^[99]. Unlike organ cancer and other solid tumors, blood cancer (including multiple myeloma, leukemia, and lymphoma) is formed in the bone marrow or the lymphatic system. Existing treatments for blood cancers include chemotherapy, radiation, immunotherapy, and transplantation^[100,101]. Chemotherapy is the primary treatment for liquid tumors. However, as anticancer drugs are easy to produce drug resistance, the survival rate of patients is low, so the recurrence rate is high. Therefore, there is an urgent need for a targeted drug delivery system to improve the effectiveness of solid and liquid tumor therapy. After modification and modification of nanomaterials, nanocarriers can be given the ability to actively target and passively target tumor cells (including microenvironment, receptors, ion channels, organelles, etc.), which can increase the chemical drugs enrichment in drug-resistant tumor cells and safety. Meanwhile, nanocarriers themselves or cooperatively delivered various drugs can resist tumor drug resistance through phototherapy-chemotherapy, photothermal-chemotherapy, immunochemotherapy, gene therapy-chemotherapy, and other ways. Different types of nanoparticles have received considerable attention in the therapy of various solid tumors, leading to several successful drug delivery systems entering clinical practice over the years [Table 2]. In the following, we detail the evolution of nanoparticles for overcoming chemoresistant tumors. Table 2 provides a brief selection of currently approved and

Table 1. Characteristics based on partial nano drug delivery systems

Classification	Nanocarriers	Nanocarriers properties	Disadvantage
Organic nanocarriers	Liposomes	(a) Amphiphilic, biocompatible (b) Wide adaptability (c) Targeting potential (d) Ease of modification	(a) Poor stability, easy to be affected by metal radiation, high temperature, pH, and enzymes (b) Low drug loading rate
	Polymeric micelles	(a) Long retention time in the body (b) Suitable carrier for water-insoluble drug (c) Ease of functional modification (d) Biocompatible, self-assembling, biodegradable (e) Special "core-shell" structure, targeting potential	Poor physical stability, resulting in drug leakage and sudden release
	Polymeric nanoparticles	(a) Water-soluble, nontoxic, and biodegradability (b) High drug loading (c) Selective accumulation and retention in tumor tissue (EPR effect) (d) Active targeting and smart response	(a) Easy binding to negatively charged non-specific cells or proteins (b) Low gene transfection efficiency
	DNA/RNA	(a) Easy synthesis and modification (b) Low immunogenicity (c) Excellent specificity and affinity (d) Active targeting and intelligent drug release	(a) Poor cellular uptake (b) Poor stability
	HSA	(a) Safety, no immunogenicity, good biocompatibility (b) Biodegradable (c) Passive targeting	(a) Large particle size and easy degradation (b) Preparation method is easy to cause increased toxicity (c) Limited sources of HSA
Inorganic nanocarriers	Metal nanoparticles	(a) Biocompatible (b) Easy preparation	(a) Need surface modification (b) Poor biocompatibility
	Non-metallic nanoparticles		(a) Low surface potential (b) Low drug loading (c) Easy aggregation

EPR: Enhanced permeability and retention; HSA: human serum albumin.

investigational nanomaterials in the arena of chemoresistant anticancer therapeutics (approved references are 102 to 109). [Table 3](#) presents the example mentioned in subsequent sections.

INCREASE THE DRUG AGGREGATION IN MDR CELLS-PASSIVE TARGETING

The blood environment is a primary factor affecting drug accumulation in tumor tissue. Studies have shown that the blood environment is the first major obstacle for nano-drug delivery systems^[110]. The reticuloendothelial system (RES), which consists of body blood protein, opsonin, liver, and spleen, plays a prime role in the metabolism and clearance of nano drug loading system. Tumor blood vessels are hyperactive, and there is a gap between endothelial cells and the lymphatic system. Vascular leakage is associated with EPR effects^[111,112]. Most types of nanocarriers can enhance permeability and retention (EPR) effects^[113]. Nanoparticles (NP) can accumulate in tumor tissues and obtain passive targeting by utilizing the unique pathophysiological mechanism of tumor blood vessels to overcome the drug resistance of cancer cells. It was found that the key parameters affecting the effect of NPs EPR were the size and surface of NPs, and particles up to 100 nm in diameter could migrate into tumor tissues^[114]. Therefore, nanoparticles can continuously deliver drugs to tumor tissue without increasing the dose of chemotherapy drugs. As nanoparticles usually carry multiple chemotherapeutic drugs or bioactive components with multiple anti-MDR mechanisms, the in-depth development of nanomaterials will gain more benefits for MDR tumor treatment. We further introduce different kinds of nano-drug-loaded particles in the following.

Table 2. Representative examples of nanocarrier - marketed products or products in clinical trials with their indications

Classification	Compound	Indications
Liposome	Liposomal doxorubicin (Doxil, Janssen)	Karposi's sarcoma, ovarian cancer, multiple myeloma
	Liposomal vincristine (Marqibo, Spectrum pharmaceuticals)	Acute lymphoblastic leukemia
	Liposomal irinotecan (Onivyde, Ipsen biopharmaceuticals)	Pancreatic cancer
	Liposomal daunorubicin and cytarabine (Vyxeos, Jazz pharmaceuticals)	Acute myeloid leukemia with myelodysplasia related changes
	Liposomal lurtotecan (OSI-211, phase-II) ^[102]	Recurrent ovarian cancer, recurrent small-cell lung cancer
	Liposomal paclitaxel (LEP ETU, phase-I/II) ^[103]	Advanced solid tumors
	Liposomal oxaliplatin (Aroplatin, phase-II) ^[104]	Advanced colorectal cancer
Polymeric	Liposomal interleukin-2 (Oncolipin, phase-II) ^[105]	Immune stimulant for use with a liposomal vaccine against non-small cell lung cancer
	Leuprolide acetate and polymer (Eligard, Tolmar)	Prostate cancer
	Pegfilgrastim (Neulasta, Amgen)	Chemotherapy-induced neutropenia
	Dantrolene sodium (Ryanodex, Eagle pharmaceuticals)	Malignant hypothermia
	Pegaspargase (Oncaspar, Baxalta U.S.)	Acute myeloid leukemia
	PEG-PLA/paclitaxel (Genexol-PM)	Breast and lung cancer
	PLGA/goserelin acetate (Zoladex)	Prostate and breast cancer
	PLGA/leuprolide acetate (Lupron depot)	Prostate cancer and endometriosis
	PLGA/triptorelin pamoatea (Trelstar)	Advanced prostate cancer
	PLGA/leuprolide acetate (Eligard)	Advanced prostate cancer
	HPMA-copolymer-doxorubicin (PK1; FEC28069, phase-II) ^[106]	Lung cancer, breast cancer, and various other cancers
Protein nanoparticles	PEG-camptothecin (Prothecan, phase-II) ^[107]	Various cancers
	Paclitaxel-poliglumex (CT-2103; Xyotax, phase-III) ^[108]	Non-small cell lung cancer, ovarian cancer
	Denileukin diftitox (Ontak, Eisai)	Cutaneous T-cell lymphoma
Metal-based nanoparticles	Albumin-bound paclitaxel (Abraxane, Celgene)	Breast cancer, non-small-cell lung cancer, pancreatic cancer
	Colloidal gold nanoparticles coupled to TNF and PEG-thiol (CYT-6091; Cyt-immune Sciences, phase I) ^[109]	Solid tumors

PEG: Poly ethylene glycol; PLA: poly lactic acid; PLGA: poly (lactide-co-glycolide); TNF: tumor necrosis factor.

Liposomes

The liposome is one kind of nanocarrier formed by encapsulating drugs in a lipid-like bilayer. Liposomes have excellent biocompatibility due to their similar structure to the plasma membrane of biological cells. Liposome encapsulation of drugs can reduce drug toxicity, improve drug stability and bioavailability, and has gradually been widely applied as a delivery carrier for small molecule drugs and proteins^[115]. Doxil®, a lipid-based nanoparticle drug preparation approved by FDA, has been used in the clinical treatment of a variety of malignant tumors (metastatic breast cancer, ovarian cancer, multiple myeloma, etc.). Subsequently, Marqibo®, DaunoXome®, Vyxeos®, Onivyde®, and other liposome nano preparation have also been approved by FDA for tumor treatment^[116-119]. The core of the liposome is a hydrophobic region formed by lipophilic groups, and the inside of the lipid bilayer is a hydrophilic region formed by the phospholipid layer, which can co-carry hydrophilic and hydrophobic drugs. Li *et al.*^[120] prepared D- α -tocopherol polyethylene glycol-1000 succinate (TPGS) coated liposome (TPGS-liposome) as a drug delivery platform for docetaxel (TPGS-DTX-liposomes). In this drug-loaded nanosystem, liposomes are easily absorbed by cells through endocytosis to increase the cellular uptake of docetaxel. TPGS can prevent Docetaxel (DTX) from being recognized by the P-gp efflux pump when passing through the cell membrane, thus further increasing the concentration of DTX in A549/ADR cells. TPGS-DTX-liposomes are associated with decreased DTX toxicity, increased safety, reversal of MDR, and improved lung cancer therapy. Wang *et al.*^[121] prepared a novel pluronic hybrid paclitaxel-loaded liposomes (PPL). They insert Pluronic P105, a

	Active targeting-folate receptor	folate-human serum albumin (FA-HSANPs)	Taxol, 2-ME	EC109/Taxol cells	[115]
	Long internal circulation time	Bovine serum albumin (BSA)	Docetaxel, Quercetin	MDA-MB-231 cells	[147]
	Active targeting-EGFR	Human serum albumin (HSA)	DOX, MDR1 siRNA, Cetuximab	MCF-7/ADR cells	[156]
DNA/RNA	Active targeting-MUC1	MUC1 aptamer-(P-gp and Bcl-2) antisense oligonucleotides	DOX	MCF-7/ADR cells	[127]
Others	Active targeting-folate receptor	Folate-planetary ball milled (PBM) nanoparticles	Resveratrol, Docetaxel	PC3/ADR cells	[175]
	Passive targeting Photodynamic therapy	Lipid-coated carbon-silicon hybrid nanoparticles (LSC)	DOX	NCI/RES ADR cells	[161]

ADR: Adriamycin; CD44: cluster of differentiation-44; DOPE: 1,2-dioleoyl-glycero-3-phosphoethanolamine; DOX: doxorubicin; ICG: indocyanine green; IONP: iron oxide nanoparticle; MCF-7: breast cancer cells; MDCK: madin-darby canine kidney; MDR: multidrug resistance; ME: mercaptoethanol; MSN: mesoporous silica nanoparticle; MUC1: mucin 1; NCI/RES ADR cells: a multidrug-resistant ovarian cancer cell line; PEG: polyethylene glycol; PLGA: poly lactic-co-glycolic acid; PLGA-CS: (poly lactic-co-glycolic acid)-chitosan; RES: reticuloendothelial system; TPGS:

tocopheryl polyethylene glycol succinate; ZIF: zeolitic imidazolate frameworks.

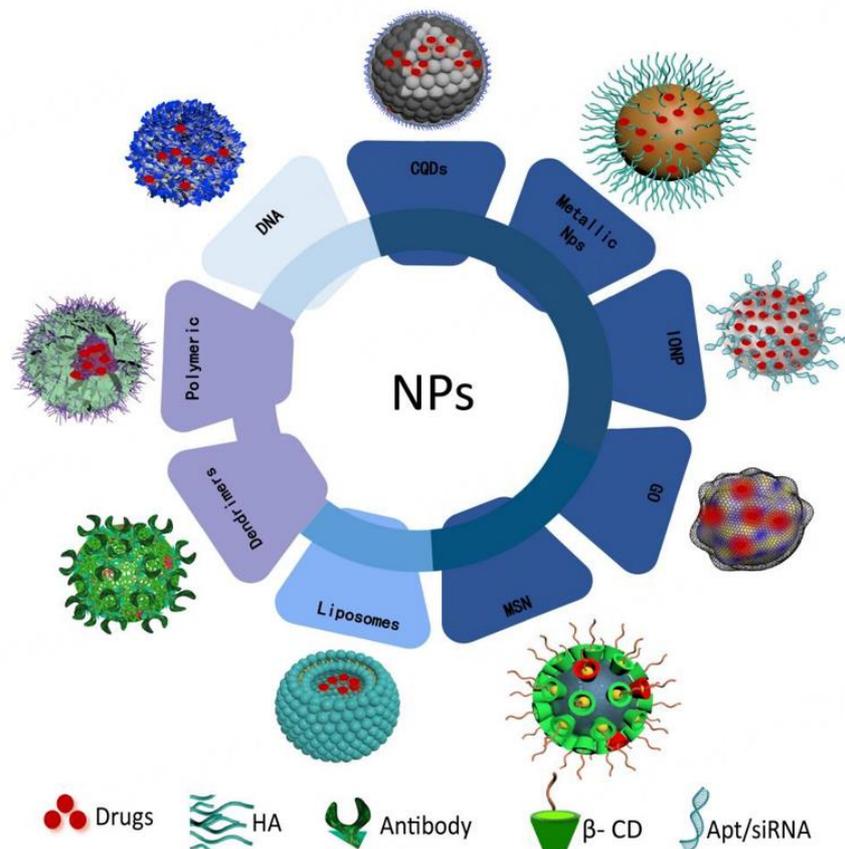

Figure 2. The application of nano-loaded drug system in anti-drug resistance of tumor cells. The advantage of EPR effects could increase the aggregation of drugs in cells, surface-modified antibodies, aptamers, and folic acid can increase the targeting effects, and drugs can also be encased in nanoparticles to escape the recognition of efflux proteins. CQDs: Carbon quantum dots; EPR: enhanced penetration and retention; GO: graphene oxide; HA: hyaluronic acid; IONP: iron oxide nanoparticle; MSN: mesoporous silica nanoparticle; NPs: nanoparticles; β -CD: β -cyclodextrin.

P-gp inhibitor, into the phospholipid bilayer of liposomes and simultaneously load paclitaxel. In drug-resistant A549/Taxol and MCF-7/ADR cells, it can be observed that the PPL + ambroxol regimen has better MDR cell sensitization and killing effect *in vitro* and *in vivo*. The Ax can inhibit cell autophagy, while Pluronic P105 can reduce the expression of P-gp. This drug delivery system can increase the retention time of the drug in the lung and resensitize the drug-resistant tumor cells. However, the disadvantage of liposome nano preparation is that its stability is relatively poor, and sometimes the drug leakage occurs after the loading of the drug, resulting in toxicity *in vivo*^[119].

Polymeric nanoparticles and polymeric micelles

Polymer nanoparticles have good biocompatibility, biodegradability, and high drug-loading efficiency^[122]. Commonly used polymer materials include artificial synthesis and natural availability. The artificial synthetic materials include polyethyleneimine (PEI), polylysine (PLL), polycaprolactone (PCL), poly lactic-co-glycolic acid (PLGA), and polyamidoamine (PAMAM)^[123-126]. Chen *et al.*^[127] designed PLGA nanoparticles to deliver vincristine (VCR) and verapamil (VRP). The synergetic effect of chemotherapy drug proliferation is significantly enhanced in MCF-7/ADR cells. The same results are observed in the

MCF-7/ADR tumor-bearing xenotransplantation model *in vivo*. Coincidentally, people found that micelles have the characteristics of penetrating and accumulating in tumor tissue; therefore, amphiphilic block copolymers have received extensive attention in the development of micellar delivery systems^[128,129]. In Guo's^[130] work, he developed an intelligent drug delivery system (DDS) to treat drug-resistant BC. The photothermal and magnetic effects of indocyanine green (ICG)-iron oxide nanoparticles (PIO NPs), DOX, and myeloid cell leukemia-1 siRNA (Mcl-1 siRNA) were encapsulated in PLGA-CS NPs. The above NPs were coated by the cancer cell membrane (CCM) of MCF-7 cells to prepare PIO-DOX-siRNA-PCSCM NPs. CCM-encapsulated intelligent drug delivery system (DDS) showed exceptional targeting. At the same time, pH stimulation and near-infrared irradiation accelerate drug release. The efflux of Dox was reduced by NP-treated MCF-7/ADR cells under a magnetic field and near-infrared laser irradiation. And the *in vitro* cytotoxicity was increased. Drug encapsulation in micelles can improve drug solubility, prolong blood circulation time, reduce side effects, and enhance antitumor activity. So far, many micelles have entered clinical trials or obtained clinical approval. For example, Poloxam, a Plank block copolymer, has been widely used to deliver small-molecule hydrophobic drugs, has been widely used to deliver small-molecule hydrophobic drugs. Genexol-PM polymer micellar nano preparations have been applied for the market and the FDA has also approved the clinical trial^[131,132].

Dendrimers

Dendritic polymer is a type of polymer nanocarrier with a star or branch structure that allows therapeutic or diagnostic agents to couple on its surface to maximize the role of tumor diagnosis and treatment^[133,134]. Pan *et al.*^[135] coupled the fourth-generation dendrimer amino polyamide amine (G4 PAMAM) with a polyethylene glycol (PEG) modified 1,2-dioleoyl-sn-glycero-3-phosphoethanolamine (PEG-DOPE) block copolymer. Amphiphilic block copolymers can be self-assembled into nano micelles, which can be co-loaded with siRNA onto PAMAM groups and encapsulate water-soluble chemotherapy drugs in hydrophobic cores. This dendrimer micelle mixing system co-delivers MDR-1 siRNA and drugs to tumor tissues through the EPR effect. The positive charge of PAMAM can promote siRNA complexation and tumor cell uptake. The DOPE residues and tertiary amines in PAMAM can improve the escape of endosomes and the intracellular transport of active components^[136]. Wang *et al.*^[137] designed a series of novel amphiphilic dendrimer micelle (PAMAM-n-PF68), and the core of the new dendrimer has large voids and a higher drug loading efficiency. The drug-loaded NPs can effectively inhibit drug-resistant cells by increasing drug uptake and reducing drug efflux. *In vivo* studies show that the dendrimer can not only increase the survival rate of nude mice bearing MCF-7/ADR tumors but also reduce the cardiotoxicity of DOX.

Inorganic nanoparticles

Nanocarriers of inorganic materials have been widely developed and studied by scholars due to their unique physical and chemical properties (such as optical, electrical, and magnetic properties, etc.), diversity of structure and function, outstanding biocompatibility and excellent biological distribution, and their ability to overcome bio-barriers at the cellular and tissue levels^[138,139]. Among inorganic nanoparticles, magnetic nanoparticles, mesoporous silica nanoparticles, carbon nanoparticles, quantum dots and nano-gold have been widely recognized and concerned by scholars as antitumor drug carriers due to their respective characteristics and advantages^[140-142]. Wang *et al.*^[143] prepared a core-shell nanocomposite, polydopamine (PDA) mediated integration of the mesoporous MSN core and the microporous zeolite imidazolate frameworks-8 (ZIF-8) shell (PDAMSN@ZIF-8), ZIF-8 and curcumin (CUR, a P-gp inhibitor) were used for plugging to prevent the premature release of DOX from the mesoporous core. Under acidic conditions, the drug-loaded nanoparticles can release CUR and DOX successively, and the CUR is preferentially released into the cytoplasm to inhibit the efflux of P-gp. These NPs realize the high capacity load of DOX and with continuous drug release characteristics.

Iron oxide nanoparticles (IONPs) are one of the most common inorganic nanocarriers. They are biocompatible and can be incorporated into the iron cycle after being degraded *in vivo*. Norouzi *et al.*^[144] developed nanoparticles with biocompatible IONPs stabilized with nanoparticles of trimethoxysilylpropyl-ethylenediamine triacetic acid (EDT). The drug delivery system can provide magnetic targeting for specific sites. At the same time, it prolongs the circulation time of DOX *in vivo* and increases DOX aggregation in MDR glioma cells.

Among the numerous carbon-based nanoparticles, graphene oxide (GO) has attracted much attention due to its favorable biocompatibility and tolerable toxicity as a nanocarrier for drug delivery^[145]. In Li's research^[146], a new drug-loaded nanosystem consisting of graphene oxide (GO) modified with two molecular beacons (MBs) and DOX was developed. When the nanosystem was uptaken, DOX was released into acidic endosomes, and MBs modified on the surface of GO can silence intracellular multidrug resistance 1 (MDR1) mRNA and upstream erythroblastosis virus E26 oncogene homolog 1 (ETS1) mRNA, effectively inhibit the expression of P-gp, further prevent DOX efflux.

Gold nanoparticles (AuNPs) are ideal nanocarriers with a small volume ratio, large surface area, high biosafety, easy synthesis, and strong reactivity to cells. Even more remarkable, the gold nanoparticles showed photothermal effects when irradiated by a near-infrared laser at 808 nm. Compared with a single gold nanoparticle, the photothermal or photoacoustic imaging effect of its clusters or combinations is more prominent, with improved drug loading ability, enhanced tumor targeting, and increased drug accumulation in tumors^[147]. Wang^[148] prepared an Au nanorod Cluster (AuCR) using the emulsion/solvent evaporation method by self-assembly of DOX and amphibious poly (curcumin-co-dithiodipropionic acid) b-biotinylated poly(ethylene glycol) with Au nanorod (AuNR). The AuCR can be decomposed into an independent AuNR unit at an intracellular concentration of 5 mM GSH to trigger DOX release at pH (pH 6.8 or 5.0). The system can increase DOX uptake in ADR tumor cells and inhibit DOX exportation.

NPS TARGETING THE DRUG-RESISTANT TUMOR CELL BIOMARKERS-ACTIVE TARGETING

Active targeting is a high-performance method to deliver the “cargo” (such as therapeutic drugs and genes) into drug-resistant tumor cells by specific targets without affecting healthy tissues, with better therapeutic effects and less toxicity^[149]. The outermost layer of drug-loaded nanopatforms with active targeting functions mainly consists of different types of targeted ligands, such as antibodies, peptides, aptamers, and small molecules. Generally, folate, hyaluronic acid, cell-penetrating peptide, transferrin, and biotin are common targeting modification molecules^[150]. For instance, Liu *et al.*^[151] prepared hyaluronic acid-modified liposomes containing baicalein and DOX. *In vivo* and *in vitro* studies show that compared with DOX alone, the prepared target functional nanoparticles have a stronger inhibitory effect on the proliferation of breast cancer-resistant MCF-7/ADR cells. Liu *et al.*^[152] prepared folate-bound human serum albumin nanoparticles (FA-HSANPs) that carry taxol and the chemical sensitizer 2-methoxyestradiol (2-ME). Due to the combination of folic acid and folic acid receptors, the drug-loaded nanoparticles entering EC109/Taxol cells are increasing. The co-encapsulation of PTX and 2-ME in FA-HSANPs can prolong the circulation time, improve the antitumor effect, and reduce the side effects of PTX. It also exhibits highly potent cytotoxicity and apoptosis-inducing activities in the G2/M phase of PTX-resistant EC109/Taxol cells. Meanwhile, 2-ME can effectively reduce the expression of drug resistance-related proteins in EC109/Taxol cells and reverse its MDR to PTX to some extent.

Epithelial-mesenchymal transformation (EMT) in solid tumors promotes tumor progression, MDR, migration, and differentiation^[153]. Shome *et al.*^[154] used Poly (D,L-lactic-co-glycolic acid) (PLGA) as the

core, the secondary layer covered with Au-Cu nanoclusters, and the outermost layer are transferrin. It can target the transferrin receptor overexpressing triple-negative breast cancer (TNBC) and have available cell internalization ability as well as highly anti-cell proliferation ability. In addition, in EMT-induced TNBC cells, reactive oxygen species (ROS) are produced after co-incubation with nanocomposites, which can induce apoptosis by altering mitochondrial membrane potential. At the same time, the down-regulation of EMT reduced the migration ability of TNBC cells. A 4.63-fold reduction in ABCC1 expression was observed in MDA-MB-231 cells.

The aptamer is a kind of short-chain oligonucleotide with high sensitivity, biocompatibility, biodegradability, and poor immunogenicity. By modifying aptamer sequences on the nanoparticles, selective active targeting of ligands can be achieved^[155,156]. Moreover, aptamers have the advantages of convenient synthesis, chemical modification, and high stability. In this regard, some tumor biomarkers that can be detected by targeting ligands include epithelial cell adhesion molecule (EpCAM), mucin-1 (MUC1), nucleolin, prostate-specific membrane antigen (PSMA), HER2, etc.^[157-160]. Recently, many targeted aptamers have been studied, including AS1411, 5TR1, HApt, and so on^[161-163]. Pan *et al.*^[164] used DNA origami technology to assemble MUC1 aptamer functionalized rectangular origami (Apt-origami) with P-gp and Bcl-2 antisense oligonucleotides (Apt-origami-ASO) and then load Dox (Apt-DOA). This Apt-DOA shows good lysosomal escape and drug-responsive release in HeLa/ADR and MCF-7/ADR cells. Simultaneously, it can also significantly silence Bcl-2 and P-gp proteins and induce cell apoptosis.

Nucleolin is a membrane shuttle protein that is overexpressed in the cytoplasm and cell membrane in metastatic and rapidly dividing breast cells. Li *et al.*^[165] developed a nucleolin-targeting delivery system [Lip (Ap-Dox)] with AS1411-DOX on the inner layer and liposome on the outer layer to avoid drug resistance in breast cancer (MCF-7/Adr). The advantage of the above NPs is the transmembrane affinity of liposomes to deliver nanoparticles into cells and release Ap-Dox, which increases the accumulation of Ap-Dox in cancer cells. In addition, this targeting of AS1411-nucleolin can accumulate Dox in the nucleus, thus highly enhancing its therapeutic efficacy against drug-resistant cancer cells by effectively bypassing P-gp. This novel nano-drug treatment strategy for breast cancer provides different insights into the future design of NP-delivery drugs.

NPs target efflux and transfer system to overcome tumor resistance

One way to overcome the MDR controlled by ABC transporter is to use ABC transporter inhibitors to make tumor cells sensitive to chemotherapy drugs. ABC transporter inhibitors were combined with anticancer drugs to improve drug sensitivity. However, the toxicity of the MDR reversal agent limits its application. Nevertheless, the enthusiasm for ABC efflux transporters to overcome MDR is still high. Delivery of drugs into cells by employing a nanocarrier can enhance the accumulation of nano drugs in cells and reverse the efflux of ABC transporters. This method has become one of the most effective methods to overcome the drug resistance of tumor cells^[166].

Currently, commonly used MDR effector inhibitors include cyclosporine, verapamil, Taliqueta, and curcumin^[167,168]. The scientists also found that some surfactants also have anti-MDR effects, such as Solutol®HS15, Cremophor®EL, Tween®80, and TPGS, all of which contains PEG in their hydrophilic parts.^[167,169-171] These nanoparticles are also good carriers for drug delivery. Zhang *et al.*^[172] studied the effect of the surface charge of PAMAM dendrimer on the exocytosis and mechanism of multidrug-resistant tumor cells. In drug-resistant human breast cancer cells (MCF-7/ADR cells), exocytosis kinetics, pathway, and mechanism were systematically analyzed. The results prove that the positive charge on the surface of PAMAM dendrimers promoted exocytosis, while the neutral and negatively charged dendrimers had a

slight effect on exocytosis in MCF-7/ADR cells. PAMAM-NH₂ with positive charges is more likely to be distributed in mitochondria and nuclei, which is an ideal mitochondrial targeting agent and gene-drug carrier for multidrug-resistant tumor therapy.

Mao *et al.*^[173] designed polyethylene glycol (PEG, MW: 2K) to deliver DOX (PEG_{2K}-DOX). PEG_{2K}-DOX nanoparticles significantly increased the uptake and cytotoxic activity of MCF-7/ADR and KBv200 to DOX, and their IC₅₀ values decreased to 1.130% and 42.467%, respectively. Compared with doxorubicin, PEG_{2K}-DOX nanoparticles shows significantly improved plasma pharmacokinetics, enhanced *in vivo* therapeutic efficacy against MDR xenografts, and better safety *in vivo*. Suo *et al.*^[174] has studied and synthesized a multiwalled carbon nanotubes dense coating with phospholipid-poly(ethylene glycol) (Pab-MWCNTs). By connecting MWCNTs to P-gp antibodies, the combination of body targeting and laser-guided heat therapy was realized. Pab-MWCNTs can penetrate deeply within tumor spheroids, but after brief exposure to near-infrared, both P-gp-transfected 3T3 cells and P-gp-expressing drug-resistant cancer cells showed higher lethal activity. Singh *et al.*^[175] prepared a novel nano-drug system called the planetary ball milled (PBM) nanoparticles (FA-RES + DTX-NP) that were coated with resveratrol (RES), combined with docetaxel (DTX), and surfacing coupled with folic acid (FA), which could enhance the bioavailability of resveratrol (RES) and DTX to treat advanced metastatic PCa. Planetary milling technology has attracted more and more attention for the advantages of preparing nanoparticles without additive or final dewatering steps to recover nanoparticles. Over the years, the ball milling process has been explored for nano reduction of different polymer materials, including starch, cellulose, and protein-based polymers, for different applications^[176,177]. The cytotoxic effect of FA-RES + DTX-NP nanoparticles is very effective and can reduce the concentration of free drug (DTX) by 28 times. After FA-RES+DTX-NP treatment, the expressions of NF-κB p65, COX-2, pro (BAX, BAK), and anti-apoptotic (Bcl-2, Bcl-XL) genes were significantly decreased. In addition, treatment of DTX-resistant PCa cells with FA-RES + DTX-NP negatively affected the ABC transporter marker, thereby limiting the multidrug-resistant phenotype of cancer cells and effectively enhancing the intracellular concentration of the drug, thereby exerting its cytotoxic effects.

NANO DRUG DELIVERY STRATEGY FOR REGULATING APOPTOSIS AND METABOLISM-RELATED FACTORS

In the human body, apoptosis is a highly programmed cell death process^[178]. When apoptosis is defective, it may also lead to drug resistance to chemotherapy drugs. And this defect may be caused by the inactivation of apoptosis-promoting genes and activation of anti-apoptotic proteins of the Bcl-2 protein family, as well as survival signal proteins (Survivin, FLIP, and NF-κB)^[65]. In the development of fighting against drug resistance of tumor cells, people have studied the proteins related to the regulation of apoptosis and developed inhibitors and drug-loaded nanoparticles that can interfere with the process of apoptosis. Recently, inhibitors of Bcl-2 and MCL-1 anti-apoptotic proteins have been developed to overcome drug resistance, such as ABT-263 (Navitoclax) against Bcl-2 and S63845 against MCL-1^[179-181]. For example, Vivo-Llorca *et al.*^[182] prepared MSN-apMUC1 containing Navitoclax and S63845. By modifying the transmembrane protein MUC1 aptamer overexpressed in breast cancer cells on the surface of mesoporous silica nanoparticle (MSN), the system can be actively targeted to the MDR cells. In addition, the MSN gap also carries an inhibitor of anti-apoptotic proteins. The drug-loaded nano platform could effectively target Triple-Negative Breast Cancer (TNBC) cells and successfully induce apoptosis. The drug delivery system improves the antitumor activity and is effectively targeted to TNBC cells.

The down-regulation of the *C-Myc* gene contributes to the occurrence of a series of human tumors by regulating endogenous and exogenous apoptosis pathways^[183]. In Wang's^[184] study, it was confirmed that multiwalled carbon nanotubes (MWCNTs) could reduce the expression of ABC transporter in human

colorectal adenocarcinoma Caco-2 cells by regulating the expression of C-Myc. Overexpression of C-Myc reversed the inhibitory effect of MWCNT on ABCB1 and ABCC4 expression.

COMBINATION-BASED NANOPARTICLE APPROACHES DIRECTED AGAINST MDR

Nano-drug platform co-delivers chemotherapeutic drugs and sensitizers

In addition to the emerging P-gp inhibitory nanomaterials mentioned earlier, some products extracted from natural plants have also been gradually proven to have anti-P-gp efflux effects. These natural products mainly include alkaloids, coumarins, flavonoids, and terpenes^[185]. For example, quercetin (QT) in flavonoids has been shown to induce apoptosis, inhibit angiogenesis, and inhibit oxidative stress and mutation in several human cancer cells^[186]. Desale *et al.*^[187] synthesized a novel intravenous bovine serum albumin (BSA) co-loaded Docetaxel (DTX) and quercetin (QT) nanoparticle (DTX-QT-BSA-NPs). In this drug delivery platform, BSA plays a role in prolonging the circulation time of nanoparticles *in vivo* and the active targeting of NPs to tumors. QT is used as a chemical sensitizer and is first released to inhibit the action of P-gp efflux transporters. The *in vivo* assay demonstrates that the two drugs significantly enhance the accumulation of DTX in MDA MB-231 (P-gp efflux sensitive) cells by nanoparticle encapsulation compared with free DTX and DTX-BSA-NPs. DTX-QT-BSA-NPs increased the titer of therapeutic drugs in tumor cells.

In recent years, scientists have observed that the anti-malarial drug, chloroquine (CQ), is an inhibitor of lysosomes. CQ can inhibit the fusion of lysosomes and affect the degradation of late autophagy^[188]. It is a potential natural chemosensitizer. Sun *et al.*^[189] prepared Poly(lactic-co-glycolic acid) (PLGA) and D-alpha-tocopheryl polyethylene glycol succinate (TPGS) as carriers to co-delivered DOX and CQ. As a chemical sensitizer, CQ can increase the accumulation of drugs in cancer cells by protecting DOX from autophagy degradation. NP_{DOX+CQ} is pH-sensitive and stable in the neutral environment of normal tissue cells and blood but dissociates in the weakly acidic environment of tumor cells and releases loaded drugs, thus achieving antitumor effects. More importantly, NP_{DOX+CQ} can avoid the recognition of P-gp and thus reduce drug resistance.

Nano platform co-delivers chemotherapy drugs and genes

Co-delivery of antitumor drugs and genes can improve the effectiveness of treatment. On the one hand, genes can increase the drug sensitivity of tumor cells and thus can reduce the drug's adverse reactions. On the other hand, it can overcome the problem of low transfection efficiency in gene therapy, which leads to poor therapeutic effects^[190,191]. Gene therapy usually refers to the therapeutic genes in human target cells in a certain way to correct or replace disease-causing genes and correct gene defects, play the role of biomedical therapy, and achieve the purpose of treating diseases. Small interfering RNA, small RNA, long non-coding RNA, and small hairpin RNA have shown great potential in current-period gene therapy^[192,193]. They play important roles in regulating tumor of multidrug resistance, the expression of cell cycle-related genes, the expression of DNA repair ability-related genes after cell damage, inducing autophagy, and increasing the sensitivity of chemotherapy drugs to targets. Yalamarty^[194] prepared a 2C5-modified MDM with siRNA and DOX (2C5-MDM-D-R). Specifically, the tumor-targeting monoclonal antibody 2C5 (mAb 2C5)-PEG_{7k}-DOPE was inserted into a mixed dendritic molecule micelle containing 4th generation (G4) polyamidoamine (PAMAM)-PEG_{2k}-DOPE and PEG_{5k}-DOPE. The MDR1 siRNA binds electrostatically to the cationic charge on the G4 PAMAM dendrite molecule. The micelle has shown active targeting against tumors in breast (MDA-MB-231) and ovarian (SKOV-3TR) MDR cell lines. MDR1 siRNA inhibited the drug efflux and increased the accumulation of drugs in the tumor cells to reduce the off-target effect. In Wei's^[195] study, a cancer cell membrane (CM) coated with calcium carbonate (CC) nanoparticles was designed to co-deliver miR-451 and DOX to solve the dilemma in bladder cancer treatment (MCC/R-A). The system can target retention and bypass extracellular barriers. In addition, miR-451 overcomes the MDR

of cancer cells by down-regulating the expression of P-gp, thereby increasing cellular drug retention in BIU-87/Adr. The therapeutic effect of MCC/R-A on BIU-87/Adr was significantly enhanced, which was better than miR-451 or DOX alone. Yang *et al.*^[196] used Human serum albumin (HSA) as the carrier to deliver Dox and MDR1 siRNA simultaneously, and the outer layer was modified with cetuximab. Cetuximab in this nano-loaded system targets overexpressed epidermal growth factor receptors (EGFR) in MCF-7 /ADR cells, so DOX and siMDR1 to tumor sites, enhancing gene silencing and cytotoxic activity.

The synergistic effect of immunotherapy and chemotherapy on different mechanisms is a hot research topic in cancer medicine and has a broader clinical application prospect. Immunotherapy by RNA interference is beneficial to long-term block the interaction of PD-1/PD-L1 (Programmed cell death protein 1 and its ligand) and reduce the proliferation activity of cells^[197,198]. Tang^[199] used mixed micelles to co-deliver Paclitaxel (PTX) and PD-L1 siRNA for melanoma treatment. The mixed micelles could reduce the expression of PD-L1 and p-S6K(mTOR pathway activation markers) in B16F10 cells. Furthermore, cytotoxic T cell immune response is promoted, and mTOR(Mammalian target of rapamycin) pathway activation is inhibited, which can cooperate with chemotherapy to reduce tumor proliferation activity.

Chemotherapeutic drugs combined with photothermal therapy

Near-infrared laser has the advantages of high efficiency in penetrating tissue and safety, which can be used in tumor treatment. Dong *et al.*^[200] designed a molybdenum disulfide (MoS₂) modified NPs with hyaluronic acid (HA) by taking advantage of its fine particle size and high photothermal conversion efficiency. Under the irradiation of an 808 nm laser, the temperature of MoS₂ can rise from room temperature to 52 °C within 10 min, which can effectively inhibit the proliferation of drug-resistant tumor cells and significantly reduce the expression of membrane transporters. In vivo experimental observation shows that the tumor growth inhibition rate in the MoS₂-HA + laser group is as high as 96%, indicating that MoS₂-HA/DOX can primarily deliver drugs and maintain the in vivo drug concentration, improving the effect of combined photothermal chemotherapy. Wang *et al.*^[201] successfully constructed a nano drug delivery system with lipid-coated carbon-silicon hybrid nanoparticles (LSC) as the carrier to carry the chemotherapy drug DOX. Under 780 nm laser irradiation, the nanosystem can target mitochondria and produce reactive oxygen (ROS). The ROS can oxidize NADH into NAD⁺ to reduce the amount of ATP available to the efflux pump and promotes MDR cancer cells to return to “normal” for at least 5 days. In vivo data shows that drug-loaded LSC nanoparticles combined with NIR laser therapy can effectively inhibit the growth of multidrug-resistant tumors without significant systemic toxicity. The role of the nanoparticles is also verified in two drug-resistant cell models, paclitaxel-resistant and irinotecan resistant, indicating that this design can effectively overcome the broad-spectrum drug resistance of tumors.

Chemotherapeutic combined with photodynamic therapy

Photodynamic therapy (photodynamic therapy, PDT) is one of the important adjuvant treatments for cancer. Compared with traditional treatment, PDT is less invasive and less damaging to normal tissues. In addition, it can effectively induce immunogenic cell death (ICD) and stimulate immunity, which is an ideal minimally invasive treatment for tumors^[202,203]. Photosensitizers mainly include the porphyrin family (hematoporphyrin derivatives, benzoporphyrin derivatives, 5-aminolevulinic acid, Texaphyrins), the chlorine family (Purlytin, Temoporfin, Photochlor), and the dye family (Phthalocyanine, phthalocyanine)^[204]. The photosensitizers have limitations in clinical applications due to the following properties: poor solubility in water, low chemical purity, and poor tissue penetration. The combination of photosensitizers and nanomaterials can increase the efficiency of PDT as well as eliminate its side effects. In addition, nanoparticles can simultaneously carry chemotherapy drugs and photosensitizers into drug-resistant tumor cells to synergistically inhibit the proliferation of drug-resistant tumor cells. Wei *et al.*^[205] used acetylated Chondroitin sulfate (AC-CS) as a long-cycling

nano craft and combined protoporphyrin IX (PpIX) onto AC-CS (ACP) via an ester bond. DOX and Apatinib (Apa) can be simultaneously encapsulated into amphiphilic ACP micelles (ACP Dox + Apa). When exposed to 635 nm light, PpIX was activated to produce ROS, then the release of DOX and Apa were triggered. At the same time, excessive ROS have a strong PDT effect on mitochondria or nuclei and eventually lead to apoptosis. This novel nanosystem reverses tumor MDR through Apa-enhanced DOX sensitivity combined with photosensitizer-mediated PDT.

