GENERAL INFORMATION

About the Journal

Journal of Cancer Metastasis and Treatment (JCMT), ISSN 2454-2857 (Online), ISSN 2394-4722 (Print), is a peer-reviewed and continuously published online journal with print on demand compilation of articles published. The journal's full text is available online at www.jcmtjournal.com. The journal allows free access (Open Access) to its contents and permits authors to self-archive final accepted version of the articles on any OAI-compliant institutional/subject-based repository. The journal focuses on cancer metastasis and treatment, including the initiation, development, progression, metastasis and treatment of neoplastic diseases. The coverage includes basic and clinical studies related to cancer cell, cell biology, oncology, radiation therapy and radiology, obstetrics and gynecology, pediatrics, surgery, hematology, neuro-oncology, *etc.* The journal is indexed by CAS, Google Scholar, EBSCO, Eurasian Scientific Journal Index, Root Indexing, Wanfang Data, DRJI, J-Gate, SHERPA/RoMEO, CNKI, JournalTOCs, JournalGuide, and ResearchBib.

Information for Authors

Manuscripts should be prepared in accordance with Author Instructions.
Please check www.jcmtjournal.com/pages/view/author_instructions for details.
All manuscripts should be submitted online at <https://oaemesas.com/jcmt/>.

Copyright

CONTENTS

- 1 Mass spectrometry-based metabolomic profiling of prostate cancer - a pilot study**
Krzysztof Ossoliński, Joanna Nizioł, Adrian Arendowski, Anna Ossolińska, Tadeusz Ossoliński, Jakub Kucharz, Paweł Wiechno, Tomasz Ruman
J Cancer Metastasis Treat 2019;5:1 <http://dx.doi.org/10.20517/2394-4722.2018.63>
- 2 Axillary recurrence after intramammary sentinel lymph nodes metastases with capsular extravasation**
Paulo R. De Alcantara Filho, Stephania Martins Bezerra
J Cancer Metastasis Treat 2019;5:2 <http://dx.doi.org/10.20517/2394-4722.2018.62>
- 3 Cancer stem cells, stemness markers and selected drug targeting: metastatic colorectal cancer and cyclooxygenase-2/prostaglandin E2 connection to WNT as a model system**
Reem Ali ALHulais, Stephen John Ralph
J Cancer Metastasis Treat 2019;5:3 <http://dx.doi.org/10.20517/2394-4722.2018.71>
- 4 A pilot study for distinguishing basal cell carcinoma from normal human skin tissues using visible resonance Raman spectroscopy**
Cheng-hui Liu, Binlin Wu, Laura A. Sordillo, Susie Boydston-White, Vidyasagar Sriramoju, Chunyuan Zhang, Hugh Beckman, Lin Zhang, Zhe Pei, Lingyan Shi, Robert R. Alfano
J Cancer Metastasis Treat 2019;5:4 <http://dx.doi.org/10.20517/2394-4722.2018.55>
- 5 Meeting Abstracts of the 3rd International Workshop No-Cancer 2018 - understanding cancer cell biology to improve diagnosis and therapy**
Ciro Isidoro, Gianluca Gaidano
J Cancer Metastasis Treat 2019;5:5 <http://dx.doi.org/10.20517/2394-4722.2018.108>
- 6 A non-toxic approach for treatment of breast cancer and its metastases: capecitabine enhanced photodynamic therapy in a murine breast tumor model**
Sanjay Anand, Anton Yasinchak, Taylor Bullock, Mukul Govande, Edward V. Maytin
J Cancer Metastasis Treat 2019;5:6 <http://dx.doi.org/10.20517/2394-4722.2018.98>
- 7 Wrong place at the wrong time: how retrograde trafficking drives cancer metastasis through receptor mislocalization**
Sabrina A. Maisel, Joyce Schroeder
J Cancer Metastasis Treat 2019;5:7 <http://dx.doi.org/10.20517/2394-4722.2018.82>
- 8 Microinvasive breast cancer with supraclavicular lymph node and ovarian metastasis as clinical findings: a rare case report**
Sefa Kurt, Hikmet Tunc Timur, Hasan Bahadır Saatli, Ali Ibrahim Sevinc, Emine Çagnur Ulukus
J Cancer Metastasis Treat 2019;5:8 <http://dx.doi.org/10.20517/2394-4722.2018.80>

- 9 **Studies of postpartum mammary gland involution reveal novel pro-metastatic mechanisms**
Taylor R. Wallace, Sarah E. Tarullo, Lyndsey S. Crump, Traci R. Lyons
J Cancer Metastasis Treat 2019;5:9 <http://dx.doi.org/10.20517/2394-4722.2019.01>
- 10 **Radiotherapy of brain metastases from non-small cell lung cancer**
Esra Korkmaz Kirakli, Ufuk Yilmaz
J Cancer Metastasis Treat 2019;5:10 <http://dx.doi.org/10.20517/2394-4722.2018.73>
- 11 **Is active targeting of brain metastases of breast cancer superior to passive targeting?**
Nermeen H. Kamal, Fatema El-Amrawy, Heba Abdullah Ali, Ivan Edafiohgo, Mohamed Ismail Nounou
J Cancer Metastasis Treat 2019;5:11 <http://dx.doi.org/10.20517/2394-4722.2018.89>
- 12 **Metabolic rewiring of stem cells and differentiated cells in cancer: the hypothetical consequences of a GABA deficiency in endocrine pancreas**
Maurice Israël
J Cancer Metastasis Treat 2019;5:12 <http://dx.doi.org/10.20517/2394-4722.2018.78>
- 13 **A review of the effects of healthcare disparities on the experience and survival of ovarian cancer patients of different racial and ethnic backgrounds**
Matthew Kaufman, Ana Cruz, Janese Thompson, Srinivasa Reddy, Nisha Bansal, Joshua G. Cohen, Yanyuan Wu, Jay Vadgama, Robin Farias-Eisner
J Cancer Metastasis Treat 2019;5:13 <http://dx.doi.org/10.20517/2394-4722.2018.25>
- 14 **Sequential treatment with doxorubicin and zoledronic acid has no additive effects in an aggressive model of established bone metastases**
Mari I. Suominen, Rami Kähkönen, Jukka P. Rissanen, Jussi M. Halleen, Pirkko Härkönen, Sanna-Maria Kähkönen
J Cancer Metastasis Treat 2019;5:14 <http://dx.doi.org/10.20517/2394-4722.2018.64>
- 15 **Targeting histone lysine-specific demethylase KDM1A/LSD1 to control epithelial-mesenchymal transition program in breast cancers**
Carmen D. Saccà, Francesca Gorini, Susanna Ambrosio, Stefano Amente, Barbara Majello
J Cancer Metastasis Treat 2019;5:15 <http://dx.doi.org/10.20517/2394-4722.2018.95>
- 16 **hnRNP E1 at the crossroads of translational regulation of epithelial-mesenchymal transition**
Simon Grelet, Philip H. Howe
J Cancer Metastasis Treat 2019;5:16 <http://dx.doi.org/10.20517/2394-4722.2018.85>
- 17 **AF1q inhibited T cell attachment to breast cancer cell by attenuating Intracellular Adhesion Molecule-1 expression**
Jino Park, Jae Yeon Hwang, Alexandra Thore, Soojin Kim, Tomiteru Togano, Shotaro Hagiwara, Juwon Park, William Tse
J Cancer Metastasis Treat 2019;5:17 <http://dx.doi.org/10.20517/2394-4722.2018.84>

- 18 Window of opportunity trials in head and neck cancer**
Janice L. Farlow, Andrew C. Birkeland, Paul L. Swiecicki, J. Chad Brenner, Matthew E. Spector
J Cancer Metastasis Treat 2019;5:18 <http://dx.doi.org/10.20517/2394-4722.2018.100>
- 19 Understanding convergent signaling regulation in metastatic breast cancer cells using a bioengineered stem cell microenvironment**
Bridget Mooney, Yangzi Isabel Tian, Erin Rousseau, Yubing Xie
J Cancer Metastasis Treat 2019;5:19 <http://dx.doi.org/10.20517/2394-4722.2018.93>
- 20 Synergistic inhibition of SCR1- and ERBB2-driven brain metastatic breast cancer cells**
Shahnaz R. Ansari, Zain Jandial, Xiwei Wu, Xueli Liu, Mike Y. Chen, Khairul I. Ansari
J Cancer Metastasis Treat 2019;5:20 <http://dx.doi.org/10.20517/2394-4722.2018.68>
- 21 Contribution of alternative splicing to breast cancer metastasis**
Xiangbing Meng, Shujie Yang, Jun Zhang, Huimin Yu
J Cancer Metastasis Treat 2019;5:21 <http://dx.doi.org/10.20517/2394-4722.2018.96>
- 22 PIM-1 inhibition with AZD1208 to prevent osimertinib-induced resistance in EGFR-mutation positive non-small cell lung cancer**
Jillian Wilhelmina Paulina Bracht, Niki Karachaliou, Jordi Berenguer, Manuel Fernandez-Bruno, Martyna Filipiska, Carlos Pedraz-Valdunciel, Carles Codony-Servat, Jordi Codony-Servat, Rafael Rosell
J Cancer Metastasis Treat 2019;5:22 <http://dx.doi.org/10.20517/2394-4722.2018.111>
- 23 Central regulation of breast cancer growth and metastasis**
Jeremy C. Borniger
J Cancer Metastasis Treat 2019;5:23 <http://dx.doi.org/10.20517/2394-4722.2018.107>
- 24 Complex interaction of adiponectin-mediated pathways on cancer treatment: a novel therapeutic target**
Massimo Monks, Foivos Irakleidis, Peng H. Tan
J Cancer Metastasis Treat 2019;5:24 <http://dx.doi.org/10.20517/2394-4722.2018.79>
- 25 Photodynamic therapy in cancer treatment - an update review**
Ancély Ferreira dos Santos, Daria Raquel Queiroz de Almeida, Leticia Ferreira Terra, Maurício S. Baptista, Leticia Labriola
J Cancer Metastasis Treat 2019;5:25 <http://dx.doi.org/10.20517/2394-4722.2018.83>
- 26 Metabolic alterations and the potential for targeting metabolic pathways in the treatment of multiple myeloma**
Dustin Rizzieri, Barry Paul, Yubin Kang
J Cancer Metastasis Treat 2019;5:26 <http://dx.doi.org/10.20517/2394-4722.2019.05>
- 27 Stereotactic radiosurgery in the era of novel systemic therapy for lung cancer brain metastases**
Sarah Mudra, Shruti Bhandari, Prashant Tripathi, Neal Dunlap, Goetz Kloecker
J Cancer Metastasis Treat 2019;5:27 <http://dx.doi.org/10.20517/2394-4722.2019.09>

- 28 **Contralateral axillary metastasis: is surgical treatment the best option?**
 María Julia Giménez, Jesús Manuel Patrón, Giovanni Vento, Ana Bayón, Vincenzo Maisto, Isidro Bolumar, Rosa Ferrer, Josep Asensi, Joaquin Gavila, Rafael Estevan
J Cancer Metastasis Treat 2019;5:28 <http://dx.doi.org/10.20517/2394-4722.2018.75>

- 29 **Can microcalcifications' characteristics predict the risk of breast cancer metastasis to bone?**
 Rita Bonfiglio, Manuel Scimeca, Alessandro Polidori, Clara Nazzaro, Giselda De Silva, Elena Bonanno
J Cancer Metastasis Treat 2019;5:29 <http://dx.doi.org/10.20517/2394-4722.2018.88>

- 30 **Breast cancer metastasis to the stomach**
 Francesco D'Angelo, Alessia Rampini, Silvia Cardella, Laura Antolino, Giuseppe Nigri, Stefano Valabrega, Paolo Aurello, Giovanni Ramacciato
J Cancer Metastasis Treat 2019;5:30 <http://dx.doi.org/10.20517/2394-4722.2018.86>

- 31 **Meeting abstracts of Colossal Facet Conference - 2nd World Congress on Cancer 2018 "Oncology and Cancer therapeutics in the 21st century"**
 Ciro Isidoro
J Cancer Metastasis Treat 2019;5:31 <http://dx.doi.org/10.20517/2394-4722.2019.21>

- 32 **Targeting autophagy with small molecules for cancer therapy**
 Sree Karani Kondapuram, Sailu Sarvagalla, Mohane Selvaraj Coumar
J Cancer Metastasis Treat 2019;5:32 <http://dx.doi.org/10.20517/2394-4722.2018.105>

- 33 **Peripheral biomarkers for pediatric brain tumors: current advancements and future challenges**
 Markus J. Bookland, Antonina Kolmakova
J Cancer Metastasis Treat 2019;5:33 <http://dx.doi.org/10.20517/2394-4722.2018.110>

- 34 **Sensitive and specific detection of circulating tumor cells promotes precision medicine for cancer**
 Qin-Qin Huang, Xing-Xiang Chen, Wei Jiang, Shui-Ling Jin, Xing-Yu Wang, Wei Liu, Shi-Shang Guo, Jian-Cheng Guo, Xing-Zhong Zhao
J Cancer Metastasis Treat 2019;5:34 <http://dx.doi.org/10.20517/2394-4722.2018.94>

- 35 **Breast cancer, metastasis, and the microenvironment: disabling the tumor cell-to-stroma communication network**
 Gerald J. Mizejewski
J Cancer Metastasis Treat 2019;5:35 <http://dx.doi.org/10.20517/2394-4722.2018.70>

- 36 **Cancer stem cells in liver metastasis from colon adenocarcinoma express components of the renin-angiotensin system**
 Anantha Narayanan, Susrutha K. Wickremesekera, Bede van Schaijik, Reginald W. Marsh, Helen D. Brasch, Swee T. Tan, Tinte Itinteang
J Cancer Metastasis Treat 2019;5:36 <http://dx.doi.org/10.20517/2394-4722.2018.77>

- 37 **The molecular interaction of ADAMTS-1 and fibulin-1 and its potential contribution to breast cancer biology**
Yamina Mohamedi, Tania Fontanil, Teresa Cobo, José A. Vega, Juan L. Cobo, Olivia García-Suárez, Juan Cobo, Santiago Cal, Álvaro J. Obaya
J Cancer Metastasis Treat 2019;5:37 <http://dx.doi.org/10.20517/2394-4722.2018.81>
- 38 **ESR1 alterations and metastasis in estrogen receptor positive breast cancer**
Jonathan T. Lei, Xuxu Gou, Sinem Seker, Matthew J. Ellis
J Cancer Metastasis Treat 2019;5:38 <http://dx.doi.org/10.20517/2394-4722.2019.12>
- 39 **Stem cells, immortality, and the evolution of metastatic properties in breast cancer: telomere maintenance mechanisms and metastatic evolution**
Nathaniel J. Robinson, Derek J. Taylor, William P. Schiemann
J Cancer Metastasis Treat 2019;5:39 <http://dx.doi.org/10.20517/2394-4722.2019.15>
- 40 **Prognostic and predictive role of hyponatremia in cancer patients**
Alessandro Peri
J Cancer Metastasis Treat 2019;5:40 <http://dx.doi.org/10.20517/2394-4722.2019.14>
- 41 **The lncRNA BORG: a novel inducer of TNBC metastasis, chemoresistance, and disease recurrence**
Alex J. Gooding, Kimberly A. Parker, Saba Valadkhan, William P. Schiemann
J Cancer Metastasis Treat 2019;5:41 <http://dx.doi.org/10.20517/2394-4722.2019.11>
- 42 **Training and evaluation of a knowledge-based model for automated treatment planning of multiple brain metastases**
Vishruta A. Dumane, Tsu-Chi Tseng, Ren-Dih Sheu, Yeh-Chi Lo, Vishal Gupta, Audrey Saitta, Kenneth E. Rosenzweig, Sheryl Green
J Cancer Metastasis Treat 2019;5:42 <http://dx.doi.org/10.20517/2394-4722.2019.08>
- 43 **Autophagy in breast cancer metastatic dormancy: tumor suppressing or tumor promoting functions?**
Alyssa La Belle Flynn, William P. Schiemann
J Cancer Metastasis Treat 2019;5:43 <http://dx.doi.org/10.20517/2394-4722.2019.13>
- 44 **Chemotherapy-induced immunological breast cancer dormancy: a new function for old drugs?**
Sanam Peyvandi, Qiang Lan, Girieca Lorusso, Curzio Rüegg
J Cancer Metastasis Treat 2019;5:44 <http://dx.doi.org/10.20517/2394-4722.2019.16>
- 45 **Operative treatment of metastatic breast cancer in the spine with regard to molecular phenotypes**
Daniel Adler, Wojciech Pepke, Michael Akbar
J Cancer Metastasis Treat 2019;5:45 <http://dx.doi.org/10.20517/2394-4722.2019.03>

- 46 **Differential expression and function of the endogenous lactate receptor, GPR81, in ER α -positive/HER2-positive epithelial vs. post-EMT triple-negative mesenchymal breast cancer cells**
Denisse Tafur, Patrick Svrcek, Bruce White
J Cancer Metastasis Treat 2019;5:46 <http://dx.doi.org/10.20517/2394-4722.2018.102>
- 47 **Cellular plasticity and metastasis in breast cancer: a pre- and post-malignant problem**
Jacob M. Smigiel, Sarah E. Taylor, Benjamin L. Bryson, Ilaria Tamagno, Kelsey Polak, Mark W. Jackson
J Cancer Metastasis Treat 2019;5:47 <http://dx.doi.org/10.20517/2394-4722.2019.26>
- 48 **Significance of trace element quantities in the prostatic secretion of patients with benign prostatic hyperplasia and prostate cancer**
Vladimir Zaichick, Sofia Zaichick
J Cancer Metastasis Treat 2019;5:48 <http://dx.doi.org/10.20517/2394-4722.2019.07>
- 49 **The role of hypoxia-induced factor 1 α in breast cancer**
Carlos Henrique F. Peiró, Jéssica A. Encina, Matheus M. Perez, Glauco S. A. Aquino, Glaucia L. Veiga, Fernando Fonseca, Beatriz C. A. Alves
J Cancer Metastasis Treat 2019;5:49 <http://dx.doi.org/10.20517/2394-4722.2018.109>
- 50 **A new view of the mammary epithelial hierarchy and its implications for breast cancer initiation and metastasis**
Lindsey J. Anstine, Ruth Keri
J Cancer Metastasis Treat 2019;5:50 <http://dx.doi.org/10.20517/2394-4722.2019.24>
- 51 **Paxillin serine 178 phosphorylation in control of cell migration and metastasis formation through regulation of EGFR expression in breast cancer**
Saertje Verkoeijen, Ya-Feng Ma, Wies van Roosmalen, Reshma Lalai, Martine H. A. M. van Miltenburg, Marjo de Graauw, Bob van de Water, Sylvia E. Le Dévédec
J Cancer Metastasis Treat 2019;5:51 <http://dx.doi.org/10.20517/2394-4722.2019.06>
- 52 **Circulating microRNAs and liquid biopsy: murine xenograft models for technical validation of clinical protocols**
Jessica Gasparello, Matteo Allegretti, Chiara Papi, Elena Giordani, Patrizio Giacomini, Roberto Gambari, Alessia Finotti
J Cancer Metastasis Treat 2019;5:52 <http://dx.doi.org/10.20517/2394-4722.2019.17>
- 53 **Radiotherapy of brain metastases from small-cell lung cancer: standards and controversies**
Lucyna Kepka
J Cancer Metastasis Treat 2019;5:53 <http://dx.doi.org/10.20517/2394-4722.2018.114>

- 54 **Diagnosis and management of brain metastases: an updated review from a radiation oncology perspective**
Gutiérrez-Valencia Enrique, Sánchez-Rodríguez Irving, Balderrama-Ibarra Ricardo, Fuentes-Lara Jesús, Ríos-Martínez Alan, Vázquez Aldana Arroyo Iñigo, Bayardo-López Luis, Hernández Chávez Allan, Puebla-Mora Ana Graciela, Nader-Roa Liliana, Espíritu-Rodríguez Roque

Abstract

Aim: Prostate cancer (PCa) is the most commonly diagnosed non-skin cancer among men. Serum prostate-specific antigen level is used as a standard PCa biomarker for over 20 years. However, it has only 33% specificity and 86% sensitivity (for the cutoff value for prostate biopsy of > 4 ng/mL). This leads to overdiagnosis and overtreatment. In-depth insight into PCa metabolomics enables discovery of novel PCa biomarkers.