CONCLUSION

Through continuous efforts, scientists have made great progress in uncovering the mechanisms of drug resistance in cancer. The occurrence of MDR in tumor cells is mainly due to overexpression of transmembrane proteins, abnormal signal transduction pathways, mutations in drug targets or related enzyme systems, dynamic activation of the DNA repair system, and the developing adaptation of cancer cells to the microenvironment, etc., which leads to reduced drug sensitivity. The mechanism of MDR in tumors is very complex, and it is difficult to reverse the drug resistance with a single preparation. However, how to overcome cancer resistance is still an unsolved problem. As more nanomedicine is developed and optimized, the advantages of nanomedicine will become an attractive strategy for reversing or overcoming cancer resistance.

The rational design of a nano drug delivery system can enhance drug solubility, system stability, targeting, and biocompatibility. In general, through the improvement and modification of nanomaterials, the drugs it carries can be more internalized into cells, increasing the concentration of drugs in drug-resistant tumor cells. At the same time, different drugs can also combine with proteins on the cell membrane to reduce drug efflux. Furthermore, these drug-loaded nanoparticles can interfere with the metabolism and apoptosis of drug-resistant tumor cells, silence drug-resistant genes, and downregulate the synthesis of drug-resistant related proteins. In addition, nano drug delivery systems can realize the therapy multi-target and multi-pathway combined, which is one of the future development directions of tumor therapy. It indicates that nanomaterials show a highly competitive application prospect in drug delivery of drug-resistant tumor cells. In this paper, we systematically summarize different strategies based on nanomedicine to improve the efficacy of chemotherapy in drug-resistant tumor cells, including enhancing the drug enrichment of chemotherapy drugs, improving pharmacokinetics, controllable modifications, and reversing the drug resistance of tumor cells in combination with chemotherapy. Compared with traditional preparations, nano drugs can maintain stability in systemic circulation after injection, protect drugs from damage utilizing plasma protein binding, increase circulation time, and realize efficient accumulation and function of therapeutic components in tumor sites. Therefore, the nanocarrier drug delivery with unique functionality and systemic circulation stability is a novel strategy for overcoming MDR. Among the drug-loaded nanoparticles mentioned in this paper, compared with traditional drug-delivery system carriers, polymer micelles have a higher drug-loading capacity, longer drug circulation time, and lower systemic toxicity. Liposomes are used as delivery carriers for water-soluble drugs (such as proteins or DNA), while insoluble drugs are surrounded by a hydrophobic bilayer. However, due to the instability of the membrane, drug loading is limited. Fortunately, PEG-modified phospholipids prevent the recognition and uptake of liposomes by RES, prolong the retention time of drugs in the blood circulation, and can be enriched in tumor cells in tissues or organs other than the liver and spleen by the EPR effect^[206]. The safe dose of inorganic nanomaterials is uncertain and can cause oxidative stress in normal tissues, which may affect the function of some vital organs. Secondly, most inorganic nanomaterials enter cells through endocytosis, and their uptake by tumor cells directly affects the therapeutic effect. How to improve the targeting of inorganic nanomaterials to tumor tissue is the focus and difficulty of research. In short, the application of nanomaterials in MDR tumors is still in its infancy. The biological safety of nano drug delivery systems still

needs to be further explored. These issues include optimizing nano delivery systems to make them more suitable for human use, avoiding or reducing possible toxic and side effects, and degradation and excretion of nanoparticles. In addition, the methods of reversing tumor drug resistance by the nano-drug delivery system still need to be innovated. The efficiency of nano drug delivery systems in MDR tumors can be improved by combining immunology, photodynamics, acoustic dynamics, and other methods may be a key research strategy for future research.

DECLARATIONS

Authors' contributions

Made substantial contributions to the conception and design of the study: Sun X, Chen K, Shen J
Provided administrative, technical, and material support: Zhao P, Lin J

Availability of data and materials

Not applicable.

Financial support and sponsorship

This work was financially supported by the National Nature Science Foundation of China (No. 21671150, 52073145, 21877084), the Key Research Project (NO. 2021ZDZX4019), and the Technological Innovation Project (pdjh2021b0266) of Guangdong Province.

Conflicts of interest

All authors declared that there are no conflicts of interest.

Ethical approval and consent to participate

Not applicable.

Consent for publication

Abstract

Clear cell renal cell carcinoma (ccRCC) is the most common histological subtype of renal cell carcinoma. The prognosis for patients with ccRCC has improved over recent years with the use of combination therapies with an anti-programmed death-1 (PD-1) backbone. This has enhanced the quality of life and life expectancy of patients with this disease. Unfortunately, not all patients benefit; eventually, most patients will develop resistance to therapy and progress. Recent molecular, biochemical, and immunological research has extensively researched anti-angiogenic and immune-based treatment resistance mechanisms. This analysis offers an overview of the principles underpinning the resistance pathways related to immune checkpoint inhibitors (ICIs). Additionally, novel approaches to overcome resistance that may be considered for the trial context are discussed.

Keywords: Renal cell carcinoma, immunotherapy, treatment resistance, tumor microenvironment, intrinsic factors

INTRODUCTION

Renal cell carcinoma (RCC) accounts for 3%-5% of all malignancies in adults, with an incidence of about

400,000 cases yearly and mortality in approximately 175,000 cases worldwide in 2020^[1-4]. Around one-fourth of patients present initially with metastasis, with the rest recurring after nephrectomy^[5].

The most common histological pattern of renal tumors is clear cell renal cell carcinoma (ccRCC), which accounts for 70%-90% of the disease, followed by papillary (10%-15%) and chromophobe RCCs (3%-5%)^[6,7].

In the past few decades, the mainstay of treatment of metastatic RCC (mRCC) involved vascular endothelial growth factor receptor tyrosine kinase inhibitors (VEGFR-TKI)^[8,9]. Monoclonal approaches to the same target, as characterized by bevacizumab, have been unsuccessful. A study by Motzer *et al.* showed no improvement in OS in patients with mRCC treated with atezolizumab plus bevacizumab^[10]. When this immunologically “hot” tumor microenvironment is exposed to immune checkpoint inhibitors and/or inhibitors of VEGF as a combination, outcomes are significantly and clinically improved compared to VEGFR-TKI monotherapy alone^[7,11]. Unfortunately, a cure is still not achievable for the vast majority of these patients presenting in the metastatic setting.

This review aims to summarize the molecular mechanisms that drive resistance to immune checkpoint inhibitors and their clinical implications in patients with mRCC.

Molecular mechanism of resistance to immune checkpoint inhibitors

Resistance to ICIs therapy has been classified into primary (initial) resistance and secondary (acquired) resistance^[12]. Part of the classification is based on imaging response to ICI therapy, defined by the Response Evaluation Criteria in Solid Tumors (RECIST) v1.1 criteria^[13]. Primary resistance is defined as the best response of progressive disease (PD) or stable disease (SD) for less than 6 months of ICI initiation. Patients with secondary resistance develop progressive disease after having a response or stable disease for greater than six months. Various mechanisms have been postulated for developing primary and secondary resistance in solid tumors, including mRCC, which can be broadly subcategorized into patient-related factors, tumor cell-related factors, or factors related to the tumor microenvironment (TME). The precise role of these mechanisms and a variety of others in primary and secondary resistance in the context of mRCC remains to be fully elucidated. However, a better understanding of these complex mechanisms is crucial to optimizing treatment approaches for those resistant to mRCC disease^[14].

Patients'-intrinsic factors

Patients'-intrinsic factors play a vital role in the immune response to the therapy. Several factors are related to the immune response in cancer therapy and are summarized in [Table 1](#).

Gender

Gender-related factors may be attributed to confounding behaviors, such as male patients with increased exposure to smoking^[15]. Another possible hypothesis is the role of estrogen modulation. Estrogen upregulates the activities of T-cells and PD-1 expression on cells^[16,17]. A recent meta-analysis showed a significant disparity in overall survival (OS) between men and women with metastatic cancers with pooled OS in men was HR = 0.72 (95%CI: 0.65-0.79) and in women was HR = 0.86 (95%CI: 0.79-0.93), with a positive interaction value^[15].

In a randomized trial in patients with ccRCC, treated with nivolumab or everolimus in a second-line setting, the hazard ratio (HR) for death in males was 0.70 (95%CI 0.50-0.90) compared to 0.84 (0.57-1.24) in women, which was similar to patients with melanoma or small cell lung carcinoma treated with ICIs^[18].

Table 1. Molecular mechanism of resistance - patient's intrinsic factors

Factor	Theorized mechanism	Potential outcomes
Gender ^[15-18]	Exposure to mutagenic factors (i.e., Smoking, exposure is higher in men) Estrogen modulation leads to: (a) Increased expression of FoxP3 (b) Modulation of PD-1 expression	Differences in tumor histology Increased regulatory T-cell, dendritic cell, and macrophage activity.
Obesity ^[19]	Both pro-tumor and anti-tumor activity	Mixed outcomes in patients with RCC
Sarcopenia ^[95]	Low skeletal mass index	Worse prognosticator
HLA genotype ^[25,26]	Classical HLA-1 Molecules resulting in High Divergent Expression	Greater response to ICI treatment
Gut microbiome ^[27,28]	Fecal Microbiota Transplant resulting in upregulation of CD4+ T cell and PD-L1	Improved ICI response
Antibiotic/Steroid use ^[29,33]	Antibiotic Use causing dysbiosis Steroids altering T-cell activation, altering gut microbiota	Decreased ICI response May result in favorable disease course due to other factors

PD-1: Programmed cell death protein 1; HLA: human leucocyte antigen; ICI: immune checkpoint inhibitors.

Obesity

Obesity has shown variable modification capabilities in a human cell with both pro-tumor (increased VEGF, vascular endothelial growth factor, hypoxia, angiogenesis, plasmacytoid dendritic cells, and mast cell infiltration) and anti-tumor activities (increased T-cell and natural-killer cell response and decrease intratumor PDL-1 expression)^[19]. Several studies have shown the beneficial effects of obesity on survival in patients with RCC^[20,21]. Utilizing CT based body composition, correlations with specific phenotypes were found (i.e., Adipose, skeletal density vs. sarcopenia). While the exact mechanism to an increased BMI results in positive outcomes, theories include tumorigenic immune dysfunction *vs.* T-cell antigen cross-reactivity. This has the potential to improve sensitivity to ICI therapy. In contrast, an analysis of those with a similar phenotypic profile who were receiving Anti-PD-1 therapy showed a reduction in therapeutic response (lower PFS) as compared to their leaner counterparts^[22-24].

Malnutrition and sarcopenia

Sarcopenia has been associated with adverse outcomes even before the immunotherapy era^[22-24]. A retrospective multicenter real-world study found that sarcopenic patients had significantly worse OS (HR = 2.2, 95%CI: 1.3-3.6, $P = 0.0026$) when treated with ICIs. On multivariate analysis, low muscle mass was associated with an inferior OS^[25]. Similarly, malnutrition has shown poor prognosis and quality of life in patients with lung cancer and is useful in predicting the response to the treatment^[26,27].

Human leucocyte antigen genotype

Human leucocyte antigen (HLA) class 1 genes usually underlie the control of cancer with the diverged presentation of proteins that can influence response to ICIs^[25,26]. This hypothesis suggests that patients with heterozygous divergent alleles have a more extensive presentation of peptides to assist T-cell response than less divergent HLA alleles. Patients with melanoma having high divergent alleles receiving ICIs respond better to the treatment. The outcomes were significantly different with 20 months in patients with high divergent alleles than 8 months in patients with low-divergent alleles (HR = 0.43, 95%CI: 0.2-0.8, $P = 0.0094$)^[26]. Similar outcomes were observed in non-small cell lung cancer patients who received ICIs^[25,26]. So far, there is a lack of specific studies for patients with RCC to understand the difference between high versus low divergent alleles and their response to the treatment^[25,26].

Gut microbiota

Fecal microbiota transplantation (FMT) has been studied as a predictive factor for a response to ICIs treatment. Routy *et al.* found a positive correlation between response to ICI and *Akkermansia muciniphila* in mice receiving anti-PD-1 blockade^[27]. It has also been noticed that the FMT from a patient who responded to ICIs in germ-free mice improves ICI efficiency but, unfortunately, not in non-responding patients. FMT upregulates helper T-cells (CD4+) and natural killer T- cells (NKT) in the spleen, resulting in improved response to ICIs. In a prospective randomized control trial, the gut microbiome modulation in patients with mRCC has been associated with improved PFS^[28], which will be discussed later in this paper.

Antibiotics and use of steroids

The alteration in the gut microbiome predicts the response to immunotherapy. It has been observed that dysbiosis with antibiotics has been associated with poor outcomes in patients treated with ICIs^[29]. Other retrospective studies by Lalani^[30], Derosa *et al.*^[31], and Tinsley *et al.*^[32] also showed a negative association between antibiotic use and outcomes in patients with RCC, with a significant decrease in PFS^[30-32]. Derosa *et al.*^[31] and Tinsley *et al.*^[32] also showed a reduction in OS. On multivariate analysis, antibiotic use was an independent predictive factor for worse outcomes in patients with RCC^[31,32].

The use of steroids is routine in oncology patients for symptom management. A dose of > 10 mg prednisone or equivalent induces immunosuppression by altering the T cell activation with the expansion of M2 macrophages and thus altering the gut microenvironment. In a multicentre study by Arbour *et al.*^[33], baseline higher steroid dose was associated with lower ORR (7% vs 18%), progression-free survival (PFS) ($P < 0.001$), and OS ($P < 0.001$). However, steroids used to manage immune-related adverse events have shown no negative impact on the efficiency of ICIs^[34-36]. Indeed, patients that develop severe immune-related adverse events and need systemic steroids have a more favorable disease course in recent real-world data^[37].

TUMOR CELL INTRINSIC FACTORS

Tumor cell-intrinsic factors are cell-related factors that can identify the response to the therapy and are summarized in [Table 2](#).

Signalling pathways

Interferon-gamma signaling pathway

The activation of interferon-gamma (IFN- γ) activates Janus kinase (JAK), and interferon regulatory factor 1 (IRF1), leading to the expression of PDL1. Patients with dysregulation of the IFN- γ pathway were shown to develop resistance to ICIs^[38]. The IFN- γ recruits immune cells and enhances MHC-1 antigen presentation, which is essential for the antiproliferative and proapoptotic signals^[39,40]. The dysregulation of JAK genes has been associated with a lack of response to the IFN- γ and, thus, with PD1 inhibitors^[41].

Mitogen-activated protein kinases

Mitogen-activated protein kinases (MAPK) is associated with VEGF, IL-6, IL-8, and IL-10 production, inhibiting T-cell functions and immune cell recruitment. The MAPK pathways downregulate antigen presentation and MHC expression and decrease the sensitivity to antiproliferative effects of IFN- γ and TNF alpha^[38,42].

PI3K/mTOR/AKT pathway

Patients with ccRCC have altered PI3K/AKT pathway along with alteration in the expression of PTEN^[43]. These lead to the inhibition of immunosuppressive cytokines and auto phagosome, resulting in decreased T cell response, cell recruitment, and cell-mediated death. The loss of PTEN has been associated with the

Table 2. Molecular mechanism of resistance - tumor cell-intrinsic factor

Factor	Theorized mechanism	Potential outcomes
IFN- γ dysregulation ^[39-41]	Loss of JAK-1&2 Function resulting in decreased PD-L1 expression	Resistance to PD1 Inhibitors
MAPK ^[38,42]	Decreased immune cell recruitment with decreased MHC-1 antigen presentation	Increased proliferation and decreased apoptosis
	Increased production of VEGF, IL-6,8 and 10 inhibiting T-cell function	Increased resistance
PI3K/AKT alteration ^[43,44]	Downregulation of antigen/MHC expression	Increased proliferation and decreased apoptosis
	Loss of expression of PTEN resulting in: Cytokine suppression Inhibition of auto-phagosome activity	Decrease ICI response due to poor recruitment.
Wnt/ β -catenin overexpression ^[45,46,48]	Absence of T-cell expression and T-cell exclusion	Resistance to ICI therapy
Loss of MHC ^[96-99]	Loss of MHC-1 and 2	Resistance to ICI therapy

IFN- γ : Interferon-gamma; PD-L1: programmed death ligand 1; JAK: janus kinase; MHC: major histocompatibility complex; VEGF: vascular endothelial growth factor; IL: interleukin; PI3K: phosphoinositide 3-kinases; PTEN: phosphatase tensin homolog; ICI: immune checkpoint inhibitors; MAPK: mitogen-activated protein kinase.

worse outcome in patients treated with ICIs therapy^[44].

Wnt/ β -catenin pathway

Wnt/ β -catenin is involved with stem cell embryogenesis, immune regulation, and cell differentiation. In most cancers, it is overexpressed, reducing the expression of T cells and thus resulting in resistance to ICIs^[45-48].

Insufficient tumor antigenicity

Investigations highlighted a correlation between poor antigenicity and decreased sensitivity to ICIs^[49,50]. Repeat analysis supports the idea that these tumor neoantigens can be targeted to promote a positive response to checkpoint blockade. This concept can be applied to a variety of malignancies.

It is important to highlight that despite an understanding of the molecular patterns of resistance to ICIs in this context, no current biomarkers, molecular or otherwise, are validated for use in the clinic to help determine therapy selection.

TUMOR MICROENVIRONMENT

Tumor microenvironment (Tme) includes tumor cells and other cells interacting with them. These cells are crucial for tumor cells' development, progression, and relapse. Factors that can affect the TME are summarized in [Table 3](#).

Tumor-associated macrophage

During inflammation, macrophages transform to M1 (classical) or M2 (alternative) activation. M1 produces inflammatory cytokines (ie. IL-6, IL-12, and IL-23), whereas the later correlates with the subsets of M2a, M2b, M2c, and M2d, respectively^[51,52]. In 2011, a study found poor survival in patients with RCC with a high burden of M2 (CD163+)^[53]. The diverse and extensive tumor-associated macrophages in the TME of patients with RCC indicate cancer progression and metastases. Strategies to direct therapeutic response to suppress tumor-associated macrophage recruitment have shown some improvement in the response^[54], but macrophage-targeted therapies still need to be implemented in clinical settings

Table 3. Molecular mechanism of resistance - tumor microenvironment

Factor	Theorized mechanism	Potential outcomes
Tumor-associated Macrophage activation ^[51-53]	Greater M1 and M2 Macrophage activation, M2 (CD163+) subset correlated to poor survival outcomes	Nivolumab improved PFS in high M2 density activation
High T-cell density ^[56]	Higher CD8+ infiltration associated with poorer clinical outcomes in ccRCC patients	Prognosticator for worse potential outcomes
B-cell and tertiary lymphoid structures ^[50,57,62]	Increased B cell-related genes associated with strong memory response Tertiary lymphoid structures promote Regulatory T-cell activation	Great response to therapy Prognosticator for positive potential outcomes.
Hypoxia ^[64-67]	Increased recruitment and infiltration of myeloid-driven suppressor cells, decreased function of cytotoxic T-cells Induction of HIF-1a and 2a, increasing PD-L1 expression, and VEGF generation	Immune evasion Immune evasion

PFS: Progression-free survival; ccRCC: clear cell renal cell carcinoma.

The TME associated with abundant cells has shown an overall better response to ICIs ($P < 0.001$) as compared to TKI treatment ($P = 0.15$)^[55]. Voss *et al.* found that the TME, with abundant infiltrative cell types, was associated with a good response to ICIs ($P < 0.001$), which was the opposite in patients treated with TKIs ($P = 0.15$)^[55]. In another trial, patients treated with nivolumab having higher densities of M2 macrophages showed better PFS (HR = 0.69, $P = 0.016$), but no significant improvement in OS ($P = 0.5$)^[56].

T cells

RCC is a tumor mainly enriched with T cells, particularly CD8+ T cells. The presence of CD8+ T cells is correlated with poor outcomes^[57,58]. Choueiri *et al.* reported that high CD8 infiltration was associated with poor clinical outcomes in patients with ccRCC treated with sunitinib versus the avelumab-axitinib combination^[59]. This was discordant from another phase II study, NIVOREN-GETUG AFU 26, which showed that patients with high CD8+ infiltration treated with Nivolumab have poor PFS (HR = 3.96, $P < 0.0001$) and OS (HR = 2.43, $P = 0.04$)^[56]. Interestingly, Voss. *et al.* identified no correlation between the CD8+ cell infiltrations and survival in mRCC when treated with ICIs^[55].

The Cancer Genome Atlas analysis showed that patients with RCC have more regulatory T-cells and are associated with poor clinical outcomes (HR = 1.59, 95%CI: 1.23-0.06; $P < 0.01$)^[60].

B cells and tertiary lymphoid structures

B cells assist T-cell regulation and differentiation through different pathway activation, including interleukin (IL) and growth factors^[49]. The memory of classical B cells has been associated with response against tumor-associated antigens^[50]. The Microenvironment Cells Populations-counter (MCP-counter) analysis showed that responders have higher B cell densities in the TME than non-responders in melanoma and ccRCC^[61].

Tertiary lymphoid structures are also associated with better outcomes in oncology patients. It assists in transforming cells and activating T regulatory cells^[57,62].

Hypoxia

Tumors in the hypervascular environment led to insufficient nutrition and oxygen intake, resulting in hypoxia and progression^[63]. Hypoxia induces upregulations of myeloid-driven suppressor cells that lead to

decreased function of cytotoxic T cells^[64,65]. Hypoxia also induces factor 1a (HIF-1a) and 2a (HIF-2a) to express PD-L1 in tumor cells^[66,67]. Elevated levels of HIF are associated with generating VEGF, which acts as an immune escape mechanism

by upregulating CTLA4, TIM3, LAG3, and PD-L1 on dendritic cells^[65,68]. Hypoxia causes tissue deposits of adenosine which suppresses the activity of T cells^[69].

CLINICAL IMPLICATION OF ICIS RESISTANCE

ICI resistance in the clinical trial setting

Despite therapeutic advances, ICI resistance remains a significant issue in clinical trials and real-world settings due to a lack of validated clinical tools to identify patients at risk for primary or secondary resistance. Currently, there is no clinically accessible molecular classification of mRCC, and although clinical trials investigating molecular biomarkers in mRCC populations are promising, such approaches remain restricted to the research domain.

Molecular subtypes as biomarkers of ICI response

Using molecular markers to identify subgroups of mRCC patients who experience more robust responses to ICI therapy remains a promising avenue of study.

Transcriptomic analysis in a subset of primary resected ccRCC samples obtained from patients with metastatic disease identified a 35-gene signature capable of subgrouping metastatic clear-cell renal cell carcinoma (ccRCC) into four groups (ccRCC 1-4). These subtypes were associated with differential response to sunitinib treatment, with ccRCC 1 and 4 tumors having a lower response rate and poorer survival outcomes than ccRCC 2 and ccRCC 3 subtypes. Molecular characterization of these tumor subtypes identified unique tumor microenvironments that may explain the relative response to sunitinib treatment. For example, ccRCC 4 cancers were associated with a suppressive immune microenvironment with overexpression of PD-L1 and PD-L2, while the ccRCC 2 subgroups demonstrated a more pro-angiogenic subtype^[70]. These results lead to the hypothesis that these molecular subtypes could stratify patients into groups most likely to benefit from TKI therapy, ICI monotherapy, and combined ICI therapy approaches.

This hypothesis was tested in the phase II BIONIKK trial, the first to stratify patients into treatment groups based on their molecular subtype. Patients were divided into the ccRCC risk group using the aforementioned 35-gene transcriptomic signature and were prospectively allocated into treatment groups. Patients with ccRCC 1 or 4 tumors were assigned to anti-PD1 monotherapy with nivolumab alone or anti-PD1/anti-CTLA4 with a combination of nivolumab-ipilimumab. Those patients with ccRCC 2 or ccRCC 3 group tumors received TKI therapy and a combination of nivolumab-ipilimumab. The primary outcome of this study was the overall response rate per the RECIST criteria, with survival outcomes, tolerability, and duration of the response being secondary outcomes^[71]. Meylan *et al.*^[72] further identified the biomarkers for the efficacy of Nivolumab (N) +/- Ipilimumab (I) in mRCC patients with TLS > 2 treated with N or NI showed a response rate of 73% and 71%, respectively. Both TLS > 2 and higher densities of Ki67/PD1 correlated with better response rates (80% vs. 43% $P < 0.01$) and decreased incidence of progression events (5% vs 36%, $P = 0.02$).

Another example of molecular subtyping in a trial setting comes from the IMmotion 150 and 151 study and the ongoing phase II OPTIC trial. The IMmotion 150 trial compared treatment with atezolizumab alone or in combination with bevacizumab to sunitinib in a cohort of 305 patients with previously untreated metastatic renal cell carcinoma. Though treatment with a combination of atezolizumab alone or in

combination with bevacizumab did not demonstrate improved PFS, the retrospective analysis did identify gene expression signatures associated with PFS involving angiogenesis, immunity (primarily T-effector presence and function), and myeloid inflammatory pathways. In particular, patients with a high angiogenesis signature score had an improved overall response rate and a longer PFS within the treatment sunitinib arm compared to those with low signature scores. Those with a high T-effector gene signature score experienced an improved overall response rate and longer PFS than those with a low score in the atezolizumab plus bevacizumab arm. In contrast, those with a high myeloid inflammation gene expression score experienced a shorter PFS in the atezolizumab plus bevacizumab and atezolizumab monotherapy treatment arms. These results suggest that such gene expression signatures may be useful tools in identifying patients more likely to benefit from various treatment regimens^[73].

The findings of the IMmotion 150 study were validated and expanded upon in the phase 3 open-label IMmotion 151 study, which enrolled 915 patients and allocated them to receive either a combination of atezolizumab plus bevacizumab or sunitinib monotherapy. While this trial failed to demonstrate an overall survival benefit to combination therapy, it has provided rich biomarker data for mRCC molecular subtyping^[74]. The IMmotion 151 trial retrospectively assigned patients to subgroups based on the previously identified gene expression signatures developed in the IMmotion 150 cohort. The authors again demonstrated that patients with a high angiogenesis signature score had improved PFS in the sunitinib arm, and those treated with atezolizumab plus bevacizumab had an improved PFS compared to sunitinib in subgroups with a high T-effector score or a low angiogenesis score. Based on these analyses, patients enrolled in the IMmotion 151 trial were further retrospectively classified into seven molecular subtypes - termed clusters - according to their unique genomic and transcriptomic enrichment pathways. Clusters 1 (angiogenic/stromal) and 2 (angiogenic) were enriched among the favorable risk groups as defined by the IMDC and Memorial Sloan-Kettering Cancer Center (MSKCC) scores, while clusters 4 (T-effector/proliferative), 5 (proliferative), and 6 (stromal/proliferative) were enriched among poor-risk patients.

Additionally, patients in clusters 1 and 2 demonstrated improved survival, while those in cluster 6 had poor PFS outcomes compared to other clusters, irrespective of treatment arm. Moreover, treatment with atezolizumab plus bevacizumab demonstrated improved overall response rates and longer PFS than sunitinib in clusters 4, 5, and 7 (small nucleolar RNA). Multivariable analysis of these identified molecular subtypes with clinical scores, including the MSKCC and IMDC scores, demonstrated an independent association with survival. These results suggested that these molecular subtypes may have the predictive capacity and could be incorporated with existing clinical tools to provide additional benefit, though additional prospective testing would be important prior to any clinical translation^[75]. Of note, the phase II OPTIC trial is taking the first steps towards this goal, looking to utilize these molecular subgroups to prospectively assign patients to combination ICI treatment with ipilimumab plus nivolumab or ICI-TKI therapy with nivolumab and cabozantinib. Currently, in the recruitment phase, this trial will provide critical insights into the utility of molecular subtypes for treatment stratification in mRCC (NCT05361720).

Future perspectives

The above trials are a testament to the advancements in understanding the molecular underpinnings of mRCC and the role these insights can play in tailoring therapy in this patient population. Despite this progress, there are still several areas requiring further study. First, many unanswered questions remain regarding integrating these molecular subtypes with current clinical risk criteria. Further, these approaches are time-consuming and cost-prohibitive due to their reliance on multi-omic profiling. Therefore, studies on the cost-efficacy and accessibility of these tools will be critical before a transition into the clinical landscape. Additionally, molecular signature identification may benefit from targeted therapy, as there are an increasing number of TKI and PD-1/PD-L1 options available. Therefore, although these trials' results are

promising, further study is imperative to bring molecular subtypes into the clinical setting.

Clinical implication in real-world settings

Combination of lenvatinib plus everolimus for those with primary resistance

In a cohort of 7 patients that had shown resistance to VEGF-targeted TKI's or ICI therapy, a combination of lenvatinib and everolimus as either second or third-line therapy resulted in a partial response in three patients and stable disease in three patients. Progression-free survival ranged from 3 to 15 months^[76].

Combination therapy as second-line therapy active in distinct clinicopathological features

This combination retrospective study included 343 patients, with 123 receiving Cabozantinib and 220 receiving Nivolumab. Patients receiving Nivolumab and first treated with Pazopanib showed a non-statistically significant median overall survival of 26.8 vs. 11.6 months. The OS for patients with Cabozantinib was 25.7 months as compared to Sunitinib 21.7 months, but again, not statistically significant ($P = 0.45$). Notably, Cabozantinib exhibited activity in terms of progression-free survival, particularly in patients with Clear Cell histology (7.8 vs. 5.4, $P = 0.026$) and those with good risk features (12.3 vs. 5.7, $P = 0.022$)^[77].

Another phase II trial, including a high dose of Cabozantinib with atezolizumab therapy (COSMIC 021), demonstrated an encouraging clinical response^[78]. However, the CONTACT-03 study did not show any promising results in patients treated after disease progression during or after immune checkpoint inhibitor therapy (either combination or monotherapy) (NCT04338269).

APPROACH TO OVERCOME ICI RESISTANCE

Targeting the TME

Colony stimulating factor 1 receptor inhibitor

M2 macrophages promote tumor neoangiogenesis, and progression, which play a role in the treatment's resistance. The expression of colony stimulating factor 1 receptor (CSF1R) allows switching the type 1 macrophages to the type II tumor associated-macrophages^[79]. There are phase-1 trials currently undergoing to assess the effectiveness of combining treatment with CSF1R inhibitors and ICIs (NCT02718911, NCT02526017).

Indoleamine 2,3-dioxygenase 1 inhibitors

The indoleamine 2,3-dioxygenase 1 inhibitors deprives T cells of nutrients and can be the target for treatment. A study published in 2018 on patients with metastatic ccRCC treated with Nivolumab has shown that IDO-1 overexpression (> 10%) was found in patients with an excellent response to the treatment and thus better PFS. This study suggested that IDO could be used as a biomarker for patients with RCC^[80].

A phase I/II ECHO-202/KEYNOTE 037 trial combining oral IDO-1 enzyme inhibitors with pembrolizumab was associated with a 40% objective response (8 complete and 13 with stable disease)^[81]. Unfortunately, in another phase III study, IDO-1 enzyme inhibitors failed to show a positive response in patients with melanoma, so their use was stopped after the study results^[82].

Stimulators of interferon genes and retinoic acid-inducible gene 1 agonists

The stimulators of interferon genes (STING) pathway promotes the production of pro-inflammatory cytokines^[83]. RIG-1 stimulates natural killer cells and CD8+ T cells^[84]. There are a couple of trials assessing STING agonist and retinoic acid-inducible gene (RIG-1) agonist use as monotherapy or in combination with ICIs (NCT03010176 and NCT 03739138)

Targeting HIF-2 α

Belzutifan is a first-in-class novel therapy to inhibit HIF-2 α resulting in anti-tumor activity by impairing the hypoxic signal pathway in cancer cells. A phase 1 study with patients with pre-treated ccRCC showed a 25% response rate^[85]. In a phase 2 study, patients who received prior treatments (immunotherapy or chemotherapy) were treated with Belzutifan plus Cabozantinib showed an objective response rate in 16 [30.8% (95%CI: 18.7-45.1)] of 52 patients^[86].

Another inhibitor of HIF is PT2385, which was studied in combination with Nivolumab in patients with mRCC who previously had received up to three treatments. It showed an objective response rate of 22% with a PFS of 10 months among patients receiving therapeutic doses of PT2385 versus 4.7 months in the sub-therapeutic group^[87].

Pegylated IL-2 and cytokines

IL-2 has shown anti-tumor potential by lysing tumor cells^[88,89]. In a study of patients with mRCC, high-dose IL-2 combined with Pembrolizumab has shown an objective response rate (ORR) of 69%^[90]. In a study in patients with previously untreated mRCC, Bempedaldesleukin (NKTR-214), combined with Nivolumab, showed an ORR of 54% in untreated mRCC^[91].

Targeting patient's intrinsic factor

Modulation of the gut microbiome

CBM58 is a bifidogenic live bacterium that can augment the effect of ICI by modulating the gut microbiome. The single-center randomized study (NCT03829111) in mRCC patients assessed nivolumab and ipilimumab with or without daily oral CBM588. The abundance of the bifidogenic bacterium was not seen. However, patients who received nivolumab-ipilimumab with CBM 588 had a significantly lower PFS (12.7 months vs. 2.5 months, HR 0.15, 95%CI: 0.05-0.47, $P = 0.001$) and a higher response rate (58% vs. 20%, $P = 0.06$) compared to those without CBM 588^[92].

Recently Fecal microbiota transplantation (FMT) has been shown in several studies to augment the effect of ICI and overcome resistance, particularly in patients with melanoma^[27,93,94]. Clinical trial in patients with RCC is still recruiting to assess the role of FMT in improving the efficacy of ICI (NCT04758507).

CONCLUSION

The outcomes of patients with metastatic RCC have changed significantly over the past few decades. The new therapeutic options, particularly with ICIs, have survival benefits and a durable response rate either used as a monotherapy or in combination with other therapies. However, patients may have resistance initially reflecting primary resistance or initial response to the treatment and then develop secondary resistance. Resistance to ICIs is influenced by three significant components: patient intrinsic factor, tumor cell-intrinsic factor, and contributions from the tumor microenvironment. Many innovative approaches have been studied and investigated in clinical trials to assess ICI resistance mechanisms in patients with mRCC.

Abstract

Aim: This study aimed to decipher the molecular mechanism underlying the synergistic effect of inhibitors of the mevalonate-cholesterol pathway (i.e., statins) and aminopeptidase inhibitors (APis) on APi-sensitive and -resistant acute myeloid leukemia (AML) cells.

Methods: U937 cells and their sublines with low and high levels of acquired resistance to (6S)-[(R)-2-((S)-Hydroxy-hydroxycarbonyl-methoxy-methyl)-4-methyl-pentanoylamino]-3,3 dimethyl-butyric acid cyclopentyl ester (CHR2863), an APi prodrug, served as main AML cell line models. Drug combination effects were assessed

with CHR2863 and *in vitro* non-toxic concentrations of various statins upon cell growth inhibition, cell cycle effects, and apoptosis induction. Mechanistic studies involved analysis of Rheb prenylation required for mTOR activation.

Results: A strong synergy of CHR2863 with the statins simvastatin, fluvastatin, lovastatin, and pravastatin was demonstrated in U937 cells and two CHR2863-resistant sublines. This potent synergy between simvastatin and CHR2863 was also observed with a series of other human AML cell lines (e.g., THP1, MV4-11, and KG1), but not with acute lymphocytic leukemia or multiple solid tumor cell lines. This synergistic activity was: (i) specific for APis (e.g., CHR2863 and Bestatin), rather than for other cytotoxic agents; and (ii) corroborated by enhanced induction of apoptosis and cell cycle arrest which increased the sub-G1 fraction. Consistently, statin potentiation of CHR2863 activity was abrogated by co-administration of mevalonate and/or farnesyl pyrophosphate, suggesting the involvement of protein prenylation; this was experimentally confirmed by impaired Rheb prenylation by simvastatin.

Conclusion: These novel findings suggest that the combined inhibitory effect of impaired Rheb prenylation and CHR2863-dependent mTOR inhibition instigates a potent synergistic inhibition of statins and APis on human AML cells.

Keywords: Aminopeptidase, statins, mevalonate pathway, carboxyl esterase, Rheb, mTOR

INTRODUCTION

Targeting of protein degradation pathways has provided new therapeutic opportunities for hematological malignancies. Proteasome inhibitors, with Bortezomib (Velcade®) as a prototypical representative, gained an established place in chemotherapeutic treatment regimens of multiple myeloma^[1,2]. Aminopeptidases operating downstream of the proteasome were also identified as druggable targets, with Bestatin as the founding drug displaying activity mainly against solid tumors^[3,4]. Tosedostat represents a next-generation aminopeptidase inhibitor (APi) that displays activity as monotherapy as well as in combination with various chemotherapeutic drugs, including cytarabine, daunorubicin and histone deacetylase (HDAC) inhibitors^[5-9]. Moreover, Tosedostat demonstrated clinical activity in phase I-III combination chemotherapy for acute myeloid leukemia (AML)^[6,10-18] and multiple myeloma (MM)^[19], and has been evaluated for the treatment of solid tumors^[20,21]. Tosedostat, and a close structural analogue (6S)-[(R)-2-((S)-Hydroxyhydroxycarbamoyl-methoxy-methyl)-4-methyl-pentanoylamino]-3,3 dimethyl-butyric acid cyclopentyl ester (CHR2863), are APi prodrugs with an esterase-sensitive motif^[5]. As hydrophobic drugs, they can freely diffuse into cells wherein they are converted by intracellular esterases to their hydrophilic acid active metabolites that enhance their cellular retention and promote inhibition of multiple aminopeptidases. The latter provokes an amino acid deprivation response, inhibition of mTOR activity, and blockade of protein synthesis^[5]. Recently, we demonstrated^[22] that the cytotoxic activity of CHR2863 against U937 myeloid cells relies on carboxylesterase 1 (CES1) activity. Consistently, down-regulation of CES1 and loss of CHR2863 conversion to its hydrophilic active metabolite constituted a dominant mechanism of acquired resistance to CHR2863^[22]. CES1 has an essential physiological function in cholesterol metabolism by converting cholesteryl esters to cholesterol^[23,24]. Since AML cells harbor an aberrant cholesterol metabolism^[25-27], we explored whether or not statins as inhibitors of the mevalonate-cholesterol biosynthetic pathway potentiate the cytotoxic activity of APi (pro) drugs. In earlier studies, statins displayed differential sensitization of AML cells^[28-32] but were also able to enhance the sensitivity of various anti-leukemic drugs, including cytarabine, daunorubicin and the cell cycle inhibitor UCN-01^[33,34]. Here, we discovered that various statins markedly potentiated the cytotoxic activity of CHR2863 in multiple human AML cell lines as well as in CHR2863-resistant cells, by a mechanism that involves perturbation of Rheb prenylation as an essential complementary factor to mTOR inhibition by APis. These novel findings uncover a potent therapeutic combination of statins and APis which may warrant a further clinical evaluation in AML treatment.

METHODS

Chemicals

Simvastatin (430-104-M) was obtained from Alexis Biochemicals (San Diego, CA USA). Fluvastatin (10010337) and lovastatin (10010338) were purchased from Cayman Chemical Co (Ann Arbor, MI, USA). Pravastatin (P4498), R-mevalonic acid (50838), squalene (S3632), farnesyl pyrophosphate (F6892), geranylgeranyl pyrophosphate (G6025), FTI-277 (F9803), bestatin (B8385) and daunorubicin (30450) were from Sigma Chemical Co (St. Louis MO, USA). Bortezomib was obtained from the VUmc Pharmacy department. CHR2863, (6S)-[(R)-2-((S)-Hydroxy-hydroxycarbamoyl-methoxy-methyl)-4-methyl-pentanoylamino]-3,3 dimethyl-butyric acid (CHR6768), and (S)-[3-(7-Hydroxycarbamoyl-heptanoylamino)-benzylamino-phenyl acetic acid cyclopentyl ester (CHR2875)^[5,35] were provided by Dr. A. Drummond (Chroma Pharmaceuticals Ltd, Abingdon, UK) and dissolved in dimethyl sulfoxide as 10 mM stock solutions and stored at -20 °C.

Antibodies

The following antibodies were used for Western blot analysis: CES1 monoclonal antibody (Lifespan Biosciences, Seattle, WA, USA, LS-C498701, 1:1,000 dilution) and rabbit polyclonal antibodies at 1:1000 dilutions: total Akt (#9272), phospho-Akt (Ser308) (C31E5E) (#2965), phospho-Akt (Ser473) (#9271), total mTOR (7C10) (#2983), phospho-mTOR (Ser2448) (#2971), phospho-mTOR (Ser2481) (#2974), total S6K (#9202), phospho-S6Kp70 (Th389) (#9205) and Rheb (#4935) all from Cell Signalling Technology, Danvers, MA, USA. β -Actin antibody was from Sigma-Aldrich, St. Louis, MO, USA (A2172, 1:10,000 dilutions). Secondary antibodies included goat anti-mouse or goat anti-rabbit antibodies conjugated to IRDye[®]800CW (1:10,000, Odyssey; LI-COR, Biosciences, Nebraska, USA).