Methods: Metabolomic alternation in PCa serum, urine and interstitial fluid was examined using gold-nanoparticle-based laser mass spectrometry imaging. This study included 5 patients who underwent prostate biopsy with positive result, 5 patients with negative result and 10 healthy controls.

Results: Over two hundred differentiating metabolites (87 in urine, 54 in serum and 78 in interstitial fluid) were detected. Four, twenty two and ten metabolites from urine, serum and interstitial fluid respectively showed statistical significant differential abundance between cancer and control group.

Conclusion: Comprehensive metabolomic profile of PCa has been identified. Out of 36 metabolites, 20 were identified and should be further evaluated in clinical trials as a potential PCa biomarker. Urine concentration of triglyceride (12:0/20:1) showed over 10 times higher abundance in PCa samples in comparison to healthy controls and is considered the most promising potential biomarker.

Keywords: Prostate cancer, biomarker, metabolomics, mass spectrometry

INTRODUCTION

Prostate cancer (PCa) is the most commonly diagnosed non-skin cancer and third leading cause of mortality after lung and colorectal cancer among men in Western World. Overall, during lifetime, 1 in 6 men will develop PCa and 1 in 33 will die from this disease. Moreover, at presentation 16% of patients will have locally advanced or metastatic disease. Life expectancy depends mainly on the stage and varies between < 5 years for metastatic disease to minimal risk of death at 15 years for organ-confined disease^[1]. Historically PCa was diagnosed with digital rectal examination (DRE) followed by transperineal or digitally guided transrectal biopsy, often in advanced stage. Introduction of prostate-specific antigen (PSA) testing has revolutionized diagnosis of PCa and is shown to be the better predictor of cancer than DRE or transrectal ultrasound (TRUS). Traditional PSA cutoff value for prostate biopsy is > 4 ng/mL and has only 33% specificity and 86% sensitivity for detection of PCa. As a result patients with elevated PSA are overdiagnosed and overtreated. Decrease in mortality from PCa observed in most Western countries is considered partially to be the result of PCa screening with PSA. However, screening with PSA has become one of the most debated topics in urology and is dominated by the conflicting results of 2 randomized control trials: The European Randomized Study of Screening for Prostate Cancer (ERSPC)^[2], which found a survival benefit due to screening with PSA (with the greatest benefit within Goteborg arm of ERSPC trial^[3]) while the United States Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial^[4] did not. As ERSPC study shows, to save one patient from PCa specific death, 1,055 men need to be screened and 37 patients need to be treated. Recent studies concluded that screening is associated with increased diagnosis of PCa, no PCa-specific or overall survival benefit and increased risk of overdiagnosis and overtreatment^[5]. Therefore new diagnostic tools (multiparametric MRI) and biomarkers (PCA3, kallikreins and *TMPRSS2-Erg* fusion) are constantly being developed to increase sensitivity and specificity of PCa testing. Recently a number of novel PCa biomarkers have been developed. The most promising was developed by MDxHealth - SelectMDx. It is a genomic-based test that measures the expression of two PCa-related mRNAs in urine: *HOXC6* and *DLX1* in conjunction with clinical risk factors. It's main advantage is the ability to diagnose patients with clinically significant cancer (Gleason score ≥ 7) which would be selected for prostate biopsy and to avoid identification of indolent PCa. SelectMDx negative predictive value is 98%^[6]. According to Govers *et al.*^[7] application of SelectMDx in clinical practice contributes to increased quality-adjusted life years while saving healthcare costs.

Biomarker research is based on analyzing differences in abundances of varied substances between cancerous tissue or biofluid and their healthy counterpart. This comparative analysis approach identifies and classifies the individual molecules. However, recently, a novel approach have been proposed and is called network-based analysis. Instead of focusing on specific molecule, emphasis is placed on whole cellular pathway and key molecules which are altered in the disease. Search for potential biomarkers has been conducted at every molecular level: genome, transcriptome, proteome and metabolome. Genomic and transcriptomic microarray, real time PCR and next gen. sequencing, proteomic and metabolomic mass spectrometry and nuclear magnetic resonance spectroscopy in combination with advanced bioinformatics tools allowed detailed insight into cancerogenesis. Metabolome, which is collection of all metabolites produced within cell is an endpoint of the "omics cascade" (genomics, proteomics, metabolomics) pathway and in comparison to genes and proteins which are subjected to epigenetic processes and post-translational modifications, is the most accurate representation of phenotype^[8]. Recent advances in mass spectrometry enabled discovery of numerous metabolites specific for lung, colorectal, ovarian, prostate, renal, breast and liver cancer^[9-17]. Metabolomic studies of PCa have led to the discovery of sarcosine as a potential marker of PCa. It has been demonstrated that elevated level of serum sarcosine is associated with PCa^[18,19]. However the role of sarcosine as a potential PCa biomarker has been based on studies involving a small number of subjects and has been questioned following publication of the studies of larger cohort. de Vogel *et al.*^[20] examined serum of 3000

patients with PCa and 3000 controls and showed that elevated serum levels of sarcosine were associated with decreased risk of PCa.

The difficulty in developing PCa biomarker results from the heterogeneity of this type of cancer. It has been demonstrated that factors like obesity and hormonal profile may be associated with increased risk of high grade PCa. de Cobelli *et al.*^[21] demonstrated that high body mass index (BMI) is associated with upgrading and upstaging in patients with low-risk PCa. Moreover it has been shown that low testosterone level is a predictor of upstaging and upgrading in patients with low-risk PCa^[22]. This results support inclusion of BMI and testosterone level into selection criteria for active surveillance programs.

In this study we evaluate the role of mass spectrometry in the metabolomic study of PCa and the possibility to develop potential novel PCa biomarker.

METHODS

Protocol of this study was approved by the ethics committee at the University of Rzeszów, Poland (no. 14/06/2016). Specimens and clinical data related to this study were collected after signing informed consents. Data were prospectively collected from 10 patients with elevated PSA who underwent transrectal prostate biopsy and 10 healthy volunteers between December 2016 and February 2017 at Department of Urology, City Hospital in Rzeszów. Five out ten patients were diagnosed with PCa - 3 with Gleason 7, 1 with Gleason 8 and 1 with Gleason 9. Each biopsy was performed by the same urologist at our department with extensive experience in prostate biopsies (over 10,000 performed procedures) and was examined by dedicated genitourinary pathologist using 2005 International Society of Urological Pathology Gleason grading criteria. Exclusion criteria were: active acute urinary tract infection, bleeding disorder and bowel malignancies or inflammatory bowel diseases. Collected data included age, total PSA level, DRE examination result, TRUS calculated prostate volume and full pathological report. Standard 12-core TRUS guided biopsy was performed. Before procedure, single dose of i.v. ciprofloxacin was used as an antibiotic prophylaxis. Each core was placed into a separate container.

Decision to perform prostate biopsy was based on either elevated PSA level (higher or equal to 4.0 ng/mL) or positive DRE examination. For the purpose of metabolomic analysis, 10 mL of blood, 100 mL of urine and 50 µL of interstitial fluid (IF) extracted from each biopsy core were collected from each patient who has had prostate biopsy. Control group constituted of 10 young (< 40 years old, mean 28.7) healthy volunteers with average PSA of 0.7 ng/mL and average estimated PCa risk (using multivariable ERSPC cohort PCa risk calculator) of 2%. Each volunteer donated 10 mL of blood and 100 mL of urine, no biopsies were performed in this group. Whole blood was collected and centrifuged at 3000 rpm at room temperature for 10 min.

Preparation of samples for mass spectrometry imaging

Urine, serum and IF samples were immediately stored at -80 °C until use. Urine and blood plasma samples were diluted 600 times with water and placed on target plate (0.5 µL). Tissue samples were washed with 50 µL of water and directly placed on target plate (0.5 µL). All samples of the same type (for example all urine samples) were measured on the same target plate in one mass spectrometry imaging (MSI) experiment. Extracts were placed on target plate with the aid of 3D precision translation stage system with spot diameter ca. 1.5 mm.

Mass spectrometry measurements and data handling

Mass spectrometry (MS) analysis was performed using high-resolution laser desorption/ionization (LDI)-time-of-flight (ToF)-MS based on gold nanoparticle-enhanced target (AuNPET) plate^[23] and is presented in simplified form in flowchart in [Figure 1](#). AuNPET target plates of 2.5 × 3.5 cm size and ca. 0.8 mm thickness were used with Bruker NALDI adapter. AuNPET-based surface-assisted, LDI-ToF-MS experiments were

Figure 1. Box plot of all statistically significant ($P < 0.05$) metabolites. x-axis: log10 transformed mass spectrometry intensities (to reduce the impact of variability of high-intensity peaks, intensity axis has been transformed into a logarithmic one); y-axis: m/z values. Red boxes represent cancer, white boxes - control

performed using a Bruker Autoflex Speed ToF-MS in reflectron mode. Instrument was equipped with a SmartBeam II laser (352 nm). The laser impulse energy was approximately 60-120 μ J; the laser repetition rate

was 1000 Hz; and the deflection value was set to m/z 80 Da. The first accelerating voltage was held at 19 kV and the second ion-source voltage was held at 16.7 kV. The reflector voltages used were 21 kV (first) and 9.55 kV (second). Measurement range was m/z 80-2000.

Samples were placed on AuNPET plate semi-automatically with the aid of precise positioning of 3D translation stage which allowed precise orientation of commonly used pipette (Eppendorf Research plus). Application of described stage allowed much higher spot density and repeatability which would be rather impossible in manual manner. Semi-automated solution applied allowed measurements of over hundreds of samples on one custom-made target plates of 3.5×2.5 cm size.

For each sample spot, four measurement locations (pixels) were measured and resulting spectra averaged after preliminary re-calibration. Obtained quadruplicates were additionally recalibrated and normalized, the latter was based on three most abundant gold ion peaks.

Extracts were measured in MSI mode with 20,000 laser shots per individual pixel and four pixels per sample with 300 μ m-lateral resolution. Bruker's FlexImaging 4.0 software was used for setting of MSI experiments. Mass calibration was performed using internal standards (gold ions and clusters from Au^+ to Au_9^+). Imaging data were converted to Analyze 7.5 and then to mzXML format and processed in mMass software. Obtained spectra were processed by application of baseline correction and recalibration. Spectra from four pixels of each spot were averaged and then again recalibrated. Intensities of averaged spectra of spots were normalized based on arithmetical mean of intensities of Au^+ , Au_2^+ and Au_3^+ ions with the use of software developed by our group. Resulting ion lists were then assigned with the use of monoisotopic masses available for metabolites enclosed in Human Metabolome Database (HMDB) and Pathos database within 10 ppm mass accuracy windows.

Study design

Serum and urine were collected from all the patients and categorized as follows: (1) no PCa (healthy volunteers, $n = 10$ patients); (2) presumptive benign disease (negative biopsy, $n = 5$ patients); (3) PCa (positive biopsy, $n = 5$ patients). IF collected from each prostate biopsy core was categorized as follows: (1) presumptive benign disease (negative biopsy, $n = 5$ patients); (2) PCa (positive biopsy, $n = 5$ patients). Each sample was analyzed using standardized MS protocol. Serum and urine specimens collected from patients with biopsy confirmed PCa were compared with those from healthy volunteers (no biopsy in this group). Serum and urine from patients with negative biopsy (no PCa) were excluded from this study due to lack of certainty that there is no PCa in non-biopsied regions of prostate. IF from positive biopsy cores were compared with those from negative cores. Patient characteristics are shown in [Table 1](#).

RESULTS

All statistically significant metabolites ($P < 0.05$) are shown in [Table 2](#). Statistical analysis was performed using SPSS and R software package. Four, twenty-two and ten metabolites from urine, serum and IF respectively showed statistical significant ($P < 0.05$) differential abundance between cancer and control group via Mann-Whitney U test. In addition, metabolites with m/z values of 897.7 (urine) and 307.0 (IF) were positively correlated with prostate volume (Spearman's $\rho = 0.564$, $P = 0.028$ and 0.648 , $P = 0.043$ respectively). Differences between cancer/control intensities have been presented in the form of box- [\[Figure 1\]](#) and volcano-plot [\[Figure 2\]](#) graphs. Peaks obtained from MS analyses were identified and analyzed in the context of metabolic pathways in which they appear within Pathos and HMDB.

DISCUSSION

In this study, a new methodology for rapid metabolomic analysis of human physiological liquids is proposed. MS measurements in imaging mode based on LDI apparatus, with the use of AuNPET target plate, simplify

Figure 2. Volcano plot, all differentiating metabolites. Blue dots: urine metabolites; red dots: serum metabolites; orange dots: interstitial fluid metabolites. All substances above red horizontal line are statistically significant ($P < 0.05$). *tentative identification

to the target and ~20 min of measurements. It should be noted that rapid analysis has additional advantages such as ability to preserve chemically labile low-molecular weight compounds. Additionally, it is of extreme importance that no chemicals were added to the analyzed samples. It is important to state that sample preparation was one of the simplest possible in terms of procedure as it required only dilution of unfrozen samples. For the first time, in this study, the AuNPET LDI-TOF-MS method was used to study metabolites originating from human urine, blood plasma and prostate IF. Methodology of measurements is shown on [Figure 3](#).

The decision not to examine prostate tissue but interstitial fluid was dictated by ethical and technical considerations. On one hand, fresh biopsy cores would have to be contained in high vacuum and thus they would be unfit for further pathological examination. Another possible analytical solution compatible with pathologist's examination is analysis of formalin-fixed/paraffin embedded cores. Unfortunately, only 40% of total metabolites is retained in tissue material for the mentioned type of analysis. In comparison to fresh/frozen specimens, it would introduce many contaminants like dimethyl sulfoxide, lauryl sulfate or melanin into MS analysis^[24]. IF which constitutes tumor microenvironment, often overlooked, has showed to be a highly valuable source of potential cancer biomarkers and a potential target for chemoprevention^[25,26].

Uncontrolled cancer cell proliferation requires efficiency in generation of energy. However, unfavorable tumor microenvironment (low level of oxygenation) impose activation of alternative metabolic pathways to

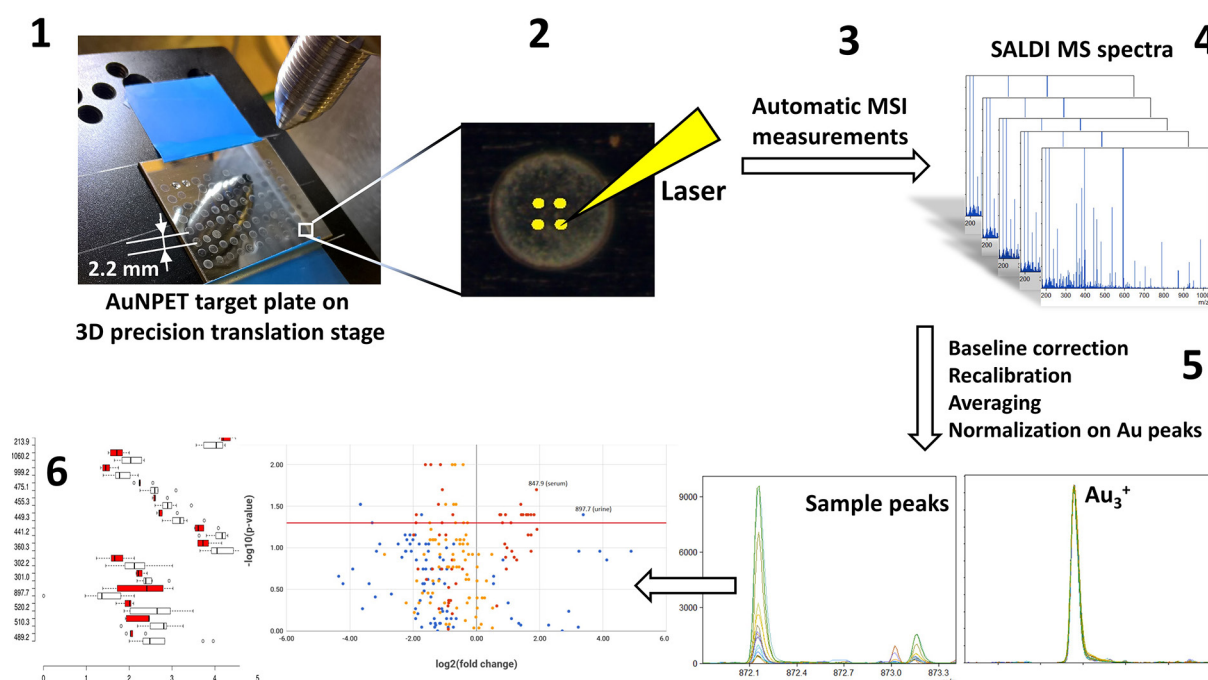

Figure 3. Flowchart for MSI analysis of interstitial fluid, urine and blood plasma samples on AuNPET target. Step 1: semi-manual application of diluted samples onto AuNPET target with the aid of 3D translation stage; 2: programming of four-pixel array per sample spot; 3, 4, 5: LDI MS measurements in imaging mode producing series of spectra; 6: data processing. MSI: mass spectrometry imaging; AuNPET: gold nanoparticle-enhanced target; SALDI: surface-assisted, laser desorption/ionization; LDI: laser desorption/ionization

ensure further development. First adaptive mechanism has been described by Otto Warburg in 1920 who discovered that malignant cells produce energy predominantly through anaerobic pathway (glycolysis), even in the presence of oxygen (Warburg effect). This increased utilization of glucose in cancer cells formed basis for positron emission tomography (PET), nuclear medicine imaging system, which uses radiolabeled analog of glucose to diagnose cancer. However, since then numerous studies have demonstrated association between alteration in glutamine, lipid and cholesterol metabolism and cancerogenesis. This is accompanied by increased uptake of exogenous lipids and activation of its intracellular synthesis. With respect to PCa, alterations of lipid and cholesterol metabolism has been broadly studied. Fatty acid beta-oxidation pathway is believed to be dominant energetic source for PCa, which is considered to be non-glycolytic type of tumor^[27,28]. This hypothesis is supported by low uptake of fluorodeoxyglucose on PET imaging^[29].

Dysregulation in cholesterol metabolism has been implicated in the pathogenesis of PCa. It is essential for cell proliferation by participation in membrane formation and steroid biosynthesis which is cornerstone of prostate cancerogenesis. It is also believed that it can play a major role in cancer progression to the castration resistant state by fueling intratumoral androgen biosynthesis in androgen deprived patient^[30,31]. This is possible due to activity of CYP17A1 enzyme, which is overexpressed in castrate resistant PCa^[32]. Cholesterol biosynthesis pathway including production of squalene by condensing two molecules of farnesyl pyrophosphate by squalene synthase (farnesyl diphosphate farnesyltransferase 1). Squalene is then transformed with the aid of squalene monooxygenase (SQLE) to lanosterol. In the final step, lanosterol is converted to cholesterol through a 19-step process.

Decreased cancer/control ratio of serum squalene was observed in this study. Increased utilization of squalene by PCa cell should be accompanied by increased activity of SQLE. This observation is consistent with the study by Stopsack *et al.*^[33] which showed that men with high SQLE expression are 8.3 times more likely to develop lethal PCa.

Elevated serum cholesterol and triglycerides (TG) has been linked with increased risk of developing aggressive PCa and recurrence after radical prostatectomy^[33-36]. However there is discrepancy between studies concerning association between serum lipids level and overall risk of developing PCa^[37-39].

Eberlin *et al.*^[40] showed that cholesterol sulfate (CS) which is the product of cholesterol sulfotransferase - SULT2B1 (within cells cholesterol occurs in form of esters, CS or hydroxycholesterol), accumulates in PCa and achieves higher concentration in comparison to benign prostate tissue. However, in our study, levels of CS in biofluids of cancer patients have not been elevated. Moreover, in comparison to control, a statistically significant decrease of intensity in urine has been observed ($P < 0.05$).

Another interesting aspect of affinity of PCa cells to adipose-rich environment is fact that most common metastatic sites are lymph nodes and bone marrow. This environment provides sufficient TG which are hydrolyzed to fatty acids to fuel mitochondrial beta-oxidation and ATP generation^[28,41]. This observation initiated research of new generation of drugs that target lipid metabolism^[28,42]. In this study increased intensity of TG in urine of PCa patients has been observed.