Cell culture

Human U937 myelomonocytic leukemia cells (ATCC, Manassas, VA, USA) and 2 sublines U937/CHR2863^{R0.2} and U937/CHR2863^{R5} (resistant to 0.2 and 5 μ M CHR2863, respectively and characterized by 14- and 270-fold acquired resistance to CHR2863) were isolated and cultured as described previously^[22]. Other human myeloid leukemia cell lines (THP1, MV4-11, and KG1), human lymphoblastic cell lines (CEM and CEM/Vbl), human ovarian carcinoma cell lines (2008 and 2008/MRP1), human breast carcinoma cell lines (MCF7/WT and MCF7/MR), human lung cancer (SW1573) and human nasopharyngeal carcinoma cells (KB) were cultured as described previously^[36-41]. Briefly, cells were grown in RPMI-1640 medium (Lonza, Verviers, Belgium) supplemented with 10% fetal calf serum (FCS, PAA Cell Culture Company, Pasching, Austria), 20 mM HEPES, 2 mM L-glutamine, and 100 U/mL penicillin/streptomycin (all from Lonza, Verviers, Belgium). The cell lines were cultured in 25 cm² culture flasks (Greiner Bio-One GmbH, Frickenhansen, Germany) in 10 mL medium at an initial density of 3 \times 10⁵ cells/mL (or 1.25 \times 10⁴/cm² for adherent cells) and in a humidified atmosphere at 37 °C and 5% CO₂. Cell cultures were passaged every 3-4 days. Cells were regularly checked, and found negative, for mycoplasma contamination.

Western blotting

Western blot analysis was performed essentially as described by Verbrugge *et al.*^[22]. Briefly, cell lysates were prepared from 5 \times 10⁶ cells suspended in 150 μ L ice-cold lysis buffer (Cell Signalling Technology, #9803) containing 4% Protease Inhibitor Cocktail (PIC) and 1 mM NaVO₄. Supernatant fractions were collected by centrifugation (13,000 \times g for 10 min, 4 °C), and 30 μ g protein aliquots were resolved on a 4%-20% TGX pre-cast SDS PAGE gels (Bio-Rad), followed by transfer onto a polyvinylidene difluoride (PVDF) membrane (Millipore, Billerica, MA, USA) suitable for chemiluminescent detection by the Odyssey Infrared Imaging System (PerkinElmer, Zaventem, Belgium). The membranes were pre-incubated in blocking buffer (Odyssey Blocking Buffer, LI-COR, Biosciences, Nebraska, USA) for 1 hr. Next, membranes were incubated

overnight (4 °C) with primary antibodies and β -actin for control of equal loading. After three washing steps (PBS/0.05% Tween20), the membranes were incubated (1 hr) with secondary antibodies, followed by antibody detection with the LI-COR Odyssey scanner (Biosciences) and digital image acquisition/quantification with the Odyssey infrared imaging system software (version 3.0.16, LI-COR Biosciences) according to the manufacturer's instructions.

Apoptosis assay

Cells were collected and washed three times with ice-cold PBS. Early phase apoptosis was determined by the Annexin-V/7AAD Kit (PN IM3614, Beckman Coulter) using a FACSCalibur flow cytometer (Becton and Dickinson, San Jose, CA) using the manufacturer's protocol. Briefly, cells were washed and resuspended in binding buffer. Annexin-V (1:10) and 7-Amino-Actinomycin (7AAD, 1:20) were added and incubated for 15 min on ice in the dark. Binding buffer was added and analyzed by flow cytometry followed within 1 hr. Annexin-V-positive and 7AAD-positive cells were considered as apoptotic cells.

Cell cycle analysis

Cell cycle analysis was performed using a FACSCalibur flow cytometer and propidium Iodide (PI) staining^[42]. Cells were washed three times with ice-cold PBS and resuspended in medium. PI (5% Propidium Iodide dissolved in PBS with 1% trisodium citrate, 0.1% RNase and 0.1% Triton X-100) was added, and cells were vortexed and measured directly by flow cytometry. Fluorescence signal was detected through the FL2 channel. FACS analysis was performed using Cell Quest software.

Miscellaneous assays

Quantitative RT-PCR analysis to assess CES1 mRNA levels and LC-MS/MS analyses to determine the conversion of the prodrug CHR2863 to its metabolite CHR6768 were performed essentially as described before^[22].

Statistical analysis of synergism

Combination indices (CI) for analysis of synergism between simvastatin and CHR2863 were calculated by CalcuSyn software (Version 1.1.1, copyright Biosoft 1996)^[43] and the multiplicative model to predict the effect of drug combinations^[44].

Statistics

A two-tailed paired Student's t-test was used for comparison between groups. Significant differences were defined at $P < 0.05$.

RESULTS

Simvastatin synergizes CHR2863 growth inhibition in parental and CHR2863-resistant U937 cells

Growth inhibitory effects of CHR2863 were determined in human U937/WT cells and two variants, one low (U937/CHR2863^{R0.2}) and one highly (U937/CHR2863^{R5}) CHR2863-resistant U937 cells^[22] in the absence or presence of a maximal *in vitro* non-toxic concentration of 2.0-2.5 μ M simvastatin [Figure 1]. For U937/WT cells [Figure 1A], simvastatin potentiated the growth inhibitory effects of CHR2863 by 14-fold (from IC₅₀: 60.9 \pm 15.8 nM to 4.3 \pm 1.3 nM). Consistently, simvastatin potentiated CHR2863 activity 18-fold in U937/CHR2863^{R0.2} cells (from IC₅₀: 682 \pm 182 nM to an IC₅₀ of 37.8 \pm 10.8 nM), which compares to the sensitivity of U937/WT cells to CHR2863 [Figure 1B]. Lastly, simvastatin also potentiated the growth inhibitory effect of CHR2863 in U937/CHR2863^{R5} cells, albeit with a lower potentiation factor, 3.3-fold (from IC₅₀: 12,900 \pm 4,300 nM to 3,900 \pm 2,200 nM) [Figure 1C]. Analysis of the dose-response effect of drug interactions at a constant dose of simvastatin and fractional effect by CHR2863 revealed remarkable combination indices (CI) well below 1 for parental and CHR2863-resistant U937 cells, indicating a strong

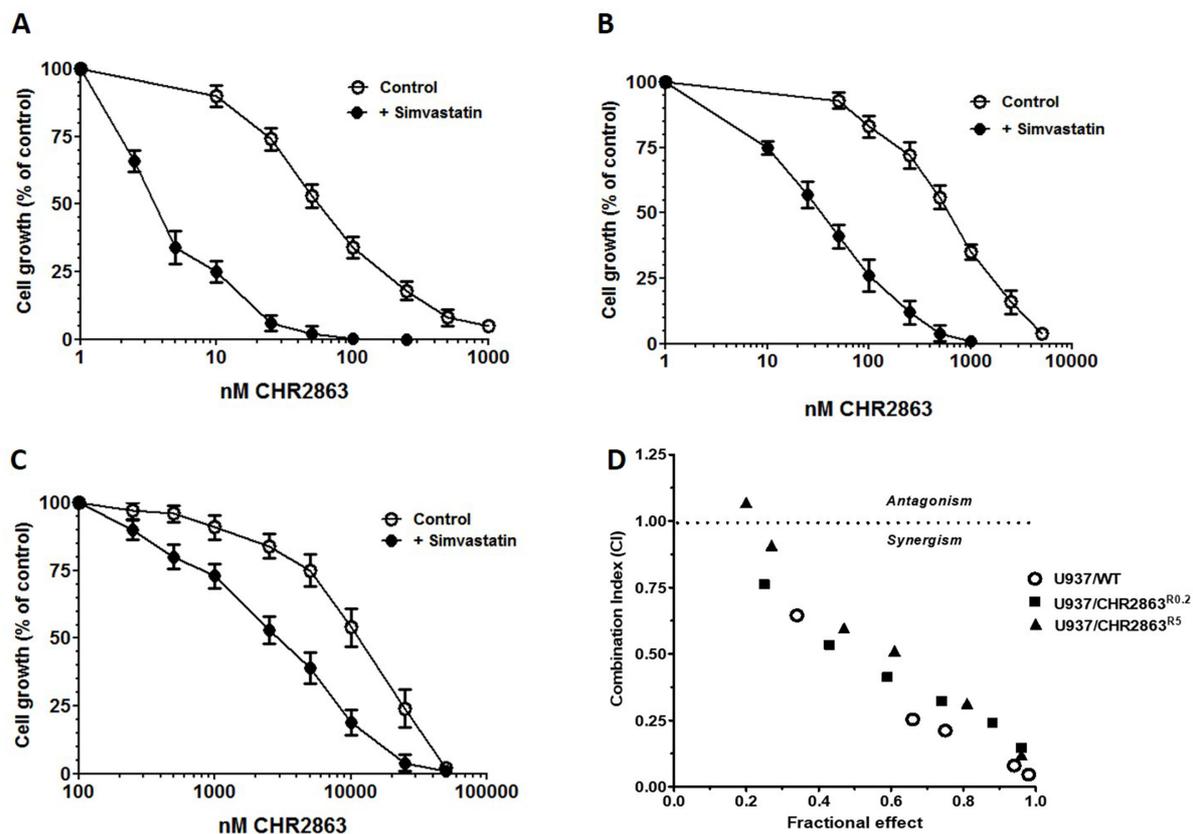

Figure 1. Growth inhibitory effects of CHR2863 for (A) U937/WT, (B) U937/CHR2863^{R0.2} and (C) U937/CHR2863^{R5} cells in the absence and presence of maximal non-toxic concentrations of simvastatin (2 μ M, 2.5 μ M, and 2.5 μ M, respectively). Cell growth inhibition was determined after 72 h of drug exposure. The results depicted are the mean \pm SE of 6-10 separate experiments; (D) Combination index - fraction affected plot from (A-C) of the combination simvastatin (fixed concentration) and CHR2863 for U937/WT, U937/CHR2863^{R0.2} and U937/CHR2863^{R5} cells. CHR2863: (6S)-[(R)-2-((S)-Hydroxy-hydroxycarbamoyl-methoxy-methyl)-4-methyl-pentanoylamino]-3,3 dimethyl-butiric acid cyclopentyl ester.

synergistic interaction [Figure 1D], especially at the FA > 0.5, which is considered as relevant because growth is almost completely inhibited.

Multiple statins synergize with CHR2863 in U937/WT and CHR2863-resistant U937 cells

We next assessed whether statins other than simvastatin also have the ability to synergize with CHR2863 activity in U937/WT and CHR2863-resistant cells. Maximal *in vitro* non-toxic concentrations of the naturally-derived statins lovastatin (2.5-5 μ M) and pravastatin (100-200 μ M), as well as the synthetic statin fluvastatin (0.5-1 μ M) exhibited comparable capacities as simvastatin to potentiate CHR2863 activity as revealed by their potentiation factors (ratio IC₅₀ CHR2863 with statin over IC₅₀ CHR2863 without statin) [Figure 2].

Statin potentiation is selective for aminopeptidase inhibitors

To assess whether statin potentiation of the APi prodrug CHR2863 also occurs with a direct APi, we tested whether the growth inhibition by bestatin^[3,45] is potentiated by simvastatin. Indeed, simvastatin potentiated both CHR2863 and bestatin activities with similar potentiation factors in U937/WT and CHR2863-resistant U937 cells [Figure 3 and Supplementary Figure 1]. Moreover, statin potentiation appeared selective for APis as no potentiation was observed for two types of other drugs: CHR2875, an HDAC inhibitor prodrug^[35],

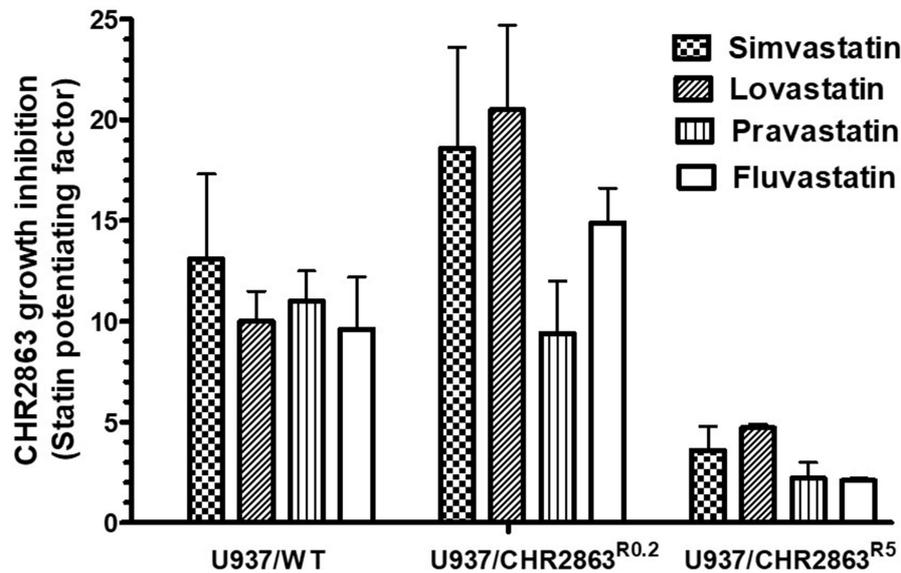

Figure 2. The potentiating effect of maximal non-toxic concentrations of various statins on the CHR2863 activity in U937/WT, U937/CHR2863^{R0.2} and U937/CHR2863^{R5} cells. The concentrations of simvastatin, lovastatin, pravastatin and fluvastatin were 2 μ M, 2.5 μ M, 100 μ M and 0.5 μ M, respectively, for U937/WT cells, and 2.5 μ M, 5 μ M, 200 μ M and 1 μ M, respectively, for U937/CHR2863^{R0.2} and U937/CHR2863^{R5} cells. CHR2863 dose response curves in combination with statins were generated over a CHR2863 concentration range of 0-1 μ M for U937/WT cells, 0-5 μ M for U937/CHR2863^{R0.2} cells and 0-50 μ M CHR2863 for U937/CHR2863^{R5} cells, essentially as shown in Figure 1. Statin potentiating factor is defined as the ratio of IC₅₀ (50% growth inhibition) of cell culture without statins vs. IC₅₀ of cell cultures in the presence of statins. Cell growth inhibition was determined after 72 h of drug exposure. The results depicted are the mean \pm SD of 3-4 independent experiments. CHR2863: (6S)-[(R)-2-((S)-Hydroxyhydroxycarbonyl-methoxy-methyl)-4-methyl-pentanoylamino]-3,3 dimethyl-butyric acid cyclopentyl ester.

which is bioactivated similarly as CHR2863, and daunorubicin evaluated in combination chemotherapy with Tosedostat for AML [Figure 3 and Supplementary Figure 1].

Statin potentiation of CHR2863 activity is primarily restricted to AML cells

To determine whether statin potentiation of CHR2863 activity occurs in various human AML cells other than U937 cells, the potentiating effect of maximal non-toxic concentrations of simvastatin was examined in multiple AML cell lines, acute lymphocytic leukemia (ALL) CCRF-CEM cells as well as a panel of (multidrug resistance-related) solid tumor cell lines [Figure 4 and Supplementary Figure 2]. As with U937 cells, CHR2863 growth inhibition was significantly potentiated by simvastatin in various AML cell lines, including THP1, MV4-11 and, to a lower extent, KG1 cells. In contrast, simvastatin had no potentiating effect in CCRF-CEM cells and a P-glycoprotein/MDR1-overexpressing subline CEM/VBL, although it should be emphasized that these cells had a low intrinsic sensitivity to CHR2863 (IC₅₀ > 10 μ M). The panel of solid tumor cell lines displayed variable sensitivity to CHR2863 (IC₅₀: 0.13-6.7 μ M); with the exception of MCF7/MR cells, none showed a potentiating effect by simvastatin. These results indicate that the simvastatin potentiating effect of CHR2863 is largely restricted to AML cells.

Simvastatin - CHR2863 combinations: impact on cell growth, apoptosis and cell cycle

An exposure of 48 h to maximal *in vitro* non-toxic concentrations of simvastatin and minimally cytotoxic (\approx IC₁₀) concentrations of CHR2863 was tested for the impact on cell viability, apoptosis induction and sub-G₁ fraction/cell cycle distribution of U937/WT, U937/CHR2863^{R0.2} and U937/CHR2863^{R5} cells [Figure 5].

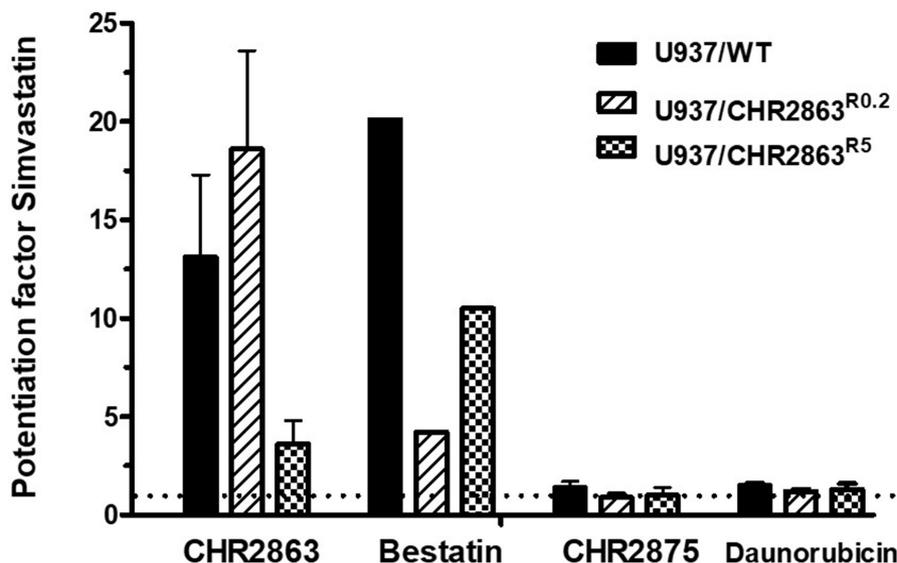

Figure 3. Selectivity of simvastatin-potentiating effect for APis. Effect of non-toxic concentrations of simvastatin (2-2.5 μ M) on the growth inhibitory activity of the APis CHR2863 and bestatin, HDAC inhibitor prodrug CHR2875, and daunorubicin in U937/WT, U937/CHR2863^{R0.2} and U937/CHR2863^{R5} cells. Simvastatin potentiation factor is defined as the ratio of IC₅₀ (50% growth inhibition) of cell culture without statins vs. IC₅₀ of cell cultures in the presence of statins. Cell growth inhibition was determined after 72 h of drug exposure. Results depicted are the mean of two separate experiments (for bestatin) and the mean \pm SD of 3-4 separate experiments for CHR2863, CHR2875 and daunorubicin. IC₅₀ values of U937/WT, U937/CHR2863R0.2 and U937/CHR2863R5 cells for CHR2863 are: 52 \pm 16 nM, 713 \pm 212 nM, and 14,047 \pm 5,521 nM, respectively; for Bestatin: 158 \pm 15 μ M, 169 \pm 32 μ M, and 177 \pm 14 μ M, respectively; for CHR2875: 158 \pm 9 nM, 86 \pm 13 nM, and 147 \pm 36 nM, respectively; and for daunorubicin: 16 \pm 1 nM, 16 \pm 2 nM, and 15 \pm 3 nM, respectively. APis: aminopeptidase inhibitors; CHR2863: (6S)-[(R)-2-((S)-Hydroxy-hydroxycarbonyl-methoxy-methyl)-4-methylpentanoylamino]-3,3 dimethyl-butylric acid cyclopentyl ester.

Bortezomib (0.1 μ M) and a high concentration of CHR2863 (6 μ M) were included as a reference control. Single doses of CHR2863 and simvastatin had no effect on cell viability, whereas their combination significantly reduced cell viability in all three cell lines [Figure 5A], which was accompanied by a significantly increased apoptosis [Figure 5B and Supplementary Figure 3A] and an increase in the sub-G₁ fraction [Figure 5C and Supplementary Figure 3B]. No visible alterations in cell cycle distribution were noted at the tested concentrations of CHR2863, simvastatin or their combination [Figure 5D]. The impact of simvastatin and CHR2863 combinations on cell viability and apoptosis for the U937 cell lines were also found for three other AML cell lines; THP1 and MV4-11 and to a lesser extent for KG1 cells [Supplementary Figure 3C].

Reversal of simvastatin potentiation of CHR2863 activity by mevalonic acid, farnesyl pyrophosphate and geranylgeranyl pyrophosphate

To determine whether or not the statin-induced inhibition of HMG-CoA reductase is implicated in the simvastatin potentiation of CHR2863 cytotoxicity, we assessed whether or not intermediates of the mevalonate pathway, i.e., mevalonic acid (MVA), farnesyl pyrophosphate (FPP) and geranylgeranyl pyrophosphate (GGPP) were able to abrogate the potentiating effect of simvastatin. Increasing concentrations of MVA fully abrogated simvastatin potentiation of CHR2863 growth inhibition in U937/WT, U937/CHR2863^{R0.2} and U937/CHR2863^{R5} cells [Figure 6A]. Likewise, increasing concentrations of FPP also abrogated the simvastatin potentiation effect of CHR2863 in U937/WT and U937/CHR2863^{R0.2} cells, albeit to a slightly lower extent than MVA [Figure 6B]. Of note, FPP failed to abrogate the simvastatin

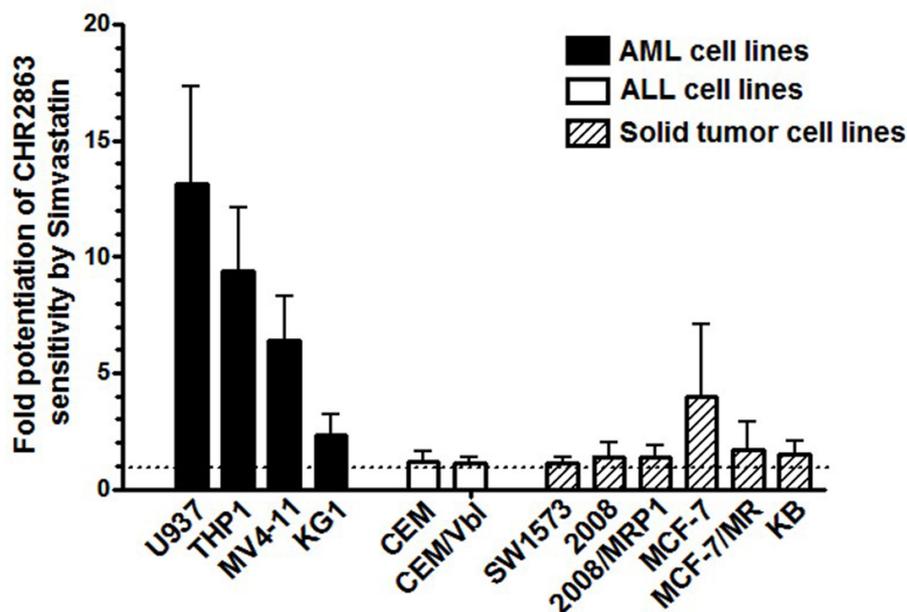

Figure 4. Simvastatin potentiation of CHR2863 activity in human AML cell lines vs. human lymphoid and solid tumor cell lines. Cell growth inhibition was determined after 72 h of drug exposure in the absence or presence of maximal non-toxic concentrations of simvastatin, being (between brackets) for: U937 (2 μ M), THP1 (2.5 μ M), MV4-11 (2.5 μ M), KG1 (10 μ M), CCRF-CEM (2.5 μ M), CEM/Vbl (2.5 μ M), SW1573 (0.2 μ M), 2008 (0.75 μ M), 2008/MRP1 (2.5 μ M), MCF7 (1 μ M), MCF7/MR (2.5 μ M) and KB (1 μ M). Simvastatin potentiation factor is defined as the ratio of IC_{50} (50% growth inhibition) of cell culture without statins vs. IC_{50} of cell cultures in the presence of statins. IC_{50} values (between brackets) for CHR2863 for the various cell lines (in the absence of simvastatin) were: U937 (61 \pm 16 nM), THP1 (1172 \pm 807 nM), MV4-11 (282 \pm 51 nM), KG1 (394 \pm 144 nM), CCRF-CEM (11,170 \pm 5,100 nM), CEM/Vbl (29,100 \pm 5,900 nM), SW1573 (6,625 \pm 3,020 nM), 2008 (2,020 \pm 1,080 nM), 2008/MRP1 (6,700 \pm 2,560 nM), MCF7 (453 \pm 400 nM), MCF7/MR (386 \pm 64 nM), and KB (132 \pm 50 nM). The results depicted are the mean \pm SD of 3-5 independent experiments. CHR2863: (6S)-[(R)-2-((S)-Hydroxy-hydroxycarbonyl-methoxy-methyl)-4-methyl-pentanoylamino]-3,3 dimethylbutyric acid cyclopentyl ester.

potentiation effect of CHR2863 in U937/CHR2863^{RS} cells [Figure 6B]. Lastly, GGPP abrogated the simvastatin potentiation effect of CHR2863 in U937/WT and U937/CHR2863^{Ro.2} cells at an optimal concentration of 0.1 μ M; above this concentration, the abrogating effect was lost [Figure 6C]. GGPP was also unable to abrogate the potentiation effect of simvastatin in U937/CHR2863^{RS} cells [Figure 6C].

Given the variable effects of FPP in abrogating the potentiating effect of simvastatin of CHR2863 in U937/WT and U937/CHR2863^{Ro.2} cells vs. U937/CHR2863^{RS} cells, we further examined whether a farnesyltransferase inhibitor (FTI-277) had similar effects on CHR2863 potentiation in these cells. Combinations of FTI-277 and CHR2863 were synergistic in U937/WT and additive in U937/CHR2863^{Ro.2} cells, whereas U937/CHR2863^{RS} cells were resistant to FTI-277 and no potentiation was found [Supplementary Figure 4].

Simvastatin potentiation of CHR2863: mechanistic studies

To explore the mechanistic basis underlying the potentiation of CHR2863 growth inhibition by simvastatin, we first examined whether simvastatin upregulated the expression of carboxylesterase 1 (CES1), the enzyme mediating the conversion of CHR2863 to its active metabolite CHR6768^[22]. Western blot analysis revealed that CES1 expression (as well as its other family members CES2 and CES3) in U937/WT, U937/CHR2863^{Ro.2}, and U937/CHR2863^{RS} cells was not altered by simvastatin and CHR2863 alone, in combination, and in combination with MVA [Supplementary Figure 5]. Notably, U937/CHR2863^{RS} cells

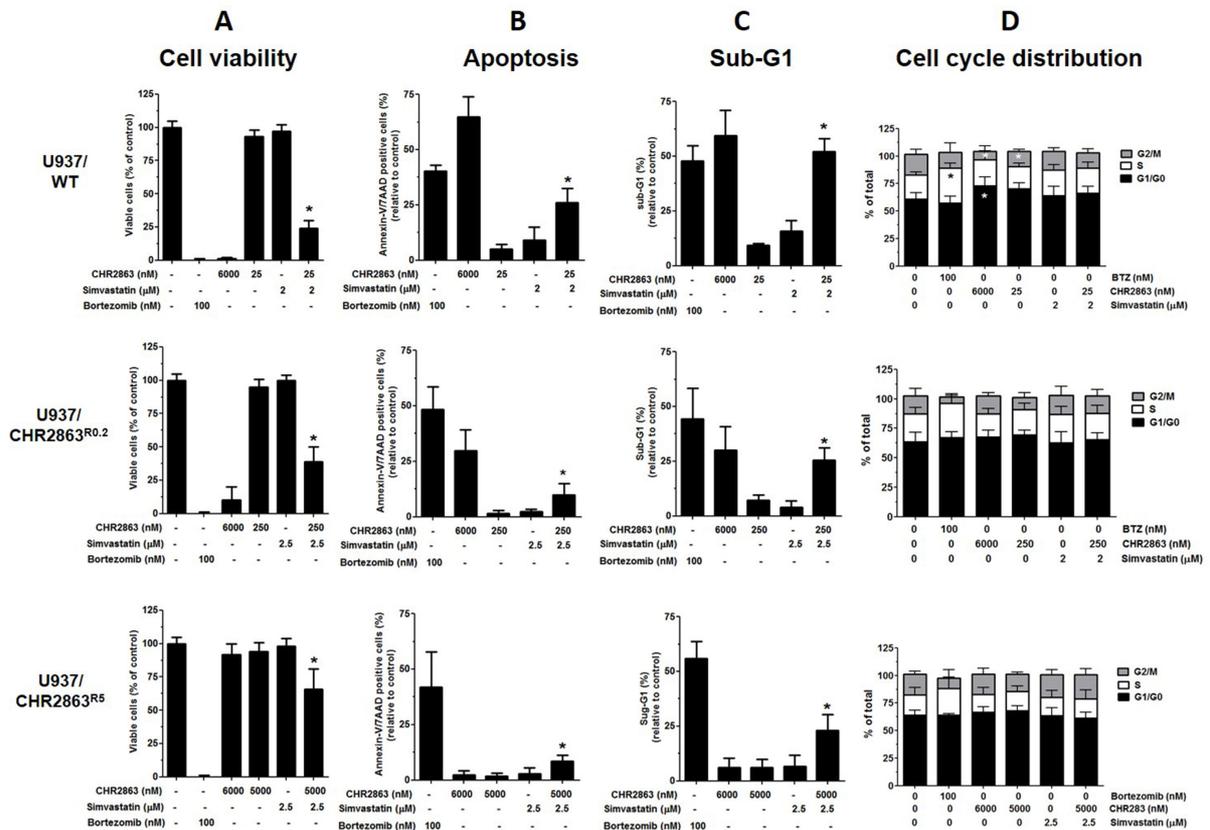

Figure 5. Effect of simvastatin and CHR2863 combinations on cell viability, apoptosis induction and cell cycle distribution in U937/WT, U937/CHR2863^{R0.2} and U937/CHR2863^{R5} cells. Simvastatin concentrations used for U937/WT cells, U937/CHR2863^{R0.2} and U937/CHR2863^{R5} cells were maximal in vitro non-toxic concentrations: 2 μM, 2.5 μM and 2.5 μM, respectively. For CHR2863, minimally cytotoxic (≈ IC10) were selected (from Figure 1), i.e., 25 nM, 250 nM and 5 μM for U937/WT cells, U937/CHR2863^{R0.2} and U937/CHR2863^{R5} cells, respectively. Cells (3 × 10⁵/mL in 10 mL medium) were incubated for 48 h with the indicated concentrations of simvastatin, CHR2863 and their combination and assessed for the impact on (A) cell viability, (B) apoptosis induction, (C) sub-G1 fraction and (D) cell cycle distribution. Cells incubated for 24 h with bortezomib or 48 h with 6 μM CHR2863 served as a control for cell growth inhibition and apoptosis induction. Percentages of apoptotic cells in control untreated U937/WT, U937/CHR2863^{R0.2} and U937/CHR2863^{R5} cells were 4.6% ± 1.9%, 5.2% ± 1.2% and 6.1% ± 0.9%, respectively. Sub-G1 fractions in control untreated U937/WT, U937/CHR2863^{R0.2} and U937/CHR2863^{R5} cells were 4.2% ± 2.0%, 9.1% ± 6.5% and 8.2% ± 2.2%, respectively. The results depicted are the mean ± SD of 4-5 independent experiments. *Combination statistically significant (P < 0.05) different compared to single drugs control cells. CHR2863: (6S)-[(R)-2-((S)-Hydroxy-hydroxycarbonyl-methoxy-methyl)-4-methyl-pentanoylamino]-3,3 dimethylbutyric acid cyclopentyl ester.

displayed markedly decreased CES1 expression levels as shown earlier^[22]. Consistent with unaltered CES1 expression levels in the presence of simvastatin, the ability of U937/WT and U937/CHR2863^{R0.2} cells to enzymatically convert CHR2863 to its active metabolite CHR6768 was unchanged, while U937/CHR2863^{R5} cells had lower levels in line with their lack of CES1 activity [Supplementary Figure 6].

Aminopeptidase inhibition can regulate mTOR activity^[5]. Therefore, we evaluated whether concentrations of simvastatin and CHR2863 which showed an enhanced growth inhibitory effect (after 48 hr drug incubation) were also associated with an altered cellular phosphorylation status of intermediates of the ERK/Akt/mTOR pathway. Analysis of pERK(Thr202/Tyr204), pAkt(Ser473), pmTOR(Ser2448), pmTOR(Ser2481) and pS6Kp70(Th389) levels in U937/WT, U937/CHR2863(200), and U937/CHR2863(5μM) cells showed no major differences upon exposure to CHR2863, simvastatin, MVA, and their combinations [Supplementary Figure 7]. This suggests that other mechanisms play a prominent

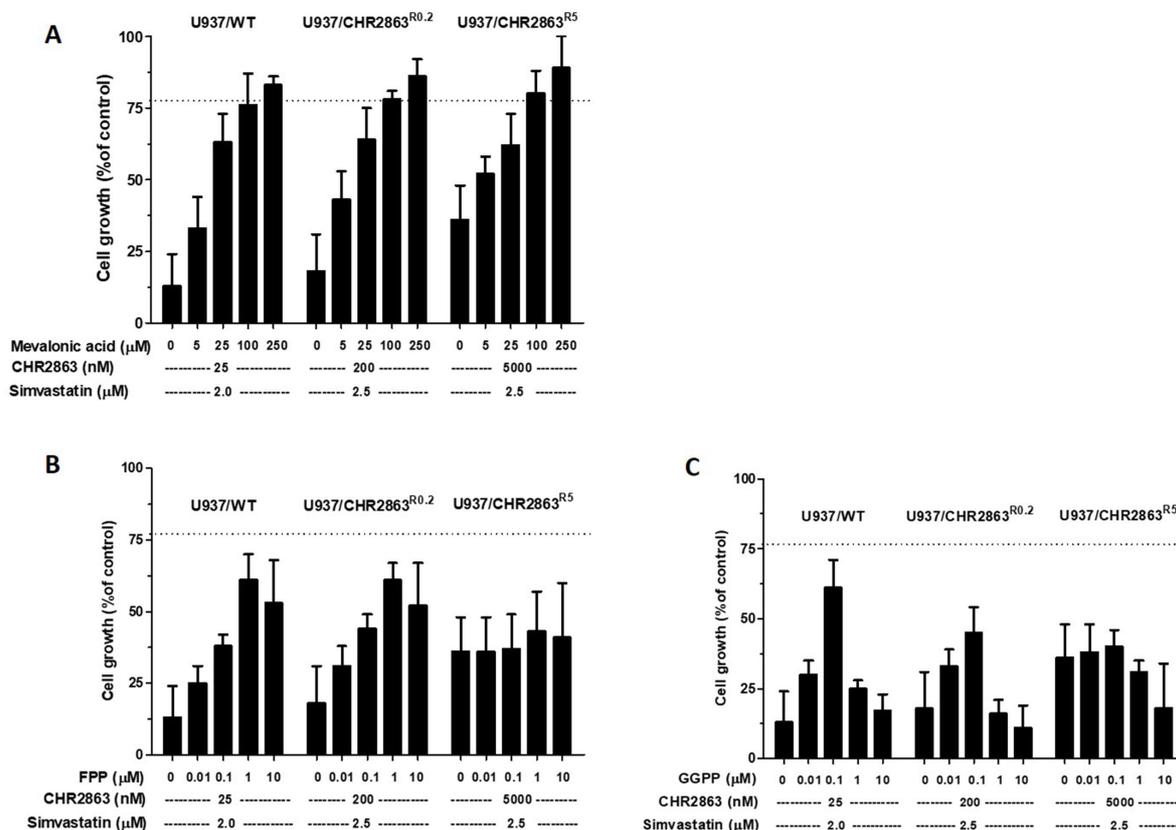

Figure 6. Effects of mevalonic acid, farnesyl pyrophosphate and geranylgeranyl pyrophosphate on simvastatin potentiation of CHR2863 activity. U937/WT, U937/CHR2863^{R0.2} and U937/CHR2863^{R5} cells were incubated for 72 h with the indicated concentrations of CHR2863 and non-toxic concentration of simvastatin in the presence of increasing concentrations of (A) mevalonic acid, (B) farnesyl pyrophosphate (FPP) and (C) geranylgeranyl pyrophosphate (GGPP). Results, presented as cell growth relative to control, are the mean \pm SD of 4 independent experiments. The dashed line indicates the mean growth inhibition by CHR2863 alone. CHR2863: (6S)-[(R)-2-((S)-Hydroxy-hydroxycarbonyl-methoxy-methyl)-4-methyl-pentanoylamino]-3,3 dimethyl-butiric acid cyclopentyl ester.

role in the synergy between statins and CHR2863.

Statins are known to impair the prenylation and thus membrane localization of various proteins^[46-48]. In the context of mTOR activation, it has been demonstrated that lysosomal membrane integration of Rheb protein is of relevance and is prenylation-dependent^[49-51]. To this end, we examined whether under conditions that potentiated CHR2863 activity, simvastatin interfered with Rheb prenylation in U937/WT, U937/CHR2863^{R0.2} and U937/CHR2863^{R5} cells. Indeed, exposure to simvastatin resulted in a marked increase in unprenylated Rheb in all three tumor cell lines [Figure 7], as did the exposure to FTI-277. The level of unprenylated Rheb was maintained in CHR2863 + simvastatin combinations, whereas exposure to CHR2863 alone had no effect on Rheb prenylation status. MVA and FPP, but not GGPP, abrogated the unprenylation impact of simvastatin alone and in combination with CHR2863. Hence, this profile of Rheb unprenylation parallels the statin and inhibitor FTI-277-induced potentiation of CHR2863 activity in U937/WT, U937/CHR2863^{R0.2} and U937/CHR2863^{R5} cells.

A composite summary model which proposes a mechanistic basis for the synergistic action of APis and statins in AML cells is presented and discussed in [Figure 8].

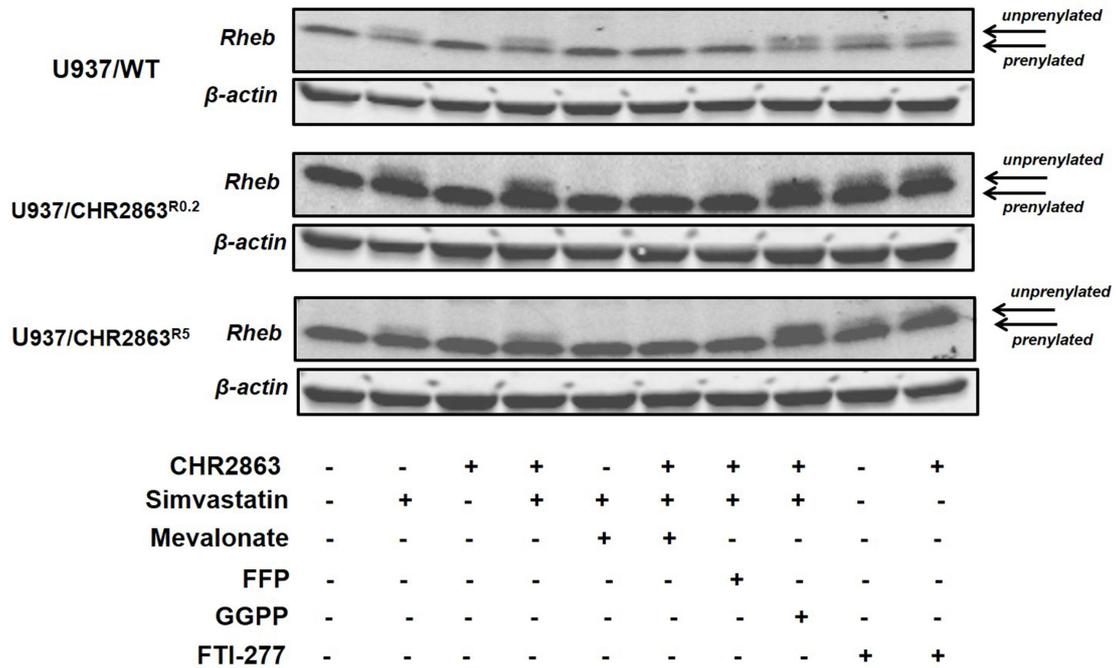

Figure 7. Effect of simvastatin and CHR2863 combinations on Rheb prenylation. U937/WT, U937/CHR2863^{R0.2} and U937/CHR2863^{R5} cells were incubated for 48 h with simvastatin, CHR2863, and their combination (as described in Figure 5), with or without the addition of MVA (100 μM), FPP (2 μM), GGPP (1 μM) or FTI-277 (10 μM). The slower (upper) migrating band represents unprenylated Rheb, and the faster (lower) migrating band represents prenylated Rheb. CHR2863: (6S)-[(R)-2-((S)-Hydroxy-hydroxycarbonyl-methoxy-methyl)-4-methyl-pentanoylamino]-3,3 dimethyl-butiric acid cyclopentyl ester.