Fatty acids transport inside mitochondria is possible by its conjugation to carnitine. Giskeødegård *et al.*^[43] reported elevated serum level of four acyl carnitines in PCa patients in comparison to benign prostatic hyperplasia (BPH) control and Saylor *et al.*^[44] observed decrease in serum acyl carnitines concentration after 3 months of androgen deprivation therapy. In comparison, no acyl carnitines was elevated in our study, moreover, serum nonanoylcarnitine intensity of PCa patients was decreased in comparison to control ($P = 0.05$).

One of the most studied dietary-factor related with PCa risk is daily intake of omega-3 fatty acids, however results are still inconsistent. Only alpha-linolenic acid (ALA) out of all n-3 polyunsaturated fatty acids (ALA, eicosapentaenoic acid, docosapentaenoic acid, and docosahexaenoic acid) is essential (cannot be synthesized in the body and must be obtained from food). Recent meta-analysis showed only marginally significant negative association between PCa risk and intake of ALA and no significant association between ALA blood concentration and PCa risk^[45]. In this study serum ALA intensity was statistically significant lower in patients with PCa in comparison to control ($P < 0.05$).

Relationship between vitamin D (and its active metabolite - calcitriol) intake and its serum level and risk of PCa has been broadly studied. Vitamin D deficiency is associated with increased odds of PCa on biopsy and it is positively associated with higher PCa grade and stage^[46,47]. Moreover, calcitriol used alone or as a part of combination therapy is being studied in clinical trials to treat PCa^[48-50]. This is explained by the effect of vitamin D in promoting cellular apoptosis and differentiation and inhibiting cancer proliferation and angiogenesis. By decreasing expression of COX-2 gene it reduces proliferative stimulus of prostaglandin, a COX-2 product^[51,52]. Our study supports observation that serum vitamin D deficiency is relevant in pathogenesis of PCa.

Another interesting observation is higher abundance of vitamin C metabolites in the serum of patients with PCa. Relationship between daily intake of vitamin C and risk of developing PCa is highly debatable and the results are conflicting. Its antineoplastic properties are attributed to its antioxidative properties which protects DNA and RNA from oxidative damage. However at high doses it may act as a pro-oxidant rather than antioxidant^[53]. In our study elevated serum concentration of vitamin C metabolites in serum of patients with PCa has been observed.

The proliferative state of carcinoma requires both amino acids and nucleic acids to fuel cell division. We observed increased level of different amino acids in serum and simultaneously its decreased level in urine

and IF. Interestingly commercially available urine test for patients with negative DRE examination and modestly elevated PSA level has been developed which is based on a panel of four amino acids: sarcosine, alanine, glycine and glutamic acid (Prostarix™). Accumulation of modified nucleotides in a chemical process of deamination is characteristic for cellular processes involving DNA and RNA^[54]. Deaminated nucleotides (such as dITP) can be incorporated into either DNA and RNA which may result in nucleic acid instability, mistranslation and strand damage which may induce cancerogenesis^[55]. In this study we observed elevated level of dITP in serum of patients with PCa.

In conclusion, this study identifies comprehensive metabolomic profile of PCa. To the best of our knowledge, this is the first study which examined PCa IF. Moreover it combines simultaneous metabolomic analysis of serum, urine and IF, which gives most accurate insight into prostate cancerogenesis. Gold-nanoparticle-based laser MSI allowed identification of 20 metabolites which are up- and down-regulated. Identified metabolites mentioned in this study suggest their role in PCa pathogenesis and should be further evaluated in clinical trials as potential PCa biomarkers. The limitations of this study were the relatively small number of participants and the fact that small percentage of intensity values can be age-related for urine and plasma samples.

Abstract

Axillary recurrence is a rare event in patients treated with sentinel lymph node biopsy alone with the majority occurring in the first 5 years after surgery. Intramammary lymph node (IMLN) can be the primary sites of metastasis and sentinel lymph nodes, but the clinical significance, including prognosis and therapeutic approach is yet unclear, even more with capsular extravasation. IMLN metastases are strongly correlated with axillary lymph nodes involvement and therefore a guide for further surgical management of the axillary nodes.

Keywords: Breast cancer, sentinel lymph node, lymph node dissection, metastasis, locoregional neoplasm recurrence

INTRODUCTION

Reported series of patients with intramammary lymph node (IMLN) diagnosed by final histological examination are small in number and clinical significance of metastasis is still unclear^[1]. We previously reported a case of conservative breast cancer surgery with 3 positive IMLNs demonstrating extracapsular extravasation (ECE). After multidisciplinary discussion, the patient was submitted to mastectomy and no further axillary dissection. Even though the 3 IMLNs were positive, pathology examination did not reveal any signs of malignancy in the mastectomy specimen. The patient underwent adjuvant chemotherapy, radiation and endocrine therapy^[2]. Here we report the new event after 2 years of follow up.

CASE REPORT

A 44-year-old, post-menopausal female with a mammogram showing a partially defined lump of the right breast. Breast ultrasound (US) showed a circumscribed hypoechoic lesion, 1.4×1.1 cm, 3.8 cm away from the areolar complex, and also an adjacent hypoechoic microlobulated lesion of $1.4 \times 1.2 \times 1.4$ cm, both in the outer quadrants of the right breast. US-guided core-needle biopsy of the lesion revealed a high grade invasive ductal carcinoma (IDC), luminal B (estrogen receptor 30%, progesterone receptor and human epidermal growth factor receptor type 2 negative, and Ki-67 of 80%).

Magnetic resonance imaging (MRI) showed a mass with spiculated contours at early and heterogeneous post-contrast enhancement in the junction of the outer quadrants of the right breast, measuring $1.8 \times 1.6 \times 1.5$ cm [Figure 1A and B]. In addition, a circumscribed oval mass at early and homogeneous post-contrast enhancement, in lower inner quadrant, measuring $9 \times 5 \times 5$ mm and in close contact with the pectoralis muscle, which seemed to correspond to an IMLN. Second-look US was performed directly to this lymph node, which revealed a suspicious cortical thickening and a decreased hilum. A breast conserving surgery of the index lesion, plus radioguided occult lesion localization of the suspicious lesion in the lower inner quadrant and sentinel lymph node biopsy (SLNB), were performed. The pathology report of the lesions identified an IDC, no special type, histology and nuclear grade III and ductal carcinoma *in situ* associated. Three axillary sentinel lymph nodes (SLNs) were free of metastases, however the suspected lesion in the lower inner quadrant resulted in 3 IMLNs, all affected by cancer metastases with ECE [Figure 2A and B].

Published literature for IMLNs does not mention capsular leakage, thus, there is no consensus for the best treatment. Pathologists admitted margins in lymph nodes were not frozen, which did not make it feasible to know if the margins of the additional lesions were disease free. Multidisciplinary recommendation was mastectomy without axillary lymph node dissection (ALND) and immediate breast reconstruction with implants, which was performed two weeks after the patient's consent in regards to the unknown probability of further disease in the IMLNs. Pathology report revealed no evidence of malignancy. The patient underwent 4 cycles of anthracycline + cyclophosphamide followed by 12 cycles of taxanes and breast + axillary, internal mammary and supraclavicular drainage chain radiation therapy + tamoxifen. After 2 years of follow up, the patient suddenly developed axillary pain and fistulization accompanied by fever, and sought the emergency room immediately [Figure 3A]. US and breast MRI showed an axillary lymph node with high T2 signaling, measuring 4.0×3.6 cm in deep contact with pectoralis muscle and a circumscribed oval mass at early and homogeneous post-contrast enhancement, located in the level 2 of the axilla, measuring 1.0×0.9 cm.

Figure 2. A: Intramammary lymph nodes affected by cancer metastases (3/3): capsular extravasation; B: capsular extravasation

Figure 3. A: Clinical presentation of axillary recurrence with fistulization; B: axillary lymph node dissection

Removal of the implant and ALND with primary closure of the chest wall was performed. Pathology report showed fragment of fibroadipous and muscular tissue compromised by carcinoma, associated to intense chronic inflammatory process abscessed. Skin and 3 axillary lymph nodes level 2 and 3 free of metastasis [Figure 3B].

DISCUSSION

IMLNs are important because they can be the primary sites of metastasis and SLNs, and when the image is identified, the presence of metastasis is more frequent than in IMLNs detected incidentally^[1]. They are involved in a variety of clinical situations, including benign lesions, tumor metastases, breast lymphomas and breast cancer, where their importance is not fully established. Nevertheless, there is evidence that IMLNs are an independent factor for poor prognosis, and they may change therapeutic decisions^[3]. Patients with metastatic IMLNs had more aggressive cancers with lymphatic and vascular invasion as well as increased axillary lymph node metastases^[4]. In a multicenter study including 33,000 SLN-negative cases from 61 observational series analysis that did not go to ALND reported an axillary recurrence (AR) rate around 0.6%^[5]. The NSABP-32 trial showed that SLNB minimized side effects with equivalent survival and regional control than ALND in the SLNB-negative setting and then quickly became the standard of care in early stage breast cancer clinically node-negative^[6]. AMAROS trial included 1,425 patients with T1-2 breast cancer, no palpable nodes and positive SLNs. Patients were randomized to ALND or axillary radiotherapy and had a median follow up of 6.1 years. No differences in 5-year AR rate was observed between the ALND vs. radiotherapy group^[7].

A retrospective study from the National Cancer Data Base evaluated women with clinically node-negative breast cancer who had nodal macro or microscopic metastases in the SLN. There were no significant differences in AR with the addition or not of ALND in macrometastasis (1.2 vs. 1, $P = 0.4$) and micrometastasis (0.6 vs. 0.2, $P = 0.063$)^[8]. When IMLN metastases were identified in the breast specimens, it has been suggested that complete ALND may be based on the axillary SLN negative status and thus, ALND can be avoided in this setting^[9]. Even though our case has not demonstrated malignancy at the surgical site, ECE is considered a sign of worse prognosis, and might be the evidence that leads us to the AR of this patient. Moreover, there is not any standard definition of ECE in the literature. Some authors have used “focal” or “extended” definition with no description regarding adjacent sites of invasion eventually^[10]. Standard definition of ECE must be identified, because the ECE might be considered by future staging systems^[11].

However, it's impossible to conclude that IMLNs metastases featuring ECE might be an independent outcome factor and its clinical meaning is yet controversial and unknown.

Abstract

Few studies have reported on the analyses of drugs targeting enriched populations of cancer stem cells (CSCs) as a means for identifying potent anti-CSC agents. This review evaluates recent information on the identification and functions of specific CSC surface markers, with particular emphasis on colorectal cancers and the screening of drugs to eliminate such cells. Many of these CSC markers are found commonly expressed on CSCs from different cancer types as well as embryonic stem cells. These markers are often related to hypoxic activation of the WNT/ β -catenin pathway, cyclooxygenase-2/prostaglandin E signalling and their relationship to LGR5. By effectively using drugs that inhibit these pathways to kill the CSC population, or otherwise forcing them out of dormancy into active cell division, cancers should become more susceptible to chemotherapy. Such combinational therapies targeting both CSCs and proliferating tumor cells should greatly improve upon the current basis for treatment.

Keywords: Cancer stem cells, colorectal cancer, markers, selective drug targeting

GENERAL BACKGROUND TO CANCER STEM CELLS

Our understanding of the roles played by cancer stem cells (CSCs), their importance during the progression of cancer and justification for why they should be specifically targeted to eliminate cancer as a disease remains limited. Evidence supporting the “cancer stem cell” hypothesis is mounting such that CSC existence

has become generally accepted. Analysis of PubMed reveals the increasing importance of CSCs with over two thousand publications in 2008 increasing to nearly 7000 annually at the present time and 70,831 in total. The involvement of the CSC population and their contribution to the circulating tumor cells (CTCs) and metastatic cancers is also becoming established. After therapy, drug resistant and dormant CSCs reactivate as major contributors towards tumor recurrence, generating further tumor masses. From this latter perspective we propose that it will be essential to not only identify the CSCs, but also the means for selectively targeting these cells to eliminate them if we are to improve upon current cancer therapy. In recent years, several reviews have covered the identification of markers for colorectal CSC (CR-CSC)^[1], including that of the definitive colorectal cancer (CRC) stem cell marker, LGR5^[2-4].

In 2010, the question was posed: “How can we identify and analyze colon CSCs and what agents are being designed to kill this chemotherapy-refractory population?”^[5]. The CSC model accounts for tumor initiation, metastasis, drug resistance, and relapse and CSCs within the tumor bulk have the capacity to self-renew, differentiate, and give rise to new tumors (reviewed in^[6-8]). In the present systematic overview, the focus is the identification and drug targeting of CSC populations and developing strategies for improving the therapy of advanced stage colorectal cancer by eliminating CSCs. Controversy has grown around the proposal of targeting the CSC population and whether it would be beneficial to patient outcomes^[6]. In their treatise on the problems with the CSC model, these authors pointed out tumor heterogeneity and growth dynamics, which can be interpreted as cell plasticity in that cancer cells in a more differentiated state can re-enter the CSC pool. In addition, they argue that targeting a rare population of tumorigenic cells (such as CSCs) without consideration of the bulk of proliferating cells may not change patient outcomes^[6]. By necessity, the principle of clonal extinction applies in terms of the need to eliminate all of the cancer cells, including the CSCs and their differentiated progenitors if we are to overcome cancer^[7]. Simply put, one must kill the roots of the tree, or it will grow back [Figure 1] and was originally proposed as the “Dandelion hypothesis” for CSCs^[8]. This will require not only killing the rapidly dividing, more differentiated cancer cell population as is currently targeted by commonly used chemotherapies, but also the more dormant and drug resistant CSCs existing within the tumor population.

One of the key aspects of CSCs that should be borne in mind is their property of “stemness” and by this is meant not only their capability of self-renewal and differentiation, but also that despite being sourced from different tissue origins, the various types of CSCs with their less differentiated phenotypes, will share properties and markers in common with embryonic stem cells (ESCs), reflecting their similarity in terms of earlier stages of development^[9,10]. It is only when the CSCs differentiate that they will express greater sets of uniquely characteristic markers for the particular cell lineages that they encompass^[11]. It is in this light that the markers for the CR-CSCs are discussed below, and are discussed in reference to related findings of similar markers found expressed on the ESCs and CSCs alike across a range of different cancer types^[9,10,12].

CSC IDENTIFICATION AND GENERAL DEFINITION

The definition of CSCs is similar to that applied to the normal tissue stem cells: the ability of a small sub-population of cells existing within a tissue which when isolated and reintroduced into the host have the capacity to reform complete tissues containing the range of cellular phenotypes similar to the original tissue from whence the stem cells were derived^[12,13]. Thus, CSCs possess characteristics associated with normal stem cells, specifically multipotency in the ability to give rise to all cell types found upon pathological examination of an excised tumor^[11]. The most commonly used method for identifying and isolating CSCs is via their characteristic cell surface markers, many of which were originally discovered from studies of normal tissue development, including from hematopoiesis and embryonic stem cells and which are also found co-expressed on CSCs^[9].

The major surface markers that have been used to identify colorectal CSCs to enable their definitive isolation are the focus of this review, as well as improved means for testing anticancer cytotoxic drugs targeting

Figure 1. A: Targeting cancer stem cells: current treatments with conventional chemotherapy are not highly efficient against the cancer stem cells (CSCs) residing in tumors which resist chemotherapy or radiation and post-treatment will undergo self-renewal, differentiation and tumor regrowth or metastasize causing relapse and formation of additional tumors. However, drugs targeting the CSC population (such as celecoxib) can be used to eliminate the CSCs, either by direct cytotoxic effects or by sensitizing these tumor cells to other chemotherapy, resulting in the clonal extinction of the entire tumor cell population; B: The treatment concept of targeting CSCs (also known as the “Dandelion hypothesis”) by analogy proposes that by eliminating the roots (CSC population), the plant (tumor) can not become re-established whereas cutting the flowering stalks, stem or branches away will allow regrowth^[8]

their elimination. These findings should then be applicable to other CSC types. Historically, CSCs were extracted from solid tumors and partially purified as a poorly or negatively staining side population (SP) by flow cytometry, so-called because of their hallmark characteristic to exclude the nuclear DNA staining, fluorescent Hoechst series of dyes, such that CSCs could be separated from the bulk of other tumor cells that were highly positive for the nuclear DNA stain^[14]. These poorly stained “SP” CSCs often showed much greater stem-like self-renewal and increased tumor-initiating capability and were responsible for tumor recurrence because they were more resistant to many forms of chemotherapy^[14].

Other methods have also been used to enrich for CSCs, including growing tumor cells suspended in serum-free defined media or above agarose to form spheres or spheroids or by selective uptake of the Aldefluor™ stem cell stains because CSCs show greater expression of aldehyde dehydrogenase 1^[15]. The use of such methods for the identification and definition of CSCs has been complicated by observations that in the

case of leukemias, only a few cancer cells isolated from the blood of leukemic animals were sufficient for transferring the leukemia into naïve healthy animals receiving the transfused cells^[16]. Thus arose the basis for disputing the very existence of CSCs and whether all cancer cells are self-endowed with the capability of giving rise to whole tumors.

Since the discovery of CSCs, we have witnessed further complexities with the emergence of the epithelial to mesenchymal transition (EMT) hypothesis by which it was proposed that tumor cells transit back and forth between the two different states during the processes of invasion, migration and metastasis to form tumors at distant sites^[17]. However, this view has been made less certain given recent evidence showing that multiple phenotypes are present within both the tumors and CTCs, which exist rather as mixtures of cells including both epithelial and mesenchymal types^[18]. The emerging evidence from a range of studies would rather suggest a dynamic tumor heterogeneity with cancer cell plasticity existing as the consequence of genetic and metabolic changes, environmental differences and reversible adaptation of cellular properties, all proceeding within the context of a hierarchical system of tumorigenic CSCs differentiating into non-tumorigenic progeny (for reviews, see^[19-21]).

During the course of progression within the primary tumor microenvironment, with expanding growth and increasing cellular demands on the limited availability of nutrients and oxygen supply, there follow frequent rounds of intermittent hypoxia, hypoglycemia and acidosis occurring within the tumor microenvironment^[22]. Such conditions are the drivers for the production of greater numbers of the CSCs as a percentage of the total tumor population (reviewed in^[23]). In addition, such stressors within tumors give rise to cancer cells showing a higher capacity to invade into nearby tissues, extending beyond the tumor boundary, migrating from the site of the primary tumors into the circulatory system to produce metastases. In this manner, the tumor spreads into distant locations, some involving advanced release of exosomes, interactions with immune cells and extracellular matrix to lay down the framework for future tumor beds at these remote sites as premetastatic niches^[24].

Recent evidence has shown that the CTCs have a stem cell phenotype as evidenced by their expression of embryonic transcription factors (including OCT4, SOX2 and NANOG^[25]), and contain mixtures of epithelial and mesenchymal phenotypes (reviewed in^[26-28]). Furthermore, analyses of CTCs derived from the peripheral blood of colorectal cancer patients showed that they exhibit a more CSC-like phenotype^[28], including expression of CSC markers such as LGR5, establishing these as prognostic markers for disease progression and metastasis in CRC patients. From these observations, it would appear that the CTC population includes CSCs in their mix and that such cells are highly metastatic [Figure 2]. Despite these complexities, our ability to identify and target the CSC populations with specific cytotoxic drugs must improve if we are to eliminate the cause of cancers and their metastasis, given their significantly enhanced tumor-initiating potential.

CR-CSCS, WNT SIGNALLING AND SURFACE MARKERS IN COMMON WITH OTHER CANCER TYPES

The self-renewal of CSCs is regulated by various modulators, including WNT/ β -catenin, Notch and Hedgehog signalling, and at the transcriptional level by the pluripotency transcription factors such as OCT-3/4, KLF4, SOX2, and c-MYC, chromatin remodeling complexes, and non-coding RNAs (reviewed in^[29]). WNT signalling cascades cross-talk via the fibroblast growth factor (FGF), Notch, Hedgehog and transforming growth factor beta (TGF β)/bone morphogenetic protein signalling cascades to regulate expression of the functional CSC surface markers that have been identified, such as CD44, CD133 (PROM1), epithelial cell adhesion molecule (EPCAM) and LGR5 (GPR49) (reviewed in^[30]). The CSC regulatory signalling pathways such as WNT have become a target with implications for therapeutic interventions in cancers, albeit that its complexity poses significant challenges^[31]. The WNT/ β -catenin pathway is involved in the regulation of CSCs as with normal stem cells and their differentiation during embryogenesis and in the adult^[30,31].

Figure 2. Circulating tumor cells (CTCs) include cancer stem cells (CSCs): tumor cells can migrate around the body via the blood vessels and this population includes CSCs that metastasize to invade into other organs, forming tumors by colonizing at distant sites such as in the spleen, and the liver. By applying drugs that are cytotoxic for CSCs (such as celecoxib) greatly reduces the incidence of tumor metastases and tumor recurrence. CRC: colorectal cancer

The great majority (> 90%) of colorectal cancers have mutations in one of two genes involved in the WNT signalling pathway: either in the adenomatous polyposis coli or β -catenin (CTNNB1) genes and this has meant that WNT signalling has become an important cancer therapeutic target^[32]. In 2016, studies examining the role of the Traf2- and Nck-interacting kinase (TNIK), an essential regulatory component of the WNT regulated T-cell factor-4 (TCF-4) and β -catenin transcriptional complex, showed that the small drug molecule NCB-0846 inhibited TNIK and abrogated colorectal cancer stemness^[33]. This drug was potent at inhibiting the growth of colon cancer patient derived xenograft tumor models and resulted in smaller tumors. Hence, based on the above studies it is clear that WNT signalling plays a key role in the regulation of CR-CSCs. We ascertain that the relationship of the CSC markers to colorectal cancer provides a unique opportunity for anticancer drug discovery and on this basis the CR-CSC markers that have been identified to date are discussed further in the next sections. Their relationship to the WNT/ β -catenin pathway for stem cell regulation is also highlighted where relevant.

The ATP binding cassette transporters/multiple drug resistance/P-glycoproteins

As described above, the ability to exclude the fluorescent nuclear DNA stains was an early hallmark of CSCs and has since been ascribed to their higher surface expression levels of the ATP binding cassette transporters (ABC) (a.k.a multidrug resistance or P-glycoproteins)^[34]. These proteins are expressed on the outer cell membrane and will pump compounds such as chemotherapeutic drugs or DNA stains out of the cancer cells. One member of the family, ABCG2 (a.k.a. breast cancer resistance protein) was shown to expel a wide variety of exogenous and endogenous compounds from liver CSCs^[35] and is prevalent on human colorectal cancer samples^[36]. Membranous ABCG2 levels of expression in colorectal cancer independently correlate with shortened patient survival times^[37].

The ABC transporters play significant roles in the distribution, absorption and elimination of substrate drugs and bestow multidrug resistance to cancer cells by maintaining the export or efflux of chemotherapeutic agents, preventing entry thereby avoiding attaining the toxic levels inside the cancer cells required to kill them. ABCG2 overexpression has also been observed in some human cancer cell lines and is widely expressed on liver cancer stem cells^[38]. Consequently, the ABC transporters are viewed and regarded as possible universal biomarkers for stem cells, both normal and cancer stem cells alike^[39]. Moreover, the

evidence supports ABCG2 as playing a vital role in enhancing stem cell proliferation and in the case of esophageal squamous carcinoma has been shown to be required for the maintenance of the stem cell phenotype^[39,40].

Therefore, ABCG2 has applications not only in the identification of the CSCs, but also for allowing the possibility of blocking its function as one way for improving selective drug targeting of tumors and their CSC population during the course of anticancer chemotherapy^[41]. Despite the supportive evidence that ABCG2 is a stem cell marker, there are limitations since the exact role of the ABCG2 signalling pathway and its regulation is not well understood^[42,43]. Although the molecular mechanisms regulating ABCG2 expression are not clearly understood, it is likely that the MYC oncogene plays an important role in promoting its expression in some cancers^[44].

In studies of “SP” cells isolated from human colorectal cancer cell lines, it was shown that expression of ABC transporter genes, such as ABCB1 and ABCG2 was significantly higher, linked with greater resistance to 5-FU and irinotecan, and higher activation of the WNT signalling pathway, than for the non-SP cells^[45]. In addition, silencing β -catenin expression to inhibit WNT decreased significantly more SP cells than non-SP cells, decreased transcription of the ABC transporter genes and the silenced cells became relatively sensitive to paclitaxel and irinotecan. Hence, these results indicate that ABC expression is regulated by WNT signalling. EMT induces a switch in WNT signalling from a β -catenin/E-cadherin/Sox15 transcription factor complex to the β -catenin/Twist1/TCF-4 complex, the latter of which then binds to promoters of the CSC-related genes^[46]. In this study, it was shown that Twist1 binding to β -catenin enhanced the transcriptional activity of the β -catenin/TCF-4 complex, including by binding to the proximal promoter region of the ABCG2 gene to promote ABCG2 expression as one CSC marker^[46].

Zhang *et al.*^[35] showed that the sensitivity of hepatocarcinoma cells to the chemotherapeutic drugs, doxorubicin or 5-fluorouracil inversely correlated with surface levels of the ABCG2 marker. The levels of ABCG2 expressed on cancer cells including colon cancer lines also closely correlated with tumorigenicity, drug resistance, proliferation and metastatic ability and therefore, the ABC transporters could be considered as critical and universal biomarkers for all CSCs^[34,35,47,48]. The results above of WNT signalling correlating with ABCG2 expression levels also support strategies aimed at inhibiting the WNT signalling pathway as a means for targeting chemotherapy-resistant colon cancer cells, including the CSCs.

CD133

CD133 (a.k.a. prominin-1) has been widely touted to be a CSC marker and was originally recognized as a stem cell marker found on rat neuroepithelial stem cells^[49]. CD133 and its role as a CSC biomarker has recently been reviewed^[50]. As a common biomarker, CD133 has been used for identifying many different types of CSCs, including those originating from gliomas^[51], colorectal^[10,52,53], lung^[54], liver^[38], and prostate cancer^[55]. However, CD133 has been shown to function in regulating glucose uptake for glucosamine production under conditions of increased glucose and glycolysis and is involved in autophagy^[56,57].

Despite the fact that CD133 can mark the tumor-initiating cell populations in several solid tumors, studies have shown that it does not play a crucial role in the process of CSC maintenance. Thus, unlike knocking down CD44 expression which inhibited tumorigenesis of CR-CRC cells, knocking down CD133 gene expression had no effect^[58]. CD133 expression is also not restricted to the stem cell population because both the CD133⁺ and CD133⁻ metastatic colon cancer cells were equally capable of initiating tumor production^[59]. Hence, CD133 expression is more a reflection of the level of glucose availability and is not necessarily a specific marker of CSCs.

CD44

CD44 is an extensively glycosylated surface protein as a major component of the extracellular matrix involved in cell-cell interactions, cell adhesion and migration and is one of the cellular receptors for

hyaluronic acid (HA), thereby linking binding to selectin, collagen, osteopontin, fibronectin and laminin in the extracellular matrix^[60]. HA binding to CD44 also facilitates complex activation of receptor protein tyrosine kinases of the epidermal growth factor receptor family in several types of cancer^[61]. Upon HA binding to CD44 on the cell surface, increased levels of cell proliferation and survival occur through downstream signal activation of the MAPK and PI3K/AKT pathways^[62]. Studies have also indicated that CD44 plays a significant role in the invasive and tumorigenic stemness capacity of several tumor cell types, including breast^[63], prostate^[64], pancreatic^[65] and mesothelioma^[66,67]. CD44 surface levels on tumor cells were shown to positively correlate with prostate cancer CTCs in the bloodstream of patients^[68].

Genetic knockdown of CD44 prevented the formation of tumors by colorectal CSCs^[58]. CD44 either alone or in combination with other cell surface markers can be used to enrich for CSCs from multiple tumor types including breast^[69,70], prostate^[71,72], colon^[73,74], pancreas^[65], and head and neck squamous cell carcinomas^[75]. However, given the relatively high levels of CD44 expressed on the cancer cell population, it would appear that CD44 is more a marker of the invasive, metastatic cell population and is not specific, per se for the CSCs.

CD13

The CD13 gene encodes the enzyme aminopeptidase N, a Zn^{2+} dependent membrane-bound ectopeptidase preferentially degrading proteins and peptides with an N-terminal neutral amino acid. CD13 is overexpressed in multiple cancer types as well as on the surface of vasculature endothelial cells in tumors undergoing angiogenesis, making it a promising target^[76]. CD13⁺ cells form clusters or foci within the tumors, are typically in the G₀ phase of the cell cycle and also found present in the fractionated “SP” of CSCs from hepatocarcinoma^[77,78]. Haraguchi *et al.*^[79] showed that CD13⁺ cancer cells surviving after chemotherapy or radiation treatment in tumors removed from hepatocarcinoma patients were found present within enriched fibrous capsular regions of the tumors and had decreased levels of DNA damage caused by reactive oxygen species (ROS). Thus, they proposed that the cancer cells appeared to be protected from treatment-induced apoptosis by expressing CD13. In their mouse xenograft models treated simultaneously with a CD13 inhibitor (either using a neutralizing antibody or the peptidase inhibitor, Ubenimex) and the genotoxic chemotherapeutic drug, 5-fluorouracil (5-FU), the combination diminished tumor levels significantly and was far more effective than 5-FU used alone^[79]. Their studies have since been confirmed in other studies where CD13 inhibitors were used as an adjuvant therapy together with ROS-inducing chemotherapy or radiation treatment as a potential treatment method that could improve survival rates of patients with hepatocarcinoma^[79-81]. The tripeptide NGR that targets CD13, conjugated with anticancer drugs has been similarly used to target human hepatocarcinoma growth by killing cancer stem cells and suppressing angiogenesis^[82]. Although CD13 expression has been associated with human colon cancer and poorer prognosis^[83], targeting its functional role as a marker on CR-CSCs has not yet been tested such that the usefulness of CD13 as a CR-CSC marker remains unclear.

LGR5

LGR5 is a member of the Leucine-rich-repeat-containing G-protein-coupled receptors (also known as GPR49) which belong to the seven transmembraneous G-protein-coupled receptor superfamily. The LGR1-5 family are regulatory receptors involved in WNT signalling^[84] and can bind to the furin-like repeat FU2 domains of the R-spondin 1-4 stem cell growth factors to potentiate WNT signalling^[85,86]. However, R-spondin 1 (RSPO1)/LGR5 can also directly activate TGF β signalling in a cooperative interaction with the TGF β type II receptor on colon cancer cells to enhance the TGF β -mediated growth inhibition and stress-induced apoptosis^[87]. Knockdown of *Lgr5* attenuated downstream TGF β signaling and increased cell proliferation, survival, and metastasis in an orthotopic model of colon cancer *in vivo*^[87]. Upon RSPO1 stimulation, LGR5 formed complexes with TGF β receptors^[87]. Hence, the net effects of LGR5 expression will also depend on its interplay with both the WNT and TGF β signalling systems as well.

LGR5 is found expressed in many organs including the brain, reproductive organs, mammary glands, the intestinal tract, stomach, hair follicles and the eyes^[88]. The *Lgr5* gene is itself a WNT signalling target and prostaglandin E2 (PGE2) treating colorectal cancer cell lines enhances LGR5 expression whereas *Lgr5* knockdown using siRNA inhibited the PGE2 survival response and induced cell death^[84]. These results suggest that the PGE2 promotion of colorectal cancer cell survival at least in part proceeds via increasing LGR5 expression. Given the relationship of LGR5 with WNT signalling and PGE2 production by cyclooxygenase-2 (COX-2), it is likely that NSAIDs cause regression in familial adenomatous polyposis patients by interfering with the LGR5/WNT mechanism for promoting cancer stemness and cell survival. X-gal staining using the transgenic *Lgr5* promoter driving β -galactosidase revealed that, following villus morphogenesis, *Lgr5* expression became restricted to dividing cells assembling in the intervillus region and within the distal small intestine^[89]. *Lgr5* deficiency is also known to cause premature Paneth cell differentiation within the small intestine, without affecting the differentiation of other cell lineages, nor the proliferation or migration of epithelial cells^[89].

LGR5 was shown to be a biological marker for intestinal stem cells in the murine small bowel of *Lgr5*-EGFP-IREScreERT2 mice, as well as being useful for cell lineage tracing studies where the LGR5⁺ stem cells developed into the different cell types comprising the intestinal crypt^[88]. LGR5 expression has been closely linked with tumorigenesis including that of liver, colorectal, as well as ovarian cancers (for review, see^[90]). In the normal intestine, LGR5 is solely expressed by the cycling crypt columnar cells and genetic lineage tracing studies identified these columnar cells in the base of the crypts as self-renewing, multipotent cells and are therefore considered to be genuine intestinal stem cells^[91,92]. LGR5 has also been shown to be expressed in the stem cell niche by actively cycling cells of the murine hair follicle where lineage tracing and transplantation studies revealed that the LGR5⁺ cells were retained for long periods and generated new hair follicles^[93]. LGR5 expression in multiple other organs has led to the proposal that it represents a global marker of adult stem cells (reviewed in^[94]).

Since LGR5 is involved in WNT signalling, it is not surprising that LGR5 and its ligands, the R-spondins are important for normal brain development^[95] and hypoxia stimulates neural stem cell proliferation by increasing hypoxia-inducible factor-1 α (HIF-1 α) expression and activating WNT/ β -catenin signaling^[96]. Hence, it is likely that WNT acts by increasing LGR5 expression to promote stemness and brain CSCs^[97]. LGR5 functions in the maintenance of brain CSCs and the transcribed levels of *Lgr5* is greater in these cells and in the case of glioblastoma has been associated with poorer prognosis^[97]. In addition, immunofluorescence staining revealed the localization of LGR5⁺ cells in sections of glioblastoma and *Lgr5* siRNA knockdown led to lower expression of the neuronal L1 cell-cell adhesion molecule^[97].

Most colorectal cancer cell lines and sporadic colonic adenomas exhibit significant LGR5 expression^[98], although this is linked with stemness and renewal but not tumor progression because overexpressing LGR5 caused greater cell-cell adhesion, reduced tumor growth, invasiveness, migration and metastasis^[98,99]. Recently, LGR5 was established as a definitive surface marker for colorectal CSCs (reviewed in^[90,100]), particularly when co-expressed with CD44 and EPCAM^[101]. In these studies, the triple positive cells exhibited more pronounced CSC-like traits with LGR5-positive subpopulations showing higher capacities for colony formation, self-renewal, differentiation, and tumorigenicity as well as higher expression of stemness genes than did any other subpopulation. Thus, LGR5 is a marker for early CSCs and relates to their WNT promoted self-renewing capacity. Enhanced LGR5 expression remains persistent during adenoma to carcinoma transition in human CRC samples, but markedly declines in the budding cancer cells at the invasive tumor fronts, and was not associated with either WNT- or EMT-signalling pathways^[98]. In the latter study, LGR5 overexpression attenuated proliferation, migration, and colony-forming capacities in colon cancer cells. Unfortunately, the levels of TGF β expressed by these cells were not analysed in these studies^[96,98,99] given the observations above that TGF β switches the role of LGR5 to inhibit growth. These

findings indicate that LGR5 can function as a tumor suppressor promoting maintenance of stemness during CRC progression and that LGR5 is a suitable marker of CSCs.

The most definitive studies for LGR5 as a CR-CSC marker were obtained by using a tamoxifen inducible suicide gene inserted into the *LGR5* gene of transgenic mice^[2,4] (reviewed in^[102]). The suicide gene could be triggered upon expression of LGR5 and activated by the injection of tamoxifen, resulting in death of the colon CSCs by tamoxifen. The more differentiated tumor cells do not transcribe LGR5 and hence, do not express the suicide gene, such that they survived. When the suicide mechanism was activated in growing tumors in mice, the LGR5-positive CSCs were eliminated. As long as the suicide mechanism was maintained then tumors regressed but when their suicide was no longer induced (by tamoxifen withdrawal), then differentiated tumor cells filled the void and reacquired CSC qualities with rapid tumor regrowth. Furthermore, it was shown that metastasis and growth of preestablished metastases was halted. These findings showed that unlike cancer at the primary tumor site, metastases were dependent on preexisting LGR5⁺ CSCs, so that once these CSCs were eliminated, reacquiring the CSC phenotype in the metastases was not possible^[4]. Hence, LGR5 is expressed in CR-CSC and these studies support the Dandelion hypothesis [Figure 1B], such that advanced metastatic CRC should be amenable to elimination by anticancer drugs that target the CSCs.

CD326 (EPCAM)

The surface marker, EPCAM (also referred to as 17-1A, TROP-1, CD326, GA733-2, KS1/4 or gp40) is a type 1 transmembrane glycoprotein and a calcium-independent homophilic cell adhesion receptor of 30-40 kDa, encoded by the *TACSTD1* gene^[103]. EPCAM is expressed by several human epithelial tissues, progenitor cells, cancer cells, stem and germ cells^[104]. This protein marker was discovered initially as an antigen expressed on colon cancers that was involved in cell-cell adhesion and the structure of EPCAM comprises an extracellular domain, thyroglobulin domains, epidermal growth factor domains, transmembrane domain and a short intracellular domain (ICD) consisting of 26 amino acids known as EpICD^[105,106]. *EpCAM* (*TACSTD1*) may be an oncogene as the encoded EpICD can be proteolytically released to signal into the cell nucleus by engagement with elements of the WNT signalling pathway including activation of the β -catenin/MYC pathway resulting in tumor cell proliferation (reviewed in^[106]). Expression of the EPCAM marker is elevated in malignant neoplasia and most cancers abundantly express EPCAM^[104].

In normal human cells, EPCAM is located in the intercellular spaces at the tight junctions formed between adjacent epithelial cells^[107]. Hence, it is inferred that EPCAM is sequestered in normal epithelial, whereas it becomes uniformly spread around the surfaces of cancer cells, where it is readily accessible to antibodies targeting it. The role of EPCAM in tumor progression and development is controversial, as is its relationship to another cell adhesion molecule, E-cadherin^[105]. EPCAM has been proposed to act as a molecule for homophilic cell to cell adhesion, which would prevent the occurrence of metastasis^[103]. It has a protective function in CRC since the deletion of *EpCAM* leads to an increased risk of developing CRC^[108] and when overexpressed on CRC cells, inhibits their metastasis^[109].

In contrast, EPCAM expression inhibits the extent of E-cadherin mediated cell to cell adhesion, enhancing metastasis^[110], although EPCAM has been proposed to bind to E-cadherin, both of which are important to the stability of the tight junctions (reviewed in^[107]). In addition, overexpressing EPCAM in tumor cells can enhance WNT signaling to promote the proliferation of cancer cells^[111]. In breast carcinoma, high levels of EPCAM expression are associated with poorly differentiated tumors^[112], development of larger cancers, nodal metastasis and poor survival of the patients^[113]. Marked EPCAM expression on breast carcinomas has been linked to poorer prognosis for both node positive and negative diseases^[114]. In 2009, the European Union approved the EPCAM antibody, Catumaxomab, a bivalent monoclonal antibody which cross-links between T cells (via CD3 receptor binding) and EpCAM on tumor cells in order to promote the elimination

of ascitic tumor cells. This therapy has contributed greatly to the management of breast cancer patients with malignant ascites and peritoneal carcinomatosis^[115]. EPCAM is also expressed by almost all human adenocarcinomas, retinoblastoma, hepatocellular and squamous cell carcinomas^[116].

EPCAM can be downregulated when cancer cells undergo EMT^[117], during the dissemination of cancer cells into other tissues. Hence, detecting cancer cells in blood as CTCs using EPCAM as a marker is likely to miss the invasiveness/migration events of tumor cells. EPCAM is also expressed by the normal breast epithelial cells, although its role in the homeostasis of normal breast tissue is unclear^[118]. In the human kidney 2 (HK-2) proximal cell line grown under hypoxic conditions, the activity of the *Epcam* promoter is increased two fold and in both HK-2 cells and primary kidney proximal cells, EPCAM protein expression is increased after hypoxia and reoxygenation^[119]. The widely distributed expression of EPCAM on most cancer cells makes EPCAM unsuitable as a specific marker of CSCs.

CD271 (p75NTR)

CD271 was identified as the low-affinity nerve growth factor receptor (LNGFR), also known as the p75 neurotrophin receptor (p75NTR) belonging to the tumor necrosis factor receptor and low-affinity neurotrophin receptor superfamily and is a marker for cells of neural crest embryonic origin^[120]. Previously, human CD271 was shown to be expressed on cells of the peripheral and central nervous system and was suggested to be involved in the survival, development as well as differentiation of neuronal cells^[121]. CD271 or LNGFR is also found expressed on a wide range of other cell types including follicular dendritic cells, mesenchymal stem cells (MSCs), astrocytes, Schwann cells, neural crest stem cells, oligodendrocytes, sensory and autonomic neurons and mesenchymal cells^[122].