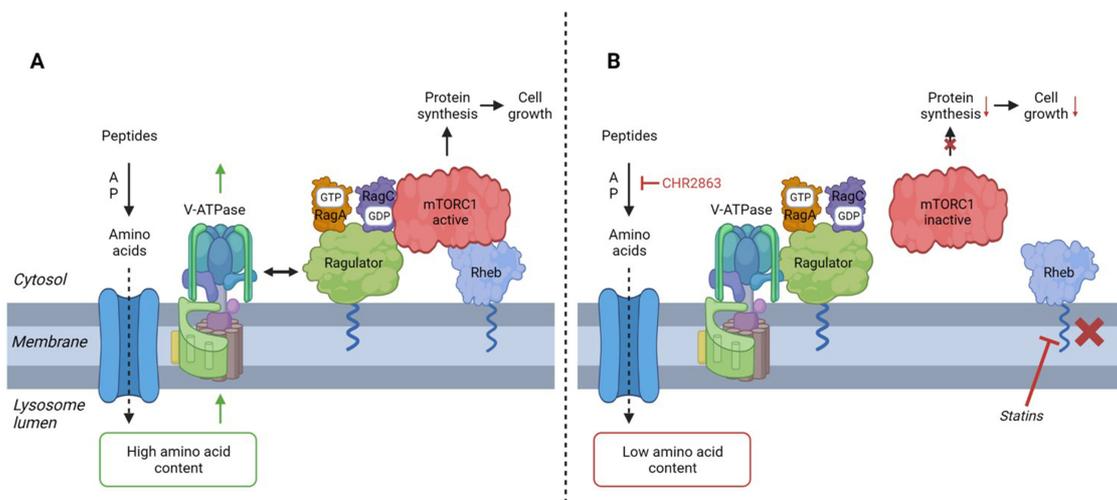

Figure 8. Proposed model for synergistic action of statins and API CHR2863. (A) Peptide breakdown by aminopeptidases provides amino acids for re-utilization in protein synthesis. According to previously described models^[49-51,56,62,63,66], an increased intralysosomal amino acid content triggers dissociation of V-ATPase and Ragulator-Rag-mTORC1 complex. Binding of the latter complex to (prenylated) Rheb (in the lysosomal membrane) and membrane association of Ragulator will then induce mTOR activation and initiation of protein synthesis; (B) Inhibition of aminopeptidases by CHR2863 (or bestatin) will reduce the intralysosomal amino acid content and dissociation of the Ragulator-Rag complex from mTORC1. By a different mechanism, statins may block Rheb prenylation and abolish its lysosomal membrane localization. The combined effect of CHR2863 and statins may then synergize in impairing mTOR activation, protein synthesis and inhibiting cell growth. The figure was created via BioRender. APi: Aminopeptidase inhibitor; CHR2863: (6S)-[(R)-2-((S)-Hydroxy-hydroxycarbonyl-methoxy-methyl)-4-methyl-pentanoylamino]-3,3 dimethyl-butiric acid cyclopentyl ester.

DISCUSSION

Aberrant cholesterol metabolism is a characteristic feature of AML cells and has been exploited for therapeutic interventions with statins as inhibitors of HMG-CoA reductase, the key enzyme in the MVA-cholesterol pathway^[26,46,52]. Both *in vitro* and *in vivo* studies demonstrated that high concentrations of statins can induce apoptosis in AML cells through perturbations of prenylation and membrane anchoring of proteins involved in signal transduction pathways. These include disruption of Ras family members and pro-survival pathways such as MEK/ERK and PI3K/Akt/mTOR^[29-31,53-56]. Furthermore, statins also elicit additive/synergistic effects with various other chemotherapeutic drugs^[33,34,57]. The current study is the first report to reveal that non-toxic concentrations of statins markedly potentiate the growth inhibitory effects of either a prodrug (CHR2863) or a direct inhibitor (bestatin) of aminopeptidases in human AML cells. Hence, these findings bear important implications for future therapeutics as well as overcoming chemoresistance in AML.

APis such as Tosedostat and its close structural analogue CHR2863 are prodrugs that rely on esterase activities for their conversion to active metabolites that can inhibit multiple aminopeptidases, thereby provoking amino acid depletion^[5]. Earlier, we demonstrated that CES1 is the most likely candidate enzyme for the bio-activation of these prodrugs, given the high CES1 expression in myeloid cell lines and M4 and M5 FAB subtypes of AML clinical specimens^[22]. The role of CES1 in this enzymatic bio-activation was further substantiated by the fact that acquired resistance to CHR2863 in AML cells was mediated by downregulation of CES1 expression. Regarding CHR2863 resistance, combinations of *in vitro* non-toxic concentrations of statins were able to sensitize 14-fold resistant U937/CHR2863^{R0.2} cells, hence restoring WT sensitivity. Highly (270-fold) CHR2863 resistant U937/CHR2863^{RS} cells could also be sensitized by co-administration of statins, albeit to a lower extent (3-4 fold), even given the fact that active metabolite formation was almost 100-fold lower than in WT cells. Statin-dependent sensitization of CHR2863-resistant cells did not involve increased CES1 expression and/or enhanced active metabolite formation, suggesting that other mechanisms account for this potentiation effect. In drug combination experiments, the combination of simvastatin and CHR2863 led to a significant enhancement of apoptosis induction as reflected in the high accumulation of cells in sub-G₁ fraction, whereas treatment with either drug alone had a minimal effect. Beyond apoptosis, it cannot be ruled out that alternative mechanisms, e.g., ferroptosis^[58,59], contribute to cell death. Furthermore, cell cycle analysis of simvastatin + CHR2863 combinations did not reveal any distinct cell cycle arrest in G₁/G₀-, S- or G₂/M-phase, suggesting that the drug treatment did not interfere with specific cell cycle phases or checkpoints.

Further experiments with intermediates of the MVA-cholesterol pathway, including FPP, GGPP and MVA, were performed to identify the mechanism underlying statin-dependent potentiation of CHR2863 activity. Apoptosis induced by statins in AML cells was reversed by the addition of MVA and GGPP rather than FPP^[28]. With respect to simvastatin potentiation of CHR2863 activity in U937 cells, GGPP reversed the potentiation effect in a narrow concentration range around 100 nM; above this concentration, the reversal effect was lost. The mechanistic reason for this decline in reversal effect beyond 100 nM GGPP is unclear and warrants further studies. The full reversal was observed with increasing concentrations of FPP and MVA, suggesting that perturbations in protein farnesylation are involved in the potentiation effect. Interestingly though, highly CHR2863-resistant U937/CHR2863^{RS} cells were unresponsive to FPP, which could be consistent with their refractoriness to the farnesyltransferase inhibitor FTI-277 [Supplementary Figure 4]. In parental U937/WT cells, synergistic growth inhibitory effects of FTI-277 and CHR2863 combinations mimicked the simvastatin-CHR2863 combinations; however, upon the acquisition of CHR2863 resistance, the potentiation effect of FTI-277 on CHR2863 activity was gradually lost. Ding *et al.* showed that acquired resistance of U937 cells to another FTI, tipifarnib, involved alterations in Rheb

prenylation and loss of inhibition of Rheb-induced mTOR signaling^[60]. Consistently, the acquisition of CHR2863 resistance was also shown to be accompanied by activation of the Akt/mTOR pro-survival pathway, as reflected by a marked gain of sensitivity to the mTOR inhibitor rapamycin^[22]. Given that Rheb prenylation is required for mTOR activation^[56,61-66], loss of prenylation through the action of statins and FTIs is likely to constitute a mechanistic basis for the synergistic effect with CHR2863, hence causing mTOR inhibition via amino acid depletion. Indeed, the present study showed [Figure 7] that the loss of Rheb prenylation provoked by simvastatin and FTI-277 was consistent with their potentiation effect on CHR2863 activity, whereas retention of Rheb prenylation by MVA or FFP abrogated this potentiating effect. However, it is remarkable that synergistic concentrations of simvastatin and CHR2863 had no apparent impact on Akt and mTOR phosphorylation patterns in U937 cells and CHR2863-resistant sublines. Therefore, further studies are required to identify other markers downstream of mTOR and to identify the mechanism of induction of apoptosis contributing to the synergy between statins and APis in AML cell lines and clinical specimens.

Many therapeutic interventions for AML are designed based on aberrant PI3K-Akt-mTOR signaling in AML cells^[67]. Both statins and APis harbor properties interfering with this master regulator pathway and the current study provides a mechanistic rationale for their combination [Figure 8]. Whereas AML cells have shown heterogeneity in statin-induced apoptosis^[29], the current study indicates that non-toxic concentrations of various statins synergize with APis in multiple AML cell lines. Non-toxic concentrations of statins, as employed in the *in vitro* studies, are readily achievable *in vivo*^[26,68,69]. One earlier clinical study showed that Tosedostat combined with cytarabine or decitabine in untreated elderly AML or high-risk MDS patients was tolerated^[14]; however, more recent studies revealed no survival benefit^[16] or even inferior outcome in this patient category^[18]. Although statin use was not reported in these studies, one could speculate that statin use, along with a high Tosedostat dosing, could contribute to over-potential of the drug. Therefore, it would be of interest to design a clinical study with lower doses of Tosedostat in a patient group of well-documented statin users to achieve an optimal potentiating effect and clinical benefit. Collectively, exploring the optimal combined efficacy of statins with APis in general and Tosedostat in particular deserves further exploration in the clinical setting of AML treatment.

In conclusion, this study revealed that non-toxic doses of statins could markedly potentiate the activity of aminopeptidase inhibitor (APi) drugs; both direct inhibitors like Bestatin and APi prodrugs like CHR2863 to (drug-resistant) human acute myeloid leukemia (AML) cells. The molecular basis underlying the potent synergistic inhibition of statins and APis on AML cells involved a dual inhibitory effect of impaired Rheb prenylation abrogating mTOR activation and APi-dependent mTOR inhibition. Given the fact that many cancer patients take statin medication for the treatment of other comorbidities, these novel findings call for awareness of the synergistic drug action of statins with APi-containing chemotherapeutic regimens and/or potential toxicities. These notions may warrant further evaluation in clinical studies including APis.

DECLARATION

Acknowledgments

Dr. Krige D (Chroma Pharmaceuticals) is acknowledged for the gift of CHR2863 and helpful discussions. Dr. Verbrugge SE, Dr. Honeywell R and Lin M are acknowledged for excellent technical assistance. Assaraf YG is the recipient of a Visiting Professor Award from the Royal Netherlands Academy of Arts and Sciences, Netherlands Organization for Scientific Research and Cancer Center Amsterdam/VU Institute for Cancer and Immunology.

Abstract

Early identification of breast cancer (BC) patients at a high risk of progression may aid in therapeutic and prognostic aims. This is especially true for metastatic disease, which is responsible for most cancer-related deaths. Growing evidence indicates that the translationally controlled tumor protein (TCTP) may be a clinically relevant marker for identifying poorly differentiated aggressive BC tumors. TCTP is an intriguing protein with pleiotropic functions, which is involved in multiple signaling pathways. TCTP may also be involved in stress response, cell growth and proliferation-related processes, underlying its potential role in the initiation of metastatic growth. Thus, TCTP marks specific cancer cell sub-populations with pronounced stress adaptation, stem-like and immune-evasive properties. Therefore, we have shown that *in vivo* phospho-TCTP levels correlate with the response of BC cells to anti-HER2 agents. In this review, we discuss the clinical relevance of TCTP for personalized therapy, specific TCTP-targeting strategies, and currently available therapeutic agents. We propose TCTP as an actionable

clinically relevant target that could potentially improve patient outcomes.

Keywords: Breast cancer, metastasis, TCTP, stem cells, therapy resistance, biomarker

INTRODUCTION

Identification of crucial genes with therapeutic implications at an early stage of disease is a central challenge in tailoring therapeutic strategies. Estrogen receptor (ER) expression, progesterone receptor (PR) expression, and human epidermal growth factor receptor-2 (HER2) overexpression or amplification are well-established biomarkers that drive treatment decisions for patients with breast cancers (BC)^[1]. Multi-parameter genomic assays, such as Oncotype DX and MammaPrint, are being used for patients with hormone receptor-positive (ER⁺/PgR⁺) and HER2⁻ early breast cancer who may benefit from adding chemotherapy to adjuvant endocrine therapy^[2,3]. Specific gene signatures are still missing for non-ER⁺/HER⁻ clinical BC subgroups because, among those reported in the literature, none are in clinical use^[4].

Besides genomic studies, transcriptomic, proteomic and metabolomic analysis, or multi-omics data are all useful to discover biomarkers with an unprecedented level of complexity, as required for the current knowledge landscape of diseases. Further, post-translational modifications or subcellular localizations shape the level and the functional state of a protein, which cannot be detected by genomics-based approaches^[5]. Last but not least, the relationship between protein and mRNA is very complex and highly influenced by cell types and cell states. Thus, transcript levels by themselves should not be deemed sufficient to predict protein levels^[6,7].

There are two current frontiers of cancer therapy, on one side, identifying clinically relevant alteration and, on the other side, doing this as early as possible during the progression of the disease. For example, despite advances in breast cancer detection and treatment, predicting which patients will develop overt metastatic disease remains a challenge. This is not simply a formidable technological challenge; it implies fundamental questions related to the degree of similarity between metastatic tissues and its primary source. However, it appears clear that prometastatic mutations may be represented very early in the primary tumor. For instance, Estrogen Receptor 1 (ESR1) mutation status, which has been associated with acquired resistance to endocrine therapy, is present not only in metastatic lesions but also in primary BC^[8].

After this general introduction, we intend to make the case here for translationally controlled tumor protein (TCTP), whose complex biology and link to clinical parameters may represent a good and practical example of the mentioned concepts.

We start from clinical observations highlighting the promising role of TCTP as a clinically relevant prognostic and predictive biomarker for identifying BC tumors at a high risk of progression early on. We also discuss signaling pathways that may impinge on stemness, drug resistance and poor response to immunotherapy. Finally, we explore strategies for targeting TCTP and the consequences of affecting TCTP expression in aggressive cancer cells.

CLINICAL RELEVANCE OF TCTP IN CANCER

TCTP, also known as histamine-releasing factor (HRF), fortilin, P23, is encoded by the *TPT1* gene located on chromosome 13q12→q14^[9]. The gene produces two TCTP mRNA isoforms which are different in the length of their 3'-UTR [Figure 1]. In this present work, we will refer, for convenience, to the shorter isoform, which is the most generally expressed in normal and cancer tissues^[10].

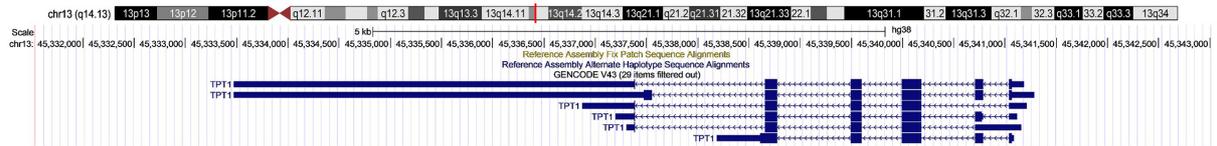

Figure 1. Genomic organization of TPT1. The UCSC genome browser was used to display the location and genomic organization of TPT1 on chromosome 13q14. Scheme of the TPT1 major types of alternative splicing is displayed (<http://genome.ucsc.edu>). UCSC Genome Browser on Human (GRCh38/hg38). TPT1: Tumor protein, translationally-controlled 1.

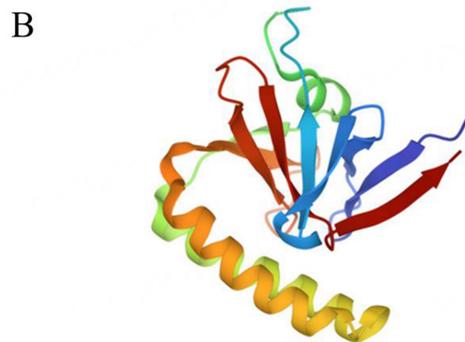

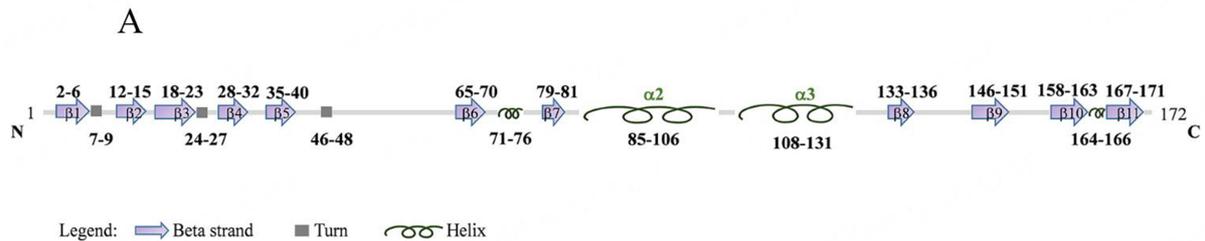

Figure 2. The peculiar structure of TCTP. (A) A cartoon representation of the secondary structure of human TCTP. Reference sequence from UniProt P13693^[11]. β -strands, α -helices and turns elements are indicated in the legend. The N-terminal region includes a flexible loop extending from β 5 to β 6 strands. It contains a highly conserved signature and the Ser46 and Ser64 residues which are phosphorylated by the polo-like kinase Plk1, a crucial player in mitosis. A second conserved signature is found in the C-terminal region; (B) The crystal structure of the human TCTP (PDB Code 1YZ1^[12]) discloses the α -helical hairpin (formed by Helix H2 and Helix H3), whose structure is similar to the H5-H6 helices of BCL-2 family proteins, and the β -stranded domain that shows a structural analogy with the guanine nucleotide exchange factors (GEF) Mss4/Dss4 protein families^[13], suggesting a similar role for TCTP as GEF for Ras homolog enriched in brain (Rheb) in the mTORC1 pathway^[14]. The flexible loop is not detectable in the crystal structure. TCTP: Translationally controlled tumor protein.

The gene encodes the protein TCTP, which is highly conserved throughout evolution and without any sequence homology to other proteins [Figure 2].

TCTP as a prognostic marker

Emerging clinical evidence has shown that the TCTP protein expression was dysregulated in many diseases^[15], including various hematological^[16,17] and solid tumors [Table 1]. Further, a high TCTP status was positively correlated with the pathological grade and markedly associated with shorter overall survival [Table 1]. Interestingly, the levels of TCTP were higher in metastatic lesions than in the corresponding primary gallbladder (GBC)^[22] and colorectal carcinoma (CRC)^[27].

Table 1. TCTP expression and clinical outcomes

Cancer	Expression level	Histological and prognostic features	Refs
Breast	High	Poor differentiation Short survival	[18] [19]
Epithelial ovarian cancer	High	Poor differentiation Short survival Lymph node metastasis	[20]
Cervical cancer	High	Poor differentiation Lymph node metastasis	[21]
Gallbladder cancer	High	Poor differentiation Metastasis Short survival	[22]
Pancreatic ductal adenocarcinoma	High	Lymph node metastasis Poor differentiation	[23]
Glioma	High	Poor differentiation Short survival	[24] [25]
Colorectal cancer	High	Poor differentiation Metastatic Short survival	[26] [27]
Prostate	High	Poor differentiation Metastasis Short survival	[28] [29]
Lung adenocarcinoma	High	Poor differentiation Short survival	[30]
NSCLC	High	Tumor size Short survival	[31]
Cholangiocarcinoma	High	Short survival	[32]
Neurofibromatosis type 1	High	Malignant phenotype	[33]
Neuroblastoma	High	Poor differentiation Short survival	[34]

TCTP: Translationally controlled tumor protein.

In breast cancer tissues, TCTP expression levels were higher compared to the corresponding normal tissues, and, notably, a high TCTP status was positively correlated with the pathological grade and was associated with shorter overall survival^[18]. Interestingly, TCTP was enriched in PKH26 dye-retaining human normal mammary stem cells^[35]. Further, TCTP enrichment was recorded in poorly differentiated high-grade BC tumors^[18], the latter known to contain more cancer stem cells (CSCs) than lower-grade tumors^[35]. Relevant to this, a high TCTP status has also been correlated to the presence of mutated P53 tumors and with high proliferative activities^[18]. Loss of p53 function enabled acquisition of stem cell properties and led to Myc activation, thereby increasing the expression of a mitotic signature identifying BC patients at high risk of mortality and relapse^[36].

Moreover, TCTP mRNA levels were significantly upregulated in ovarian cancer (OC) organoids generated from pluripotent stem cells (iPSC) of patients bearing the germline pathogenic breast cancer susceptibility gene 1 (*BRCA1*) mutation^[37]. These findings highlight the potential role of TCTP as a biomarker in OC since patient-derived-organoids (PDOs) are a clinically valuable representation of the sourcing tumor^[38]. This again echoes the above-mentioned data showing that TCTP levels are higher in poorly differentiated tissues compared to the well-differentiated ones in several tumors. Understanding the relationships between the *BRCA1* genomic status and the higher level of TCTP in prognostic terms, in OC and additional tumors, may represent an important future investigation.

TCTP as a predictive marker

We have shown that TCTP, in the phosphorylated form, was a clinically relevant biomarker for a more aggressive BC^[19]. TCTP was specifically phosphorylated by Polo-like kinase 1 (PLK1) on Ser46 and Ser64 residues^[39-41], both located in the flexible loop of the protein, as reported by Malard *et al.*^[42]. PLK1 was a crucial player in mitotic progression^[43]. It was highly expressed in preinvasive in situ breast carcinomas^[44], and correlated with high Ki-67 levels, TP53 mutations and poor clinical outcomes in primary BC^[45,46]. Further, overexpression of PLK1 played a critical role in tumors that have escaped estrogen deprivation therapy^[46,47], and was a strong predictor of worse survival in a large cohort of ER-positive BC patients^[46-48].

We and others have shown that inhibition of PLK1 impaired TCTP phosphorylation^[19,39,40], suggesting that a functional PLK1/TCTP axis could be critical for cancer progression. Consistently, both high levels of phospho-TCTP and PLK1 were found in neuroblastoma from patients with adverse prognostic factors^[34], in agreement with our data showing that high levels of phospho-TCTP were correlated with high histological grade and with worse pathological parameters in primary BC tissues. Interestingly, the number of phospho-TCTP positive cells significantly increased (> 10%) when tumors were resistant to trastuzumab therapy (first line of treatment) and progressed towards the metastatic stage [Figure 3]^[19]. These findings suggest that phospho-TCTP may be a promising independent prognostic biomarker and a possible predictor of response to treatment. Tumors endowed with a higher fraction of cancer cells with a positive phospho-TCTP staining may exhibit increased drug resistance. A high phospho-TCTP status may allow classification of patients into responders and non-responders for trastuzumab therapy. Thus, targeting these cells with dihydroartemisinin (DHA) (see below) may improve long-term clinical outcomes, as recently suggested by our findings in HER2+BC cells resistant to trastuzumab therapy^[49].

TCTP as a non-invasive diagnostic biomarker

Accessible biomarkers are a valuable and promising non-invasive tool for early diagnosis of BC. Serum tumor biomarkers such as carcinoembryonic antigen (CEA), cancer antigen (CA)-15-3, and CA-125 have been used for early detection of metastatic breast cancer (MBC). However, expression levels of these markers may be affected by anti-hypertensive medications or inflammatory diseases^[50], thus raising concerns about their diagnostic accuracy.

TCTP has been shown to be secreted during allergic reactions and to promote immunoglobulin E (IgE)-mediated activation of mast cells and basophils. Its levels also increased in the serum of patients affected by rheumatoid arthritis (RA), suggesting a potential role as a biomarker in autoimmune and inflammatory disease^[51,52].

Recently, a transcriptome profiling analysis has shown that TCTP mRNA levels increased in the saliva of BC patients compared to healthy ones^[53]. In addition, ischemia and hypoxia induced TCTP secretion in blood samples of CRC patients, suggesting that circulating TCTP levels may play a role in CRC progression^[27]. Moreover, the levels of TCTP were higher in the plasma of patients with cervical cancer^[21] or squamous cell carcinomas (SCCs)^[54] when compared to healthy subjects, suggesting its potential role as a novel non-invasive biomarker in several cancer types.

Extracellular vesicles (EVs) have also been proposed as reliable diagnostics biomarkers for the early detection of cancer. EVs are a heterogeneous population of vesicles that comprise three main classes: exosomes, shed microvesicles, and apoptotic bodies. EVs play a role in regulating intercellular communications by transferring biological information like proteins, lipids, and nucleic acids between cells^[55].

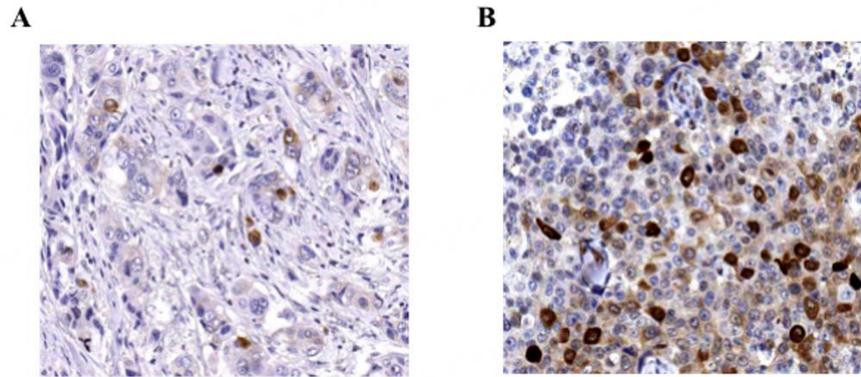

Figure 3. Correlation between Phospho-TCTP expression and response to trastuzumab therapy. Representative images of the immunohistochemical staining of phospho-TCTP in HER2 + BC patients (A) responsive and (B) non-responsive to trastuzumab. From Lucibello *et al.* "Phospho-TCTP as a therapeutic target of dihydroartemisinin for aggressive breast cancer cells". *Oncotarget*, 2015 [Figure 6]^[19]. BC: Breast cancers; HER2: human epidermal growth factor receptor-2; TCTP: translationally controlled tumor protein.

TCTP is a leaderless protein that could be secreted through the non-classical exosome pathway by cancer cell lines^[56]. Recently, it has been shown that TPT1 transcripts were highly expressed and enriched in all EV subtypes from the human colon cancer LIM1863 cell line, thus speculating that it could be translated upon EV uptake in recipient cells^[57]. It has been shown that the TCTP protein was sequestered into exosomes and released from endothelial cells in patients with pulmonary arterial hypertension (PAH). TCTP uptake from the circulation by pulmonary artery smooth muscle cells induced aberrant vascular remodeling, suggesting TCTP is a relevant biomarker in PAH disease^[58].

Altogether, all these data suggest the potential of TCTP as a non-invasive biomarker in several diseases and pave the way for further studies strengthening its potential extracellular role in cancer diagnosis and prognosis.

TCTP as an immune-resistance factor

Oxidative stresses, lack of nutrients, radio and chemotherapy can trigger cell death responses. While programmed cell death ensures, at least initially, the removal of apoptotic bodies by phagocytes, death by necrosis results in the release of protein factors, called damage-associated molecular patterns (DAMPs), in the extracellular environment. These proteins have a well-defined intracellular function. However, when they are released in the tumor microenvironment (TME) through interaction with specific receptor molecules, such as Toll-like receptors (TLRs) or receptors for advanced glycation products (RAGE) present on epithelial cells or resident inflammatory cells, they induce recruitment of immune-inflammatory cells. Among them, there are immune cells with potent immunosuppressive activities as the myeloid-derived suppressor cells (MDSCs)^[59,60].

Recently, it has been shown that TCTP was a crucial immunosuppressive danger factor released by dying tumor cells in the TME. TCTP promoted the recruitment of polymorphonuclear MDSCs (PMN-MDSC) into TME, which in turn blocked the antitumor function of CD8+T cells and NK cells. In detail, TCTP, through its binding to TLR2 on myeloid cells, stimulated the CXCL1 family chemokine expression, which in turn recruited PMN-MDSCs. This specific pathway was sufficient for the recruitment of PMN-MDSCs as no additional signals, such as G-CSF and GM-CSF, were required^[61]. Notably, in this setting, the inhibition of TCTP, with a specific monoclonal antibody (55F3) or with DHA (see below), decreased MDSCs in the TME, inhibited tumor growth, thereby enhancing the efficacy of the immune checkpoint blockade (ICB)^[61].

Thus, TCTP is a relevant player in such immunosuppressive circuits, and its inhibition may be effective in clinically viable combinatorial settings. Consistently, interrogating a TCGA colorectal data set showed that TCTP expression levels were negatively correlated with an antitumor immune signature of cytotoxic lymphocyte or NK cells. In CRC, a higher TCTP expression was elevated specifically in tumor cells and correlated with advanced disease and, notably, with PMN-MDSCs (CD15+ cells) representation within the tumor^[61]. This latter observation correlates with the fact that the mesenchymal transition of high-grade breast carcinoma may be induced by MDSCs infiltrating the primary tumor^[62].

The programmed death ligand-1 (PD-L1) is an immune checkpoint molecule and informative biomarker for anti-PD-1 therapy. Aberrant expression of PD-L1 may be induced through the dysregulation of several oncogenic pathways and contributes to immune escape^[63,64]. TCTP was recently shown to induce resistance to anti-PD-L1 therapy, decrease T cell trafficking to the tumor and confer resistance to cytotoxic T lymphocyte-mediated tumor cell killing. In this frame, TCTP induced activation of EGFR-AKT signaling, and notably, the phosphorylation of TCTP by PLK1 was required for EGFR-AKT signaling and for establishing an immune-resistant phenotype^[65]. It follows that inhibition of TCTP by DHA enhanced the efficacy of T cell-mediated therapy. Consistently, the expression of the TCTP mRNA was significantly higher in the patients unresponsive to anti-PD-L1 therapy, and it inversely correlated with T cell infiltration and CD8+T cell signatures in various types of cancer^[65].

All these findings raise the intriguing possibility that TCTP might mark a subpopulation of cancer cells bearing immune-evasive properties. Finally, TCTP levels and status may predict the efficacy of anti-PD-1/PD-L1 immunotherapy, and, again, TCTP itself could be an actionable target for combinatorial therapies improving the response to T cell therapy or immune checkpoint blockade.

TCTP MAY MARK POORLY DIFFERENTIATED CELLS WITH STEM-LIKE PROPERTIES AND RESISTANCE TO THERAPY-INDUCED STRESS

Epithelial-mesenchymal transition (EMT) is a property of epithelial stem cells^[66]. EMT is involved in tissue remodeling during embryonic development and in several pathophysiological processes in adult life, such as invasion and spread of tumor metastasis. During EMT, cells gradually acquire a mesenchymal cell phenotype characterized by a loss of contact with neighboring cells by changing cell shape and increasing the ability of migration and invasion. EMT is the first step towards metastasis. Disseminated cancer cells then undergo a mesenchymal-epithelial transition (MET) to re-initiate tumor growth. Epithelial and mesenchymal states are not endpoints of a transition but rather the expression of reversible phenotypic states. This phenotypic plasticity enables cancer cells to adapt to specific microenvironments, metabolic, immune, and therapeutic challenges^[67-69]. Reactivation of developmental programs may be a critical step in the progression of cancers. Thus, genes and signaling pathways playing key roles in embryonic development pathways are often reactivated or dysregulated during tumorigenesis and metastasis^[70].

TCTP knockout mice and TCTP-deficient mutants of *Drosophila* died in the early stage of embryogenesis^[71,72], suggesting defects in embryo development. A recent study by Kwon YV and colleagues has shown that TCTP was required for maintaining *Drosophila* intestinal stem cells (ISCs) during normal homeostasis and tissue damage. In such a setting, TCTP increased Akt1 levels and its phosphorylation, which in turn promoted stem cell proliferation^[73]. TCTP was enriched in PKH26 dye-retaining breast cancer stem cells, as previously mentioned^[18], and in glioma stem cells^[74].

TCTP has been shown to be a positive regulator of EMT. TCTP overexpression in polarized epithelial LLC-PK1 cells enhanced their cell motility, and invasiveness via mTORC2/Akt/GSK3 β /b catenin pathway and promoted EMT-related markers and morphological changes^[75]. TCTP was a target of transforming growth factor- β 1 (TGF- β 1), a potent inducer of EMT, in lung carcinoma cells. TCTP overexpression induced the protease urokinase plasminogen activator (uPA), which in turn induced extracellular matrix degradation, up-regulation of mesenchymal markers like vimentin, and reduction in epithelial markers, such as E-cadherin^[76].

Several studies have shown a strong correlation between the expression levels of TCTP and the degree of metastasis [Table 1]. Importantly, silencing of TCTP suppressed pulmonary metastasis in melanoma-bearing mice^[75], or liver metastasis in an *in vivo* model of GBC metastasis^[22]. These data highlight the role of TCTP in the progression of the disease and its potential as a target in metastatic lesions.

Reorganization of cytoskeleton and changes in cell shape are essential for cancer cell mobility^[67]. In *Xenopus* XL2 cells, TCTP was localized in a subset of actin-rich fibers of migrating cells, therefore, may regulate cell shape. Indeed, its reduction in XL2 and HeLa cells provoked drastic MT-dependent shape change^[77]. Along this line, in LLC-PK1-renal proximal tubular epithelial cells, overexpression of TCTP induced a rearrangement of actin cytoskeleton and formation of stress fibers, which played a crucial role in cell mobility regulation^[75].

We have observed that depletion of TCTP in breast cancer cells induced alterations in cell morphology, specifically an enlarged size and flattened shapes^[78]. Notably, in several cancer cells, a decrease in TCTP levels significantly reduced cell migration and invasion^[22,31,75]. We have also shown that a reduction of TCTP in its phosphorylated form induced an increase in microtubule density.

Thus, the phosphorylated and non-phosphorylated forms of TCTP must be kept in equilibrium to maintain the dynamic instability of microtubules and the cell shape. We also found that phospho-TCTP activity was crucial during mitosis, reminiscent of its mentioned link to cell proliferation^[49].

We have also observed that TCTP is a critical survival factor that protects cancer cells from oxidative and metabolic stresses. Notably, arsenic trioxide (ATO), a pro-oxidant agent, induced up-regulation of TCTP, suggesting that chemotherapeutic treatments, through induction of TCTP expression, may select cells with a survival advantage^[78]. This is intriguing since adaptation to stress and invasive ability are recognized features of stem-like cancer cell subpopulations. In this context, it is worth noting that EMT was shown to be an important propeller of cancer stem cell emergence^[66].

Consistent with these data, in several tumors such as breast, lung, CRC and melanoma, a high TCTP status increased resistance to radio- and/or chemotherapy^[79-82].

In chemo-resistant cells, the induction of TCTP was regulated through phosphoinositide-3-kinase (PI3K)/Akt/mTORC1 pathways^[79], whose aberrant activation during malignant progression might result in loss of control of cell growth and survival, and the development of drug resistance^[83].

Radiation may induce DNA damage by generating reactive oxygen species (ROS). TCTP knockdown sensitized cancer cells to radiation-induced DNA damage, reminiscent of its cytoprotective role under oxidative stress conditions^[78], and activated p53, which in turn prevented proliferation of damaged cells^[81], consistent with data showing that p53 and TCTP work as reciprocal regulators^[18].

High levels of TCTP correlated with resistance to radiotherapy in high-grade glioma patients^[25]. High-grade glioma tumors are characterized by an enrichment of CD133-positive cells with stemness properties, which may persist after therapy leading to tumor relapse^[84]. In this context, TCTP could play a crucial role, as it has been shown that it is essential for cell proliferation and survival of primary glioma CD133-positive cells^[74].

Altogether, these findings suggest that high TCTP levels could delineate a population of stem-like cancer cells with metastatic potential and pronounced stress adaptive properties, including chemo- and radio-resistance. This fits well with the above observations that TCTP could be a relevant indicator of high-grade malignancy.

Genomic analysis of TCTP in BC tumor

The Cancer Genome Atlas Breast Invasive Carcinoma (TCGA-BRCA) or Molecular Taxonomy of Breast Cancer International Consortium (METABRIC) databases showed a higher expression of TPT1/TCTP in normal breast tissues than in primary breast tumors. In addition, these analyses showed no differences in mRNA levels: (i) among the PAM50 subtypes of BC; (ii) among specific stages of the tumor; (iii) in metastatic vs. no metastatic tumors; (iv) in TP53 mutated tumors vs. TP53 wild-type tumors [Figure 4].

Moreover, the survival analysis from the Kaplan-Meier plot showed a positive correlation between high TPT1/TCTP mRNA levels and patient survival [Figure 5]. All these data are in apparent disagreement with the aforementioned data and suggest that mRNA levels of TCTP do not predict protein levels^[6].

Things change when considering specific features of BC patients: when the analysis was restricted to estrogen receptor (ER)-negative tumors, characterized by more aggressive behavior [Figure 6], a high TCTP status positively correlated with shorter overall survival, thus suggesting the high degree of heterogeneity among BC subtypes.

In OC, instead, high levels of TCTP mRNA and protein were both significantly associated with poor overall survival [Figure 7]. Since OC is characterized by a history of sequential relapses after a second-line therapy^[85], and given the involvement of OC cancer stem cells (CSC) in OC relapse^[86], this indirectly links TCTP to the CSC biology, thus echoing the previous observation. See the availability of data and material for more details.

STRATEGIES TARGETING TCTP

For a more systematic view of the potential therapeutic approaches toward TCTP, we will divide the following discussion into subparagraphs.

Non-coding RNA

Non-coding RNA (ncRNAs) play key regulatory roles in oncogenesis through epigenetic, transcriptional, post-transcriptional, and translation modulation. ncRNAs can be used as biomarkers or can be therapeutically targeted in cancer therapy^[87]. They are grouped into two main types according to transcript size: small (< 200 nucleotides; ncRNAs) and long (> 200 nucleotides; lncRNAs)^[88].

Post-transcriptional gene regulation of TPT1 by potential ncRNAs in breast cancer remains largely unexplored. Recent works have shown that the lncRNA TPT1 antisense RNA 1 (TPT1-AS1) was dysregulated in tumors and associated with patient prognosis and clinically relevant features^[89]. Conversely to TCTP, TPT1-AS1 was downregulated, and this predicted poor prognosis in BC. TPT1-AS1 played a role

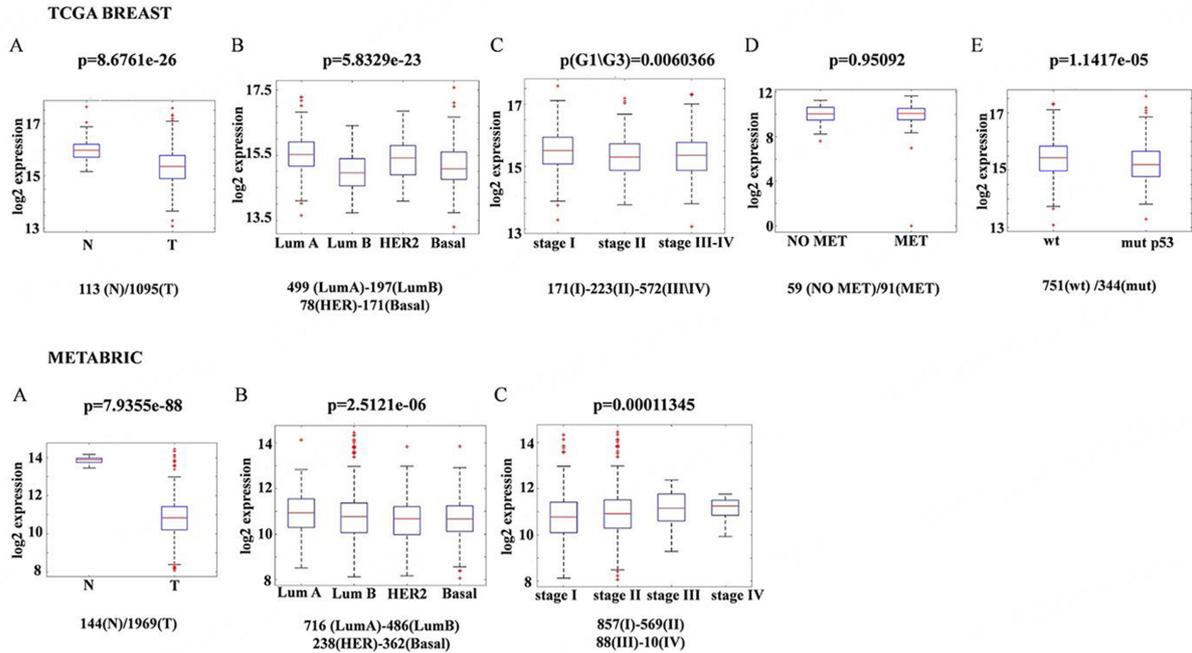

Figure 4. TPT1/TCTP transcripts in BC and normal tissues. Boxplot from TPT1/TCTP RNAseq gene expression data of TCGA (upper panel) and METABRIC databases (Lower panel). (A) in normal tissue and primary breast cancer tissue; (B) in different PAM50 breast cancer subtypes; (C) in different stages of the tumor; (D) in metastatic (91 samples) vs. no metastatic tumors (59 samples); (E) in TP53 mutated tumors vs. TP53 wild-type tumors. BC: Breast cancers; MET: mesenchymal-epithelial transition; METABRIC: molecular taxonomy of breast cancer international consortium; TCGA: the cancer genome atlas; TCTP: translationally controlled tumor protein; TPT1: tumor protein, translationally-controlled 1.