Studies have shown that CD271 (LNGFR) is a predominant biomarker expressed by MSCs isolated from the bone marrow^[123]. The fibroblastic colony forming units (CFU-F) in MSC populations could be established only by the CD271⁺ cell fractionation, whereas no CFU-F's were obtained with the CD271⁻ cell population. CD271 is a highly specific marker expressed on the surface of freshly isolated bone marrow MSCs^[124]. CD271 may not be a specific marker for all tissues, because as a marker it failed to isolate MSCs from umbilical cord blood^[123].

CD271 was identified as a marker for the CSC population within human melanomas and its usefulness as a melanoma CSC marker has been well documented^[121] and was shown to be crucial for maintaining the tumorigenicity and stem-like properties of melanoma cells^[125]. CD271 has also been characterized as a stem cell marker for a small percent of cells in oesophageal squamous cell carcinoma^[126,127] and was associated with CSCs^[128] with high metastatic potential in CTCs from these cancer patients^[129]. CD271 confers an invasive and metastatic phenotype to head and neck squamous cell carcinomas through the upregulation of the EMT transcription factor, Slug^[130] which also promotes stemness. Thus, CD271 appears to be a marker of CSCs across a range of cancer types.

CD271 overexpression on melanoma cells suppressed *in vitro* activation of melanoma specific cytotoxic T lymphocytes^[131]. Moreover, the expression levels of PD-L1 and CD271 on the melanoma cells were both increased by IFN γ such that PD-L1 levels were related to those of CD271, and together with PD-L1 strongly and additively suppressed melanoma specific CTL activation^[131]. CD271 expression on melanoma cells has also been linked to p53 activity, the DNA damage response and chemotherapeutic drug resistance as well as migratory properties to form metastases^[132-134]. The higher expression levels of CD271 may determine specific properties of brain trophic metastatic melanoma cells^[135,136].

Hypoxia induced activation of the HIF-1 α and HIF-2 α as well as their target genes enhances tumorigenicity, self-renewal, resistance to chemotherapeutic drugs and metastatic potential and is associated with increased

surface levels of CD271 as a stem cell marker (reviewed in^[137,138]). However, CD271 expression has also been reported to inversely correlate with hypoxia (HIF-1 α expression) in skin samples from human melanomas analysed histologically at different stages of progression^[139] and likely reflects a delay in its expression after hypoxic induction. CD271 was noted to be highly expressed on the cells in the dermal nests of the biopsied melanomas from human skin samples^[139,140].

In this regard, hypoxia and HIF activation induce *Oct4* gene expression, which will in turn activate CD271^[141]. Thus, transfected gene expression of OCT4 caused melanoma cell dedifferentiation, acquiring features of CSCs such as multipotent differentiation capacity and expression of melanoma CSC markers, ABCB5 and CD271^[141]. Mechanistically, *Oct4*-induced dedifferentiation was associated with increased expression of endogenous stemness factors, OCT4, NANOG and KLF4, and changes in global gene expression enriched for general transcription factors. The reverse study, applying RNAi-mediated knockdown of *Oct4* in the dedifferentiated melanoma cells, led to diminished CSC phenotypes^[141]. Moreover, OCT4 expression in melanoma cells was induced by hypoxia and its expression was detected in a sub-population of melanoma cells from clinical samples^[141]. Overexpressing CD271 on human melanoma cell lines was shown to reduce their invasive and metastatic traits, whereas CD271⁺ melanoma cells showed less adhesive, more highly proliferative and invasive traits *in vitro* and *in vivo*^[142]. Mechanistically, similar to EPCAM, it was found that the CD271 ICD regulated proliferation^[143]. CD271, originally expressed in the epidermis of skin reconstructs, also disappeared when melanoma started to invade the dermis^[142]. Thus, CD271 has been identified as a suitable CSC marker, at least in the case of melanoma.

CD35 (Cripto-1)

Mouse and human Cripto-1 proteins range in sizes from 24 to 36 kDa and are found in complexes associated with other proteins of between 14 to 60 kDa. Cripto-1 is glycosylated at N- and O-linked asparagine and serine residues respectively^[144]. It is a member of the epidermal growth factor (EGF)-related family of growth factors, also known as the EGF-Cripto-1-FRL-1-cryptic (CFC) family. The EGF-CFC proteins are all associated with the cell surface and their structures including an amino terminal region, a modified EGF-like domain, a preserved CFC cysteine rich domain and a short hydrophobic COOH-terminus for attaching to the glycosylphosphatidylinositol (GPI) membrane anchor^[144]. The soluble, biologically active form of Cripto-1 generates from the detachment of the GPI by GPI-phospholipase D such that Cripto-1 can act either as a soluble ligand or a cell-membrane anchored protein^[144].

Cripto-1 was found highly expressed in a subpopulation (up to 60%) of human embryonal carcinoma cells which showed CSC-like properties, expressing OCT4, SOX2, and NANOG. Cripto-1 has a role in the maintenance of stem cells and their malignant progression^[145] as a multifunctional modulator during embryogenesis, as well as being important for oncogenesis^[144,146]. In the process of embryogenesis, Cripto-1 plays an important role in association with the TGF β ligand, Nodal^[147]. Cripto-1 is highly expressed in many different human tumors, findings consistent with its role as a marker of the undifferentiated CSCs^[148-150].

Cripto-1 is one of the master regulators of embryonic development along with the Notch/CSL, and WNT/ β -catenin systems^[151]. Hence, Cripto-1 is a surface marker for the identification of stem and quiescent cancer cells including the CSC phenotype in colorectal cancers and similar to the other CSC markers LGR5, EPCAM and CD271 described above, Cripto-1 expression is also up-regulated by hypoxia when HIF-1 α binds to the hypoxia response elements^[145,152] within the promoter of human or mouse Cripto-1 genes^[153]. Hypoxia can enhance production of beating cardiomyocytes and modulates the differentiation of mouse ESCs and Cripto-1 is required for the hypoxia-induced differentiation of mouse ESCs into cardiomyocytes, helping to regulate stem cell self-renewal and proliferation^[153]. It follows that Cripto-1 could be a potential marker for sub-populations of tumor cells with stem-like properties.

CD15 (stage-specific embryonic antigen 1)

Stage-specific embryonic antigen 1 (SSEA1; also called CD15 or non-sialylated Lewis X antigen) refers to a carbohydrate based antigenic epitope (3-fucosyl-*N*-acetyl-lactosamine) synthesized by fucosyltransferases (FUT4, FUT9) and is linked with cell adhesion, differentiation and migration. This marker is associated with the proteoglycan, phosphacan (a.k.a. protein tyrosine phosphatase receptor-Z1; RPTPZ1; PTPRZ1) which regulates the proliferation, self-renewal and differentiation of stem cells^[154]. RPTPZ1 is a receptor for the extracellular matrix protein, tenascin C recently linked with EMT, metastasis, recurrence and poor survival of CRC patients^[155].

CD15/SSEA1 is expressed by murine embryonal stem cells, murine embryonic carcinoma cells, as well as human and murine germ cells^[156]. SSEA1 has been widely used as a positive surface marker for undifferentiated normal stem cells from mice but not for human stem cells^[39]. Thus, upon differentiation of the murine embryonal stem cells or embryonal carcinoma cells, expression of SSEA1 is down-regulated, whereas during human embryonal stem or carcinoma cell differentiation, SSEA1 expression is increased. The SSEA-1 marker is commonly used for identifying stem cells because it can be readily detected using the monoclonal antibody, MC-480, as a cell surface antigen involved in cell differentiation. This monoclonal antibody has also been commonly used as a standard reagent for detecting embryonic stem cells^[157].

SSEA-1/CD15/FUT4 was found commonly overexpressed on metastatic CRC patients (43%) and was associated with lower levels of intratumoral CD3⁺ and CD8⁺ T cells, as well as poorer patient outcomes in terms of responses to treatment or progression-free survival (PFS) than those CRCs that were CD15/FUT4-low or negative^[158]. Studies of brain development have shown that expression of CD15/SSEA1 is predominantly associated with *O*-mannose-linked glycans of the phosphacan/RPTPZ1^[159] and high levels of RPTPZ1 expression have also been reported present in human CRC samples^[160]. Hence, although SSEA-1 may be a putative CSC marker in the case of murine CRC, it is likely to show a more widespread expression on human CRC cells.

COX-2 AND CELECOXIB AS AN APPROVED DRUG FOR COLORECTAL CANCER, ALSO TARGETS CSCS, INCLUDING CR-CSCS

Celecoxib was approved nearly 20 years ago by the USFDA for the treatment and prevention of some forms of colorectal cancers, including familial adenomatous polyposis and sporadic colorectal adenoma. The anticancer effects of celecoxib were claimed due to its potential for inhibiting the enzyme, COX-2 in the CRC cells^[23,161-163]. COX-2 (also known as prostaglandin-endoperoxide synthase 2) uses arachidonic acid to produce the prostaglandin H₂ required to synthesize the prostanoids including thromboxane, prostaglandins such as PGE₂ and prostacyclin. COX-2 is overexpressed in many cancer cell types, including CRC^[164] when compared to levels in the corresponding normal cells. Moreover, COX-2 was recently detected in the CTC populations from CRC patients, where COX-2 expression was associated with those tumor CTCs positive for vimentin and Twist as two markers detected co-expressed at a higher frequency in patients with metastases compared to those without (72.0% vs. 42.8%)^[165].

The role of COX-2/PGE in CRC and relationship to LGR5/WNT activation and survival of CSCs

The tumor cell inhibitory mechanism of celecoxib was proposed to involve counteracting the increased levels of COX-2 enzymatic function in colorectal cancer cells [Figure 3], thereby causing the suppression of cancer cell growth (^[166], reviewed in ^[167]). As outlined above, one of the mechanisms of action by inhibiting COX-2 likely involves interfering with the WNT/PGE₂ signaling pathways that would otherwise promote greater levels of LGR5 and cancer cell stemness. Among the tumor-sustaining prostaglandins produced by COX-2, PGE₂ is associated with enhancing cancer cell survival, growth, migration, invasion, angiogenesis, and immunosuppression^[168] and can act in an autocrine/paracrine manner to promote tumor growth and survival^[169] [Figure 3]. Inhibiting COX-2 with celecoxib would thereby block the growth stimulating effects

Figure 3. Celecoxib prevents CSC growth and tumor angiogenesis by inhibiting the COX-2/PGE2/VEGF and WNT/LGR5 stemness pathways. COX-2 is required for the production of prostanooids, including PGE2, which is released by tumor cells and stromal cells. PGE2 acts in an autocrine/paracrine manner binding to surface members of the prostanooid receptor family (EP1-4) to increase cancer cell stemness, angiogenesis (via production of VEGF and FGF), invasiveness (via matrix metalloproteinases MMP-2, MMP-9) and thereby promotes tumor metastasis. Celecoxib is an anticancer drug that is cytotoxic for CSCs, inhibiting COX-2/PGE2 production and stemness, thereby down-regulating the WNT/LGR5 signalling pathway, inhibiting angiogenesis and promoting the anticancer immune response. CSC: cancer stem cell; CTC: circulating tumor cell; VEGF: vascular endothelial growth factor; FGF: fibroblast growth factor; COX-2: Cyclooxygenase-2; PGE2: prostaglandin E2; PGH2: prostaglandin H2; TCF-4: T-cell factor-4; TNIK: Traf2- and Nck-interacting kinase; AA: arachidonic acid

derived from the COX-2 production of prostaglandins as cytokine-like factors stimulating growth, CSCs and metastases^[170,171]. Levels of PGE2 correlate with colonic CSC markers (CD133, CD44, LGR5, and SOX2 messenger RNAs) in human colorectal carcinoma samples suggesting that it is a marker for CR-CSC^[171]. Thus, PGE2 induced CSC expansion by activating nuclear factor-kappa B (NF-κB) via the PGE2 receptor 4 (EP4) and PI3K/MAPK signaling, promoting the formation of liver metastases by colorectal cancer cell lines injected into mice^[171].

Angiogenesis is one of the classical hallmarks of cancer, promoting new blood vessel formation from pre-existing vessels, thereby facilitating the supply of blood borne nutrients and oxygen to the tumor cells^[172]. As early as 1999, celecoxib was recognized as an important chemotherapeutic agent in colorectal cancer treatment^[173] because of its ability to potently inhibit angiogenesis by preventing vascular endothelial growth factor (VEGF) and FGF production, reducing growth of gastrointestinal cancer xenografts in nude mice^[174]. COX-2/PGE2 activation increases VEGF expression by colon cancer cells, thereby promoting tumor angiogenesis (reviewed in^[175,176]).

Evidence for COX-2/PGE playing a role in many other cancer types besides CRC and is a CSC drug target

These early findings have since been confirmed in many subsequent studies of other cancers as well including lowering microvessel density in gastric cancer models by inhibiting COX-2 mediated PGE2 production and VEGF expression^[177,178], and in head and neck^[179], pancreatic^[180], Lewis lung cancers and sarcomas^[181] (reviewed in^[182]). In more recent studies of dimethylhydrazine-induced colorectal cancer models, NSAIDs

like celecoxib decreased the rate of adenocarcinomas, markedly lowering angiogenesis parameters including VEGF, MMP-2, MMP-9 and MCP-1 levels^[174,183]. More importantly, inhibiting COX-2 with celecoxib was found to block the PGE₂-induced tumor repopulating capacity, which otherwise promoted chemoresistance in bladder cancer xenografts^[184] as well as CSC expansion and metastasis in colorectal cancer models^[171].

The role of COX-2 in CSC survival and repopulation after therapy has been reviewed elsewhere^[185], such that it has become clear that inhibiting COX-2 is an effective method for preventing treatment failure due to tumor repopulation. Moreover, celecoxib, as a selective COX-2 inhibitory drug, has also been reported to promote the apoptosis of colon cancer cells^[186]. The prostaglandin, PGE₂ produced by COX-2 activates pro-survival pathways preventing apoptosis of colon cancer cells^[187] (reviewed in^[168,188]). Celecoxib, by inhibiting COX-2 facilitates the activation of various apoptotic pathways in colorectal cancer cells, including p53, p38 and BAX pathways^[189].

Another aspect of the prostaglandins produced by COX-2 activity is that some, such as PGE₂, are pro-inflammatory cytokine-like factors that modulate the anticancer immune response^[190]. Celecoxib's anticancer inhibitory effects (resulting from lower prostaglandin levels) also include promoting an enhanced immune response. Thus, celecoxib inhibition of COX-2 prevents the switching from a Th1 to a Th2 immune response, where Th2 would be more favorable to cancer cell survival. The immune response switch to Th2 is induced by increased levels of COX-2 which also leads to decreased production of the NF- κ B activated cytokines that would otherwise induce Th1 proliferation, including interferon gamma (IFN- γ), tumour necrosis factor-alpha, and IL-2. Moreover, COX-2 activity promoted expression of cytokines including IL-6, IL-4, and IL-10 which preferentially activate Th2 type immune responses^[191], thereby enabling the cancer cells to evade the host immune system.

Tumor-associated COX activity in a mouse melanoma model driven by oncogenic mutation in *Braf* (similar to the situation in human melanoma) was shown to be a key suppressor of type II IFN (IFN- γ) and T cell-mediated tumor elimination, inducing an inflammatory signature more typically associated with cancer progression^[192]. COX-dependent immune evasion was also shown to be critical for tumor growth in a range of models including melanoma, colorectal, and breast cancers^[192]. Notably, tumor immune escape could be reversed by a combination of an immune checkpoint blockade inhibitor together with COX inhibitors. Hence, the COX-2/PGE pathway can promote tumor growth, survival and evasion of the immune response and highlights the importance of using NSAIDs such as celecoxib to inhibit the COX-2/PGE based activities in tumors.

We have shown that celecoxib has a fourth component to its anticancer function based on direct effects in killing cancer cells by targeting their mitochondria to increase the respiratory substrate driven production of reactive oxygen species such as superoxide, thereby activating the intrinsic apoptotic pathway^[23,193]. Although many of the NSAIDs show similar properties and ability to act as cytotoxic anticancer drugs (reviewed in^[194]), celecoxib was found to be by far the most outstanding^[23,193] and was highly effective at inhibiting growth of triple negative breast cancer spheroids^[195]. In this regard, in many animal models of cancer, celecoxib has been shown to chemosensitize cancer cells in a synergistic manner to enhance the cytotoxic effects of commonly used chemotherapies, such as the anthracycline drugs doxorubicin and epirubicin^[196-200] and platinum-based chemotherapies^[164,199,201-206]. In murine models of colorectal cancer, synergistic anticancer effects were obtained by combining celecoxib with the common CRC chemotherapeutic drug, 5-fluorouracil (5-FU)^[207] or with oxaliplatin^[208].

In human hepatomas, Chu *et al.*^[209] showed that celecoxib promoted death of the CSC population and suppressed stemness and progression by up-regulating the tumor suppressor function of the tyrosine phosphatase, PTEN. In related studies^[84,210], celecoxib was shown to target CSCs and suppress their self-renewal, sensitizing them against chemoresistance as well as inhibiting their EMT. Further, these studies

showed that celecoxib attenuated metastasis and tumorigenesis by inhibiting the synthesis of PGE₂, thereby down-regulating the WNT/LGR5 pathway activity, including for colorectal CSCs^[84]. Hence, celecoxib has shown a range of highly beneficial and intriguing properties as an effective anticancer drug in animal tumor models and provides an example of a drug affecting the WNT/LGR5 signaling pathway in CSCs to prevent CSC survival and metastasis.

Clinical studies of colorectal cancer patients receiving treatment with celecoxib over the long-term for several years have been successfully completed^[211-214]. In most of these studies, celecoxib was used in combination with chemotherapy and showed significant improvements with inclusion of celecoxib, resulting in decreased rates of metastases and incidence of recurrence. In a large trial from 2006, the results of the Adenoma Prevention with Celecoxib (APC study) showed that continued dosing (400 mg) of celecoxib daily in patients diagnosed with colorectal polyposis and treated over prolonged periods of three years significantly decreased the recurrence of adenoma and advanced adenoma, when compared to placebo^[215]. In follow-up studies, it was reported that although the effects of celecoxib diminished two years after treatment was halted, there was still a considerable treatment benefit at five years^[216,217]. Overall, the risk for advanced adenoma relative to placebo was lowered by 52% on low-dose 200 mg bi-daily (vs. 57% at 3 years) and 51% on high-dose 400 mg bi-daily (vs. 66% at 3 years)^[217]. Hence, long term use of celecoxib has consistently proven to significantly lower the formation of advanced colorectal cancers in such studies.

We have previously extensively reviewed the outcomes of human clinical trials with celecoxib to treat cancer and which have often shown that sustained, long-term use over several years provided significant benefits in terms of patient outcomes, particularly against metastatic recurrence of cancers^[23]. To summarize from the trial outcomes, unfortunately many such clinical trials underway during the last decade suffered from being prematurely terminated because of the growing recognition at the time of cardiotoxic side effects associated with the use of certain COX-2 inhibitors (coxibs), such as Vioxx (rofecoxib)^[218]. Although this resulted in a total ban for Vioxx, elevated cardiotoxicity was ruled out for celecoxib in 2015, when it was approved by the USFDA after it was found to be as safe as ibuprofen or naproxen^[219]. As an example of one prematurely terminated study, a Phase II trial was reported in 2018 concerning the effects of celecoxib (400 mg twice daily, every day) plus or minus chemotherapy with IFL (irinotecan, 5-fluorouracil (FU), and leucovorin; each cycle comprising IFL over 4 weeks then 2 weeks with no IFL) for previously untreated or unresectable metastatic CRC confirmed by biopsy^[155].