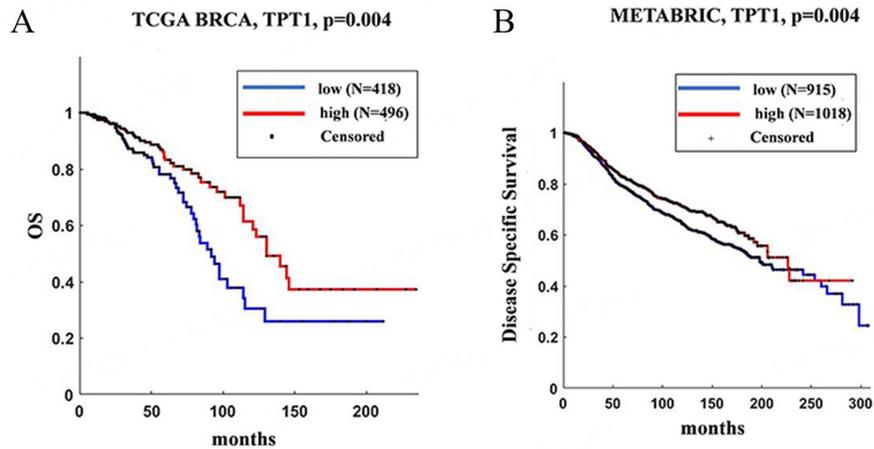

Figure 5. High TCTP levels correlate with better clinical outcomes in BC patients. (A) TCGA survival curve (B) and Disease-Specific Survival in METABRIC dataset of BC patients separated according to TPT1 expression levels. as a tumor suppressor gene^[90,91], and notably, it was subjected to epigenetic regulation through DNA methylation. Elango and colleagues have shown that TPT1-AS1 was the most induced lncRNA in response to DNA methyltransferase inhibition in triple-negative breast cancer (TNBC) models^[92]. DNA methyltransferase inhibitors reverse epigenetic alterations, resulting in reactivation of tumor suppressor genes,

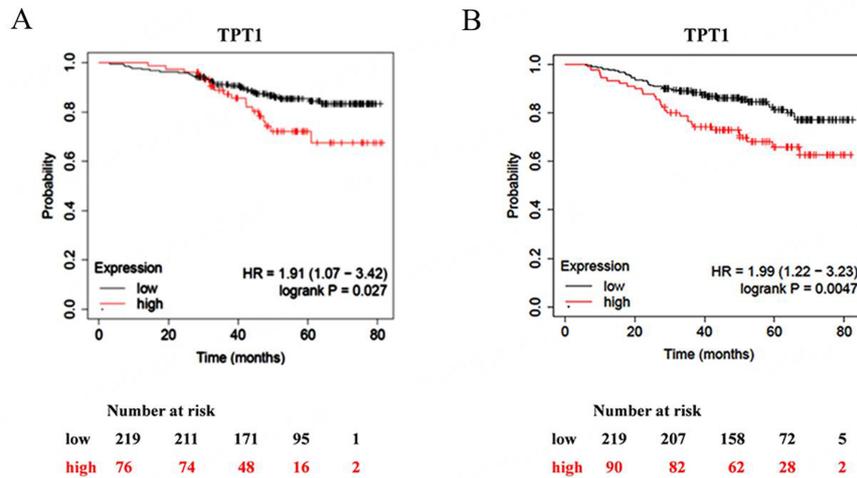

Figure 6. Overall survival is shorter in BC patients with higher TCTP expression. Kaplan-Meier analysis of overall survival in BC patients based on KM plotter database of: (A) PAM50 HER2 and (B) PAM50 basal subtypes. BC: Breast cancers; HER2: human epidermal growth factor receptor-2; TCTP: translationally controlled tumor protein; TPT1: tumor protein, translationally-controlled 1.

which in turn leads to cell cycle arrest and/or apoptosis, and thus suggests that re-expression of TPT1-AS1 could be an approach to be pursued in breast cancer therapy.

More in detail, the TPT1-AS1 is a transcript from the antisense strand of *TPT1* gene that may positively regulate the expression of TPT1. Consistent with this, TPT1-AS1 promoted tumor progression by upregulating TPT1 levels in epithelial ovarian cancer (EOC). In addition, the high expression of TPT1-AS1 was associated with unfavorable clinic-pathological features and poor prognosis in EOC^[93]. The dual functions of TPT1-AS1 suggest that its role should be carefully considered in a tissue-specific manner. Further studies are therefore required to characterize the complex interaction network that regulates TPT1-AS1 activity in a specific tissue or context and to understand its underlying mechanisms.

Clinically available compounds

Drug repositioning is a promising strategy to identify new therapeutic applications of drugs already approved by regulatory agencies for other diseases. The use of clinically approved or advanced phase compounds is justified by the need to maximize the timing for therapeutic advancements since those compounds already have a consolidated safety profile and a characterized pharmacokinetic/pharmacodynamic profile. Thus, those compounds are in principle amenable to phase 2 studies. Below we will list some of the compounds falling into this category, whose mechanism of action is directly or indirectly linked to perturbing the levels or post-translational status of TCTP [Tables 2-4].

Dihydroartemisinin

One clinically available TCTP-targeting agent is DHA [Figure 8], the active metabolite of all artemisinin compounds (as artesunate, artemether). Artemisinin is the active principle in *Artemisia annua*. Artemisinin and its derivatives are a family of sesquiterpene trioxane lactone. These agents were discovered as anti-malarial agents by Dr. Youyou Tu, who received the Nobel Prize in Physiology or Medicine in 2015. Currently, the water-soluble derivative of artemisinin, Artesunate Amivas, has received approval for malarial patients from the Food and Drug Administration (FDA) and the European Medicine Agency (EMA).

Beyond the “anti-malarial effect”, these pharmacological compounds were selectively cytotoxic to cancer cells, as shown by numerous *in vitro* and *in vivo* studies^[94,95], which have led to the groundwork for the design of phase 1 clinical trials for solid tumors. These compounds have exhibited a good therapeutic index after long-term treatment in patients with metastatic breast cancer or cervix carcinoma^[96-98].

Several observations have shown that DHA is bound specifically to TCTP^[99-101]. Further, DHA inhibited TCTP-dependent cell migration and invasion of GBC cells, and notably, DHA decreased GBC metastases and improved survival in tumor-bearing mice. TCTP is a clinically relevant target in GBC^[22]; thereby, TCTP-targeting DHA could be an anti-metastatic strategy to be explored at an early stage of disease.

We have shown that the levels of phospho-TCTP were crucial for the mitotic process. By decreasing phospho-TCTP levels, DHA induced mitotic spindle aberrations and the formation of disorganized microtubule structures^[49]. At least partially through this mechanism, DHA increased the sensitivity of BC cells to chemotherapy^[19] and to trastuzumab emtansine (T-DM1) in BC cells resistant to trastuzumab (first-line of treatment)^[49]. T-DM1 is an anti-human epidermal growth factor receptor 2 (HER2) antibody-drug with a stable linker to emtansine (DM1), a microtubule inhibitor. Recently, it has been shown that T-DM1 reduced the risk of disease recurrence in patients with residual invasive BC after neoadjuvant therapy (NAT) comprised of HER2-targeted therapy and chemotherapy^[102]. As partially suggested before, we may

speculate that the addition of DHA to T-DM1 may allow a dose reduction for T-DM1 and could help prevent adverse side effects, therefore improving the quality of life for patients.

Targeting TCTP with DHA may offer an unforeseen rationale for combination treatments in cancer immunotherapy as well, according to what was previously mentioned^[61,65]. Immunotherapy represents a promising therapeutic approach for TNBC, and recently, pembrolizumab (anti-PD1 antibody) plus chemotherapy was approved for the treatment of advanced TNBC with high PD-L1 expression^[103]. However, resistance to immune-checkpoint inhibitors (ICIs), including aberrant activation of oncogenic signaling pathways and/or an immunosuppressive TME, is a significant challenge. Predictive factors, as well as discovering new actionable targets for combinatorial therapy, will improve the response rate of TNBC to ICIs. In this context, TCTP appears to be an interesting subject of investigation. Thus, targeting TCTP may enable chemosensitization of cancer cells previously subjected to conventional therapy and to biological agents [Table 2].

Sertraline and thioridazine

Sertraline (Zoloft) is a selective serotonin reuptake inhibitor. Thioridazine is an antipsychotic drug used to treat schizophrenia. These agents, used in the management of psychiatric disorders, have shown promising anticancer effects as well^[18,104].

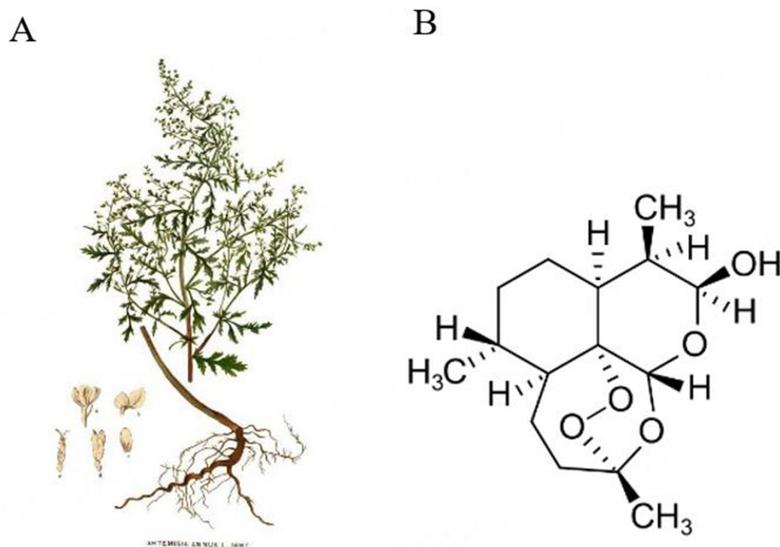

Figure 8. (A) Representative image of *Artemisia Annua*. https://commons.wikimedia.org/wiki/File:Artemisia_annua_-_001x.jpg. Created by: Oceancetaceen - Alice Chodura, Public domain, via Wikimedia; (B) Chemical structures of dihydroartemisinin. [https://commons.wikimedia.org/wiki/File:Artemimol_\(2\).svg](https://commons.wikimedia.org/wiki/File:Artemimol_(2).svg). Created by: Benff, CC BY-SA 4.0 <<https://creativecommons.org>>

Thioridazine and sertraline induced a significant reduction of TCTP levels, which in turn increased p53 levels, thus restoring the sensitivity of tumor cells to apoptosis. In addition, sertraline reduced the mammosphere-forming efficiency of ErbB2 cells, consistent with data showing that silencing of TCTP in ErbB2 cells resulted in a decreased ability to form mammospheres^[18,105]. TCTP was also a critical target of sertraline and thioridazine in melanoma cells. Both drugs restored p53 function and inhibited invasion/migration and clonogenicity of melanoma cells by targeting TCTP. Notably, in vivo experiments on a mouse melanoma model have shown that sertraline was more effective in inhibiting tumor growth than dacarbazine, a chemotherapy agent that has been approved for treating advanced melanoma^[106]. In prostate cancer cells, sertraline decreased TCTP, phospho-TCTP and survivin and induced apoptotic cell death. Further, sertraline inhibited the expression of cancer stem cell markers, CD44 and aldehyde dehydrogenase 1 (ALDH1), in prostate cancer cell cultures^[107]. By using affinity purification-based proteomic profiling, Li *et al.* found that TCTP interacted with proteins involved in DNA repair. In breast cancer cells, inactivation of TCTP by sertraline enhanced UVC irradiation-induced apoptosis and increased the sensibility to etoposide and olaparib, a DNA-damaging drug and a PARP1 inhibitor, respectively^[108]. Interestingly, such action may converge into the evoked chemosensitizing effect of TCTP [Table 3].

Whether sertraline and thioridazine may directly or indirectly perturb the function of TCTP is a matter of interesting ongoing debate^[109].

Rapamycin

Rapamycin is a natural anti-fungal antibiotic. Rapamycin and its analogs are currently being used in clinical as potent immunosuppressants and antiproliferative agents. Rapamycin inhibits the Target of Rapamycin Complex 1 (TORC1) activity with high specificity. TORC1 is a highly conserved protein kinase that belongs to the PI3K family. It is a crucial regulator of cell proliferation and growth that integrates and senses different signaling networks. Its signaling dysregulation is frequently observed in several pathological conditions and in aggressive and therapy-refractory cancers, among these BC^[83,110].

Studies in *Drosophila melanogaster* and structural studies in human models have shown the involvement of TCTP in TORC1 signaling. It has been reported that TCTP controlled cell growth and proliferation by positively regulating the Ras homolog enriched in brain (Rheb) activity, an important upstream activator of mTORC1^[14,72,111,112].

In addition, TCTP mRNA belongs to the class of 5'-TOP mRNAs (containing a 5'-terminal oligopyrimidine tract, 5'-TOP) whose translational activity is largely controlled through the PI3-K/Akt/mTORC1 pathway^[113]. In colon cancer cells and in HeLa cells, serum stimulation increased the expression of TCTP, and this was inhibited by rapamycin or mTOR kinase inhibitors. In addition, in colon cancer, TCTP protein levels were upregulated by the mTORC1 pathway in response to 5-fluorouracile (5-FU) and oxaliplatin treatment, suggesting a protective role of TCTP against the cytotoxic action of those anticancer drugs. Consistent with this data, mTOR kinase inhibitors prevented the onset of this TCTP-driven drug resistance phenotype^[79].

Further, a positive feedback loop between TCTP and mTOR contributed to neurofibromatosis type 1 (NF1)-associated tumor, and rapamycin was effective in down-regulating TCTP expression, suggesting that the TCTP protein level was controlled by mTOR-dependent translational regulation^[33].

Recently, it has been shown that Rapamycin induced TCTP proteolysis, thereby enhancing the efficacy of DNA-damaging drugs, such as cisplatin and doxorubicin, in lung carcinoma cells, suggesting a novel strategy for enhancing chemosensitivity in lung cancers^[80].

Unfortunately, the mentioned compelling evidence has not yet generated clinically meaningful results, and this general observation is related to the poor activity of mTOR inhibitors observed so far in clinical trials. However, everolimus, an mTOR inhibitor, has been approved in combination with exemestane, an aromatase inhibitor, in HR⁺/HER2⁻ endocrine-resistant MBC^[114].

It is possible that multiple TCTP targeting agents may be combined to increase the effect: for example, preclinical studies have shown that the combination of artesunate, a specific inhibitor of TCTP (see above), and rapamycin was more effective in killing malignant peripheral nerve sheath tumors (MPNSTs) compared to the effect induced by exposure to a single drug^[33] [Table 4].

CONCLUSION

TCTP may mark specific subpopulations of cancer cells with pronounced stress adaptation, stem-like and immune-evasive properties and capable of surviving conventional agents or targeted therapies [Figure 9].

It may work by interacting with key factors involved in cancer progression, including metabolic modulators. TCTP may also be involved in the tumor-TME crosstalk [Figure 10], and it may aid in stratifying specific cancer subsets. Thus, further studying TCTP and its complex behavior in cancer may reveal important knowledge towards patient stratification for both therapeutic and prognostic purposes. We also evoke the need to study the complex biology and the TCTP-modulating agents in more clinically relevant models, such as patient-derived-organoids. This may aid in solving some of the apparent contradictions in the behavior of this interesting and complex protein, down to a tumor- and patient-specific level. This effort is currently ongoing in our labs. Altogether, we suggest that TCTP may mark an aggressive sub-population of cancer cells that could emerge under the pressure of conventional therapies. Additionally, based on the preclinical evidence, we propose that TCTP could be an actionable target of clinically available compounds aimed at targeting TCTP highly expressing tumors, with the purpose of attenuating their resistance to

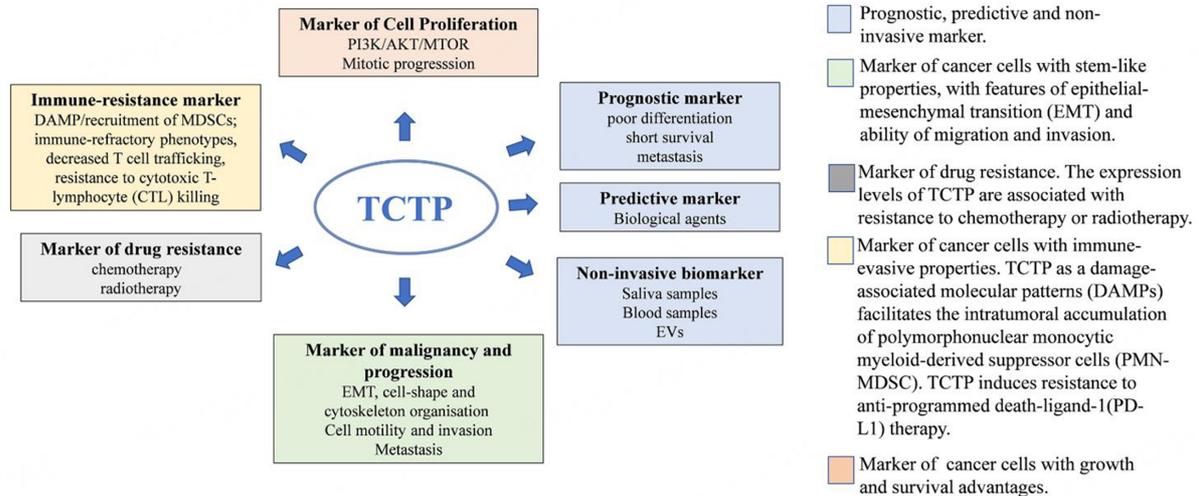

Figure 9. Schematic overview of the potential application of TCTP in cancer. EVs: Extracellular vehicles; MDSCs: myeloid-derived suppressor cells; TCTP: translationally controlled tumor protein.

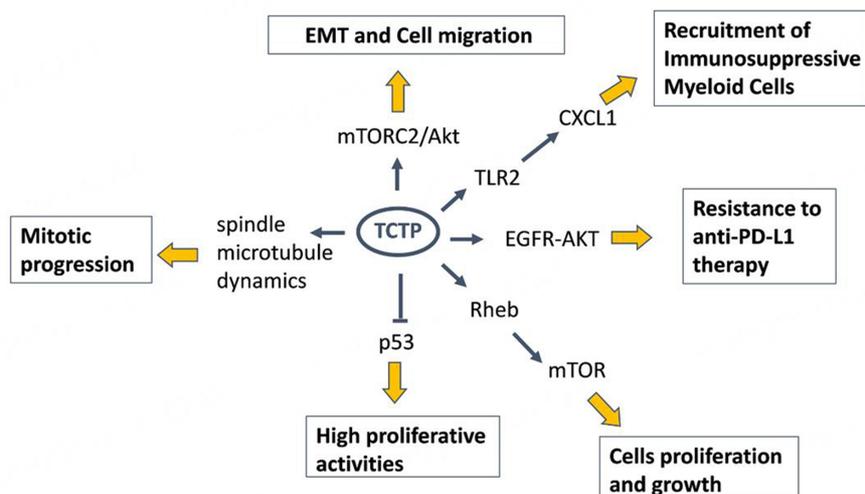

Figure 10. Pleiotropic functions of TCTP. A cartoon showing the major TCTP-related pathways. TCTP can promote cell proliferation by acting: (1) as a guanine exchange factor for the GTP-binding protein Rheb, a crucial player in the mTORC1 pathway; (2) by inducing P53 degradation; (3) by regulating spindle morphology and mitosis progression, when it is phosphorylated by PLK1. TCTP can act as an immune-resistance factor via activation of TLR2 on myeloid cells, which in turn induces cytokines production and the recruitment of immune-suppressive cells. TCTP, in the phosphorylated form, can induce the activation of the EGFR/AKT pathway, thus promoting an immune resistance to anti-PD-L1 therapy. TCTP can promote cell migration and EMT markers through the mTORC2 pathways. EMT: Epithelial-mesenchymal transition; PD-L1: programmed death ligand-1; PLK1: polo-like kinase 1; TCTP: translationally controlled tumor protein.

therapy and progression. Targeting TCTP with DHA, sertraline or rapamycin holds promise for more effective synergistic combinations. This warrants further investigations, which are ongoing in our lab. Thus, we believe that two important factors may converge in delineating the study, and the targeting of TCTP can be an opportunity for personalized therapy. On one hand, the fact that TCTP marks a cell subpopulation of cancer cells, which represent obvious candidates for resistance to therapy, as also suggested by the prognostic value of both TCTP and phospho-TCTP levels; on the other hand, the availability of compounds with an established safety profile capable of reducing the levels of the protein and altering its

phosphorylation state. What is mentioned here may represent a starting point for considering TCTP measurement and targeting as a translationally relevant opportunity.

Statistics

Statistical analyses were performed using R software^[115]. ANOVA or Student's *t*-test was used for normally distributed data and for non-normally distributed data, as appropriate. *P*-values smaller than 0.05 were considered statistically significant.

DECLARATIONS

Authors' contributions

Critical review, editing, commentary, and bioinformatic analysis: Santamaria G, Cioce M

Critical review, editing, and commentary: Rizzuto A, Fazio VM, Viglietto G

Conceptualization, literature search, original draft preparation, visualization, and editing: Lucibello M

Availability of data and material

Data from the METABRIC study is deposited in the European Genome-phenome Archive and can be downloaded from European Genome-phenome Archive: METABRIC, (<https://www.ebi.ac.uk/ega/studies/EGAS00000000083>). The TCGA breast cancer dataset can be downloaded from the TCGA Data Portal website, (<http://tcga-data.nci.nih.gov/tcga/>).

Financial support and sponsorship

None.

Conflicts of interest

All authors declared that there are no conflicts of interest.

Abstract

Aim: Ferroptosis is a non-apoptotic form of cell death caused by lethal lipid peroxidation. Several small molecule ferroptosis inducers (FINs) have been reported, yet little information is available regarding their interaction with the ATP-binding cassette (ABC) transporters P-glycoprotein (P-gp, ABCB1) and ABCG2. We thus sought to characterize the interactions of FINs with P-gp and ABCG2, which may provide information regarding oral bioavailability and brain penetration and predict drug-drug interactions.

Methods: Cytotoxicity assays with ferroptosis-sensitive A673 cells transfected to express P-gp or ABCG2 were used to determine the ability of the transporters to confer resistance to FINs; confirmatory studies were performed in OVCAR8 and NCI/ADR-RES cells. The ability of FINs to inhibit P-gp or ABCG2 was determined using the fluorescent substrates rhodamine 123 or purpuin-18, respectively.

Results: P-gp overexpression conferred resistance to FIN56 and the erastin derivatives imidazole ketone erastin and piperazine erastin. P-gp-mediated resistance to imidazole ketone erastin and piperazine erastin was also reversed in UO-31 renal cancer cells by CRISPR-mediated knockout of *ABCB1*. The FINs ML-162, GPX inhibitor 26a, and PACMA31 at 10 μ M were able to increase intracellular rhodamine 123 fluorescence over 10-fold in

P-gp-expressing MDR-19 cells. GPX inhibitor 26a was able to increase intracellular purpurin-18 fluorescence over 4-fold in ABCG2-expressing R-5 cells.

Conclusion: Expression of P-gp may reduce the efficacy of these FINs in cancers that express the transporter and may prevent access to sanctuary sites such as the brain. The ability of some FINs to inhibit P-gp and ABCG2 suggests potential drug-drug interactions.

Keywords: Ferroptosis, drug resistance, P-glycoprotein, ABCG2

INTRODUCTION

Ferroptosis is an iron-dependent form of non-apoptotic cell death arising from direct or indirect inhibition of glutathione peroxidase 4 (GPX4), leading to lipid peroxidation and unsustainable levels of reactive oxygen species (ROS)^[1]. One of the first reported inducers of ferroptosis, erastin, was described before the concept of ferroptosis was completely understood. Erastin was found to selectively kill transformed human foreskin fibroblasts expressing mutant HRAS compared to isogenic cells expressing wild-type HRAS^[2]. The mechanism of cell death induced by erastin was not apoptosis, as the hallmarks of apoptotic cell death such as annexin V staining and caspase 3 cleavage were not observed, although death was accompanied by cell membrane permeabilization^[2]. The term “ferroptosis” was later coined for this novel form of cell death as iron chelators and antioxidants were found to potentiate erastin-mediated toxicity, suggesting an iron-dependent increase in ROS was responsible^[3]. Additionally, ferroptosis could not be inhibited by caspase inhibitors and was found to occur independently of the apoptosis effector proteins Bak and Bax^[3].

The target of erastin was identified to be the cystine/glutamate antiporter, system x_c^[3]. Inhibition of the antiporter leads to depletion of glutathione and inactivation of GPX4^[4]. Subsequent to the discovery of erastin, other small molecules have been developed to induce ferroptosis by direct or indirect inhibition of GPX4. These ferroptosis inducers (FINs) include modified forms of erastin such as erastin2^[5], imidazole ketone erastin^[6] and piperazine erastin^[4], as well as the inhibitors FIN56^[7], RSL3^[8], FINO₂^[9], PACMA31^[10], GPX4 inhibitor 26a^[11], and ML-162 and ML-210^[12].

In an attempt to identify cancers that might be effectively treated by ferroptosis induction, Yang *et al.* tested erastin toxicity in 117 cancer cell lines and identified renal cell carcinomas as being particularly sensitive to ferroptosis^[4]. This intrigued us, as renal cell carcinomas are often positive for expression of P-glycoprotein (P-gp, encoded by the *ABCB1* gene), an ATP-binding cassette (ABC) multidrug efflux pump that confers drug resistance^[13,14]. Some reports have also suggested that expression levels of another ABC transporter, ABCG2 (encoded by the *ABCG2* gene), also expressed in kidney cancers, can predict overall survival in patients with clear cell renal carcinoma^[15]. Additionally, both P-gp and ABCG2 localize to the gastrointestinal tract as well as to other barrier sites, such as the blood-brain barrier (BBB)^[16]. Expression at these sites is linked to their role in limiting the oral bioavailability of chemotherapy drugs and brain penetration of several targeted therapies^[16,17]. We thus sought to characterize the interactions between small-molecule ferroptosis inducers and the transporters P-gp and ABCG2.

METHODS

Chemicals

Erastin, doxorubicin, rhodamine 123, and FIN56 were purchased from Sigma-Aldrich (St. Louis, MO). Erastin2, imidazole ketone erastin, RSL3, ML-162, FINO₂, GPX4 inhibitor 26a, JKE-1674, and JKE-1716 were from Cayman Chemical (Ann Arbor, MI). Valspodar was obtained from MedChemExpress (Monmouth Junction, NJ). Romidepsin was from Selleck Chemicals (Houston, TX). Purpurin-18 was

purchased from Frontier Scientific (Logan, UT). Piperazine erastin was from TargetMol (Wellesly Hills, MA). SN-38 was obtained from LKT Laboratories (St. Paul, MN). RSL3 was purchased from Tocris (Minneapolis, MN). Fumitremorgin C (FTC, > 95% purity) was synthesized in-house by the Developmental Therapeutics Program at the National Institutes of Health (Bethesda, MD).

Cell lines

OVCAR8, NCI/ADR-RES and UO-31 cells were obtained from the Division of Cancer Treatment and Diagnosis Tumor Repository, National Cancer Institute (Frederick, MD) and are grown in RPMI-1640 with 10% FBS, glutamine and Pen/Strep. A673 cells (from ATCC, Manassas, VA) were seeded and transfected with empty vector (EV) or vector containing full-length, human *ABCB1* or *ABCG2* using Lipofectamine 2000 (Invitrogen, Waltham, MA). Cells were selected with hygromycin, and clones were isolated by limiting dilution. Selected clones were grown in DMEM with 10% fetal calf serum, glutamine and Pen/Strep, as well as 300 µg/mL hygromycin to maintain expression of the transporters. P-gp-overexpressing MDR-19 cells and *ABCG2*-overexpressing R-5 cells were derived from HEK293 cells and have been previously characterized and described^[18]. Transfected HEK293 cells were grown in MEM with 10% fetal calf serum, glutamine and Pen/Strep along with 2 mg/mL G418 to maintain expression of the transporters. All cell lines were routinely tested for mycoplasma using the MycoAlert PLUS Kit (Promega, Madison, WI) test kit and their identities were confirmed by STR analysis (performed by ATCC, Manassas, VA).

Oligonucleotides

The following oligonucleotides (generated by Eurofins, Inc, Louisville, KY) were used in this study:

ABCB1-START:

5'- GGGGACAACCTTTGTACAAAAAAGTTGGCACCATGGATCTTGAAGGGGACCGCAATGG

ABCB1-END:

5'- GGGGACAACCTTTGTACAAGAAAGTTGATTATGCTAGCTGGCGCTTTGTTCCAGCCTGG

ABCG2-START:

5'- GGGGACAACCTTTGTACAAAAAAGTTGGCACCATGTCTTCCAGTAATGTCTGAAGTTTTTATCCC

ABCG2-END:

5'- GGGGACAACCTTTGTACAAGAAAGTTGATTAAGAATACTTTTAAAGAAATAACAATTTTCAG

Generation of entry clones

Entry clones for *ABCB1* and *ABCG2* were constructed by PCR amplification of cDNA sequences flanked by Gateway Multisite recombination sites (Thermo Fisher Scientific, Waltham, MA). PCR was carried out with 200 nM of each oligo listed in the table above using Phusion polymerase (New England Biolabs, Ipswich, MA) under standard conditions and an extension time of 180 s. PCR products were cleaned using the QiaQuick PCR purification kit (Qiagen, Germantown, MD). The final PCR products were recombined into Gateway Donor vector pDonr-253 using the Gateway BP recombination reaction using the manufacturer's protocols. The subsequent Entry clones were sequence verified throughout the entire cloned region.

Subcloning for mammalian expression constructs

Gateway Multisite LR recombination was used to construct the final mammalian expression constructs from the Entry clones using the manufacturer's protocols (Thermo Fisher Scientific, Waltham, MA). The Gateway Destination vector used was pDest-305 (Addgene, Watertown, MA, #161895), a mammalian

expression vector containing a Gateway attR4-attR2 cassette based on a modified version of pcDNA3.1. This vector backbone contains a hygromycin resistance marker for antibiotic selection. A human elongation factor 1 (EF1) promoter was introduced using a Gateway att4-att1 Entry clone (Addgene, Watertown, MA, #162920). Final expression clones were verified by restriction analysis and maxiprep DNA was prepared using the Qiaprep Maxiprep kit (Qiagen, Germantown, MD).

Generation of ABCB1 knockout UO-31 cells

CRISPR-mediated knockout of *ABCB1* in UO-31 cells was achieved by co-transfecting cells with knockout and homology-directed repair vectors for *ABCB1* (obtained from Santa Cruz Biotechnology, Dallas, TX) using Lipofectamine 2000 (Invitrogen) and subsequent selection with puromycin (3 $\mu\text{g}/\text{mL}$). Knockout clones were subsequently isolated, and loss of P-gp was verified by flow cytometry following antibody staining with phycoerythrin-labeled UIC-2 antibody as described below.

Cytotoxicity assays

Cells were seeded in opaque white, 96-well plates at a density of 2,500 cells/well and allowed to attach overnight. Cells were then treated with increasing concentrations of the desired compound and incubated for 72 h. Cell TiterGlo (Promega) was then used to determine luminescence values for each concentration according to the manufacturer's instructions. The data were modeled using nonlinear regression curve fitting (sigmoidal, 4 parameter logistic curve model in GraphPad Prism 9 for MacOS v 9.5.1, GraphPad Software, Boston, MA) to determine the concentration at which 50% of cell growth was inhibited (GI_{50}). Where noted, cytotoxicity assays were performed with 10 μM valsopodar to inhibit P-gp.

Flow cytometry assays

To measure cell surface expression of P-gp or ABCG2, trypsinized cells were incubated for 20 min. at room temperature in 2% bovine serum albumin/PBS with phycoerythrin-labeled UIC-2 antibody or phycoerythrin-labeled 5D3 antibody, respectively, according to the manufacturer's instructions (both from ThermoFisher, Grand Island, NY). Cells were also incubated with the corresponding phycoerythrin-labeled isotype control - IgG2a kappa for P-gp and IgG2b kappa for ABCG2 (both from ThermoFisher). P-gp or ABCG2 transporter activity was measured using rhodamine 123 or purpurin-18, respectively^[19]. Cells were trypsinized and incubated for 30 min in complete medium (phenol red-free Richter's medium with 10% FCS and penicillin/streptomycin) with the desired fluorescent substrate (0.5 $\mu\text{g}/\text{mL}$ rhodamine 123 to detect P-gp or 15 μM purpurin-18 to detect ABCG2) in the presence or absence of 25 μM concentrations of the desired FIN or a positive control inhibitor (10 μM valsopodar for P-gp or 10 μM fumitremorgin C for ABCG2) for 30 min at 37 $^{\circ}\text{C}$ in 5% CO_2 . Subsequently, cells were washed and incubated in substrate-free medium for 1 h at 37 $^{\circ}\text{C}$ continuing with or without inhibitor. Cells were subsequently analyzed with a FACSCanto flow cytometer (BD Biosciences, San Jose, CA) and data analysis was performed using FloJo v 10.4.2 (FlowJo LLC, Ashland, OR).

ATPase assay

The ATPase assay was performed as described previously^[20]. Total membrane vesicles were prepared from High Five insect cells overexpressing P-gp. The membranes were diluted with ATPase assay buffer (50 mM MES-Tris, pH 6.8 containing 50 mM KCl, 5 mM NaN_3 , 1 mM EGTA, 10 mM MgCl_2 , 2 mM DTT and 1 mM ouabain) to reach a final concentration of 100 $\mu\text{g}/\text{mL}$ and were incubated with the compounds at the noted concentrations for 10 min in the presence or absence of 0.3 mM sodium orthovanadate. The addition of 5 mM ATP (5 mM) started the reaction (20 min at 37 $^{\circ}\text{C}$), after which SDS (2.5% final concentration) was added to terminate the reaction. The amount of inorganic phosphate released was quantified and the results were reported as a percentage of vanadate-sensitive ATPase activity with DMSO.

RESULTS

Generation and characterization of A673 cells that overexpress P-gp or ABCG2

As the A673 cell line was reported to be sensitive to FINs^[4] and did not express P-gp or ABCG2, we transfected this cell line with either empty vector (A673 EV) or vectors containing the genes encoding human P-gp (A673 B1) or ABCG2 (A673 G2). We selected single clones with high levels of P-gp or ABCG2 based on measurement of antibody staining by flow cytometry and further characterized positive clones. As seen in [Figure 1A](#), A673 B1 or A673 G2 cells were found to have much higher levels of the transporter proteins, as shown by increased staining with UIC-2 antibody or 5D3 antibody (orange histogram), respectively, compared to A673 EV cells which were negative for both transporters. P-gp-overexpressing MDR-19 cells and ABCG2-overexpressing R-5 cells served as positive controls for P-gp or ABCG2 surface expression, respectively (data not shown). Functional assays were also used to confirm transporter activity. A673 B1 cells readily transported rhodamine 123 and A673 G2 cells demonstrated increased purpurin-18 efflux, as shown by the left shift of the blue histogram for the two substrates, compared to empty vector-transfected cells (A673 EV), as illustrated in [Figure 1B](#).

To verify that transporter levels were adequate to confer resistance to known substrates, we performed cytotoxicity assays with the P-gp substrate doxorubicin as well as the ABCG2 substrate SN-38. As seen in [Figure 1C](#) and [Table 1](#), A673 B1 cells were resistant to doxorubicin, whereas A673 G2 cells exhibited little to no resistance to this compound. A673 G2 cells displayed increased resistance to SN-38. Having confirmed that the transfected cells expressed high levels of the desired transporters and that the transporters were indeed functional, we proceeded to use them to characterize the ability of P-gp and ABCG2 to confer resistance to FINs.

P-gp overexpression confers resistance to modified erastin derivatives

A673 EV, A673 B1 and A673 G2 cells were then used in 3-day cytotoxicity assays to determine whether the transporters could confer resistance to the FINs. While resistance due to the expression of ABCG2 or P-gp was not seen with most FINs examined, this was not true for some erastin derivatives that had been modified to improve water solubility. Overexpression of P-gp conferred relatively high levels of resistance to imidazole ketone erastin and piperazine erastin [[Figure 1C](#)], but we observed no resistance to erastin. FIN56 appeared to be a weak P-gp substrate, as A673 B1 cells were about 6-fold resistant [[Table 1](#)]. ABCG2 overexpression did not confer appreciable resistance to any of the FINs examined.

Since P-gp overexpression appeared to confer resistance to some FINs, we validated the results in parental OVCAR8 ovarian cancer cells and P-gp-overexpressing NCI/ADR-RES cells that were derived from OVCAR8 cells by selection with doxorubicin. As shown in [Figure 2A](#), OVCAR8 cells do not express P-gp, as determined with the P-gp-specific monoclonal antibody UIC-2, while NCI/ADR-RES cells express high levels of the transporter, as shown by increased staining with the UIC-2 antibody in NCI/ADR-RES cells. Additionally, rhodamine efflux was observed in the NCI/ADR-RES cells, but not in the OVCAR8 cells. In this model system, when we performed cytotoxicity assays in the presence or absence of 10 μ M valsopodar, a P-gp inhibitor, we observed that P-gp overexpression conferred resistance to imidazole ketone erastin, piperazine erastin, and FIN56, and that valsopodar reversed the resistance. P-gp overexpression in the NCI/ADR-RES line was not found to confer resistance to erastin or erastin2 [[Figure 2B](#) and [Supplementary Table 1](#)], in agreement with the results from the A673 cells.

Deletion of ABCB1 in UO-31 cells increases sensitivity to erastin derivatives

The renal carcinoma cell line UO-31 is known to have detectable levels of P-gp and displays rhodamine efflux^[21]. To determine if the expression of P-gp in this cell line is high enough to confer resistance to imidazole ketone erastin or piperazine erastin, two of the best substrates for P-gp, we performed CRISPR-mediated deletion of *ABCB1* and selected two clones that had lost expression. As shown in [Figure 3A](#), while

^aResults presented are mean GI₅₀ values +/- SEM (μM). Relative resistance (RR) value was determined by dividing the GI₅₀ value for A673 cells expressing a transporter by the GI₅₀ value for the A673 EV cells. Three independent experiments were performed.