Unfortunately, because the Phase II trial was prematurely terminated, only short-term use of celecoxib in patients could be analyzed with follow up to 2 years, and which would not be expected to show significant effects based on the earlier findings outlined above. This Phase II study was further complicated by a protocol variation with the inclusion of 81mg aspirin added with celecoxib to mitigate against possible cardiotoxicity in the high-risk cardiovascular subjects. This trial was limited to a median of three treatment cycles (a total of ~ 20 weeks of daily celecoxib). Nevertheless, the results showed promise in that PFS and overall survival (OS) of patients was improved at 8.7 and 19.7 months, respectively when compared to the historical IFL alone treated controls of 7 and 15 months. After modifying the study protocol, the overall survival was ~91% at one year and 50% at 2 years (median OS = 24.2 months), and the authors could not exclude the possibility of added survival benefit with celecoxib slowing progression of disease. A larger, multicentred Phase III trial (Alliance/SWOG C80702) is underway with FOLFOX (5-FU + oxaliplatin + folinic acid = leucovorin) every 2 weeks for 24 weeks, plus celecoxib (400mg daily treatment extended to 3 years) with longer term follow-up to include 6-year survival and will complete in December 2019.

CONCLUSION

Based on the supportive findings reviewed here, the importance of cytotoxic drugs targeting the CSC population has become self-evident, with significant ramifications for the future of anticancer drug design

and treatment. It should be possible to identify and thereby improve the development of drugs used as biological modifiers to eliminate the CSC populations by relying on the selective biomarkers Cripto-1, ABCG2, LGR5 and CD271 to aid in the analysis of CSC drug sensitivity. From the range of evidence provided, it is apparent that such CSC markers are expressed in common across many cancer types and with ESCs. In this manner, the CSC biomarkers can be used to separate enriched CSC populations from the other non-tumorigenic cells and normal stem cells using cell-sorting technology to then identify those drugs with greater potential for specifically and selectively targeting the CSCs by activating their cell death programs. One such drug is celecoxib, with one of its properties being an inhibitor of the COX-2/PGE production by CSCs, otherwise required for promoting greater LGR5 expression and WNT signalling to enhance CSC proliferation.

Cancer treatments have repeatedly failed due to their inability to target and kill the CSCs because these cells are highly resistant to commonly used chemotherapies, having greater survival and metastatic properties. The CSCs can remain dormant, only to then become reactivated, with their capacity for self-renewal and extensive proliferation, metastasis and differentiation giving rise to recurrent tumors, even after extended periods post-treatment. Therefore, it will be essential to be able to identify the CSCs, isolate and study their characteristics in greater detail in order to develop better drug treatments, such as celecoxib, and where the evidence is compelling that such drugs can then either promote or induce the death of the CSCs, both in the circulation and in tumor niches.

DECLARATIONS

Authors' contributions

Both authors contributed equally to the writing, construction and editing of the manuscript as well as drawing of the figures.

Availability of data and materials

Not applicable.

Financial support and sponsorship

ALHulais RA was supported by the Higher Education of Saudi Arabia (King Abdullah Scholarship) for her PhD program.

Conflicts of interest

Both authors declared that there are no conflicts of interest.

Abstract

Aim: The aim of the study is to test visible resonance Raman (VRR) spectroscopy for rapid skin cancer diagnosis, and evaluate its effectiveness as a new optical biopsy method to distinguish basal cell carcinoma (BCC) from normal skin tissues.

Methods: The VRR spectroscopic technique was undertaken using 532 nm excitation. Normal and BCC human skin tissue samples were measured in seconds. The molecular fingerprints of various native biomolecules as biomarkers were analyzed. A principal component analysis - support vector machine (PCA-SVM) statistical analysis method based on the molecular fingerprints was developed for differentiating BCC from normal skin tissues.

Results: VRR provides a rapid method and enhanced Raman signals from biomolecules with resonant and near-resonant absorption bands as compared with using a near-infrared excitation light source. The VRR technique revealed chemical composition changes of native biomarkers such as tryptophan, carotenoids, lipids and proteins. The VRR spectra from BCC samples showed a strong enhancement in proteins including collagen type I combined

with amide I and amino acids, and a decrease in carotenoids and lipids. The PCA-SVM statistical analysis based on the molecular fingerprints of the biomarkers yielded a 93.0% diagnostic sensitivity, 100% specificity, and 94.5% accuracy compared with histopathology reports.

Conclusion: VRR can enhance molecular vibrational modes of various native biomarkers to allow for very fast display of Raman modes in seconds. It may be used as a label-free molecular pathology method for diagnosis of skin cancer and other diseases and be used for combined treatment with Mohs surgery for BCC.

INTRODUCTION

Several studies have reported that skin cancer is in an increasing trend worldwide. Each year, new cases of skin cancer have been reported to have a greater incidence than breast, prostate, lung and colon cancers combined. Basal cell carcinoma (BCC) is the most common skin cancer, accounting for about 80% of the non-melanoma skin cancers (NMSC) which includes BCC and squamous cell carcinoma (SCC). Before the age of 65, 40%-50% Americans will have BCC or SCC skin disease occurring. There are about 4 million cases of BCC diagnosed in the USA annually^[1-4]. Although BCC lesions rarely metastasize and have a high curable rate, they frequently expand quickly and may not only become a cosmetic problem but infiltrate surrounding tissue causing functional problems. Therefore, early detection and rapid and accurate diagnosis become very important for treatment.

Currently, clinical routine diagnosis of skin cancer is performed using biopsy and histopathology. The gold standard method requires freezing or reagent preparation of the biopsy tissue prior to microscopic analysis. This requires skilled technicians and expert histopathologists to perform the diagnosis, as well as considerable time before the results are available. This leads to a diagnostic accuracy of about 80% depending on expertise and training^[5-9]. A new diagnostic technique that is more rapid with higher accuracy would be a great clinical advantage. A search is ongoing for a fast and accurate way for diagnosis while treating cancers.

An optical biopsy (OB) technique would offer many advantages including in situ evaluating lesions. There is a panoply of OB techniques, such as label-free native fluorescence, Raman spectroscopy (RS), optical coherent tomography, and other optical imaging techniques for *ex vivo* and *in vivo* cancer detection in human tissues and cells. These techniques have advanced significantly since the earliest reports in 1984, 1987, 1991 and 1992 by Alfano's group^[10-13]. In particular, OB techniques for *ex vivo* detection of a panoply of different cancer types such as NMSC have progressed in recently years. Some fluorescence spectroscopic techniques for diagnosis of BCC have been reported, such as fluorescence confocal microscopy that has been used to detect BCC skin cancer margin in Mohs excisions without the need of frozen and fixed section processing^[14-20]. RS technique has some unique features such as using intrinsic biomarkers and operating *in situ* and in a time period of many minutes or seconds. This has led to a rapid progress in seeking commercial instrumentation for researchers and clinical applications in BCC and other skin cancer diagnoses^[21-36]. Most of the reports demonstrated spectral differences between normal skin tissue and BCC lesions using near-infrared (NIR) laser excitation only. Some reported the use of high power and very long signal collection time (e.g., 300 mW of power and minutes of time) on cells and tissues^[24,25]. The NIR Raman method which uses excitation light sources at 671 nm, 785 nm, 830 nm or 1,060 nm has limitations for practical applications described as follows: (1) NIR Raman method only detects non-resonant biomolecule components; (2) NIR laser source requires long excitation time. Even a confocal micro Raman system has poor signal-to-noise (S/N) ratio since the spectral peaks are weak and not enhanced. Increasing excitation light intensity and

longer exposure time will limit the practical application^[24,26,30]; and (3) The NIR light penetrates relatively deep and excites a large volume in the skin compared to visible light. Thus, it is subjected to variations in the molecular content of the target tissue yielding a low selectivity distinguishing the abnormal from the normal target sites.

We have recently developed a novel visible resonance Raman (VRR) technique using 532 nm as the excitation source which can address the aforementioned limitations of NIR RS technique and extend the Raman technique so that it detects both non-resonant and resonant biomedical components. The vibrational resonance effect occurs in resonance Raman (RR) spectroscopy when the energy of the excitation approaches an optical transition energy level, which greatly enhances the scattering. The RR signal intensity may be enhanced 10^2 to 10^3 times, typically 10 to 100 folds, compared with non-resonance signal, since Raman scattering cross section is inversely proportional to the fourth power of the wavelength. In particular, RR using 488 nm and 532 nm excitation wavelengths gives almost seven and five times more intense Raman signal than using 785 nm excitation wavelength, respectively.

One will have many advantages of resonance Raman over conventional non-resonance Raman if 532 nm is used for excitation in biomedical diagnosis. Since cells and tissues contain many large biomolecular chromophores and other large conjugated molecules with multiple vibrational bonds, they experience stretching and bending vibrations that can be enhanced by the excitation laser and the RR spectra collected from them exhibit enhanced peaks. Specific biomolecules in the cell and organelles contain fluorophores, such as flavins, NADH, NAD, collagens, elastin, carotenoids, tryptophan, hemeproteins, mitochondria and cytochromes. The resonance enhanced signals from these biomolecules suggest that the 532 nm excitation wavelength matched (or closely matched) the molecular absorption bands for these biochemical compounds in the cells and tissues. For example, the metalloprotein such as hemoglobin, has one absorption band at 534 nm. Similarly, the mitochondrial electron transport protein, cytochrome c, has one absorption band at 552 nm (under the hypoxia conditions). The 532 nm is in the tail of the absorption band of flavins and lactate. Carotenoids and flavins have pre-resonance absorption bands about 480 nm and 500 nm which fall in the pre-resonance range of the excitation wavelength of 532 nm. The molecular vibrations of flavins were enhanced by more than 100 times. Therefore, the VRR spectral peaks are greatly enhanced, and much sharper than those from NIR non-resonance Raman. The first RR using 488 nm and 514 nm was noticed in cancer tissue by Alfano *et al.*^[11] in 1987. The VRR method has been used to produce enhanced S/N results in the biomedical fields. More recently, the VRR technique has been used on human brain, breast, vulnerable atherosclerotic plaque, gynecological tissues, gastrointestinal tissues, and atherosclerotic abdominal aortic tissues studies^[37-43]. The VRR spectra *ex vivo* exhibited native molecular signatures that could be used as optical molecular histopathological criteria to distinguish abnormal from normal tissues. The 532 nm wavelength is like a “magic” wavelength for tissue to generate extraordinarily high Raman signals for quasi real-time measurements. It is just inside the key fluorophores’ absorption and emission regions in tissue.

This study focuses on VRR spectral analysis of normal and BCC human skin tissues performed *ex vivo* using a confocal micro-Raman system. It investigates the depth dependence of BCC which reveals a process of status change, and demonstrates the discrimination and classification between normal and BCC skin tissues using molecular vibrational fingerprints and a statistical model. The statistical model is based on principal component analysis (PCA)^[44] and supports vector machine (SVM)^[43,45-48]. To the best of our knowledge, this study is the first to detail and discuss the depth dependence of BCC in correlation with statuses, and to distinguish BCC from normal skin tissue using the VRR technique. This is a pilot study on BCC skin cancer using VRR performed as a basis for longer studies using 532 nm and other visible laser wavelengths.

METHODS

RR spectra of sliced samples of human skin normal and BCC tissues were measured using a confocal micro-Raman spectrometer, with a 532 nm laser for excitation at low power (3.5 mW) for under 30 s. Fifty-five RR

Figure 1. A photograph (side view) of the original human BCC skin specimen used in the experiments (left). The specimen was sliced in vertical direction indicated by the red line. Twenty-eight slices were made with 50 μm thickness for each slice. In the middle is the photograph of a piece of vertical slice of BCC with the size of 5.6 mm \times 8.3 mm \times 50 μm , where the yellow arrow indicates the direction of measurement steps in depth. The right images were taken from the top and bottom edges of the BCC slice. The red arrows show the sites at the top and bottom of the slice where the two images are taken. BCC: basal cell carcinoma

spectra were obtained and analyzed from thirty-six slices of skin tissue samples.

Tissue sample preparation

The human skin normal and BCC specimens were obtained from the National Disease Research Interchange (NDRI, Philadelphia, PA) under the City College of CUNY Institutional Review Board (IRB). The BCC tissue was from the left ear of a 77-year-old white male. The normal skin sample was from the adjacent area of this BCC tissue. The RR spectra of sliced BCC and normal skin samples were measured, including 28 vertical section slices from one BCC sample and 8 horizontal section slices from one normal sample. Each slice is approximately 8.4 mm long and 5.6 mm wide with a thickness of 50 μm . One vertical section slice of BCC sample was selected for measurement at 6 steps of depths with 100 μm step size, and 9 steps of depths with 500 μm step size, starting from the top surface of the skin toward the bottom as shown in Figure 1.

The irregular-shaped skin specimens were snap-frozen with no chemical treatment. They were kept in a -80 $^{\circ}\text{C}$ freezer and shipped with dry ice for all tests. Tissue sections were cut with a thickness of 50 μm and mounted on uncoated glass microscope slides using Leica CM1080 Cryostats at -20 $^{\circ}\text{C}$. The specimens were thawed to ambient room temperature for the spectroscopic studies.

Measurement of RR spectra of BCC and normal skin sliced tissues

All of the RR spectra were collected directly from a region of interest on each sliced specimen. The raw RR spectrographs (without subtracting the baseline) were produced using the software of NGSlabSpec and ORIGIN 2015. A total of 55 spectra were collected from normal and BCC tissues at the following sites: 12 spectra from eight sections of normal specimen; 15 spectra from one vertical section of BCC sample that was selected for measurements at 6 depths with 100 μm separation, and 9 depths with 500 μm separation; and 28 spectra from the centers of 28 vertically sliced sections of BCC sample. Typical spectra are shown in Figure 2.

The instrument used in this study was WITec alpha300 Raman microscope system (WITec: Wissenschaftliche Instrumente und Technologie GmbH, Ulm, Germany), equipped with a Nikon 20X objective (Nikon Instruments, Melville, NY, USA). The excitation light source was a 532 nm solid-state diode laser (Verdi-2, Coherent Company, Santa Clara, CA, USA) with a maximum output power of 50 mW. Each piece of slices was placed on the stage of the system to collect data. The excitation beam was focused on the sample with

Figure 2. A set of typical resonance Raman raw spectra collected from a horizontal section of normal human skin sample, and a vertically sliced BCC skin sample measured at different depths. (Top), the spectrum was from dermis layer of normal skin showing nine feature peaks; (middle), the spectrum was from the vertically sliced BCC sample at a depth of 100 μm . There are eight characteristic peaks including increased peaks at 753 cm^{-1} and 1,589 cm^{-1} , but intense carotenoids peaks at 1,161 cm^{-1} and 1,521 cm^{-1} disappeared compared to the normal tissue (top); (bottom), the spectrum was from BCC sample at a depth of 1,100 μm , substantially similar to the depth of 100 μm , with six Raman peaks, but carotenoids peaks at 1,161 cm^{-1} and 1,521 cm^{-1} are present and obviously weaker than normal tissue sample (top). Those peaks of 753 cm^{-1} and 1,589 cm^{-1} greatly decreased in comparison with the depth of 100 μm . BCC: basal cell carcinoma

a spot diameter of 1 μm and the power of the beam at the sample position was kept at 3.5 mW. RR spectra were collected using a one-second integration time and 30 accumulations, with a system resolution down to the optical diffraction limit of ~ 200 nm. The spectra were collected over the spectral range of 400-4000 cm^{-1} . The spectral resolution was 2 cm^{-1} in the range of interest^[41,42]. All the spectra were collected at ambient room temperature. Student's *t*-test was used to determine if particular RR peak intensities between normal and BCC samples were significantly different.

RR spectral data analysis method by PCA-SVM

The baseline of each raw Raman spectrum was fitted to a polynomial using an asymmetric Huber function as the loss function^[49]. The difference between the raw spectra and the baselines were calculated. Each baseline-subtracted Raman spectrum was then normalized using its Euclidean norm, and used for subsequent analysis.

Raman peaks in the normalized baseline-subtracted Raman spectra were first investigated. Student's *t*-test was used to determine if particular RR peak intensities between normal and BCC samples were significantly different. Then unsupervised machine learning algorithms such as PCA were used to analyze the entire spectral data, reduce dimension and detect underlying spectral features.

PCA finds the uncorrelated components that explain the most variance in the signal. It has been widely used for various applications, such as spectroscopy^[50], face recognition^[51] and optical imaging^[52]. Mathematically, PCA solves an eigenvalue equation, and finds a set of orthonormal eigenvectors which are considered principal components (PCs) corresponding to the eigenvalues which are the variances of the PCs in the data. For Raman spectral data contained in a matrix $X_{M \times N} = \{x_1, \dots, x_N\}$, where M is the number of wavenumbers, and N is the number of spectra or samples (assuming $M > N$). PCA considers the spectral data x_i to be linear combinations of PC loadings $\{w_j\}$ with scores $\{h_{ji}\}$, i.e., $X_{M \times N} \approx W_{M \times N} H_{N \times N}$, where $W_{M \times N} = \{w_1, \dots, w_N\}$ and $H_{N \times N} = \{h_1, \dots, h_N\}$. To calculate the PCs, the data matrix is "mean centered" first, i.e., the mean of each row is calculated and subtracted off that row. Then an eigenvalue equation of the covariance matrix of the "mean centered" data matrix X' is solved to find the eigenvectors and the corresponding eigenvalues. The eigenvectors are the PC loadings, and eigenvalues are the variances explained by the corresponding PCs. In practice, this can be solved using singular value decomposition^[53] of the data matrix X' , i.e., $X' = U \Sigma V^T$, where U and V are left and right singular vectors, and $\sigma_i = \text{diag}\{\Sigma\}$ are the singular values. Columns of $U_{M \times N}$ are taken to be the PC loadings, i.e., $W = U$, eigenvalues $\lambda_i = \sigma_i^2$, $H = \text{pinv}(W)X$, where pinv denotes pseudo inverse, and $\text{pinv}(W) = (W^T W)^{-1} W^T$.

The PC scores contained in H are essentially the projection of the spectral data in matrix X onto the PCs or "eigenspectra". The PC scores h_i are a set of mixing coefficients of the PCs. These scores can be considered as the characteristic information of the spectra (samples) and used for classification. Alternatively, PC scores obtained from the mean-centered data matrix can also be used, and they are simply different from those obtained from the raw data with a shift in the origin.

Then the PC scores of different spectra (samples) were used for classification after standardization. The scores were standardized for each spectrum using the following formula: (score - "score mean")/"score standard deviation". An SVM with a linear kernel was used for classification. SVM attempts to find a hyperplane (a boundary line in two dimension) to separate two classes with the largest distance from the nearest class members (data points) which are called support vectors. Once the SVM classifier is trained, it is tested for classification using all the data points, which is called re-substitution validation. Various combinations of features were tested for classification. Since the contributions due to higher-order PCs significantly decrease according to the eigenvalues, limited number of PCs need to be evaluated and compared. More thorough search of optimal feature selection may be carried out^[47,48]. The classification performance of the SVM classifier was evaluated using statistical measures including sensitivity, specificity, and accuracy, along with the receiver operating characteristic (ROC) curve^[54,55]. To plot the ROC curve for the SVM classifier, the positive class (cancer) posterior probability (a data point classified into positive class) for each data point was calculated by using a sigmoid function to map the SVM scores which are the distances from the data points to the SVM separation line^[56]. Then the posterior probabilities were used to calculate the true positive rate (i.e., sensitivity) and false positive rate (i.e., 1 - specificity) by varying the threshold and generate the ROC curve for true positive rate vs. false positive rate. The area under ROC curve (AUROC)^[55,57] was calculated

Figure 3. A set of typical resonance Raman spectra collected from a horizontally sectioned normal human skin sample, and a vertically sliced basal cell carcinoma skin sample measured at a depth of 100 μm . Both plots are displayed in the enlarged scale regions of low wave-number 700-1,800 cm^{-1} and high wave-number 2,700-3,150 cm^{-1}

to show the performance of the classifier. AUROC represents the probability that a classifier will rank a randomly chosen positive sample before a randomly chosen negative one. It is used as a global measure of classifier performance that is invariant to the classifier discrimination threshold and the class distribution. Perfect classification accuracy corresponds to an AUROC value of 1, while a random guess separation leads to an AUROC value of 0.5. To reduce bias in the classification with re-substitution, leave-one-out cross validation (LOOCV)^[58] was used to re-evaluate the classification performance. To perform LOOCV, each time one individual spectrum was removed from the dataset. The rest of the dataset was used to train an SVM classifier. The removed spectrum was then classified by the trained classifier for testing. This process was repeated for all spectra. In the end, sensitivity, specificity and accuracy were calculated based on the results of all testing as overall evaluation of the classification performance. All the computations for PCA-SVM were carried out in MATLAB.