UO-31 cells do stain positively with the UIC-2 antibody, as shown by increased staining with the UIC-2 antibody (orange histogram), the two knockout clones, B11 and 1F4, no longer react with the antibody, as detected by flow cytometry. Additionally, we found that the knockout clones no longer efflux the P-gp substrate rhodamine 123, as shown by increased intracellular fluorescence of rhodamine 123 (blue histogram) in the clones, suggesting that the *ABCB1* gene had been deleted. The knockout clones also demonstrate increased sensitivity to the P-gp substrate romidepsin [Figure 3B]. When we performed cytotoxicity assays with imidazole ketone erastin and piperazine erastin, the knockout clones displayed increased sensitivity to both compounds by about 3- to 4-fold compared to parental cells; however, no difference in sensitivity to erastin was noted [Supplementary Table 2]. Similar results were obtained when we performed cytotoxicity assays with imidazole ketone erastin and piperazine erastin in the presence of 10 μM of the P-gp inhibitor valsopodar [Supplementary Tables 1 and 3]. Thus, even relatively low levels of P-gp may cause resistance to the erastin analogs.

Ferroptosis inducers stimulate the ATPase activity of P-gp

The effect of erastin, imidazole ketone erastin, and piperazine erastin on the ATPase activity of P-gp was subsequently examined. While several P-gp substrates and some inhibitors have been shown to stimulate the ATPase activity of P-gp, not all substrates do so. We found that all three of the compounds stimulated the ATPase activity of P-gp to a degree comparable to that of verapamil, which is used as a positive control [Figure 4]. The ATPase stimulation serves as a confirmation of the interaction between imidazole ketone erastin and piperazine erastin and P-gp, given the close connection between ATP hydrolysis and substrate efflux^[22]. While P-gp does not appear to confer resistance to erastin in our studies, erastin does stimulate ATPase activity. This suggests that erastin interacts with P-gp, but likely has a slow off rate, potentially acting more as a weak inhibitor than a substrate.

Ferroptosis inducers inhibit P-gp- and ABCG2-mediated transport

As targeted therapies are known to act as inhibitors of ABC transporters, we next characterized the ability of the FINs to act as inhibitors of P-gp or ABCG2. At a concentration of 10 μM, erastin2, ML-162, GPX4 inhibitor 26a, and PACMA31 inhibited P-gp-mediated rhodamine 123 transport, resulting in a 5- to 10-fold

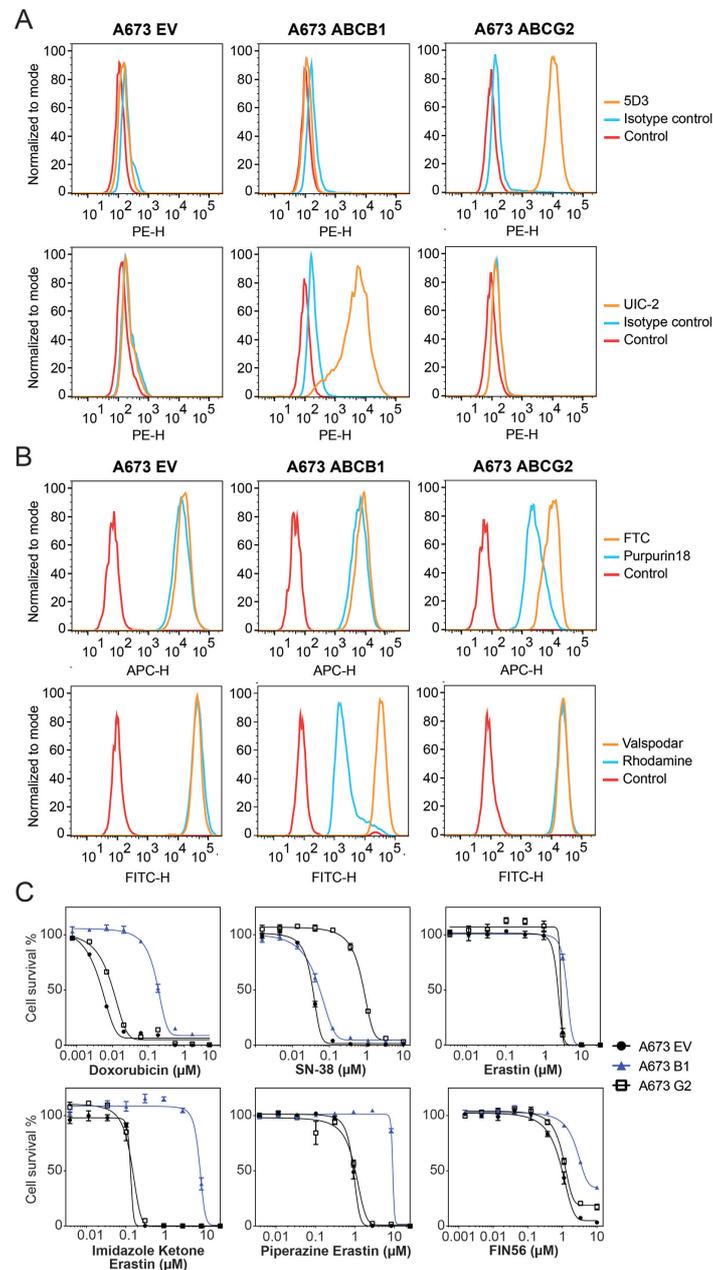

Figure 1. Characterization of A673 cells transfected to express P-gp or ABCG2. (A) Trypsinized A673 EV, B1 or G2 cells were incubated with 2% bovine serum albumin/PBS containing phycoerythrin-labeled antibody to detect ABCG2 (5D3) or P-gp (UIC-2), or the corresponding isotype control antibody for 20 min after which cells were washed in PBS. Control cells (no antibody) are denoted by red curves, isotype control staining is denoted by blue curves, and staining with specific transporter antibodies is denoted by orange curves (ABCG2 top row, P-gp bottom row). Results from one of three independent experiments are shown; (B) Trypsinized A673 EV, B1, and G2 cells were incubated with rhodamine 123 (0.5 $\mu\text{g}/\text{mL}$, for detection of P-gp) or purpurin-18 (15 μM , for detection of ABCG2) with or without appropriate inhibitor (10 μM valspodar for P-gp; 10 μM FTC for ABCG2) for 30 min, after which media was removed and replaced with substrate-free medium continuing with or without inhibitor for an additional 1 h. Cell autofluorescence (control) is denoted by red histograms, substrate efflux is denoted by blue histograms and cells with substrate and inhibitor are denoted by orange histograms. Results from one of three independent experiments are shown; (C) Three-day cytotoxicity assays were performed on A673 EV, B1, and G2 cells with doxorubicin, SN-38, erastin, imidazole ketone erastin, piperazine erastin and FIN56. Results from one of three independent experiments are shown and results are summarized in [Table 1](#).

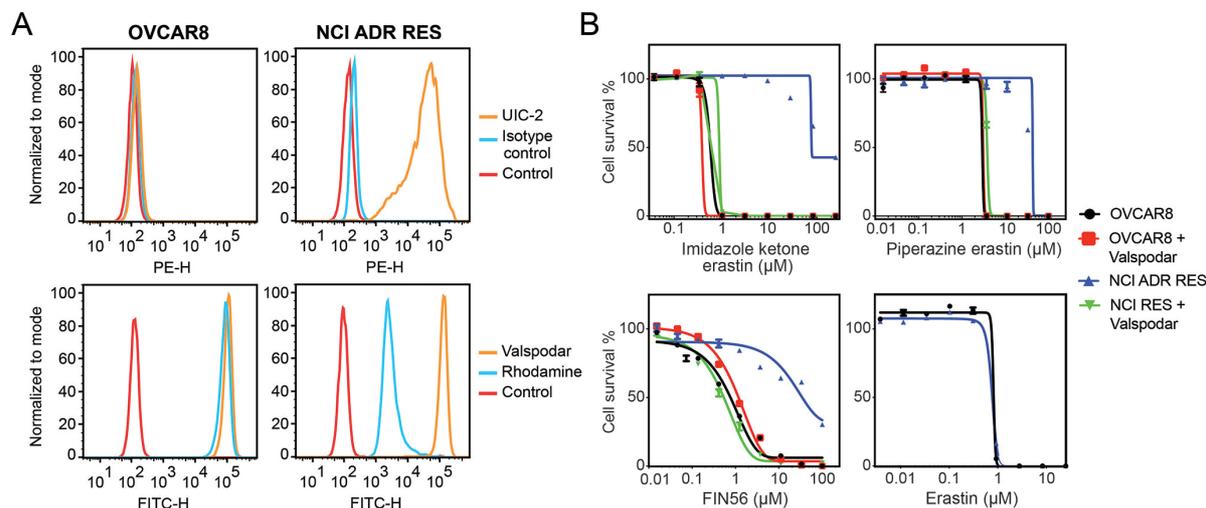

Figure 2. The OVCAR8 and NCI/ADR-RES cell line pair confirm P-gp substrates. (A) Trypsinized OVCAR8 or NCI/ADR-RES cells were incubated with 2% bovine serum albumin/PBS containing phycoerythrin-labeled UIC-2 antibody to isotype control antibody for 20 min, after which cells were washed in PBS and read on a flow cytometer. Control cells (no antibody) are denoted by red curves, isotype control staining is denoted by blue curves, and P-gp staining is denoted by orange curves (ABCG2 top row, P-gp bottom row). Results from one of three independent experiments are shown; (B) Three-day cytotoxicity assays were performed on OVCAR8 and NCI/ADR-RES cells with imidazole ketone erastin, piperazine erastin, FIN56 or erastin. Where noted, the P-gp inhibitor valsopodar was added at a concentration of 10 μM . Results from one of three independent experiments are shown and results are summarized in [Supplementary Table 1](#).

increase in rhodamine fluorescence in MDR-19 cells [Figure 5A]. In ABCG2-expressing R-5 cells, GPX inhibitor 26a had the greatest effect on purpurin-18 efflux, while piperazine erastin, ML-162, PACMA31 and RSL3 also significantly inhibited purpurin-18 efflux [Figure 5B]. These results suggest that drug-drug interactions might occur during treatment with FINs.

DISCUSSION

Ferroptosis induction by small molecules is a novel way to induce cell death in cancer cells and several cancer cell types are sensitive to ferroptosis induction, such as renal cell carcinoma, diffuse large B-cell lymphomas, as well as many chemotherapy-resistant cancer subtypes^[4,23]. FINs are effective in xenograft mouse models and have been suggested as potential cancer treatments^[6]. Despite the recent proliferation of papers describing novel molecules that can induce ferroptosis^[9-11,24], very few studies have addressed potential interactions with ABC transporters that might limit bioavailability or brain penetration. In our study, we found that the FINs FIN56, imidazole ketone erastin and piperazine erastin are transported by P-gp, suggesting that their oral bioavailability and/or brain penetration may be compromised. Additionally, we found that the FINs ML-162, GPX inhibitor 26a, and PACMA31 act as inhibitors of P-gp. Interestingly, the most potent P-gp inhibitor, GPX inhibitor 26a, was also the most potent ABCG2 inhibitor, suggesting that treatment with FINs may cause drug-drug interactions.

Our findings regarding erastin differ from those of Zhou *et al.* who reported erastin as a P-gp substrate^[25]. However, we note that they used a P-gp-expressing cell line that was generated by gradually increasing exposure to paclitaxel^[25]. While selection with paclitaxel can lead to P-gp overexpression, other mechanisms of resistance can arise^[26]. It cannot be ruled out that other mechanisms besides efflux by P-gp may have caused the resistance to erastin observed by Zhou *et al.* Unfortunately, they did not perform cytotoxicity assays in the presence of a P-gp inhibitor, which would have confirmed the role of P-gp. In contrast, we did not observe erastin resistance in cells that were transfected to express P-gp without selection with an

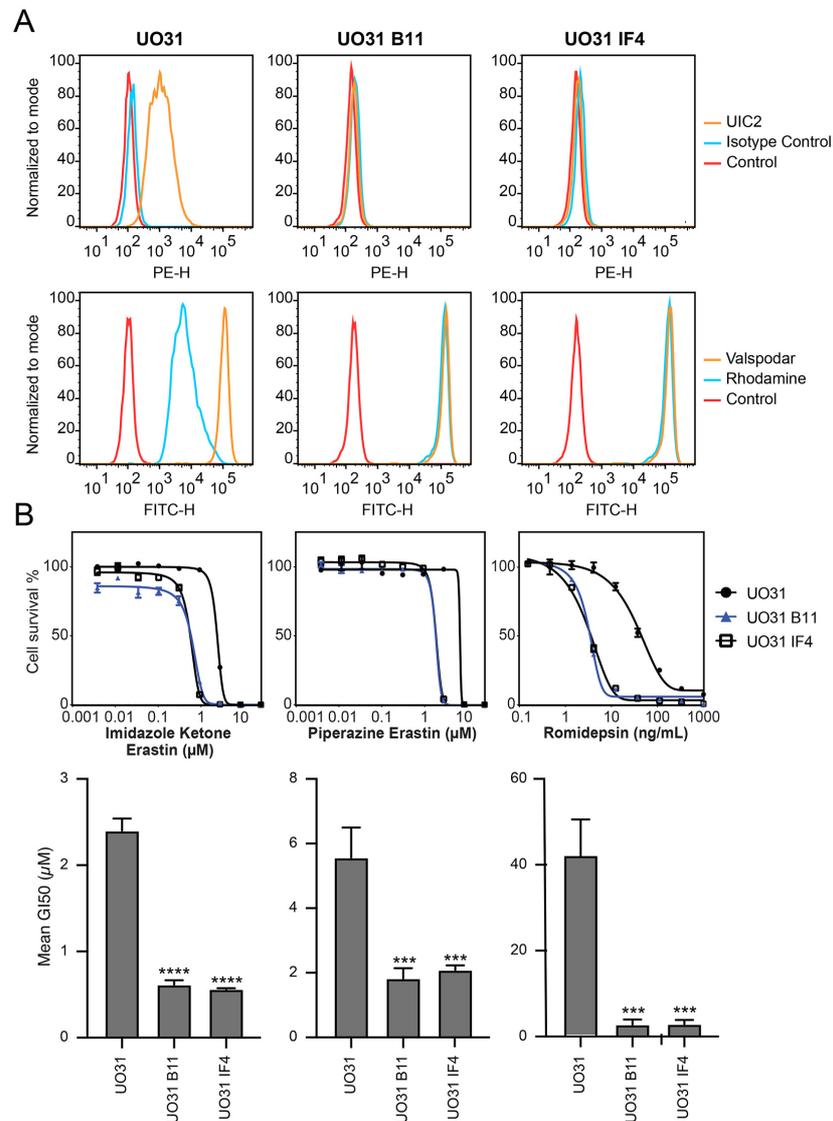

Figure 3. CRISPR-mediated deletion of *ABCB1* sensitizes UO-31 cells to FINs. (A) Top row: UO-31 cells or the *ABCB1* knockout clones (B11, IF4) were trypsinized and incubated with 2% bovine serum albumin/PBS containing phycoerythrin-labeled UIC-2 antibody or isotype control antibody for 20 min after which cells were washed in PBS and read on a flow cytometer. Control cells (no antibody) are denoted by red curves, isotype control staining is denoted by blue curves, and staining with UIC-2 is denoted by orange curves. Bottom row: Cells were incubated with rhodamine 123 (0.5 $\mu\text{g}/\text{mL}$) with or without 10 μM valsopodar for 30 min, after which media was removed and replaced with substrate-free medium continuing with or without inhibitor for an additional 1 h. Cell autofluorescence (control) is denoted by red histograms, rhodamine efflux by blue histograms, and cells with rhodamine and inhibitor are denoted by orange histograms. Results from one of three independent experiments are shown; (B) Three-day cytotoxicity assays were performed on UO-31 cells or the *ABCB1* knockout clones with romidepsin, imidazole ketone erastin or piperazine erastin. Results from one of three independent experiments are shown. GI_{50} values from 3 independent experiments are shown under the representative graphs. Significance was determined by a one-way ANOVA followed by a Dunnett test for multiple comparisons. Asterisks denote significant differences from the parental UO-31 cell line, where *** $P < 0.001$ or **** $P < 0.0001$.

anticancer drug, and this result was confirmed in a selected cell line. We thus conclude that erastin is not a P-gp substrate and that the cell line used by Zhou *et al.* may have another mechanism at work that can confer resistance to erastin^[25].

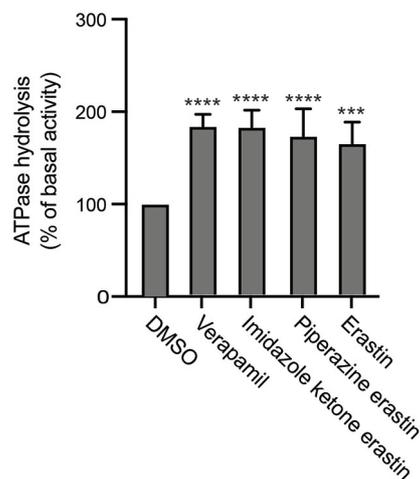

Figure 4. Effect of erastin derivatives on ATPase activity of P-gp. The effect of imidazole ketone erastin, piperazine erastin and erastin or the vanadate-sensitive ATPase activity of P-gp was determined as outlined in Materials and Methods. Basal ATPase activity was compared to that in the presence of 10 μ M concentrations of the compounds; verapamil at 10 μ M served as a positive control for stimulation of ATPase activity. Significance was determined by a one-way ANOVA followed by a Dunnett test for multiple comparisons. Asterisks denote significant differences from the DMSO control, where *** P < 0.001 or **** P < 0.0001.

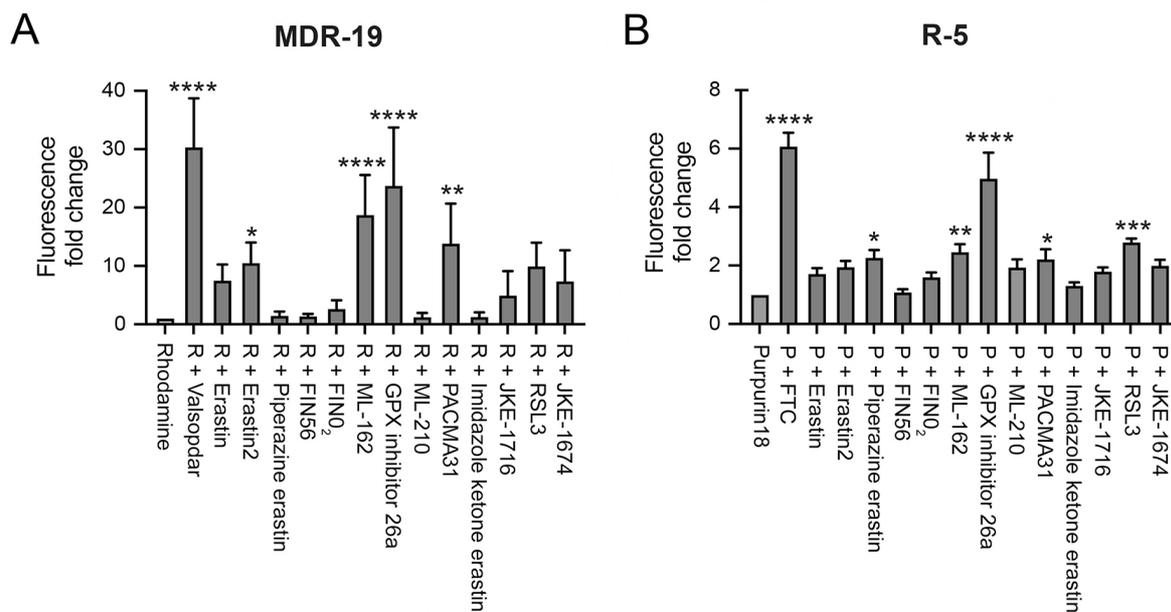

Figure 5. FINs inhibit P-gp and ABCG2 transport activity. P-gp-overexpressing MDR-19 cells (A) or ABCG2-overexpressing R-5 cells (B) were incubated with 0.5 μ M rhodamine 123 or 15 μ M purpurin-18, respectively, in the absence or presence of specific inhibitor (10 μ M valsopodar for P-gp and 10 μ M FTC for ABCG2) or 10 μ M concentrations of the FINs for 30 min after which the medium was removed and replaced with substrate-free medium with or without the inhibitor. Cells were then incubated for an additional 1 h. Inhibition of P-gp or ABCG2 was determined by calculating the fold increase in intracellular fluorescence, with fluorescence levels in cells incubated with rhodamine or purpurin-18 alone assigned a value of 1. Significance was determined from three independent experiments using a one-way ANOVA followed by a Dunnett test for multiple comparisons. Asterisks denote significant difference from the rhodamine or purpurin-18 control, where * P < 0.05, ** P < 0.01, *** P < 0.001, or **** P < 0.0001. P: Purpurin-18; R: rhodamine.

It is not surprising that the FINs, which are essentially targeted therapies, interact with drug transporters, as many targeted therapies have been shown to either be substrates or inhibitors of P-gp or ABCG2^[27]. The

BCR-ABL inhibitors imatinib, nilotinib, dasatinib, and bosutinib have been found to be substrates of P-gp and ABCG2 at low concentrations, while they act as inhibitors of the proteins at higher concentrations^[28-31]. Overexpression of *ABCB1* has been demonstrated in tumor samples obtained from patients whose tumors have developed resistance to the ALK inhibitor ceritinib in the absence of secondary ALK mutations^[32]. Ceritinib has also been reported to inhibit P-gp- and ABCG2-mediated transport^[33]. Additionally, both P-gp and ABCG2 have been shown to confer resistance to several structurally different aurora kinase inhibitors^[34,35].

The ability of P-gp and ABCG2 to affect brain penetration of targeted therapies has most dramatically been demonstrated in mouse models in which the *ABCB1* homologs *Abcb1a* and *Abcb1b* are knocked out, the ABCG2 homolog *Abcg2* is knocked out, or all of the homologous transporters have been deleted. Brain concentrations of the Janus kinase 1/2 inhibitor momelotinib 24 h after oral administration were 6.5-fold, 3-fold and 48-fold higher in mice deficient in *Abcg2*, *Abcb1a/b*, or *Abcg2;Abcb1a/b*, respectively, compared to control mice^[36]. Similarly, 24 h after oral administration of the BCR-ABL inhibitor ponatinib, brain concentrations were 2.2-fold, 1.9-fold and 25.5-fold higher in mice deficient in *Abcg2*, *Abcb1a/b*, or *Abcg2;Abcb1a/b*, respectively, compared to wild-type controls^[37]. Thus, P-gp and ABCG2 can have a profound effect of limiting brain penetration of targeted therapies that are substrates of the transporters. Brain accumulation or oral bioavailability of FIN56, imidazole ketone erastin or piperazine erastin could similarly be affected, as they were found to be transported by P-gp.

In conclusion, we have demonstrated that the FINs FIN56, imidazole ketone erastin, and piperazine erastin are substrates of P-gp, suggesting a potential reduction in oral bioavailability and brain penetration. ML-162, GPX inhibitor 26a and PACMA31 were found to inhibit the transport activity of P-gp and/or ABCG2, suggesting potential drug-drug interactions. Thus, our findings will be valuable as these compounds are pursued clinically.

DECLARATIONS

Abstract

Prostate cancer is the second most prominent form of cancer in men and confers the highest mortality after lung cancer. The term “extracellular vesicles” refers to minute endosomal-derived membrane microvesicles and it was demonstrated that extracellular vesicles affect the environment in which tumors originate. Extracellular vesicles’ involvement is also established in the development of drug resistance, angiogenesis, stemness, and radioresistance in various cancers including prostate cancer. Extracellular vesicles influence the general environment, processes, and growth of prostate cancer and can be a potential area that offers a significant lead in prostate cancer therapy. In this review, we have elaborated on the multifaceted role of extracellular vesicles in various processes involved in the development of prostate cancer, and their multitude of applications in the diagnosis and treatment of prostate cancer through the encapsulation of various bioactives.

Keywords: Extracellular vesicles, prostate cancer, stemness, chemoresistance, therapeutic delivery, diagnosis

INTRODUCTION

One of the most common forms of cancer identified in men is prostate cancer (PCa), which is also one of the deadliest, the second most common type of cancer in men after lung cancer, and the fifth most prevalent

mortality cause in males^[1]. In the United States of America alone in 2021, more than 248,000 instances of PCa were identified in men, and just under 34,000 fatalities were attributed to the disease^[2]. Over 1.4 million cases worldwide were reported, with more than 300,000 deaths related to PCa^[3]. Currently, multiple treatment strategies are used against PCa. These therapies include surgery, radiation therapy, active surveillance, and proton therapy. Apart from these, other strategies including chemotherapy, hormonal therapy, cryosurgery, and HIFU (high-intensity focused ultrasound) are also part of the current treatment regime based on the clinical conditions and outcomes^[4-10]. Active surveillance emerged as the management option for the low-risk PCa and various strategies were developed for the same^[11]. Urological guidelines proposed various treatment options depending on the stage of PCa. For example, patients with low-risk diseases are offered active surveillance and active treatment such as surgery or radiation therapy. For immediate-risk disease patients, radical prostatectomy, radiotherapeutic therapy, and pelvic lymph node dissection is the treatment option. The same treatment option applies to patients with high-risk localized disease. In addition, radiotherapy and surgery are used as a treatment for locally advanced disease^[12]. Hormonal therapy, also known as androgen deprivation therapy (ADT), is a traditional and standard therapy against PCa for over 60 years and shows its effect through the decrease in serum testosterone^[13]. Hormonal therapies have also shown combinative strategies with other standard treatment options such as radiotherapy, non-invasive treatments through medications, and hormonal therapy with surgery^[14,15]. Hormonal therapy with drugs in prostate cancer provides effective tumor growth and progression control, boosting patient outcomes and quality of life. At present, commonly used medications in hormonal therapy involve drugs such as enzalutamide, abiraterone, goserelin, bicalutamide, *etc.*^[16-21].

Following hormonal therapy for a while, the tumor develops into metastatic castration-resistant PCa (mCRPC), which has a low rate of survival and few treatment options^[22-24]. The manner in which multilaminar bodies, particularly extracellular vesicles, influence the general environment, the processes, and the expansion of PCa cells is one of the areas that has demonstrated a significant amount of potential when it comes to the treatment of PCa.

The term “extracellular vesicles” was primarily used by Rose Johnstone and her colleagues in 1970 to refer to minute endosomal-derived membrane microvesicles^[25,26]. Extracellular vesicles offer several advantages, such as the ease of therapeutic cargo loading (drugs, siRNA), the ability to penetrate through biological barriers, low immunogenicity, ease of cellular uptake, ease of surface modification, *etc.*^[27]. However, limitations such as difficulty in obtaining high quantities of pure extracellular vesicles, purification process, and disadvantages pertaining to various isolation techniques limit the application of extracellular vesicles in drug delivery. The advantages and disadvantages associated with extracellular vesicles are graphically depicted in [Figure 1](#)^[28].

Substantial numbers of researchers concentrated their attention on the roles of extracellular vesicles in the act of tumors. There is a lot of interest in how extracellular vesicles affect the environment in which tumors originate, the role that extracellular vesicles play in the progression of drug resistance in cancer cells in response to anti-cancer medications, and the role that extracellular vesicles can play in mitigating the effects of cancer and perhaps halting the process of cancer growth as well as their potentially intricate role in the delivery of chemotherapeutic agents and other bioactives in the tumor cells. Extracellular vesicles, which initially were considered molecular waste bins, now have shown a multifaceted role in cancer. Extracellular vesicles serve a significant function in angiogenesis through the transport of various pro-angiogenic biomolecules, such as vascular endothelial growth factor (VEGF), microRNAs, and matrix metalloproteinases (MMPs), and also act as key agents in metastasis through their involvement in restructuring metastatic sites to support cancer cell colonization^[29-31]; Extracellular vesicles have a key role as

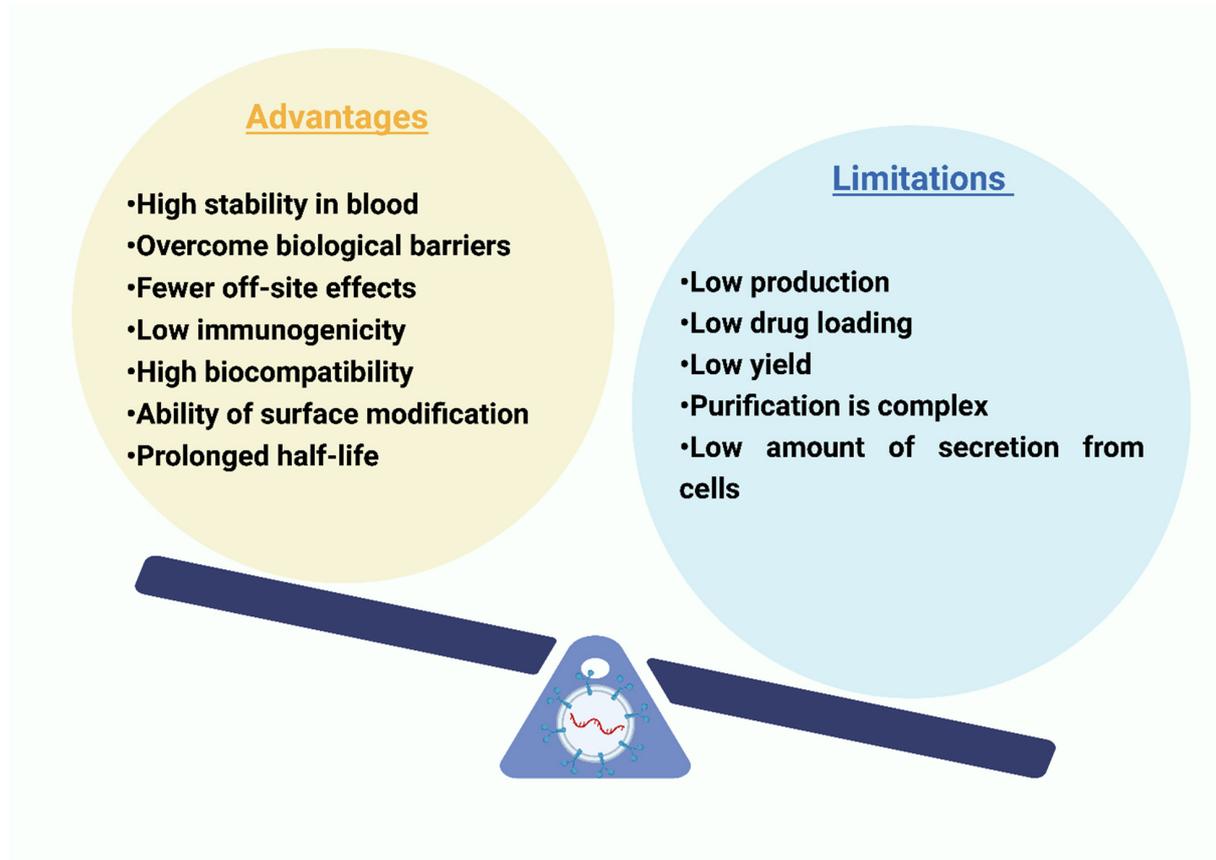

Figure 1. Graphical representation of advantages and limitations of extracellular vesicles.

biomarkers in the cancer development through its components including proteins, nucleic acids and also from other biofluids [Table 1]^[32]. While talking about the exosomal role in PCa, they have been indulged in acting as the key agent in the progression of PCa through numerous mechanisms including changes in the tumor microenvironment and angiogenesis, through the metastasis and cell proliferation, and in the drug resistance in PCa tumor^[33-43].

In this review article, we have described the multifaceted functions that extracellular vesicles play in PCa. This review focuses on the pro-tumorigenic role of extracellular vesicles in the key processes engaged in the development of PCa, such as stemness, chemoresistance, radioresistance, angiogenesis, and metastasis. Furthermore, the application of extracellular vesicles in the diagnosis and delivery of therapeutic moieties such as the siRNA, drugs, and phytoconstituents are also elaborated in this review.

PRO-TUMORIGENIC ROLE OF EXTRACELLULAR VESICLES IN PCa

Role of extracellular vesicles in stemness of PCa

Stemness refers to the phenomenon that defines the cells' capability of self-renewal and differentiation^[61]. It is a characteristic ability shown by adult stem cells to proliferate, and bolster their new generation of daughter cells and also interact with their environment to maintain a balance between quiescence, proliferation, and regeneration^[62]. In the case of cancer stem cells (CSCs), this phenomenon acts as a malignant equivalent to normal stem cells. Apart from the common features such as maintenance, sustainability, supporting the microenvironment, and self-renewal, the essential differences found in the

Table 1. List of biomarkers from extracellular vesicles in prostate cancer

Biomarkers from extracellular vesicles		The role played in prostate cancer	Cell line/ model used	References
Proteins	HSP70	Provides drug resistance, promotes invasion, stemness, and metastasis	PC3 and LNCaP	[44-46]

cancer stem cells refer to extra features that include heterogeneity in the cell population, high resistance towards hostile factors like quiescence, chemotherapeutic agents, hypoxia and low nutrient levels^[62-67].

Stemness plays an influential role in the development of PCa. The prostate stem cells reside in the basal and luminal layers and are a major target for the oncogenic transformation which suggests a role in the genesis of PCa^[68]. CSCs demonstrated an altered gene expression in exposure to hypoxia, nutrient deficiency, and oxidative stress, rendering them more mobile, invasive, and resilient to further stress. CSCs are anticipated to have endured epithelial-mesenchymal transition + , and the transition to mesenchymal marker expression is frequently one measurement of PCa progression. CSCs are predicted to invade locally and then metastasize^[69].

Extracellular vesicles portray a substantial part in the stemness of PCa. They have been shown to be involved in multiple features exhibited by PCa stem cells, such as resistance against hypoxia and tumor progression, promotion of epithelial-to-mesenchymal transition (EMT), and also the transformation of other stem cells into cancer stem cells. Ramteke *et al.* in their work discovered that extracellular vesicles derived from hypoxic PCa cells promote the cancer-associated fibroblast (CAF) phenotype in prostate stromal cells, and also elevate the property of stemness and protruding of naïve PCA (PCa) cells. They subjected human PCA PC3 and LNCaP cells to normoxic and hypoxic conditions, respectively, and extracted the extracellular vesicles released in both situations. They observed increased amounts of Annexin II, heat shock proteins (HSP90 and HSP70), and tetraspanins (CD63 and CD81) in hypoxic extracellular vesicles, which led to LNCaP and PC3 cell invasiveness and motility. Aside from that, they discover an increased amount of metalloproteins as well as increased levels of various signaling molecules. Further, in proteome analysis, they found an increased number of proteins in hypoxic extracellular vesicles, which promotes epithelial adheres junction pathway remodeling and proteins, especially in naïve PC3 cells. This study overall suggests how extracellular vesicles promote the stemness of PCa cells, affecting significant

features such as invasiveness and tumor microenvironment, leading to aggressive PCa^[44]. In another study, it was found how extracellular vesicles containing PSGR (Prostate-specific G-protein coupled receptor) promote the migration, invasiveness, and stemness of low-aggressive PCa cells. They used transcriptome sequencing to determine the differentially expressed (DE) mRNAs in low invasive cells incubated with overly expressed PC3 extracellular vesicles or negative control (NC) extracellular vesicles. They also discovered that the PSGR was stably overexpressed in PC3 cells. Internalization of PC3 PSGR + extracellular vesicles in LNCaP and RWPE-1 cells greatly promoted cell migration and invasion. After PC3 PSGR + exosome incubation, E-cadherin expression declined, while vimentin, Snail, SOX2, and OCT4a expression elevated in low invasive cells. This resulted in findings indicating that extracellular vesicles released via PCa cells induce invasiveness and stemness^[70]. An interesting study was published talking about how extracellular vesicles derived from PCa cells promoted the neoplastic reprogramming of adipose stem cells derived from the patient. They identified that extracellular vesicles obtained from PCa facilitated the transformation of adipose stem cells into neoplastic cells in the patient due to changes in the cell microenvironment. They observed that pASCs (PCa patients derived adipose-stem cells) primed with PCa cell conditioned media (CM) produced prostate-like neoplastic lesions in vivo and replicated aggressive tumors in secondary recipients, in contrast to normal ASCs (adipose-stem cells). The cytogenetic aberrations and mesenchymal-to-epithelial transition of the pASC tumors, along with the expression of epithelial, neoplastic, and vasculogenic markers, were evocative of molecular features of PCa tumor xenografts. This suggests that extracellular vesicles play a tremendous role in not only promoting the stemness, invasiveness, and growth of PCa cells but can also be an agent advocating the transformation of other stem cells into oncogenic cells^[71-73].

Extracellular vesicles in drug resistance and radioresistance of PCa

Extracellular vesicles and drug resistance

The development of resistance to treatment drugs has been an extremely difficult obstacle to overcome in PCa treatment^[43,74]. The use of chemotherapy is still considered to be one of the more traditional methods for treating advanced PCa^[5]. However, it has been demonstrated that several variables, including the heterogeneity of the tumor, epigenetic control by miRNAs, and the combinatorial outcomes of various signaling pathways, including NF- κ B/IL-6, Hedgehog, mTOR (mammalian target of rapamycin), Akt/PI3K, MAPK/ERK, and somatostatin receptors, all of these elements result in drug resistance in tumor cells^[75-79].

According to numerous research, extracellular vesicles are involved in the development of medication resistance in PCa^[42,74,80]. Extracellular vesicles have been discovered as the mechanism underlying resistance against the drug enzalutamide, and in PCa, the emergence of therapy-induced neuroendocrine differentiation stages, as demonstrated by Bhagirath *et al.* in their research^[74]. In addition, it was observed that BRN2 and BRN4, which are neural transcription factors, were liberated in PCa extracellular vesicles after the treatment with enzalutamide. These transcription factors are essential for the neuroendocrine remodeling of prostate adenocarcinomas^[74,81,82]. Kharaziha *et al.* discovered with the usage of nanoparticle tracking analysis that a greater quantity of extracellular vesicles released by DU145 PCa cells docetaxel-resistant than by DU145 PCa docetaxel-sensitive cells^[80]. Extracellular vesicles were shown to be responsible for resistance against docetaxel in docetaxel-susceptible PCa cells (DU145, LNCaP, and 22Rv1)^[42]. Following administration of the cells with docetaxel-resistant extracellular vesicles versions of 22Rv1 and DU145 (22Rv1RD and DU145RD, respectively), authors observed the liberation of MDR-1/Pgp, which is a multidrug resistance protein 1/P-glycoprotein and this transporter protein engaged in the efflux of a wide range of exogenous objects, including antineoplastic medications, from extracellular vesicles, played a probable role in imparting resistance to docetaxel-susceptible cells^[42]. Another study looked through an interesting pathway to study the chemoresistance in PCa cells. In the study, exosome-derived miR-27a, which portrays a substantial role in chemoresistance in cells of PCa, was examined. When administered

with doxorubicin, cisplatin, and docetaxel in PCa cells, there was a tremendous spike in the levels of the miR-27a; they also co-treated PC3 cells (PCa cells) with primary prostate fibroblasts (PSC27 cells) to analyze tumor treatment resistance mechanisms. The results additionally demonstrate that exosome-derived miR-27a produced by PSC-27 cells enhanced chemoresistance by suppressing P53 gene expression^[35]. Although it is not the commonly observed pathway for drug resistance, Saari *et al.* in their research made an interesting discovery. They observed that using two contrasting populations of extracellular vesicles (microvesicle- and exosome-enriched) as paclitaxel carriers in autologous PCa increased the cytotoxicity effect of the paclitaxel, regardless of the fact that cancer cell viability increased without the vesicles, but the overall net cytotoxicity effect remained increased. They also observed that this phenomenon was irrespective of the EV population and cell lines tested^[83].

In recent years, various studies demonstrated the role played by the extracellular vesicles in the development of drug resistance in PCa. Shan *et al.* observed that miRNA-423-5p from extracellular vesicles, which was secreted from cancer-associated fibroblasts, was promoting chemoresistance in prostate cancer. They observed that miRNA-423-5p from extracellular vesicles promoted chemoresistance through inhibition of GREM2 via the TGF- β pathway for taxane derivatives while suppressing the TGF- β pathway was able to partially reverse the chemoresistance^[84]. In another study, Kato *et al.* utilized the serum extracellular vesicles containing CD44v8-10 mRNA as the diagnostic marker for docetaxel resistance in prostate cancer. The results showed that the levels of CD44v8-10 protein and mRNA in cell lysates and extracellular vesicles were higher in PC-3R cells, which was a docetaxel-resistant cell line compared to normal PC-3 cells. This showed that CD44v8-10 protein had a role in the development of chemoresistance^[85]. The role of syntaxin-6-mediated extracellular vesicles in the regulation of enzalutamide resistance in prostate cancer was demonstrated. The authors observed that the enzalutamide-resistant cell lines (CWR-R1, C4-2B, and LNCaP) had a higher amount of extracellular vesicle secretion (about 2-4) times than the enzalutamide-sensitive cells. The observed mechanism underlying was found to be the upregulation of syntaxin-6 accompanied by the increase in colocalization with CD-63 in enzalutamide resistance cell lines. They also observed that knocking down syntaxin-6 with siRNAs resulted in a reduction in cell count and an enhancement in cell death in the presence of enzalutamide^[86].

Extracellular vesicles and radioresistance

Apart from the drug resistance shown in PCa in the above section, extracellular vesicles are also associated with radioresistance in PCa^[87]. In the case of PCa, following the radiation therapy, increased levels of HSP72-containing extracellular vesicles were found in PCa, leading to the conclusion that HSP72-containing extracellular vesicles are a possible patron, leading to pro-inflammatory cytokine production and immune modulation^[88]. Other than this, another phenomenon was observed in the cancer stem cells that tend to show more resistance against radiation therapy. This allows the production of extracellular vesicles that will deliver the resistance phenotype to recipient cells^[87]. This will allow for the formation of more resistant cancer cells to radiation therapy. Regarding PCa, research has demonstrated the presence of extracellular vesicles released from prostate stem cells; these vesicles have the capacity for autophagy and can also modulate the sensitivity towards radiation therapy^[89,90]. All of this suggests a strong negative role of extracellular vesicles not only as a key agent against drug and chemoresistance, but extracellular vesicles also play a quintessential role in the emergence of resistance against radiation therapy in PCa^[91]. Radiation therapy, still one of the mainstream therapies for the treatment of cancer across all types, can affect the release of content from extracellular vesicles, which has already been affected by the composition and abundance of the extracellular vesicles, affecting the extracellular vesicle-based intracellular communication.

Extracellular vesicles in metastasis of PCa

Aside from their influence at metastatic locations, tumor-derived extracellular vesicles have been shown to have a role in the invasion, development, and metastasis of tumors by interacting with cells at isolated, pre-metastatic organ locations^[92,93]. This transpires through the establishment of tumor-nurturing microenvironments, a technique known as “pre-metastatic niche generation”. The formation requires protracted intercellular communication facilitated by soluble or membrane-bound proteins originating from the original tumor^[94-96].

The tumor-originated extracellular vesicles are responsible for the extracellular matrix (ECM) remodeling via the accumulation of fibronectin and the promotion of crosslinking by the ECM-modifying enzyme lysyl oxidase (LOX). This is done with the intention of improving bone marrow-derived cell adherence, which is a critical component of the pre-metastatic niche. To improve the adherence of bone-marrow-derived cells, tumor-originated extracellular vesicles remodel the ECM through the aggregation of fibronectin and crosslinking ECM^[97-99].

Intriguingly, new research conducted by Henrich *et al.* indicates convincingly that homeostasis of cholesterol in bone marrow myeloid cells is the mediator of communication between bone marrow and PCa cells through extracellular vesicles. They observed that bone marrow myeloid cells absorb PCa extracellular vesicles, leading to an activated NF- κ B signaling, improved osteoclast formation *in vitro* and *in vivo*, and lessened myeloid thrombospondin-1 expression^[100]. A tailored biomimetic strategy involving myeloid cells *in vitro* and *in vivo* lowering cholesterol levels prevented PCa EV uptake by recipient myeloid cells, eliminated NF- κ B activity, maintained thrombospondin-1 expression, decreased osteoclast differentiation, and yielded a 77% reduction in metastatic burden^[100]. During early stages of metastasis, the EMT is a pivotal critical step. This state is triggered by tumor-derived extracellular vesicles’ autocrine and paracrine signaling and targeting proteins such as transforming growth factor-beta (TGF- β) and catenin, which are EMT-related proteins^[101,102]. Extracellular vesicles derived from PCa DU145 and PC3 cells generate a type of TGF- β capable of initiating fibroblast-myofibroblast transformation by activating the TGF-SMAD signaling pathway. This TGF- β is also capable of promoting tumorigenesis and inhibiting immune response^[103,104]. McAtee *et al.* showed in their research that prostate tumor cells containing extracellular vesicles have a protein called hyaluronidase 1 (Hyal1) in them. This protein encourages the relocation of prostate stromal cells, which ultimately speeds up the evolution of PCa^[105]. Research conducted by Josson *et al.* showed that the microRNA miR-409, which has a crucial part in the EMT in PCa, was observed in stromal-derived extracellular vesicles^[106]. Furthermore, integrins are known to play a role in metastasis and progression of cancer, and in PCa, the $\alpha_v\beta_6$ integrin is shown to enhance the ab

ility to migrate^[107]. Furthermore, the integrins derived from extracellular vesicles are also known to play a role in angiogenesis^[108]. In a research study, the proteins Integrin Subunit Alpha 3 (ITGA3) and Integrin Subunit Beta 1 (ITGB1) were found in extracellular vesicles recovered from LNCaP and PC3 cells, released in the urine of PCa patients, both of them contributing to the diaspora and invasion of both tumors^[109]. It is worth noting that Elmaged *et al.* reported that exosome-derived miR-130b, miR-125b, and miR-155 promote mesenchymal-epithelial transition (MET) and neoplastic transformation and stem cells isolated from PCa patients’ adipose tissue^[71]. Honeywell *et al.* illustrated in their research how miR-105 obtained from tumor-derived extracellular vesicles serves as a tumor suppressor and targets the cyclin-dependent kinase 6 (CDK6), which suppresses the cell proliferation^[110]. Another interesting route was discovered, bolstering a pathway for metastasis in PCa. It was also demonstrated that androgen receptors were expressed by PCa cells-derived extracellular vesicles, which, after nuclear localization, led to enhanced cell proliferation^[111]. Metastasis of lymph nodes to distant organs can be observed through the probable mediation of extracellular vesicles. Even though a mystery is shrouded suggesting the initiation of this

process by which tumor cells, it is possible that lymph node metastasis could occur through extracellular vesicles. The authors of the research, Maolake *et al.*, revealed that the tumor necrosis factor- α (TNF- α) provides a huge contribution towards metastasizing PCa lymph nodes using LNCaP, DU145, LNCaP-SF, and PC3 cell lines of PCa can be seen through the activation of chemokine (C-C motif) ligand 21/CC chemokine receptor 7 (CCL21/CCR7) axis and this discovery may mediate the influence that extracellular vesicles have on metastasis through the lymphatic pathway^[112]. Furthermore, in another research conducted, it was discovered that from the PC3, DU145, CWR-R1 PCa, and LNCaP cells, which were derived from designated metastatic PCa cell lines, integrin alpha 2 subunits (ITGA2) were found packaged in extracellular vesicles. The fact that inhibiting the release of extracellular vesicles to recipient cells in these metastatic PCa cells by knocking down ITGA2 revealed a possible function for ITGA2 in contributing to the development of the illness and the aggressive phenotypes found in PCa. With an elevated Gleason Score of 9, lymph node metastatic tissues were found to have higher ITGA2 expression than lower Gleason Score of 7 PCa tissues, implying that ITGA2 may play a role in enhancing lymph node metastasis^[49]. Furthermore, no notable differences were observed in ITGA2 protein expression levels between 24 primary PCa tissues and their matched metastatic lymph node tissues. Regardless of the fact that there were no key differences, this was the case.

Role in progression and angiogenesis

Extracellular vesicles are released constitutively by tumor cells of diverse sources. These extracellular vesicles play essential roles in the transformation of tumors into malignant forms and the progression of cancers. Extracellular vesicles' effects are mediated by the transfer of cargo, which includes a range of proteins as well as RNA (including miRNAs) and DNA^[113,114]. Cancer cells essentially require to sustain their attributes, such as immortality, continued proliferative activity, evasion of immune reactions, angiogenesis, continued invasion and metastasis, and resistance to cell death or apoptosis. The tumor microenvironment supplies this medium, which includes tumor stromal cells such as mesenchymal stromal cells, fibroblasts, pericytes, and immune cells such as T & B lymphocytes. They serve as the growth medium for the tumor cells, which are located within the tumor. The transformation of normal stroma cells into reactive stroma cells, which promotes the growth of cancer cells as well as metastasis, is a feature that is distinctive of the progression of cancer. After being impacted, the stromal cells will employ extracellular vesicles to regulate the microenvironment of the tumor, therefore promoting both the development of the tumor and its ability to metastasize^[115-117]. TME extracellular vesicles now perform the role of cellular communicators in addition to assisting with a range of activities. In the instance of PCa, DeRita *et al.* discovered that protein Src was found in PCa cell extracellular vesicles. Through integrin activation, this protein activates focal adhesion kinase, which leads to angiogenesis and metastasis^[34]. Eventually, tumor cells and the stromal cells that are in close vicinity will engage in a persistent kind of interaction^[115]. By encouraging the differentiation of fibroblasts into a myofibroblast-like phenotype that produces angiogenesis and tumor development, cancer extracellular vesicles that contain TGF- β play critical roles in the generation of stroma that promotes the growth of tumors^[30,118]. The TGF- β /SMAD3 cascade has to be activated to produce this effect. The extracellular vesicles that are produced by PCa cells have a high level of latent TGF- β expression. Through focal adhesion kinase via integrin activation, this protein triggers metastasis and angiogenesis^[119,120].

The production of extracellular vesicles by PCa cells enables the delivery of sphingomyelin and CD147 into endothelial cells, which facilitates cancer cell migration and endothelial cell pro-angiogenic activity^[121-122]. Proteins such as c-Src tyrosine kinase, IGF-R (insulin-like growth factor 1 receptor) and FAK (focal adhesion kinase) all play imperative roles in the formation and advancement of prostate tumors^[6,15,34,123-125]. Extracellular vesicles derived from PCa exhibit significant concentrations of these proteins. Angiogenesis is stimulated by the cross-talk that occurs between Src and IGF-1R^[34,126]. Extracellular vesicles rich in Src have been shown to have the ability to stimulate angiogenesis in animal models that have prostate tumors. This is

because Src is overexpressed within plasma extracellular vesicles of mice with prostate tumors. Furthermore, Src and IGF1-R affect angiogenesis by activating VEGF and VEGF-C, respectively^[127,128]. This is the case for both of these and focal adhesion kinase, which, if activated, leads to metastasis and angiogenesis^[34,129]. Cancer extracellular vesicles that contain TGF- β play critical roles in the formation of stroma that is favorable to the development of tumors. These extracellular vesicles encourage the differentiation of fibroblasts into a myofibroblast-like phenotype, which in turn stimulates angiogenesis and tumor expansion^[130-131]. The activation of the TGF- β /SMAD3 cascade is the mechanism by which this impact is produced^[132]. PCa cells are responsible for producing extracellular vesicles that have a high level of latent TGF- β expression. This latent TGF- β adheres to the exosome surface via proteoglycans, promoting the activation of SMAD3-dependent signaling cascades^[133,134]. **Figure 2** shows a graphical representation of pro-tumorigenic characteristics of extracellular vesicles in PCa.

THE ROLE OF EXTRACELLULAR VESICLES IN THE DIAGNOSIS AND THERAPY OF PCa

Utilization of extracellular vesicles in the of PCa diagnosis-recent advances

On the positive side, extracellular vesicles are widely studied for the diagnosis and therapy of PCa^[135,136]. The extracellular vesicles derived from the urine, plasma, and semen^[40,137,138] have been utilized for the diagnosis of PCa. Several studies demonstrated the utilization of extracellular vesicles in PCa diagnosis^[39,139-141]. A recent clinical investigation revealed that PCa patients may be discriminated from both Benign Prostate Hyperplasia (BPH) and healthy subjects by the expression of PSA on plasmatic extracellular vesicles. In a study, it was demonstrated as a new strategy for differentiating not just PCa from healthy persons but also from benign hypertrophy^[142]. In another study, it was found that extracellular vesicles from individuals with PCa exhibited overexpression of CA IX levels, which is related to intraluminal pH, as compared to healthy persons, and demonstrated that the PCa extracellular vesicles are acidic in nature and can be used as a biomarker in PCa^[143]. Since the literature depicts the use of extracellular vesicles in the diagnosis of PCa, in this review, we will focus on the latest advances in extracellular vesicles for the diagnosis of PCa. Li *et al.* developed a superparamagnetic conjunctions and molecular beacons (SMC-MB) based platform in which it detected and captured the prostate-specific membrane antigen-positive extracellular vesicles, thereby depicting its efficiency in the diagnosis of PCa^[144].

In another study, an economical, easy, and non-invasive method was developed for diagnosing PCa in which the extracellular vesicles containing surface proteins and miRNAs from extracellular vesicles were detected at the same time and permitted the analysis of particular miRNAs and surface proteins through one reaction^[145]. A nanoplatform for specific and quick detection, which consists of off-on signal responses and reversible conjunction, was developed in which high-affinity particles of Fe₃O₄@SiO₂@TiO₂ were employed for exosome capture and selectivity was improved through the fluorescence response PMSA aptasensor which aid in the tumor exosome detection. The study concluded that this method was fruitful for quick diagnosis^[146]. In another study reported, a microfluidic Raman biochip with immunoassay was developed for the separation and analysis of extracellular vesicles. This chip was able to differentiate the samples of PCa patients and normal samples. Furthermore, this system detected the extracellular vesicles in one hour and thus can be explored as the detection test for PCa^[147]. In summary, here we discussed some of the recent advances in the utilization of extracellular vesicles for the diagnosis of PCa. To the best of our knowledge, extracellular vesicles have been extensively utilized for the detection of PCa, and various advances such as the Raman chip and others have also been developed and employed for much rapid, non-invasive and sensitive analysis of the samples. Soon, various additional options will be developed to enhance diagnosis using extracellular vesicles.

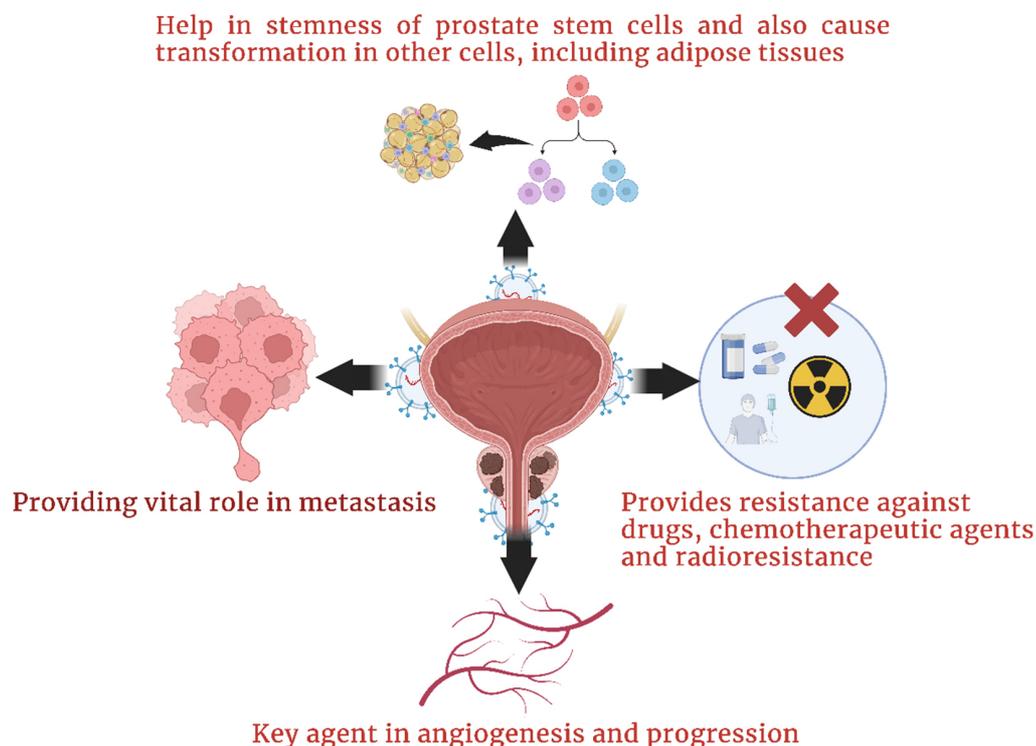

Figure 2. Graphical representation of the pro-tumorigenic characteristics of extracellular vesicles in PCa.

Extracellular vesicles in the PCa therapy

Another such advantage is its application in drug delivery. Owing to their advantages over conventional delivery systems, such as their high ability to overcome biological barriers, enhanced stability, better targeting, unnecessary accumulation in the liver, and low toxicity, extracellular vesicles are widely utilized for the delivery of drugs as well as other therapeutic moieties such as siRNA, phytoconstituents^[28,148]. The extracellular vesicles are obtained from various cells, such as tumor cells, immune cells, and mesenchymal stem cells, and are also derived from bovine milk. Of these, the extracellular vesicles derived from mesenchymal stem cells and tumor cells are widely explored for therapeutic purposes^[149]. In this section, the role of extracellular vesicles in the delivery of various therapeutic moieties such as the siRNA, chemotherapeutics, and phytoconstituents are discussed [Figure 3].

siRNA delivery through extracellular vesicles

It was shown that due to the underlying mechanisms, extracellular vesicles are found to be the right candidates for the delivery of siRNA^[148]. For this reason, extracellular vesicles are utilized for the successful delivery of siRNA for targeting various cancers such as breast cancer^[150], colon cancer, gastric cancer, and others, including PCa^[151,152]. In the context of PCa, a research study was aimed to determine the efficiency of siRNA in the inhibition of SIRT6 in a PCa model. It was demonstrated that the siRNA via the engineered extracellular vesicles caused the downregulation of the SIRT6 and blocked the metastasis and tumor growth^[153]. In another study by Krishn *et al.*, it was demonstrated that delivery of siRNAs targeting ITGB6

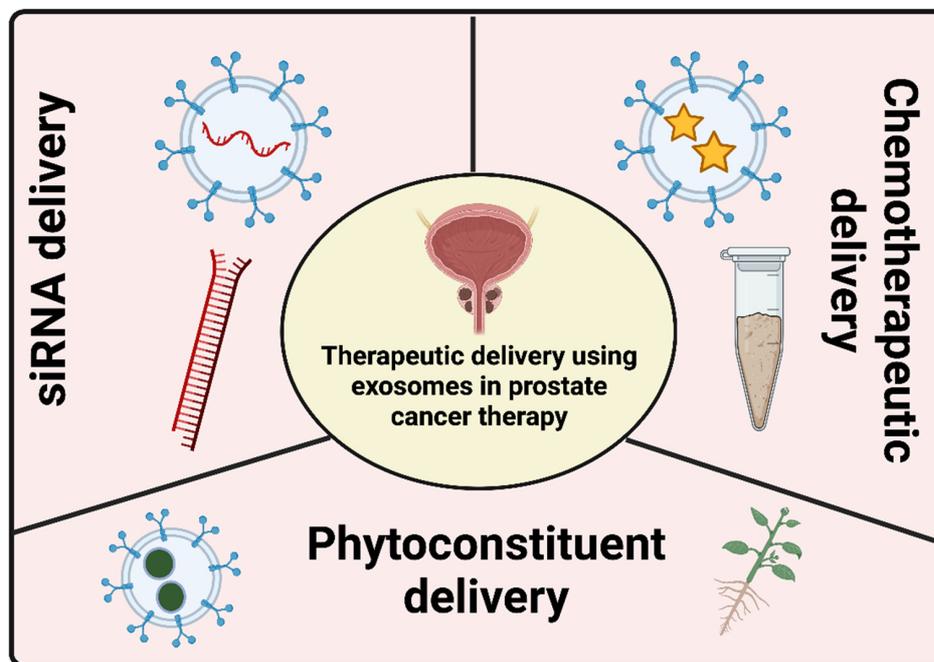

Figure 3. The application of extracellular vesicles in the therapy PCa.

into the PCa cells (PC3) led to the downregulation of $\beta 6$ subunit expression and also led to cell adhesion and migration of PCa cells on a specific substrate of $\alpha V\beta 6$ ^[154]. In an *in vivo* study on mice bearing subcutaneous prostate carcinoma, the extracellular vesicles modified with polyethyleneimine showed strong inhibition of tumor growth, which is due to the significant knockdown of the target gene^[155]. Even though siRNA delivery through extracellular vesicles has been researched widely in recent times, in our opinion, the extracellular vesicles can be utilized to a greater extent for the targeted therapy of PCa due to their effectiveness in inhibiting the target genes as well as the advantages it offers.

Drug delivery through extracellular vesicles

The extracellular vesicles are also used to carry drugs to the delivery site [Figure 3]. Followed by its isolation, the drugs are conjugated with them, which can reduce the toxicity and biocompatibility issues^[156]. Saari *et al.* isolated the extracellular vesicles from PCa cells (PC-3 and LNCaP) through a process called differential centrifugation. An increased cytotoxic effect was observed when the paclitaxel was loaded into the extracellular vesicles derived from autologous PCa cells. Furthermore, endocytosis was the key pathway involved in the delivery of paclitaxel to the parental cells, thereby demonstrating the effectiveness of extracellular vesicles as carriers for drug delivery^[83]. In another study, the urinary-derived exosomal system containing doxorubicin Exo-PMA/Fe-HSA@DOX nano vectors was explored for synergistic chemodynamic/low-dose chemotherapy of PCa. The nanosystem was shown to cause substantial internalization *in vitro* and to suppress the EGFR/AKT/NF-B pathways in cells^[157]. Not just drugs, but a combination of both drugs and siRNAs have also been delivered for PCa therapy. For example, folate-conjugated extracellular vesicles (Co-Exo-FA) were developed which are obtained from nano-complex

loaded macrophages. Docetaxel and PLK1 siRNA were loaded in this system. It was shown that the system blocked the PLK1 gene in addition to its effect on tumor growth and reduced toxicity, which demonstrated the synergistic effect of drug and siRNA combination against castrate-resistance PCa^[158].

Phytoconstituent delivery through extracellular vesicles

It has been reported that extracellular vesicles aid in the delivery of phytochemicals across biological barriers and have also been used against cancer^[159]. However, in PCa, there are very few phytochemicals delivered through the exosome in our knowledge. Overall, extracellular vesicles are utilized to transport various molecules to PCa patients, and still, a lot of molecules such as various siRNAs, drugs, and phytochemicals can be loaded into extracellular vesicles for the targeted inhibition of various genes associated with PCa, tumor growth and to target the various steps involving in the emergence of PCa. In our opinion, this area remains much unexplored.

CONCLUSION AND FUTURE PERSPECTIVE

Extracellular vesicles show a significant role when it comes to the entire scenario involving PCa. Once considered garbage bags of cells, extracellular vesicles are now being researched for their multifarious roles in cancer development. In the case of PCa, they have shown a dual persona: a negative aspect enables extracellular vesicles to contribute to proliferation and metastases while conferring resistance against the majority of chemotherapeutic agents and therapies, including radiation therapy. However, they also demonstrate a beneficial side, serving as diagnostic biomarkers and delivery vesicles for a vast array of agents, including nucleic acids, diagnostic agents, pharmaceuticals, and many more. This review aims to comprehensively cover both aspects of extracellular vesicles in PCa, encompassing their negative roles, such as involvement in angiogenesis, metastasis, proliferation, stemness, and resistance to multiple agents, alongside their roles as diagnostic agents and delivery agents for various pharmaceuticals.

There is a promising future for extracellular vesicles in treating PCa. While extracellular vesicles have shown tremendous progress as delivery vesicles for multiple agents, there is a limited number of studies focused on the delivery of phytochemicals in PCa using extracellular vesicles. Additionally, further studies can be conducted to explore how their role in drug resistance can be utilized positively while delivering antineoplastic agents in PCa. PCa has been a major threat in the male population, but future studies and the utilization of extracellular vesicles are expected to play a significant role in its treatment and mitigating its effects worldwide.

Abstract

Ovarian cancer is the most lethal gynecologic cancer. Optimal cytoreductive surgery followed by platinum-based chemotherapy with or without bevacizumab is the conventional therapeutic strategy. Since 2016, the pharmacological treatment of epithelial ovarian cancer has significantly changed following the introduction of the poly (ADP-ribose) polymerase inhibitors (PARPi). *BRCA1/2* mutations and homologous recombination deficiency (HRD) have been established as predictive biomarkers of the benefit from platinum-based chemotherapy and PARPi. While in the absence of HRD (the so-called homologous recombination proficiency, HRp), patients derive minimal benefit from PARPi, the use of the antiangiogenic agent bevacizumab in first line did not result in different efficacy according to the presence of homologous recombination repair (HRR) genes mutations. No clinical trials have currently compared PARPi and bevacizumab as maintenance therapy in the HRp population. Different strategies are under investigation to overcome primary and acquired resistance to PARPi and to increase the sensitivity of HRp tumors to these agents. These tumors are characterized by frequent amplifications of Cyclin E and MYC, resulting in high replication stress. Different agents targeting DNA replication stress, such as ATR, WEE1 and CHK1 inhibitors, are currently being explored in preclinical models and clinical trials and have shown promising preliminary signs of activity. In this review, we will summarize the available evidence on the activity of PARPi in HRp tumors and the ongoing research to develop new treatment options in this hard-to-treat population.

Keywords: PARP inhibitors, homologous recombination proficiency, ovarian cancer, PARP inhibitor resistance, replication stress

INTRODUCTION

Ovarian cancer (OC) is the deadliest gynecological tumor and the 13th leading cause of cancer mortality in the United States. In 2021, 21,410 new cases of OC were estimated, with 13,770 deaths due to this disease^[1]. Among malignant ovarian tumors, epithelial ovarian cancer (EOC) constitutes the majority, with high-grade serous ovarian cancer (HGSOC) being the most common histological subtype^[2]. The diagnosis of HGSOC commonly occurs at an advanced stage due to the consequence of non-specific symptoms and a lack of effective screening strategies^[3]. The standard treatment combines optimal debulking surgery and platinum-based chemotherapy. Nevertheless, the majority of patients develop recurrence and the efficacy of subsequent lines of treatment decreases over time^[4]. Maintenance treatment was introduced to delay disease progression after first-line treatment. The antiangiogenic agent bevacizumab has been the first targeted agent to receive authority approval in first-line treatment of International Federation of Gynecology and Obstetrics (FIGO) stage III and IV EOC^[5,6]. Subsequently, the development of poly (ADP-ribose) polymerase inhibitors (PARPi) has represented a paradigm change in the treatment of EOC and they are now incorporated into the standard of care treatment^[7].

PARPi IN OVARIAN CANCER

Poly (ADP-ribose) polymerases (PARPs) are responsible for the detection of single-strand DNA breaks (SSBs) and the recruitment of DNA repair factors at the site of DNA damage^[8]. Following PARP inhibition, SSBs are not properly repaired and PARP is trapped and the replication fork stalled with the subsequent occurrence of DNA double-strand breaks (DSBs)^[8,9]. These DNA damages activate, leading to an error-free DNA damage repair.

Approximately 15% of patients with EOC harbor a germline mutation in *BRCA1/2* (*gBRCA*)^[10]. *BRCA1* and *BRCA2* are tumor suppressor genes involved in multiple cellular pathways, such as transcription, cell cycle regulation, and maintenance of genome integrity^[11]. Specifically, they are involved in DNA DSB repair and are essential for the HRR pathway.

PARPi are particularly active in cancer cells with alterations in HRR, such as *BRCA1* or *BRCA2* pathogenic mutations, through the well-known mechanism of “synthetic lethality”^[12,13]. With the loss of HRR function, cells repair DSBs via the non-homologous end joining (NHEJ), resulting in genomic instability and cell death.

PARPi have been studied in high-grade EOC in different phase II and III clinical trials as maintenance and treatment strategies, leading to approvals by health authorities for different indications^[14-23].

HOMOLOGOUS RECOMBINATION DEFICIENCY

The most disruptive form of DNA damage is the DNA DSBs, which are repaired by NHEJ and homologous recombination^[24]. When DNA damage occurs, different enzymes are activated, including the MRE11-RAD50-NBS1 complex (MRN), the DNA damage kinase ataxia-telangiectasia mutated (ATM), and the ataxia telangiectasia and Rad3-related (ATR). Subsequently, DNA repair is activated by *CHEK2*, *BRCA1*, *BRCA2*, and *RAD51*. Other important effectors of the HRR pathway are *PALB2* and *BRIP1*^[11]. A defect in the HRR process determines a condition called homologous recombination deficiency (HRD) that occurs as a consequence of germline or somatic mutations, or epigenetic modifications of different genes involved in this pathway.

Almost 50% of high-grade EOC are characterized by HRD, with 12%-15% and 5%-7% harboring germline or somatic mutations in *BRCA1/2*, respectively^[25-27]. However, HRD also occurs due to germline or somatic mutations or epigenetic events in other HRR genes, and not all mechanisms underscoring HRD have been characterized yet^[27,28].

HRD assays and their limitations

Different types of assays, referred to as “HRD tests”, are available to select patients more likely to benefit from PARPi^[28]. HRD can be measured using different strategies, which can be categorized into four main groups and each of them has its own limitations^[28,29].

Germline or somatic mutations in HRR genes

Next-generation sequencing (NGS) of DNA extracted from peripheral blood or saliva is used to detect germline pathogenic variants of genes involved in HRR. In patients without a *gBRCA* mutation, a somatic test on formalin-fixed paraffin-embedded (FFPE) tissue is recommended, given ~5%-7% of EOC harbor a somatic mutation in *BRCA1/2*^[27,30,31]. In addition to *BRCA1/2* mutations, other causes of HRD include promoter methylation of *BRCA1* (10%) or *RAD51C* (3%) or mutations in other genes such as *ATM* or *ATR* (~2%), *CDK12* (~3%), *BRIP1*, *RAD51C*, *RAD51D*, *PALB2*, and *BARD1* (~5%)^[30]. Different studies demonstrated similar efficacy of PARPi in patients with somatic compared to germline *BRCA* mutations^[20,32,33]. Mutations in HRR genes other than *BRCA* are rare, with only limited data available on the benefit of PARPi in this setting. A retrospective analysis of the PAOLA-1 trial demonstrated that the presence of non-*BRCA* HRR gene mutations, contrary to HRD positive status, was not predictive of progression-free survival (PFS) benefit^[34]. The exploratory analysis of the ARIEL2 trial showed that the presence of loss of heterozygosity (LOH) in *BRCA* wild-type tumors was a more sensitive biomarker of response compared to other HRR gene mutations or *BRCA1* and *RAD51C* methylation^[23,33]. An important challenge in the identification of germline and somatic mutations is the definition of the functional and clinical meaning of variants of uncertain significance (VUS) and their correlation with benefit from PARPi^[35]. Despite the work of the ENIGMA (Evidence-based Network for the Interpretation of Germline Mutant Alleles) consortium to reclassify many VUS as benign or malignant, the absolute number of individuals receiving an inconclusive *BRCA1/2* test result is still significant^[36].

Genomic “scars” and mutational signatures

HRD causes genomic instability with a progressive accumulation of genomic aberrations that result in “scars” that can be measured with specific assays. These assays do not look for the cause of HRD, but to the consequences of having a defective HRR pathway. Several investigations have been conducted using single nucleotide polymorphism arrays to define a signature of genomic instability associated with *BRCA* mutations. The three major types of genomic “scars” associated with HRD are LOH, telomeric allelic Imbalance (TAI) and large-scale state transitions (LST)^[37-39]. Two commercially available genomic instability assays have been developed: the myChoice® CDx from Myriad Genetics and the FoundationFocus™ CDx_{BRCA LOH} by Foundation Medicine. The myChoice® CDx assay evaluates tumor *BRCA1/2* mutation (t*BRCA*), LOH, TAI and LST with a genomic instability score (GIS) cut off at 42^[15,16]. The FoundationFocus™ assay evaluates t*BRCA* and genomic LOH, with an initial cut-off for LOH positivity established at 14%^[26]. This cut-off was initially prospectively evaluated in the ARIEL2 trial^[23], but subsequently changed to 16% according to the ARIEL3 trial results, which corresponds to the cut-off currently used in the available assay^[22].

One of the major limitations of these genomic instability assays is the inability to define the current HRD status. Genomic scars can persist even if tumor cells have restored HRR through mechanisms, such as the

occurrence of reversion mutations in *BRCA* and other HRR-related genes^[40-42]. Notably, different cut-offs have been employed to define the presence of HRD in the different clinical trials evaluating the role of PARPi in EOC, and direct comparisons among the two approved assays are not available. Other limitations of the currently commercially available HRD tests are the limited reproducibility, their availability and cost. Several research groups are validating academic tests with the aim of overcoming such limitations and preliminary results have been recently presented^[43,44].

Mutational signatures can also be used to identify the presence of HRD. This method is based on the assumption that several mutational processes, such as smoking, carcinogens, ultraviolet radiation or defects in DNA repair mechanisms, cause somatic mutations and each of them generates a specific mutational signature^[45]. Signature 3 is the one associated with *BRCA* mutation and *BRCA1* promoter methylation in different solid tumors, including ovarian cancer^[45-47]. Hillman *et al.* conducted a retrospective whole genome sequencing (WGS) of HGSOC samples and demonstrated that the presence of signature 3 correlates with better prognosis and response to platinum agents^[48]. However, the most common genomic testing platform used in clinical practice are targeted sequencing panels with a number of identifiable mutations too small for the identification of a specific signature. To overcome this limitation, Gulhan *et al.* have developed a bioinformatics algorithm (Signature Multivariate Analysis-SigMA), which can identify the mutational signature correlated with HRD using genetic panels^[49]. In their analyses, cancer cell lines with signature 3 showed greater sensitivity to PARPi, irrespective of the *BRCA* mutational status, not only in breast and ovarian cancers but also in other tumor types^[49].

Similar to other genomic “scars” assays, the identification of a mutational signature linked to defects in DNA repair pathways also remains a historical representation of HRD and does not reflect the actual presence of the mechanism of resistance to PARPi. Another major limitation is the need for fresh frozen material to perform these assays. Despite being a promising approach, it lacks clinical validation^[28].

Functional assays

Functional assays are a dynamic assessment of the HRR status^[28]. In the presence of DNA DSBs, RAD51 forms molecular complexes (foci) at the DNA damage site, which are visible by immunofluorescence microscopy. It has been shown that cell lines with HRD are not able to form RAD51 foci when DNA damage occurs and this represents a functional reflection of a defect in the homologous recombination pathway^[50-52]. Blanc-Durand *et al.* evaluated a RAD51 functional assay in tumor samples from patients enrolled in the randomized neoadjuvant CHIVA trial assessing platinum-based chemotherapy +/- nintedanib^[53,54]. They demonstrated that RAD51-deficient ovarian tumors had better overall response rates (ORR) to neoadjuvant chemotherapy and median PFS. Notably, among *BRCA1/2* mutated EOC, patients with RAD51-proficient tumors had a poorer response to chemotherapy^[53,54]. RAD51 measurement as a surrogate for HRD has several limitations. Not all mechanisms underlying PARPi sensitivity involve a deficiency in RAD51. When PARPi sensitivity is driven by ATM or MRN complex alterations, RAD51 assay is not able to detect it because these mechanisms preserve the formation of RAD51 foci^[50]. Similarly, if the resistance to PARPi is due to a RAD51-independent mechanism, such as mutations in PARP1, it is not identified by a RAD51 assay^[55]. Additionally, the assay relies on counting and quantifying many foci, which may result in substantial inter-observer variability^[56]. The available data on RAD51 functional assays are retrospective and performed on a limited number of samples^[56]. A prospective trial that stratifies patients based on the presence of RAD51 foci is needed to validate its clinical utility.

PARPi IN HRp TUMORS

EOC associated with *gBRCA* mutations has different clinical features, such as earlier age of onset, longer survival, higher rate of visceral metastasis (e.g., liver, spleen), higher response rates to platinum and non-platinum chemotherapy (e.g., pegylated liposomal doxorubicin), and increased sensitivity to PARPi^[57-60]. It has become evident that many HGSOCS share the same biological and clinical features even when a germline or somatic *BRCA* mutation is not detected, a condition called “BRCAness”^[27]. In contrast, patients with HRp tumors have worse PFS and OS compared to patients with HRD tumors^[61,62]. A retrospective analysis of 1,271 patients with EOC showed that patients with HRp tumors have an older median age at diagnosis, have more commonly non-serous histology, require a higher number of neoadjuvant chemotherapy cycles to be considered for interval debulking surgery, and are less sensitive to platinum-based chemotherapy^[62,63].

Homologous recombination-proficient EOC also harbors different genomic features. Amplification of cyclin E1 (CCNE1) is one of the best characterized genomic alterations linked to resistance to platinum-based chemotherapy and is mutually exclusive with *BRCA1/2* dysfunction^[64,65]. CCNE1 encodes the cell-cycle regulator cyclin E1, which is required for the cell-cycle progression from G1 to S through the p21-p27-cyclin E-CDK2 pathway. CCNE1 amplification raises cyclin E levels, leading to abrogation of the G1-S cell cycle checkpoint and reduction of the G1 phase^[66]. This results in high replicative stress (RS) due to aberrant firing of the replication origin^[66]. MYC amplification is also found in HRp cancer and correlates with increased RS. MYC-amplified cancer cells are characterized by inadequate reduction/oxidation balance with accumulation of reactive oxygen species, accelerated entry in S phase and impairment in the expression of genes implicated in purine and pyrimidine biosynthesis and in the regulation of the HR pathway^[66,67].

While recent clinical trials have clearly proved the activity of PARPi in the presence of *BRCA* mutation and/or HRD, their role in the HRp population is less understood.

In the first-line setting, three trials have investigated the role of maintenance treatment with a PARPi following a complete or partial response (CR/PR) to chemotherapy [Table 1]. The PRIMA trial is a phase 3 randomized trial of niraparib vs. placebo as maintenance treatment in patients with high-risk stage III (residual disease after debulking surgery, inoperable stage III and patients who have received neoadjuvant chemotherapy) and stage IV high-grade EOC. Although an improvement in median PFS in the overall population regardless of HRD status [defined as *BRCA* mutation or/and a GIS score ≥ 42 (myChoice® assay)] was obtained with niraparib, in the HRp population, the benefit was smaller^[2]. The phase III PAOLA-1 trial investigated the addition of olaparib to bevacizumab as maintenance treatment in newly diagnosed, stage III-IV high-grade EOC after response to first-line chemotherapy^[15]. This study demonstrated a statistically and clinically significant improvement in PFS and overall survival (OS) in the overall population, in the HRD-positive/*tBRCA* and HRD-positive/*BRCAt* groups, but with no difference in the HRp population^[15,68]. Recently, the phase 3 ATHENA-MONO trial has confirmed the activity of rucaparib regardless of the HRD status, measured as LOH using the FoundationOne CDx NGS assay^[69].

The combination of veliparib with chemotherapy containing platinum compound in stage III/IV EOC was evaluated in the phase 3 VELIA trial^[70]. Patients were randomized in three different arms: chemotherapy plus placebo followed by placebo maintenance, chemotherapy plus veliparib followed by placebo maintenance, or chemotherapy plus veliparib followed by veliparib maintenance. Veliparib, administered concomitantly with chemotherapy and as maintenance treatment, improved patients' outcomes (PFS from the start of first-line chemotherapy) in the three prespecified subgroups: *BRCA* mutated, HRD positive and the overall population. The HRD population includes patients with *BRCA* mutated tumors and/or a GIS

Table 1. Results of the main randomized phase 2 and 3 clinical trials investigating PARPi in EOC, including HRp population

¹ BRCAwt, high LOH; ² BRCAwt, low LOH; ³ Data of the veliparib combination only arm are not reported; ⁴ Initially the cut off for HRD positivity was ≥ 33, subsequently revised to ≥ 42. bev: Bevacizumab; BRCAmut: BRCA mutated; BRCAwt: BRCA wild type; cht: chemotherapy; EOC: epithelial ovarian cancer; HR: hazard ratio; HRD: homologous recombination deficiency; HRp: homologous recombination proficient; ITT: intention-to-treat; LOH: loss of heterozygosity; NA: not available; NR: not reach; PARPi: poly (ADP-ribose) polymerase inhibitors; PFS: progression-free survival; vs.: versus.

score ≥ 42 (myChoice[®] assay). In the HRp subgroup, the effectiveness of the standard of care treatment was not enhanced by the addition of velaparib^[70].