RESULTS

RR raw spectra from horizontally sliced normal and BCC cancerous human skin samples in vertically section were measured. The distinctive Raman peaks that can be uniquely assigned to distinguish skin cancer lesions were obtained by the raw spectral profiles. The correlation between depth and the status of BCC cancer was found using the RR molecular fingerprints [Figures 2 and 3], by investigating the relative changes of biomarkers [Figure 4] and by calculating the ratios of peak intensities [Figure 5]. The classification of BCC cancer from normal skin tissues using PCA-SVM statistical method is shown in Figure 6.

Depth-dependent BCC assay: (1) VRR spectral fingerprints

RR spectral fingerprints of carotenoids: Figures 2 and 3 and Table 1 show the typical spectra from normal and cancerous BCC sliced skin samples. It revealed the process of evolution from normal to cancer and depth-dependence of cancer from different status with RR spectral fingerprints. The RR spectrum [Figure 2 (top)] was obtained from the center of the third piece of horizontally sliced normal sample with thickness 50 μm . The depth is around 150 μm in the normal skin tissue (corresponding to the lower epidermis layer and the dermis layer). The epidermis is usually ~ 0.1 mm thick, and ranges from 0.07 to 0.12 mm. The *dermis* is a layer of skin which is beneath the epidermis layer and is the thickest of the three layers (epidermis, dermis and hypodermis) of skin^[59-62]. The *dermis* is also called corium, whose thickness is 0.3-4.0 mm and it is composed of dense irregular connective tissue. So, we consider this normal sliced sample to be located at the dermis layer. In the RR spectrum of normal dermis skin, the resonance-enhanced intrinsic molecular fingerprints of β -carotenes (here we consider β -carotenes, because the β -carotenes and lycopene account

Figure 4. The relative concentration changes in biomarkers of tryptophan (left), carotenoids (middle) and lipids/lipoproteins (right) in the normal skin tissue and BCC skin tissues with depth-dependence. Dramatic changes on relative concentrations are shown for the lesion slices at the depth of 100 μm compared with other depths of 200 μm, 1,100 μm and 1,600 μm. Based on student's *t*-test, the difference between normal and BCC samples is statistically significant ($P < 0.05$) for biomarkers: 752, 1,161 and 1,521 cm^{-1} . The units of the numbers in the figure legends are cm^{-1} . BCC: basal cell carcinoma

Figure 5. The changes in the resonance Raman fingerprints represented by the ratios of peak intensities of biomarkers. The 1,589 cm^{-1} mode is supposed to be arising from tryptophan; 1,452 cm^{-1} mode is assigned to fatty acids-lipid protein molecules; 1,662 cm^{-1} mode is amide I combined with type I collagen; the largest ratio (I1589 to I1452) changes occurred at a depth of 100 μm in the BCC tissue (left). Based on student's *t*-test, the difference between normal and BCC samples is shown to be statistically significant ($P < 0.05$) for all biomarkers. BCC: basal cell carcinoma

for about 60%-70% of the total of the five most concentrated carotenoids content in human organisms), at 1,161 cm^{-1} and 1,521 cm^{-1} are thought to play a significant role in the normal dermis skin anti-oxidant defense system, as shown in Figure 2 (top) and Figure 3 (left). These two resonance bands are active because carotenoids have a pre-resonance absorption band which falls in the pre-resonance range of the excitation wavelength of 532 nm^[37,63-67]. The RR peaks of 1,161 cm^{-1} and 1,521 cm^{-1} disappeared in the BCC sliced sample at a depth of 100 μm as shown in Figure 2 (middle) and Figure 3 (left). This shows a clear progression of the BCC tissue mutation process in comparison with normal skin tissue, which suggests it may be a lesion with very serious status. The spectrum shown in Figure 2 (bottom) is from vertically sliced BCC sample at a depth of 1,100 μm, substantially similar to the BCC sliced at a depth of 100 μm, with RR peaks present at 1,012 cm^{-1} , 1,452 cm^{-1} , 1,662 cm^{-1} , 2,861 cm^{-1} , 2,898 cm^{-1} and 2,932 cm^{-1} . But carotenoids peaks occurring at 1,161 cm^{-1} and 1,521 cm^{-1} are obviously weaker than normal tissue sample [Figure 2 (top)], which suggest this status may be a mildly lesion. Thus, we propose that the evolution of the RR spectra of biomarker carotenoids with the depth dependence revealed the correlation between depth and the process of status change. Carotenoids are the organic and natural fat-soluble pigments and exist in plants. Human beings can obtain carotenoids from diet, such as fruits and vegetables, and its concentration depends on their daily diet and stress factor^[67,68]. Carotenoids accumulate in the epidermis through (1) diffusion from the fat tissue, blood and lymph flows, or (2) secretion via sweat glands, and sebaceous glands onto the surface of the skin and subsequent penetration. The specific importance of carotenoids is to serve as a marker substance for the entire anti-oxidative network of human skin^[69,70]. Because antioxidants form protective chains in skin tissue, they act synergistically to protect each other against the destructive action of the free radicals, and mainly reactive oxygen species^[69-73].

RR spectral fingerprints of tryptophan: in contrast, the RR peaks of 1,161 cm^{-1} and 1,521 cm^{-1} diminished sharply for BCC tissues at a depth of 100 μm while the fingerprints of tryptophan peak at 753 cm^{-1} and 1,589 cm^{-1}

Table 1. Changes in intensities of peaks in the resonance Raman spectra of human normal skin tissues compared with basal cell carcinoma skin tissues in Figure 3

Peak position (cm ⁻¹)	Normal	BCC	Suggested molecular class
753		Enhanced	Trp. DNA
859			Polyadenylic acid, collagen type I, lactate
1,012			Trp.
1,161	Intense		Carotenoids
1,254		Enhanced	Amide III, Trp.
1,316, 1,345		Enhanced	Trp. collagen, A, G, T
1,452			Collagen type I, phospholipid
1,521	Intense		Carotenoids
1,588		Enhanced	Trp. heme class, Phe, A, G
1,662, 1,666		Enhanced	Amide I, collagen
2,861-2,892			Lipids, collagen
2,932, 2,939		Enhanced	Lipoprotein, collagen, lactate

BCC: Basal cell carcinoma; Trp: tryptophan; A: adenine; G: guanine; T: thymine; Phe: phenylalanine

greatly increased in BCC tissue at a depth of 100 μm in a more serious status [Figure 2 (middle), Figure 3 (left) and Table 1], but decreased in the BCC sliced sample at a depth of 1,100 μm in a mild status [Figure 2 (bottom)]. The RR spectra of key fingerprints of tryptophan with a main vibrational mode at 1,588 cm^{-1} (W8b) were observed^[66,74]. It was found that endogenous tryptophan and metabolites contributions were accumulated in the mode of 1,588 cm^{-1} in cancers and enhanced by resonance. Researchers have reported that heterocyclic amino acid tryptophan is a key factor during the metabolic process^[74,75]. This RR vibrational mode of 1,588 cm^{-1} indicates that tryptophan may be produced in human skin cancer in the kynurenine pathway of tryptophan metabolism involved in tumor progression according to our previous studies on human brain cancer^[75-77] and that the micro-environment of malignant tumor tissues may result from tryptophan radicals^[78-80].

RR spectral fingerprints of lipids and lipoprotein: the characteristic band of spectral peaks observed between 2,861 cm^{-1} /2,898 cm^{-1} and 2,932 cm^{-1} are attributed to the vibrations of methylene ($-\text{CH}_2$) from lipids and methyl ($-\text{CH}_3$) groups from lipoproteins [Figure 3 (right), Figure 4 (right) and Table 1]. The peak near 2,932 cm^{-1} , due to the asymmetric C-H stretching of methyl groups, showed a significant increase in BCC cancer tissue at a depth of 100 μm site, while the 2,861 cm^{-1} /2,898 cm^{-1} band relatively decreased in intensity in BCC cancer tissue at a depth of 100 μm in comparison to RR spectrum of the normal skin tissue.

Depth-dependent BCC assay: (2) relative content changes of molecular fingerprints

Figure 4 showed the relative content changes of biomarkers of carotenoids (left), tryptophan (middle) and lipids/lipoproteins (right) in normal skin tissue vs. BCC cancer skin tissues with depth-dependence. The dramatic changes in relative concentrations are shown in the slice at depth 100 μm which is a BCC lesion in comparison to other status BCC lesions at depths of 200 μm , 1,100 μm and 1,600 μm . These results are consistent with the analysis of RR spectral fingerprints in the previous section. The suggested reason for the spectral changes of carotenoids is that the concentration of carotenoids decreased in BCC cancer at the depth of 100 μm , which caused the RR peaks to become too weak to detect and induced a shift in chemical vibration bonds. This change in carotenoids may be due to the structural changes within the micro-environment of malignant lesion. All these observations point out the existence of fast activation and deactivation of Raman vibrational modes.

Depth-dependent BCC assay: (3) ratio of intensity of molecular fingerprints vibration modes

Figure 5 showed the RR fingerprints changes using the ratio of the intensities of RR peaks. The 1,589 cm^{-1} mode is attributed to tryptophan; while the 1,452 cm^{-1} mode is assigned to the fatty acid/lipid protein molecules and the 1,662 cm^{-1} mode is from the amide I combined with the collagen type I molecules. The largest ratio changes of (I_{1589} to I_{1452}), (I_{1662} to I_{1452}) and (I_{2861} to I_{2932}) occurred at a depth of 100 μm from the

Figure 6. (left) is a scatter plot of scores PC1 and PC3 with the separation line (SVM classifier); (middle) ROC curve for the SVM classifier in the left panel; (right) ROC curve for the SVM classifier trained with PC1, PC3 and PC7. PC: principal component; ROC: receiver operating characteristic; SVM: supports vector machine

BCC tissue samples. These ratios of the intensities of the spectral peaks from the BCC cancer tissue at depth 100 μm are found to be much higher [Figure 5 (left and middle)] or lower [Figure 5 (right)] in comparison with those from normal skin tissue, therefore they may be used as a distinct marker to distinguish cancerous tissues from normal skin tissues. Such ratios provide an insight into the conformational changes occurring in biomolecules in these tissues. For instance, the Raman spectra of proteins (represented by the 1,662 cm^{-1} band) correspond to beta-sheets which provide insight into protein folding or the denaturation processes.

Classification based on RR spectral data of BCC and normal skin tissues by SVM

The spectral dataset including 12 spectra from sliced normal skin tissues, and 43 spectra from sliced BCC cancerous samples were analyzed using PCA. Fifty-five PCs were obtained with corresponding eigenvalues sorted in a descent order (the plots are not shown here). The first 10 PCs account for 97% of the total variance. If two PCs are selected for classification, first PC (PC1) and third PC (PC3) showed the best performance. The scatter plot of the PC scores along with a boundary line trained using SVM method is shown in Figure 6 (left). The sensitivity, specificity and accuracy of the classifier with re-substitution validation were calculated to be 97.7%, 75.0%, and 92.7%, respectively. The ROC curve was generated and shown in Figure 6 (middle). The AUROC was found to be 0.95. When PC1, PC3 and PC7 are used together for classification, it achieved optimal performance. Sensitivity, specificity and accuracy of the SVM classifier trained with all spectra were found to be 93.0%, 100%, and 94.5% with re-substitution validation. The ROC curve was generated and shown in Figure 6 (right). The AUROC was found to be 0.99. LOOCV achieved sensitivity 97.7%, specificity 66.7%, and accuracy 90.9%. The classification is shown to be effective for the diagnosis of human skin tissues using RR spectroscopy.

DISCUSSION

In conclusion, given our preliminary investigation, we have demonstrated how the molecular components and conformation change under different conditions of BCC skin cancer tissues, and shown that there is a correlation between the depth dependence of RR spectra and the status change of BCC tissue at a molecular level. At a depth of 100 μm , the VRR spectra from BCC tissue change significantly compared to the spectra from normal skin tissues due to the changes in the relative concentrations of tryptophan, carotenoids, lipids and proteins [Figures 2-5]. In addition, VRR technique with 532 nm excitation can effectively distinguish BCC from normal skin tissues. The PCA-SVM statistical analyses of the VRR data collected from human skin cancer and normal tissues were used to distinguish BCC lesions from normal skin tissues. It yielded a sensitivity, specificity and accuracy of 93.0%, 100%, and 94.5%, respectively, when compared with the histopathology analysis (as the “gold standard”) reports. This is the first evidence that the difference between human skin normal tissues and cancer lesions can be detected by VRR spectroscopy.

The VRR method has a high S/N ratio, and provides visually intuitive results for inspection. Even the raw RR spectra can be used for a direct comparison between cancerous and normal tissues. In contrast, it is much more difficult to inspect the raw Raman data acquired using NIR such as 785 nm excitation, because of the much lower S/N ratio. In fact, the raw Raman spectra are rarely provided in the literature^[81,82]. The VRR system also uses less power and shorter integration time to collect signals^[28,29,31,32], thus providing a safer and more suitable method for *in vivo* and real-time *in-situ* skin cancer diagnosis compared with other NIR or FT-Raman system. We believe we cannot obtain Raman spectra fast and at a local spot in a skin tissue to get cancer margins without using the 532 nm RR.

This pilot study shows that VRR technology may have broad clinical applications for real-time, and label-free detection of skin lesions and other human tumors such as breast and brain^[37-42,83,84]. A most recent reference to salient features of VRR in carotene in solution is given by Lu *et al.*^[85].

DECLARATIONS

Acknowledgments

The authors are grateful to Dr. K. Sutkus for his assistance to manuscript preparation and submission.

Authors' contributions

Read and revised the manuscript: All authors

Performed experiments, initiated the manuscript and performed data analysis: Liu CH

Performed the PCA-SVM analysis and wrote part of the manuscript: Wu B

Revised the manuscript: Sordillo LA

Performed experiments: Boydston-White S

Prepared the samples: Sriramoju V

Performed data analysis: Zhang C

Financially supported the study, participated in discussions and revised the manuscript: Beckman H

Participated in discussions and revised the manuscript: Zhang L, Pei Z, Shi LY

Is the principal investigator of the project, and supervised the entire study: Alfano RR

Availability of data and materials

The data that support the findings of this study are available from the corresponding author upon reasonable request.

Financial support and sponsorship

This preliminary work was supported in part by a seed grant from Sinai hospital of Detroit medical staff foundation.

Conflicts of interest

All authors declared that there are no conflicts of interest.

Ethical approval and consent to participate

In this study, the human skin normal and BCC specimens were obtained from the NDRI (Philadelphia, PA). The experimental procedures were approved by the City College of the City University of New York, IRB office.

Consent for publication

Not applicable.

Meeting Abstracts of the 3rd International Workshop No-Cancer 2018 - understanding cancer cell biology to improve diagnosis and therapy

Novara, Italy; 28-30 Oct 2018; Published: 23 Jan 2019

Correspondence to: Dr. Ciro Isidoro, Prof. Gianluca Gaidano, Università del Piemonte Orientale "A. Avogadro", Novara 28100, Italy. E-mail: ciro.isidoro@med.uniupo.it; gianluca.gaidano@med.uniupo.it

Editorial Note:

Cancer remains a leading cause of death, despite the undeniable progress made in the last decades in the diagnosis and therapeutic treatments. Further improvements are only possible if we understand more in depth how cancer develops and metastasizes, and how it produces its damaging effects on the whole organisms, including immune-suppression and cachexia, that eventually lead to patient death. The goal of the International Workshop No-Cancer 2018 “understanding cancer cell biology to improve diagnosis and therapy” held in 28-30 Oct, in Novara (Italy) is precisely to share the foremost updated knowledge on the biology of cancer and the emerging technologies for early detection of cancer cells and the new “chemo-free” therapeutic options.

This is the third international Conference on Cancer organized under the auspices of the Università del Piemonte Orientale and other Academic and Cultural institutions, and ideally follows the two previous ones “Basic to Translational Medicine 2016: focus on Cancer” and No-Cancer 2017 “From Cancerogenesis to Therapy: new paradigms, new opportunities”, held in Novara. As outlined in the title, the main objective of the present workshop No-Cancer 2018 is to discuss the current knowledge in Cancer Cell Biology with the aim of paving the design of more precise and non-invasive methods for early detection of cancer cells and of more effective and personalized therapeutic interventions.

Twelve internationally renowned speakers coming from Belgium, France, Italy, Germany, Spain, Portugal and United States will present their recent research in a two-day scientific marathon. In addition, eight short communications and thirteen flash communications have been selected from the submitted abstracts. The following topics are covered: Oncogenes, onco-suppressors and Non-Coding RNAs in Cancer development; Cancer Cell metabolism and Metabolic cross-talk between cancer cells and stromal cells; Role of diet and of microbiota in cancer progression and response to therapy; Novel non-invasive strategies for early detection of cancer, Genetic alterations predisposing to Cancer; Immune and Drug resistance; cachexia; Clinical trials with novel therapeutics. The invited lectures will focus particularly on ovary cancer, colon cancer, pancreatic cancer, breast cancer, prostate cancer, mesothelioma, and hemato-oncology.

Besides the scientific sessions, participants also can enjoy the social events, which include the city tour, classical music concert and Gala dinner.

Scientific and Social event programs and the Photogallery of the Conference are available at www.isidorolab.com.

This Special Issue of *Journal of Cancer Metastasis and Treatment* is a collection of the articles and extended abstracts that refer to the lectures presented at the Conference. Commentaries and review articles related to the theme of the Conference are also included.

Cancer is identified as the second leading cause of death worldwide with an estimated 9.6 million deaths in 2018. The mortality rate of cancer is primarily due to disease recurrence and therapy resistance. Recent studies have shown that the normal stroma in the cancer tissue is converted into an “activated” cancer-promoting niche by the cancer cells facilitating aggressive cancer growth. Normal fibroblasts in the vicinity of the cancer cells are primary recruits in this activation process. “Activated” fibroblasts, defined as cancer associated fibroblasts (CAFs), play a critical role in cancer progression, metastasis, and therapy resistance. Therefore, identifying the mechanisms underlying the conversion of normal cells to CAFs is of critical importance to define novel effective therapeutic targets. Using normal fibroblasts and patient-derived ovarian CAFs, we have identified a role for both lysophosphatidic acid-receptor (LPA) mediated canonical signaling pathways and lncRNA-hub mediated non-canonical signaling pathways in the induction and maintenance of CAF phenotype in normal fibroblasts. Our studies demonstrate the potential interplay between LPA-LPAR signaling-hub and lncRNA-signaling hub in the maintenance of the CAF-phenotype in ovarian cancer. Our results provide evidence that targeted inhibition of this signaling nexus in CAFs may represent an adjuvant therapy in ovarian cancer.

2. Obesity-associated alterations of adipose tissue microenvironment and colorectal cancer

Sandra Gessani, Manuela Del Cornò, Lucia Conti, Gloria Donninelli, Barbara Varano, Beatrice Scazzocchio, Rosaria Vari, Massimo D’Archivio, Roberta Masella

Istituto Superiore di Sanità - Center for Gender-Specific Medicine, Rome 00161, Italy.

Introduction: Obesity, a low-grade inflammatory condition, is a major risk factor for the development of several pathologies including colorectal cancer (CRC). Adipose tissue (AT) is recognized as a key endocrine

organ regulating metabolic/immune processes with a central role in obesity-associated morbidities. AT is composed of different cell types, i.e., adipocytes and almost a full spectrum of immune cells whose function is changed in obesity. The AT inflammatory process affects adipocyte metabolism and secretory profile and promotes activation of AT resident immune cells. The obesity-associated changes of this tissue are consistent with an emerging concept that immune and metabolic systems are interconnected. Notably, dietary patterns have been associated with increased/decreased CRC risk highlighting the importance of nutrients in cancer prevention.

Experimental model: Visceral AT samples collected from lean and obese subjects affected or not by CRC were assessed for immune cell, inflammatory and fatty acid (FA) profile as well as secretory function.

Results: Alterations of AT microenvironment including FA profile, inflammatory status, immune cell and secretory pattern are found in obesity and CRC. Dietary polyunsaturated FA endowed with anti- or pro-inflammatory properties are able to attenuate or exacerbate, respectively, AT inflammation.

Conclusion: AT inflammation has a key role in carcinogenesis and hyper-activated inflammatory pathways in adipocytes can subvert immune surveillance. Dissecting the complexity of events associated with and/or driving cancer development in obesity will open new avenues for lifestyle-targeted CRC prevention strategies.