In the platinum-sensitive recurrent setting, niraparib and rucaparib have shown effectiveness in the different biomarker subgroups. However, as described for the first line setting, there is a different magnitude of benefit, with higher efficacy observed in the BRCA mutated population followed by the HRD non-BRCA mutated and the HRp subgroups. This was clearly observed in the phase 3 NOVA trial, where the role of niraparib versus placebo as maintenance therapy in platinum-sensitive recurrent high-grade EOC was assessed^[20]. HRD positivity was defined when the GIS by myChoice[®] score was ≥ 42 or a BRCA1/2 mutation was present. To be noted, a potential detrimental effect on OS has been reported, and final data are awaited^[20,71].

In the same setting, the ARIEL3 trial evaluated rucaparib as a maintenance treatment, showing an improvement in median PFS in the intention-to-treat population in HRD population, defined as high-LOH (LOH score ≥ 16%) or BRCA mutated. As expected, the PFS benefit was greater in patients with LOH high-BRCAwt compared to LOH low patients^[22].

PARPi have also been investigated as a line of treatment in the ARIEL2^[23] and QUADRA trials^[21]. QUADRA was a single-arm phase II study where niraparib was administered as monotherapy in patients with recurrent HGSOc after the failure of three or more previous regimens. HRD tumors included *BRCA* mutated and/or myChoice® HRD score ≥ 42 . The ORR was 28%, with a median duration of response similar in the different subgroups of patients. Median OS was 26.0 months (95%CI, 18.1-not estimable), 19.0 months (14.5-24.6), and 15.5 months (11.6-19.0) in the *BRCA* mutated, HRD-positive, and HRp populations^[21]. The phase 2 ARIEL2 trial assessed the role of rucaparib as treatment. Part 1 of the trial included patients with platinum-sensitive high-grade EOC treated with one or more prior chemotherapy regimens. The analysis has been performed according to three prespecified subgroups: *BRCA* mutant, LOH high and *BRCA*_{wt} (cut off for LOH high 14%), or LOH low. Median PFS with rucaparib treatment was 12.8 (95%CI 9.0 to 14.7), 5.7 months (5.3 to 7.6) and 5.2 months (3.6 to 5.5) in the *BRCA* mutant, LOH high and LOH low patients, respectively. Part 2 of the trial enrolled patients with any platinum-free interval disease who had completed 3 to 4 prior chemotherapies. Patients with *BRCA* mutated tumors had a median PFS of 7.8 months and an ORR of 45.7% (95%CI, 37.2 to 54.3). In contrast, in the LOH-high and LOH-low groups, median PFS was 4.3 and 4.0 months and ORR was 16.7% (95%CI, 11.2 to 23.5) and 7.7% (95%CI, 4.2 to 12.9), respectively^[23].

The AVANOVA2 is a phase 2 trial that compared niraparib versus the combination of niraparib plus bevacizumab in patients with platinum-sensitive recurrent ovarian cancer. In the prespecified subgroup analysis, a longer PFS was observed with the combination regardless of the HRD status^[72].

Results of the main phase 2 and 3 trials of PARPi in EOC that have included HRp patients are summarized in Table 1 and Figure 1A and B.

MAINTENANCE TREATMENT IN HRp TUMORS: PARPi OR ANTIANGIOGENIC AGENTS

The antiangiogenic agent bevacizumab has demonstrated an improvement in PFS when used with chemotherapy and as maintenance in first-line settings, but also in platinum-sensitive recurrent disease^[5,6,73,74]. The GOG-218 is a 3-arm phase 3 trial assessing the efficacy of bevacizumab added to first-line chemotherapy in patients with stage III and residual disease after surgery and stage IV EOC. Patients were randomized to receive six cycles of carboplatin, paclitaxel and placebo followed by placebo (arm 1), or the same chemotherapy with the addition of bevacizumab (15 mg/kg) followed by placebo maintenance (arm 2) or carboplatin and paclitaxel with bevacizumab and bevacizumab maintenance up to 22 total administrations (arm 3). Treatment with bevacizumab concurrent plus maintenance reduced the risk of disease progression by 28% (median PFS 14.1 vs. 10.3 months; HR = 0.717; 95%CI, 0.625 to 0.824)^[5]. The difference in OS was noted only in the subgroup of patients with stage IV disease. A retrospective analysis evaluated the impact of HRR gene mutations (such as *ATM*, *ATR*, *BARD1*, *BRCA1*, *BRCA2*, *BRIP1*, *CHEK2*, *PALB2*, *RAD51C*, *RAD51D*, and others) on OS, platinum and bevacizumab sensitivity (comparing arm 1 and 3)^[75]. This analysis demonstrated that mutations in HRR might be correlated with a better PFS and OS in patients with EOC, but bevacizumab did not result in a different benefit according to the mutational status^[75].

A small retrospective study analyzed the role of CCNE overexpression in predicting the benefit of bevacizumab in 57 patients with platinum-sensitive recurrence of OC. 45.6% of the patients presented CCNE1 overexpression and 15 (62.5%) were treated with chemotherapy and bevacizumab and 11 (33.3%) received chemotherapy alone. Among patients with CCNE1 overexpression, the ORR was 100% and 50% in the group treated with or without bevacizumab, respectively. The PFS was higher in patients with CCNE1 overexpression who received bevacizumab (16.3 vs. 7.1 months, $P = 0.010$)^[76].

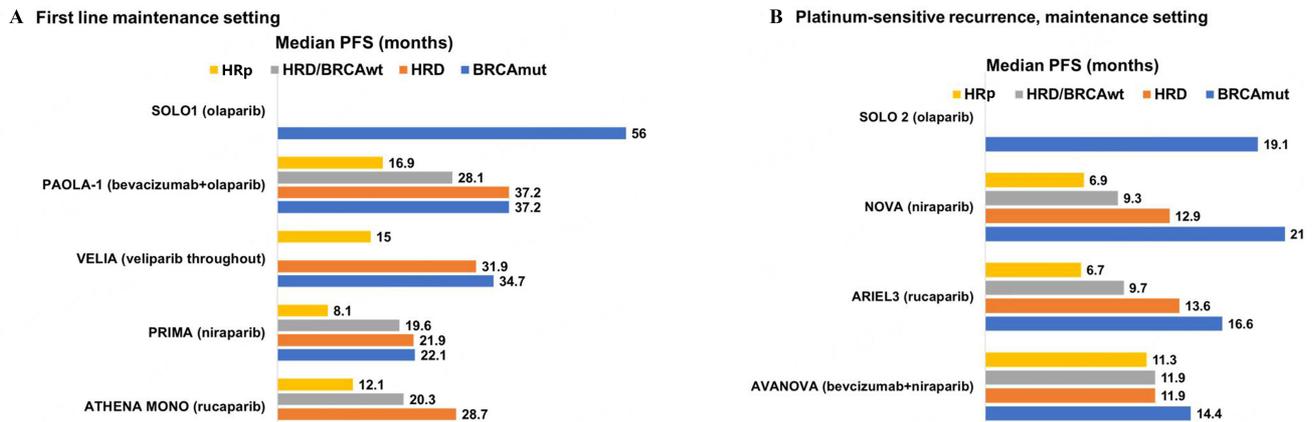

Figure 1. Indirect comparison of PFS with PARPi maintenance according to *BRCA* or HRD/LOH status in the main randomized phase 3 trials. In VELIA trial, PFS was calculated from the start of chemotherapy. ATHENA MONO: PFS in *BRCA* mutated population is not reached. BRCAmut: *BRCA* mutated; BRCAwt: *BRCA* wild type; HRD: homologous recombination deficiency; HRp: homologous recombination proficiency; LOH: loss of heterozygosity; PARPi: poly (ADP-ribose) polymerase inhibitors; PFS: progression-free survival; VELIA: PSF in HRD/BRCAwt not reported.

To date, no randomized trials comparing PARPi plus bevacizumab *vs.* PARPi alone, or PARPi *vs.* bevacizumab are available. Hettle *et al.* performed a population-adjusted indirect treatment comparison among the high-risk population of the PAOLA-1 trial matched to the PRIMA cohort^[77]. The authors compared the relative efficacy of olaparib plus bevacizumab (group 1), bevacizumab alone (group 2), niraparib (group 3) and placebo (group 4). Median PFS in the biomarker unselected population was 21.4 months (95%CI, 19.2 to 22.1) in group 1, 16.0 months (95%CI, 14.3 to 17.7) for patients in group 2, 13.8 months (95%CI, 11.5 to 15.3) for patients in group 3 and 8.1 months (95%CI, 7.31 to 8.51) for patients in the placebo arm. In the HRD population, the greater advantage was achieved with the association of PARPi and bevacizumab than from PARPi alone or bevacizumab alone, with a median PFS of 36.0 months [95%CI, 23.2-not available (NA)] for patients in the olaparib plus bevacizumab arm, 17.6 months (95%CI, 14.7 to 19.6) for patients in the placebo plus bevacizumab arm, 22.0 months (95%CI, 19.3 to NA) for patients in the niraparib arm and 10.5 months (95%CI, 8.05 to 12.1) for patients in the placebo arm. Unfortunately, because of the lack of baseline data for the HRp subgroup of the PRIMA trial, it was not possible to repeat the same comparative analysis in the HRp population^[77].

The MITO-MANGO16 trial explored the effect of adding bevacizumab to chemotherapy in patients previously treated with the same antiangiogenic agent and experiencing the first platinum-sensitive recurrence. Bevacizumab beyond progression resulted in a better PFS 11.8 *vs.* 8.8 months (HR 0.51; 95%CI, 0.41 to 0.65). In a non-preplanned subgroup analysis, PFS was not improved in *BRCA* mutated patients^[78].

In the GOG-218 and MITO-MANGO16 trials, HRD tests have not been performed, and thus, an indirect comparison with the HRp populations is not possible. Notably, it is important to highlight that in the PARPi trials, the randomization occurred after the end of the chemotherapy and patients without at least a partial response were excluded, while in the bevacizumab trials, the randomization occurred at the time of initiation of first-line treatment. Thus, the comparison of the magnitude of PFS needs to account for this difference^[5,78].

The PAOLA-1 trial failed to show a benefit of adding olaparib to bevacizumab in the HRp subgroup (HR 0.92; 95%CI, 0.72 to 1.17)^[15]. In the AVANOVA trial, the combination of niraparib and bevacizumab showed a statistically significant improvement in PFS, even in the HRp population (HR 0.40; 95%CI, 0.19 to 0.85)^[72]. The main difference between these two studies is the control arm, that is bevacizumab in the

PAOLA-1 trial and niraparib in the AVANOVA. Although a direct comparison among these trials is not feasible, these results raise the question if the HRp population could gain a higher benefit from the treatment with bevacizumab than a PARPi.

The ongoing MITO 25 trial (NCT03462212) might help in answering this question. This is a phase 1/2 trial evaluating the efficacy of carboplatin-paclitaxel and rucaparib maintenance versus carboplatin-paclitaxel-bevacizumab and bevacizumab plus rucaparib maintenance in HRD-positive HGSOc and of carboplatin-paclitaxel-bevacizumab and bevacizumab maintenance versus carboplatin-paclitaxel and rucaparib maintenance in HRp patients.

INCREASING THE EFFICACY OF PARPi IN HRp TUMORS

As previously described, the efficacy of PARPi is significantly different among HRD and HRp tumors. Thus, there is an unmet need to identify new treatment strategies to increase the activity of DNA-damaging agents in this patient population. Preclinical studies have shown that different pathways are involved in the regulation of the DDR^[79] [Figure 2]. The phosphoinositide 3-kinase (PI3K) and MEK pathways are involved in recognition of DNA damage and the promotion of homologous recombination, while the cyclin-dependent kinases (CDK) are involved in the control of the cell cycle progression and act in coordination with the DDR pathways^[80-83]. Transcriptional and epigenetic regulation has a critical role in the downregulation of HRR genes, particularly due to the close link between the DDR pathway and chromatin remodeling by histone modifications^[79]. Targeting these pathways has the potential to pharmacologically induce an HRD phenotype and might represent a powerful strategy to sensitize HRp EOC to PARPi. Several compounds have been evaluated as potential inducers of HRD and preliminary preclinical and clinical results are available [Table 2].

Transcriptional regulators

Histone deacetylases (HDACs) have a key role in gene transcription, DNA replication and repair. Preclinical research has demonstrated that HDAC inhibitors reduce DNA repair by inhibiting HR genes, which, in turn, creates an HRD-like phenotype. This, along with a perturbed replication fork progression, leads to DNA DSBs, irreversible DNA damage, and finally cell death^[84]. Gupta *et al.* studied the effects of olaparib and the HDAC inhibitor entinostat in HRp ovarian cancer xenograft models, demonstrating that the combination reduces the peritoneal spread and prolongs survival^[85]. A phase I/II study is ongoing assessing the safety and efficacy of olaparib combined with entinostat in patients with HRp ovarian cancer (NCT03924245).

The bromodomain and extraterminal (BET) protein BRD4 supports gene transcription and is implicated in the expression of proteins that regulate the cell cycle and the DDR. *BRCA* wild-type ovarian cancer cells treated with the BET inhibitor (BETi) JQ1 exhibit a downregulation of *WEE1* and the DNA factor TOPBP1^[86,87]. Moreover, the BETi INCB054329 directly represses the transcription of *BRCA1* and *RAD51* in cancer cells^[88]. The association of olaparib and JQ1 suppresses the growth of HRp EOC xenografts, while there was no significant effect of either BETi or olaparib if used as a single agent^[88]. More information on the efficacy of these combinations will become available from the phase II trial of the BETi, ZEN003694, combined with the PARPi, talazoparib, in patients with recurrent ovarian cancer progressed to prior PARPi (NCT05071937).

PI3K and MEK inhibitors

Preclinical studies have shown that treatment with a phosphatidylinositol-3 kinases inhibitor (PI3Ki) decreases *BRCA1* expression and induces an increase of γ -H2AX, a marker of DNA damage^[80]. *BRCA1/2*

Table 2. Ongoing clinical trials of PARPi in combination with new agents in EOC

Class of drugs	Phase	Combination	Population	N
HDACi	I/II	Entinostat + olaparib	Platinum-refractory or resistant, HRp EOC	NCT03924245
	I	Belinostat + talazoparib	mBC, mCRPC, EOC progressed to at least one line of chemotherapy	NCT04703920
BETi	II	ZEN003694 + talazoparib	EOC PARPi resistant and platinum-sensitive (PFI > 6 months)	NCT05071937
PI3Ki	I	BKM120 + Olaparib or BYL719 and olaparib	TNBC and EOC, progressed after at least one prior platinum-based chemotherapy	NCT01623349
	I/II	CYH33 + olaparib	Solid tumors with any DDR gene or PIK3CA mutation, including PARPi and platinum-resistant EOC	NCT04586335
	Ib	Copanlisib + niraparib	Platinum-resistant EOC and BRCA mutated PARPi resistant EOC	NCT03586661
MEKi	I/II	Selumetinib + olaparib	Solid tumors with RAS pathway alterations and PARPi resistance EOC	NCT03162627
ATRi	I/II	BAY1895344 + niraparib	Part A: DDR deficiency solid tumor. Part B: platinum-resistant/refractory or PARPi-resistant EOC	NCT04267939
	I	M4344 + niraparib	PARPi resistant EOC	NCT04149145
	II	AZD6738 + olaparib	Recurrent EOC	NCT03462342
WEE1i	II	Adavosertib + olaparib	PARPi resistant EOC	NCT03579316
CDK12i	I	Dinaciclib + veliparib	Solid tumors	NCT01434316

ATRi: ATR inhibitors; BETi: BET inhibitor; CDK: cyclin-dependent kinases; EOC: epithelial ovarian cancer; HDACi: histone deacetylases inhibitor; HRp: homologous recombination proficient; mBC: metastatic breast cancer; mCRPC: metastatic castration-resistant prostate cancer; PARPi: poly (ADP-ribose) polymerase inhibitors; PFI: platinum-free interval; PI3Ki: phosphatidylinositol-3 kinases inhibitor; TNBC: triple-negative breast cancer; WEE1i: WEE1 inhibitors.

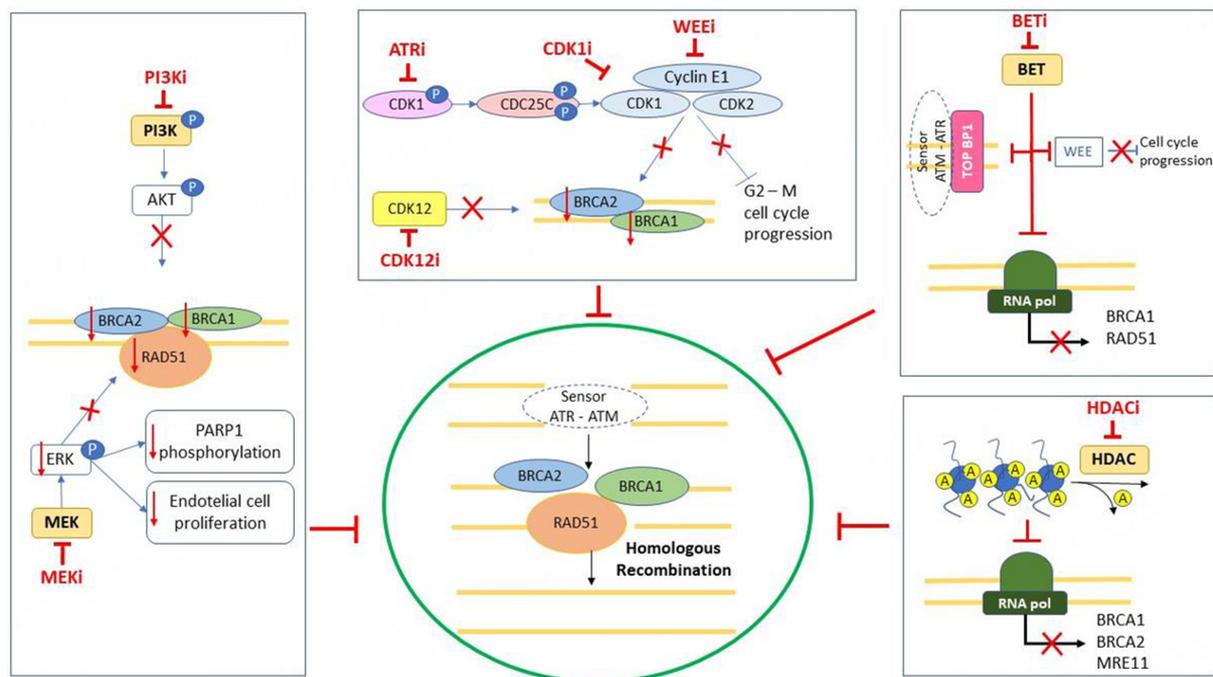

Figure 2. Cellular pathways that can be targeted to overcome PARPi resistance in HR tumors. ATM: Ataxia-telangiectasia mutated; ATR: ataxia telangiectasia and Rad3-related; CDK1: cyclin-dependent kinase 1; CDK2: cyclin-dependent kinase 2; CDK12: cyclin-dependent kinase 12; ERK: extracellular signal-regulated kinase; HDAC: histone deacetylases; MEK: MAPK/ERK kinase; PARP: poly (ADP-ribose) polymerases inhibitors; PI3K: phosphatidylinositol-3 kinase; RNAPol: RNA polymerase; TOPBP1: DNA topoisomerase II binding protein 1.

downregulation seems to be due to ERK-dependent activation of the erythroblast transformation specific (ETS) transcription factor, which inhibits *BRCA1* or *BRCA2* transcription, thereby resulting in HRD and

concomitantly increasing the sensitivity to PARPi^[80]. A phase 1b trial investigated the synergy between the PI3Ki alpelisib and olaparib in patients with breast and ovarian cancer. This study included 30 women with EOC (mainly HGSOE) and 93% had platinum resistant/refractory disease. This trial showed an ORR of 33% in *BRCAwt* platinum-resistant patients, while the ORR of olaparib or other PARPi as monotherapy in the same setting ranges from 3% to 10%^[89]. An ongoing phase 3 trial is investigating alpelisib and olaparib versus chemotherapy of physician's choice in patients with platinum-resistant *BRCA* wild type EOC (NCT04729387).

MEK inhibition decreased both the MRE11 and *RAD51* foci at DSBs as well as the *BRCA1* nuclear localization, with a consequent accumulation of DNA damage^[81]. Moreover, the increased expression of PARP1 and the decreased vascularity increases the hypoxia^[81]. It was shown that hypoxia induces transcriptional repression of *BRCA1* expression, with a consequent HRD status sustaining a greater sensitivity to PARPi^[90]. Olaparib in combination with selumetinib has been investigated in an early-phase trial in patients with *KRAS/NRAS* mutant and *BRCAwt* solid tumors, including gynecological cancers. Among 12 evaluable patients, ORR was 17%, and clinical benefit rate (CBR) 33%^[91]. Further investigations are needed to further understand the clinical activity of this combination in recurrent EOC.

Cell cycle check-point inhibitors

An effective suppression of HR and a consequent sensitization to PARPi can also be achieved through the inhibition of CDK. Inhibition of CDK12 causes a reduced expression of *BRCA1*, *BRCA2*, and *RAD51*^[92]. Inhibition of CDK1 blocks the DNA repair mechanism sustained by the HR pathway and selectively sensitizes cells to PARPi^[84]. Xia *et al.* demonstrated a synergistic effect of CDK1 and PARP inhibitors in breast cancer cells proficient for *BRCA*^[93]. Prexasertib is a checkpoint kinase 1 inhibitor (CHK1i) that showed efficacy in a phase 2 trial that enrolled 28 women with *BRCAwt* high-grade EOC. The majority (80%) had platinum-resistant or refractory disease. 8/24 evaluable patients achieved a PR (33%), and the median duration of treatment was 11.4 months^[94]. Notably, *CCNE1* amplification or copy number gain was detected in half of the patients who achieved a response. Prexasertib also showed early signs of activity when added to olaparib in patients with HGSOE previously treated with a PARPi^[95].

PARPi were also evaluated along with WEE1 kinase inhibitors in preclinical models and in clinical trials. The WEE1 kinase prevents entry into mitosis by inhibiting CDK1 and CDK2. WEE1 inhibition causes CDK1 activation, resulting in cell cycle acceleration, early mitotic entry and mitotic catastrophe, particularly when combined with DNA damaging agents^[82]. Simultaneous inhibition of PARP and WEE1 is highly toxic, but this can be mitigated by adopting a sequential treatment strategy. Normal cells have low replicative stress and DNA damage, so sequential therapy is effective for tumor cells but less toxic to normal cells^[96]. In a recent clinical trial, the efficacy of adavosertib alone or in combination with olaparib was investigated in 80 patients with EOC and PARPi resistance. Patients treated with the combination have a greater CBR (89% vs. 63%) compared to WEEi alone, but the ORR was similar between the two arms (29% vs. 23%). Among exploratory analyses, *BRCA* mutations appeared to correlate with lower ORR (20% in the adavosertib-alone arm and 19% in the adavosertib/olaparib arm) compared to the *BRCAwt* subgroup (31% in the adavosertib-alone arm and a 39% in the adavosertib-olaparib arm). Data on the benefit according to the HRD status are not yet available. Translational analyses are ongoing to identify potential predictive biomarkers^[97].

A synergistic activity among PARPi and ATR inhibitors (ATRi) has been observed in different models of ovarian cancer^[98,99]. G2-M checkpoint is lost with ATR inhibition, and as a result, cells with damaged DNA can proceed into the cell cycle, and run into mitotic catastrophe and apoptosis. In addition, PARP inhibition increases dependence on ATR/CHK1 to maintain genome stability^[98]. A study in *BRCAwt*,

CCNE1 amplified platinum-resistant ovarian cancer patient-derived xenograft (PDX) models showed that the combination of PARPi and ATRi results in tumor reduction and a significant increase in OS^[98]. A phase 2 trial investigated the combination of olaparib and the ATRi ceralasertib to overcome PARPi resistance. In 13 patients with PARPi resistance, an ORR of 46% was observed with a PFS of 7.6 months^[99]. Given these preliminary results, future clinical trials are also needed to investigate this combination in HRp EOC as a strategy to overcome intrinsic resistance to PARPi. Moreover, dose optimization trials are required to define the best schedule to overcome the important challenge of the hematological toxicity of the combinations of DDR and cell cycle checkpoint inhibitors.

Histone deacetylases (HDACs) and bromodomain and extraterminal (BET) proteins are involved in gene transcription. BET inhibition downregulates WEE and decreases the expression of TOPBP1, a protein required for the activation of ataxia-telangiectasia mutated (ATM) and ataxia telangiectasia and Rad3-related (ATR). Phosphatidylinositol-3 kinase (PI3K) inhibition decreases *BRCA1* expression, while MEK inhibition decreases RAD51 foci. In addition, MEKi increases PARP1 expression and decreases angiogenesis. The inhibition of CDK12 and CDK1 decreases the expression of proteins involved in the homologous recombination. WEE and ATR inhibition results in the loss of the G2-M checkpoint, and cells with damaged DNA advance in mitotic phase. All these mechanisms lead to homologous recombination deficiency.

TARGETING REPLICATION STRESS TO TREAT HRp TUMORS

CCNE and MYC amplified EOC have been identified as possible targets of RS response inhibitors, such as CHK1, ATRi, and WEE1 inhibitors (WEE1i). The inhibition of these checkpoints leads to inappropriate initiation of replication from multiple origins, depletion of replication factors, fork collapse, and cell death^[100]. In CCNE1-amplified HGSOC cell lines, the CDK2 inhibitor dinaciclib suppresses cell growth and cell cycle progression, inducing apoptosis with a rise of intracellular radical oxygen species (ROS) levels^[101]. The combination of a CDK2i and an AKTi also resulted in tumor regression in CCNE1-amplified cell lines of HGSOC^[102]. In MYC overexpressing ovarian cancer xenograft models, the CDK4/6i, palbociclib induced tumor regression when combined with olaparib, showing a potential synergy among these two DDR targeting agents^[103].

Among the genes identified as related to a loss of fitness in CCNE amplified cells, there is PKMYT1, which encodes the protein kinase Myt1, involved in the negative regulation of CDK1. RP-6306, a highly selective inhibitor of this target, was tested on several ovarian carcinoma cell lines and showed greater toxicity in CCNE1 amplified preclinical models alone or with gemcitabine^[104]. Following these promising preclinical results, RP-6306 enters clinical investigation as a single agent (NCT04855656) and in association with gemcitabine (NCT05147272).

The ATRi berzosertinib has been combined with gemcitabine in a phase II trial in patients with recurrent EOC and a platinum-free interval < 6 months ($n = 70$). PFS was improved in the experimental arm and the greatest benefit in PFS was obtained in patients with a platinum-free interval ≤ 3 months (PFS 27.7 weeks vs. 9 weeks, HR 0.29; 90%CI 0.12 to 0.71)^[105]. A preplanned exploratory analysis revealed a better response trend with gemcitabine alone in patients in the Signature 3-negative subgroup (reflective of HRp tumors) compared to patients in the Signature3-positive subgroup (reflective of HRD tumor)^[106]. In addition, tumors with high RS achieved a better response to gemcitabine, likely due to the gemcitabine-induced RS through inhibition of DNA repair and suppression of ribonucleotide reductase^[106].

Another promising agent in this setting is the WEE1i adavosertib, which has been investigated in different phase 2 trials in platinum-sensitive and resistance recurrent OC^[97,107-109]. Interestingly, the preliminary results of a phase 2 study of single-agent adavosertib in CCNE1 overexpressed recurrent platinum-resistant or refractory HGSOc has been presented. The WEE1 inhibitor resulted in a high ORR (53%) and a clinical benefit rate of 61%, with some patients showing sustained responses over time. Translational analyses are ongoing to better define potential predictive biomarkers of WEE1i activity^[110].

CONCLUSIONS

Targeting the HRR pathway through PARP inhibition has revolutionized the treatment of EOC. Clinical trials have proved that the HRp subgroup has a modest advantage with PARPi compared to the HRD population. Different genomic assays are now available to assess the presence of HRD. Although in most studies, HRD status detected by these assays has been shown to be able to discriminate the magnitude of PARPi benefit in BRCAwt EOC, these assays cannot reliably identify the group of HRp women with EOC that definitively derive no benefit from PARPi. HRD tests and mutational signatures, although promising, do not represent the dynamic changes in the functional status of HRD^[111].

Although a direct comparison within a randomized trial is currently lacking, the benefit of PARPi as first-line maintenance is comparable to that observed with bevacizumab in women with HRp EOC. Given that in the HRp population, no benefit was shown in adding olaparib to bevacizumab in first-line settings, bevacizumab could still represent a viable alternative for this subgroup of patients^[15]. Pending further data from ongoing clinical trials comparing PARPi vs. antiangiogenic treatment in the HRp population, the decision on the best first-line strategy should be based on the toxicity profile of the two classes of drugs and patients' comorbidities.

Different studies are ongoing to explore strategies to induce HRD and increase the sensitivity to PARPi, even in HRp tumors. Recently, new insights into the biology of HRp and platinum-resistant tumors are sustaining the development of new promising agents targeting the RS^[100]. These new agents, alone or in combination, have shown preliminary signs of activity, but their use is challenged by the safety profile and the need to define optimal doses and schedules to maximize the clinical activity while minimizing the occurrence and severity of the adverse events.

Abstract

The introduction of first-line combinations had improved the outcomes for metastatic renal cell carcinoma (mRCC) compared to sunitinib. However, some patients either have inherent resistance or develop resistance as a result of the treatment. Depending on the kind of therapy employed, many factors underlie resistance to systemic therapy. Angiogenesis and the tumor immune microenvironment (TIME), nevertheless, are inextricably linked. Although angiogenesis and the manipulation of the tumor microenvironment are linked to hypoxia, which emerges as a hallmark of renal cell carcinoma (RCC) pathogenesis, it is only one of the potential elements involved in the distinctive intra- and inter-tumor heterogeneity of RCC that is still dynamic. We may be able to more correctly predict therapy response and comprehend the mechanisms underlying primary or acquired resistance by integrating tumor genetic and immunological markers. In order to provide tools for patient selection and to generate hypotheses for the development of new strategies to overcome resistance, we reviewed the most recent research on the mechanisms of primary and acquired resistance to immune checkpoint inhibitors (ICIs) and tyrosine kinase inhibitors (TKIs) that target the vascular endothelial growth factor receptor (VEGFR). We can choose patients' treatments and cancer preventive strategies using an evolutionary approach thanks to the few evolutionary trajectories that characterize ccRCC.

Keywords: Renal cell carcinoma, resistance, tumor microenvironment, checkpoint inhibitors, target therapy

INTRODUCTION

The recent approval of the new first-line combinations, which include immune checkpoint inhibitors (ICIs) both plus VEGFR-TKIs or the anti-cytotoxic T lymphocyte antigen-4 (CTLA-4) monoclonal antibody (mAb), ipilimumab, has revolutionized the treatment of metastatic renal cell carcinoma, reporting improved outcomes in pivotal studies^[1-7]. Despite the excellent response rates, some patients are either innately resistant to therapy or eventually develop later resistance to it. Hence, a better understanding of the mechanisms underlying VEGFR-TKI and/or ICI resistance will be helpful in selecting patients who might not respond to this kind of approach and developing strategies to overcome resistance.

Today, the only validated risk assessment tool is risk stratification according to the International mRCC Database Consortium (IMDC) score, which is based upon six clinical and laboratory features^[8,9]. However, this approach lacks the ability to recognize genetic and intrinsic factors that potentially direct response to immunotherapy and has only been thoroughly validated for patients treated with single agent VEGFR-targeted therapies.

Here, we reviewed the most recent research on the factors that contribute to both primary and acquired resistance to VEGF-TKI and ICI with the aim of supplying tools for patient selection and generating hypotheses in an effort to decrease the proportion of patients who do not respond or to postpone the emergence of resistance.

MOLECULAR SUBSETS IN METASTATIC RENAL CELL CARCINOMA

Clear cell renal cell carcinoma (ccRCC) is a highly inflamed and immune-infiltrated tumor type with high expression of immune checkpoints, such as PD-L1 and CTLA-4. However, ccRCC has the peculiarity of having a high degree of infiltration by exhausted CD8⁺ tumor-infiltrating lymphocytes (TILs), immunosuppressive cells such as M2-like tumor-associated macrophages (TAMs), regulatory T cells (Tregs), and myeloid-derived suppressor cells (MDSCs), which characterized a tumor microenvironment with immunosuppressive properties^[10-12].

Immune cells (IC) are components of tumor immune microenvironment (TIME) and play an important role in modulating immune response to tumor cells^[13]. These cells could have been implicated both in immune tumor suppression and tumor escape.

More than just identifying individual cells, the microenvironment's composition could provide insight into the mechanisms causing immune escape, and choosing more effective targets could lead to better results. Using ccRCC samples, Chevrier *et al.* examined the TIME's composition and discovered a particular exhausted CD8⁺/PD-1⁺ T cell phenotype that was defined by the co-expression of inhibitory receptors and might be the cause of immune suppression. Additionally, they discovered CD38 to be a marker of exhaustion in the CD8⁺/PD-1⁺ T cell phenotype, and these cells were closely associated with the presence of regulatory CD4⁺ T cells and of a cluster of macrophages with the highest expression of CD38 and immune suppressive activity.

Rather than focusing on each cell individually, TIME composition and the number of immune cells may be able to predict outcomes more accurately^[14].

Additionally, the TIME could be altered by the use of VEGFR-TKIs and ICIs^[15-21], and the TIME may also be impacted by genetic changes in ccRCC, such as von Hippel-Lindau (VHL) and PBRM1 mutations. As a result, different genomic signatures may confer a different response to a specific treatment. Therefore, a

deeper comprehension of the molecular traits that uniquely distinguish ccRCC is required to enhance patient selection, risk stratification, and resistance mechanism definition.

Three major gene expression signatures have been identified using data from the first-line pivotal trial in mRCC (IMmotion 150, JAVELIN RENAL 101, Checkmate 214): Angiogenesis, T-effector (Teff)/IFN- γ response, and myeloid inflammatory gene expression signatures^[22-24].

Gene expression patterns that had been previously described in relation to their corresponding biology were used for the definition of gene signatures. Angio: VEGFA, KDR, ESM1, PECAM1, ANGPTL4, and CD34; Teff: CD8A, EOMES, PRF1, IFNG, and CD274; myeloid inflammation: IL-6, CXCL1, CXCL2, CXCL3, CXCL8, and PTGS2^[25-27].

Angio gene profile identified a group of patients who would respond to a VEGFR-TKI alone, resulting in superior outcomes with sunitinib in each study. Given that a high T effector gene signature may indicate an improved response to a VEGFR-TKI and ICI combination therapy, the presence of a myeloid signature in the T effector high group identified tumors that are resistant to immunotherapy when used alone, as demonstrated by the worse outcomes for patients treated with atezolizumab alone in the IMmotion 150 trial. Furthermore, a myeloid infiltrate, which is indicative of innate resistance to immunotherapy alone, could be overcome by the addition of a therapy targeting angiogenesis. Gene signatures based on a single class of genes may be effective tools that support patient selection. However, when using two immune checkpoint inhibitors, a combination of gene signatures including both innate and adaptive immune response components may be more suggestive of how TIME and therapies interact and may be more predictive of results. The “Renal 101 Immune signature”, a 26-gene subset of the gene expression signature (GES) that included regulators of innate and adaptive immunological responses (T cell and NK cell), cell trafficking, and inflammation, identified in JAVELIN RENAL 101, is an even more comprehensive molecular predictive tool, underlying the significance of CD8+ T cells in inducing immune response^[23].

Table 1 schematically summarizes the correlation of GES (Angio, Teff, Myeloid) with positive outcomes in IMmotion 150, Javelin RENAL 101, and Checkmate 214.

MOLECULAR SUBSETS IN RCC AS BIOMARKER STRATEGIES FOR PERSONALIZED TREATMENT

In 2020, McDermott *et al.* completed a significant research effort to evaluate the outcomes of patients who received a combination of checkpoint inhibitors, applying the previously developed IMmotion 150 signatures to the IMmotion 151 trial^[22]. In order to develop a new molecular categorization of RCC, they performed an integrative multi-omics analysis of 823 RCC tumors^[28,29].

Non-negative matrix factorization (NMF) was used to identify seven distinct molecular clusters, and the distribution of these clusters across IMDC risk groups was assessed. They examined the somatic alterations within each cluster and investigated the clinical outcomes of patients who received atezolizumab in combination with bevacizumab, sunitinib, and atezolizumab across clusters.

Table 2 synthesizes cluster characteristics, gene profile expression, and their correlation with outcomes.

Angiogenic clusters (1 and 2) were enriched in the favorable risk group (evaluated both according to MSKCC and IMDC risk categories) and showed better progressive-free survival (PFS). However, angiogenic

Table 1. Correlation between GES with favorable outcomes

	IMmotion 150 ^[22]			Javelin renal 101 ^[23]		Checkmate 214 ^[24]

Angio: Angiogenic; Atezo: atezolizumab; Ave: avelumab; Axi: axitinib; Beva: bevacizumab; GES: gene expression signature; Ipi: ipilimumab; Nivo: nivolumab; Sun: sunitinib; Teff: T-effector.

signature did not differentiate outcomes between arms. No correlation was also seen for patients belonging to cluster 3 (complement/-oxidation).

Otherwise, the poor-risk group was more likely to have proliferative clusters (4-6), with stromal/proliferative clusters demonstrating the shorter PFS irrespective of treatment arm. Teff/proliferative and proliferative cluster results, as well as the snoRNAs cluster, experienced better outcomes with the atezolizumab plus bevacizumab combination.

Among somatic alterations, PBRM1 mutations gave superior results, irrespective of the treatment arm. But in PBRM1 mutant patients, Atezolizumab + Bevacizumab showed improved PFS and ORR than sunitinib. Conversely, CDKN2A/B alterations identified patients with worse prognoses. However, CDKN2A/A-altered tumors had better PFS and ORR in the atezolizumab + bevacizumab arm compared with the sunitinib arm.

Better outcomes with the combination were also seen for tumors harboring loss-of-function mutations of ARID1A and/or KMT2C^[28].

In conclusion, these molecular subsets constitute a novel method of reproducible response prediction that may be useful in patient selection. As shown for clusters 1 and 2, the angiogenesis pathway confers a biological behavior that is comparable for tumors treated with a VEGFR-TKI alone or in combination. A proliferative pattern, on the other hand, suggests a lack of response to a therapy that targets angiogenesis alone and a potentially better response to a combination therapy that includes ICIs. This classification does not include the combination of dual checkpoint inhibitors, which would restrict its reproducibility. However, we are aware that nivolumab + ipilimumab has shown superior outcomes in the category of intermediate-poor risk.

The tumors from patients with favorable risk in this study exhibited a higher expression of the VEGF pathway-associated angiogenesis signature, which provides a potential explanation for why the dual combination failed to improve outcomes in the favorable risk subgroup.

Table 2. Molecular clusters by NMF, gene expression profiles, DNA alterations, and correlation with outcomes

	Cluster 1		Cluster 2		Cluster 3		Cluster 4		Cluster 5		Cluster 6		Cluster 7	
Name	Angiogenic/ Stromal		Angiogenic		Complement/ -Oxidation		Teff/ Proliferative		Proliferative		Stromal/ Proliferative		snoRNA	
Transcriptional Pathways	Angiogenesis Stroma		Angiogenesis Catabolic metabolism (FAO)		Complement cascade -oxidation		Cell-cycle Teff Anabolic metabolism (FAS)		Cell-cycle Anabolic metabolism (FAS) Myeloid inflammation		Cell-cycle Stroma		snoRNAs	
Gene expression module	TGF, WNT, Hedgehog, NOTCH		TGF, WNT, Hedgehog, NOTCH		Complement cascade		Cell-cycle		Cell-cycle		Cell-cycle		C/D box snoRNAs (SNORDs)	
	Stroma-genes: Fibroblast-derived genes <i>FAP, FN1, PSTN, MMP2</i>		Catabolic mb: <i>FAO/AMPK</i> genes		Cytochrome P450 family		Anabolic mb FAS Pentose phosphate		Anabolic mb		Anabolic mb			
			<i>Moderate expression: Teff genes</i>		<i>Moderate expression: Cell-cycle genes</i>		Teff JAK/ STAT IFN- α and - γ		Myeloid inflammation genes		EMT transcriptional genes Myeloid inflammation genes			
DNA alterations	PBRM1 VHL KDM5C PTEN		VHL PBRM1 KDM5C		VHL PBRM1 KDM5C PTEN BAP1		VHL CDKN2A/B BAP1		CDKN2A/B TP53 TFE fusions (mTORC1 pathway)		VHL CDKN2A/B TP53		VHL SETD2 PTEN