3. Monocarboxylate Transporters as targets for cancer therapy

Fátima Baltazar^{1,2}

¹Life and Health Sciences Research Institute (ICVS), School of Medicine, University of Minho, Campus de Gualtar, Braga 4710-057, Portugal.

²ICVS/3B's - PT Government Associate Laboratory, Braga/Guimarães 4806-909, Portugal.

Preference for glucose metabolism is a common feature of cancer cells. They rely mainly on glycolysis for adenosine triphosphate (ATP) production, with increased glucose uptake and lactic acid production, leading to acidification of the microenvironment. This metabolic phenotype is associated with features of cancer aggressiveness, including invasion, metastasis, evasion from the immune system, angiogenesis and resistance to therapy. To cope with the high production of acids, cancer cells depend on the activity of proton exchangers and transporters, which export protons to the microenvironment. Among these, are monocarboxylate transporters (MCTs), which play a dual role in tumours, by removing lactate from the cancer cells and also helping in the regulation of intracellular pH. Thus, considering their role in cancer, MCTs represent attractive targets in cancer therapy.

We have studied the expression of MCTs in a variety of human cancer tissues including glioblastoma (GBM) by immunohistochemistry and also blocked MCT activity in different *in vitro* and *in vivo* models. MCT1 and MCT4 were found to be overexpressed in human GBM samples compared with diffuse astrocytomas and non-neoplastic samples. MCT1 targeting decreased cell glycolytic metabolism, migration, and invasion, induced cell death and sensitized GBM cells to temozolomide *in vitro*, and reduced tumour size and angiogenesis *in vivo*. Additionally, MCT1 is involved in the crosstalk between glioma cells and endothelial cells, and MCT1 targeting either in the tumour cells or endothelial cells decreased endothelial cell proliferation, migration and vessel assembly.

MCT1 is overexpressed in human gliomas and its inhibition decreased cancer cell aggressiveness and sensitized cancer cells to chemotherapy. Additionally, MCT1 mediates endothelial cell metabolic

reprogramming, and, thus, targeting MCT1 in both tumour cells and brain endothelial cells may be a promising therapeutic strategy for the treatment of GBM.

4. Metformin: toward drugging the metabolic control of epigenetics in cancer

Javier A. Menendez

Catalan Institute of Oncology-Girona Biomedical Research Institute, Girona 17007, Spain.

There is a growing appreciation that metabolic rewiring affects the epigenome in a manner that facilitates cancer formation, progression, and therapeutic resistance. An improved understanding of how the interplay between cell metabolism and the epigenome regulates major cell fate decisions such as cell differentiation, proliferation, and/or cell death, might radically amend the way we prevent and treat cancer. Metformin, a biguanide derivative that has long been a cornerstone in the treatment of type 2 diabetes (T2D), could help to accelerate the development of novel strategies capable of therapeutically tuning the metabolism-epigenome axis to battle cancer. This talk will summarize the most recent evidence collected in our laboratory unraveling the capacity of metformin to operate as a poly-therapeutic agent targeting the biologic machinery in charge of the metabolic recoding of cancer epigenetics. On the one hand, metformin can alter the abundance of mitochondrial metabolites that are substrates of chromatin-modifying enzymes (e.g., acetyl-CoA for histone acetyltransferases) by altering the energy status of the cell downstream of its primary inhibitory action on mitochondrial respiratory complex I. On the other hand, biocomputational approaches based on artificial intelligence coupled to experimental validation reveal that metformin is: (1) a direct SIRT1-activating compound that improves the catalytic efficiency of SIRT1-mediated deacetylation in cancer-prone conditions of low NAD⁺; and (2) a potent regulator of S-adenosyl methionine - mediated methylation reactions via direct and specific inhibition of a central reaction of the folate cycle, namely the conversion of serine to glycine by the mitochondrial serine hydroxymethyltransferase 2 enzyme. The biguanide metformin, which, sixty years after its introduction in Europe as a first-line therapeutic for T2D, may now be seen as an archetypal compound aiming at drugging the metabolism-epigenome axis in cancer.

5. PIK3C2G loss promotes pancreatic cancer development and metabolic rewiring

Miriam Martini, Maria Chiara De Santis, Edoardo Ratto, Luca Gozzelino, Abhishek Uttamrao Derle, Paolo Ettore Porporato, Emilio Hirsch

Molecular Biotechnology Center, Dip of Mol Biotechnology and Health Science, Torino 10126, Italy.

Introduction: Pancreatic ductal adenocarcinoma (PDAC) is the most lethal cancer across the world, with incidence equaling mortality. A wealth of studies have identified the PI3K/mTOR axis as an important player in PDACs, impacting on tumor growth and metabolism. In particular, PI3K-C2γ, differently from other PI3Ks, is mainly expressed in the pancreatic tissue where it plays a critical role in controlling glucose metabolism.

Experimental model: Mouse model of PDAC (K-RASG12D/Trp53R172H/CrePdx1) was crossed with mouse strain lacking PI3K-C2γ expression. Mice were weekly followed for survival, tumor appearance and growth. Tumor lesions were evaluated by histopathological and immunofluorescence analysis. Functional *in vitro* and *in vivo* experiments were performed.

Results: PI3K-C2 γ loss was modeled by deleting *PIK3C2G* gene in a mouse model of pancreatic cancer (KPC). We found that its PI3K-C2 γ loss was sufficient to initiate and promote pancreatic tumor development, strongly reducing mice survival rate (18 weeks vs. 36 weeks) and driving rapid progression to PDAC. In pancreatic tumors reduced expression of PI3K-C2 γ expression was significantly associated with poor survival and resistance to chemotherapy. We reported that lysosomal localization of PI3K-C2 γ is responsible for mTORC1 inhibition under conditions of serum deprivation. In addition, we also observed that PI3K-C2 γ loss promotes the metabolic rewiring of PDAC, through the control of several metabolic factors, including glucose and monocarboxylate transporters and glycolytic enzymes (PKM2, HK2 and LDH). Furthermore, the use of rapalogs in KO KPC delay tumor progression.

Conclusion: PI3K-C2 γ is a novel tumor suppressor in pancreatic cancer and the metabolic phenotype of PI3K-C2 γ -deficient tumors can be exploited for specific therapeutic strategies.

6. Alleviating the Warburg effect: preliminary clinical results in advanced malignancies resistant to chemotherapy

Laurent Schwartz

Assistance Publique des hôpitaux de Paris, 3 avenue Victoria, Paris 75004, France.

Chlorine dioxide and Methylene blue are known generators of free radicals. These free radicals are known to enhance the efficacy of the mitochondria.

The goal of this abstract is to describe the first fourteen patients with advanced incurable cancer treated, with a combination of metabolic treatment (lipoic acid, hydroxycitrate) and chlorine dioxide. All but one patient had failed conventional chemotherapy. Only three patients underwent concomitant conventional chemotherapy. There was no major side effect but nausea and diarrhea. All but one patient responded to treatment. Two more patients were treated with Methylene Blue and metabolic treatment for advanced tumors. One had low dose chemotherapy, the other one, with metastatic pancreatic cancer had no other treatment. Both responded. Rigorous clinical trials are warranted.

7. Ketogenic diets during radiotherapy against cancer

Rainer J. Klement

Department of Radiation Oncology, Leopoldina Hospital Schweinfurt, Robert-Koch-Straße 10, Schweinfurt 97422, Germany.

The altered glucose metabolism of tumor cells is a long-known phenomenon that also contributes to resistance against radiotherapy by securing ATP production important for DNA repair, promoting tumor repopulation and increasing the pool of anti-oxidative molecules for protection against reactive oxygen and nitrogen species (ROS/RNS). In theory therefore, impairing the glucose metabolism of cancer cells is expected to lead to radiosensitization. Deduced from the hypothesis that cancer is a metabolic disease with mitochondrial dysfunction a hallmark of most tumor cells, ketogenic diets - i.e., diets systemically downregulating glycolysis and supporting ketone body and fat oxidation - have been proposed to selectively target tumor cells which in contrast to normal cells would be weakened when glucose and insulin levels are reduced. While many preclinical studies indeed found evidence for a reduction of tumor glycolytic

metabolism and growth through ketogenic diets, some others found no, or even pro-tumor effects. However, all studies published to date that combined a ketogenic diet with radiotherapy have found a radiosensitizing effect on tumor cells. Mechanisms include a selective increase in ROS and RNS production, ATP reduction and epigenetic impairment of DNA repair through histone deacetylase inhibition by the ketone body β -hydroxybutyrate, similar to the short chain fatty acid butyrate. The same mechanisms would not apply to normal tissue which is metabolically flexible and even able to initiate an anti-oxidative stress response when switching from glycolysis to mainly mitochondrial respiration fueled by fatty acids and ketone bodies. The hypothesis is therefore that combining a ketogenic diet with radiotherapy could benefit cancer patients in terms of larger tumor control probability for a given radiation dose without affecting or even decreasing the probability of normal tissue toxicity. While this hypothesis has been confirmed in preclinical studies, clinical data are limited thus far by small patient numbers, lack of control groups and lack of systematically collecting hard clinical endpoints such as local tumor control, overall survival and radiotherapy-induced side effects. However, there is some evidence that ketogenic diets could also benefit cancer patients in terms of better maintaining lean body mass which would be relevant especially for frail patient population such as those with head and neck or esophageal cancer. Given the proven safety of ketogenic diets when applied over several weeks in cancer patients, their combination with radiotherapy (as well as other established cancer treatments) deserves further study with a focus on important clinical endpoints.

8. Blocking the mitochondrial pyruvate carrier to inhibit lactate uptake by cancer cells and induce tumor radiosensitization

Cyril Corbet¹, Estelle Bastien¹, Lionel Mignon², Bénédicte F. Jordan², Arnaud Marchand³, Patrick Chaltin³, Holger M. Becker⁴, Olivier Feron¹

Introduction: Lactate-based metabolic symbiosis between glycolytic and oxidative cancer cells is known to facilitate tumor growth. Compounds with the capacity to block this lactate exchange thus represent attractive therapeutic modalities to impact on tumor progression.

Experimental model: Several models, including *Xenopus* oocytes, 3D tumor spheroids and human tumor xenografts in nude mice, were combined with state-of-the-art metabolomics strategies (Seahorse respirometry, *in vitro* ¹³C tracing experiments, and *in vivo* hyperpolarized ¹³C-pyruvate monitoring) to characterize the mode of action of 7ACC2, an anticancer compound originally reported to block lactate influx but not efflux.

Results: We identified 7ACC2 as a potent inhibitor of the mitochondrial pyruvate carrier (MPC) activity which consecutively blocks extracellular lactate uptake by promoting intracellular pyruvate accumulation. Importantly, while both 7ACC2 and the MCT1 inhibitor AR-C155858 efficiently inhibited lactate influx, only the former could also block compensatory oxidative glucose metabolism. Moreover, while in 3D tumor spheroids MCT1 inhibition led to cystostatic effects, MPC activity blockade induced cytotoxic effects. This potent growth inhibitory action associated with exacerbated 7ACC2-mediated metabolic alterations (i.e., blockade of lactate- and glucose-fueled TCA cycle) led to a reduction in hypoxia as proven in spheroids via pimonidazole and carbonic anhydrase IX staining and *in vivo* through electron paramagnetic resonance

measurements. We showed that this induced tumor reoxygenation could benefit radiotherapy. Indeed, pre-challenge of tumor-bearing mice with 7ACC2 considerably improved the anticancer efficacy of either single high dose or fractionated low dose radiation therapy.

Conclusion: This study positions MPC as control point for lactate metabolism and expands on the anticancer potential of MPC inhibition.

9. The anti-neoplastic effect of triiodothyronine on hepatocellular carcinoma is preceded by reversion of the Warburg metabolism and inhibition of the pentose phosphate pathway

Andrea Perra¹, Marta Anna Kowalik¹, Lavinia Cabras¹, Silvia Giordano², Andrea Rasola³, Amedeo Columbano¹

¹Department of Biomedical Sciences, University of Cagliari, Cagliari 09124, Italy.

²Department of Biomedical Sciences, University of Padova, Padova 35122, Italy.

³Department of Oncology, University of Torino, IRCCS Candiolo, Candiolo 10060, Italy.

Introduction: Liver carcinogenesis, from its very early steps, is characterized by reduced activation of thyroid hormone nuclear receptors (THR_s), and an altered glucose catabolism that leads to a Warburg metabolism and a strong induction of the pentose phosphate pathway (PPP). The administration of the THR_s agonist, triiodothyronine (T₃), reverts the preneoplastic hepatocytes to a fully differentiated phenotype and prevents the development of hepatocellular carcinomas (HCC), but its effects on glucose metabolism have not yet been fully explored. Given the strong link between THR_s activation and metabolism, the aim of this study is to verify whether T₃ is able to restore the physiological PPP activity and energetic metabolism in neoplastic liver.

Experimental model: Rats were subjected to the Resistant-Hepatocyte model of liver carcinogenesis and treated with T₃ at 10 weeks, when preneoplastic nodules reached the maximal expansion, or at 10 months after initiation, when HCCs appeared. Rats were killed after 4 or 7 days of T₃ treatment.

Results: The treatment with T₃ for 7 days resulted in a reduction in the number of preneoplastic lesions. This effect was preceded by a change in the expression of key genes regulators of the glucose metabolism. The immunohistochemical and enzymatic study of liver sections confirmed that the reversion of the Warburg phenotype and inhibition of the PPP occurs before the disappearance of the preneoplastic lesions. The same effect was evident also in fully developed HCCs.

Conclusion: Our results indicate that, at least in part, the antineoplastic effect of T₃ depends on the ability of the activated THR_s to revert the Warburg phenotype together with an inhibition of the PPP.

10. The interaction between the transcription factor STAT3 and the Ca²⁺ channel IP3R3 regulates Ca²⁺ release from the endoplasmic reticulum and apoptosis

Lidia Avalue^{1,*}, Annalisa Camporeale^{1,*}, Giampaolo Morciano^{2,*}, Elena Ghatti¹, Valeria Orecchia¹, Carlotta Giorgi², Paolo Pinton^{2,*}, Valeria Poli^{1,*}

¹Department of Molecular Biotechnology and Health Sciences, University of Torino, Torino, 10126, Italy.

²Department of Morphology, Surgery and Experimental Medicine, University of Ferrara, Ferrara, 44121, Italy.

*Equal contribution.

In many tumors the signal transducer and activator of transcription (STAT) 3 has been found to be constitutively active exerting two different functions, both required for cell transformation: (1) activating transcription of its canonical target genes; and (2) regulating energy metabolism and mitochondrial functions. These different activities are mediated by distinct phosphorylation events. In particular, phosphorylation on residue Y705 is responsible for the nuclear activities, while phosphorylated S727 is involved in regulating OXPHOS activities via mitochondrial localization.

We recently reported the localization of STAT3, in both its serine- and tyrosine-phosphorylated forms, to the endoplasmic reticulum (ER) in breast cancer cell lines displaying constitutive activation of this factor. In these cells, S727-phosphorylated STAT3 is able to reduce ER Ca^{2+} storage and release, thus contributing to resistance to Ca^{2+} mediated apoptosis upon oxidative stress stimuli. Indeed, Ca^{2+} release from the ER represents a crucial event in the regulation of life/death decision of cells, and its regulation is mainly exerted by inositol 1,4,5-trisphosphate receptors, and in particular by type 3 (IP3R3), a calcium channel that in response to IP3 stimulation allows Ca^{2+} transfer from the ER to the mitochondrial associated membranes. We observed that STAT3 can physically interact with IP3R3. Moreover, STAT3 silencing increases IP3R3 expression by decreasing IP3R3 proteasoma-mediated degradation, suggesting that constitutively active STAT3 can inhibit apoptosis by regulating IP3R3 abundance and activity. Accordingly, we found an inverse correlation between IP3R3 and STAT3 protein levels in basal-like breast cancers, a cancer subtype that often shows constitutive STAT3 activation. All together, these data indicate that S727-phosphorylated STAT3 can promote IP3R3 degradation via direct interaction, thus reducing Ca^{2+} exit from the ER and conferring resistance to apoptosis.

Thus, in addition to the previously characterized nuclear and mitochondrial functions, we described a novel contribution of STAT3 constitutive activation in conferring aggressiveness to breast cancer cells, and in particular to basal-like breast cancers. This is exerted via localization of STAT3 to the ER, interaction with IP3R3 and regulation of its degradation, that leads to decreased calcium release and thus resistance to apoptosis.

11. Targeting acidic, nutritional and oxidative stresses in cancer

In metazoans, sensing the availability of oxygen and key nutrients (glucose, amino acids, fatty acids) is integrated with growth factor and hormone signaling. This multiple nutrient and energy checkpoint converges on the activation of the master protein kinase TORC1, critical for engaging cells in the cell cycle and promoting growth. Cells have evolved sophisticated regulatory systems to rapidly respond to several lethal stressors including metabolic acidosis, nutritional depletion and reactive oxygen species. Cancer cells respond in multiple ways to escape and thrive these microenvironment stresses thus offering several strategies to combat cancer resilience before and after therapeutic treatment.

In this lecture we will discuss how we can exploit cancer vulnerabilities (metabolic tumor acidosis, amino acid depletion and oxidative stress) to propose novel anticancer targets capable to either arrest tumor growth or to kill cancer cells.

12. The role of diet related short chain fatty acid acetate in colorectal cancer: therapeutic implications

Ana Preto

Centre of Molecular and Environmental Biology (CBMA), Department of Biology, School of Sciences, University of Minho, Braga 4710-057, Portugal.

Colorectal cancer (CRC) is an important public health concern worldwide, particularly among populations that adopt Western-style diets. The use of dietary propionibacteria found in dairy products, which produce short-chain fatty acids (SCFA), has been suggested as a possible strategy in the prevention and therapy of CRC. The SCFA acetate has been proved by us and others to induce apoptosis in CRC cells. Our group has been focusing on unravelling the mechanisms underlying acetate-induced apoptosis and on understanding the precise role of acetate in CRC cells.

We showed that acetate induces partial lysosome membrane permeabilization with specific cathepsin D (CatD) release to the cytosol in CRC cells. We verified that CatD has an anti-apoptotic role by the degradation of damaged mitochondria when autophagy is impaired, protecting CRC cells from acetate-induced apoptosis. Moreover, we demonstrated that acetate enters CRC cells by a sodium dependent monocarboxylate transporter 1 and passive diffusion by aquaporins. We also found that MCT-1 and/or MCT-2 seems to mediate acetate transport in CRC cells exposed to acetate. Additionally, we observed that acetate upregulates MCTs expression and promotes plasma membrane re-localization of MCT-1 and triggers changes in glucose metabolism. Further, we explored the combined treatment of acetate with the glycolysis inhibitor 3BP and we demonstrated that 3BP potentiates acetate-induced apoptosis in CRC cells.

Our results established a protective role of CatD in acetate-induced apoptosis which could negatively impact the efficacy of acetate. Thus, the use of CatD inhibitors in combination with strategies to increase acetate concentrations in the colon, like nutraceuticals, should be explored. Our findings also support a novel approach for CRC therapy based on the association of acetate with 3BP or other anti-cancer agents whose transport is mediated by MCTs.

13. Implementing new diet formulations in order to shape microbiota and reverse chemoresistance in the frame of pancreatic cancer

Gastroenterology Unit IRCCS “Casa Sollievo della Sofferenza” Hospital San Giovanni Rotondo, Foggia 71013, Italy.

Introduction: Despite recent advances in treatment options, pancreatic cancer (PC) remain a highly malignant disease and due to its poor prognosis it is ranked as the fourth leading cause of cancer-related deaths worldwide. We have previously demonstrated that manipulating the dietary intake of total amount of calories (using a short-term fasting cycles approach) or replacing carbohydrate with resistant starch have the potential to improve the efficacy of chemotherapy against PC. The aim of this talk is to clarify the effect of the engineered resistant-starch (ERS) mimicking diet on the growth of cancer cell lines *in vitro*, on the composition of fecal microbiota, and on tumor growth in an *in vivo* pancreatic cancer mouse xenograft model. Moreover we will shed light on the interaction between the microbiota and chemotherapeutic drugs.

Experimental model: Pancreatic cancer xenograft mice were subjected to different dietary approaches such as intermittent fasting cycles or ERS diet to assess tumor growth as compared to mice fed with a standard diet. The composition and activity of fecal microbiota and metabolomics profiles were further analyzed by next generation sequencing (NGS) technology and LC-MS analysis of serum respectively.

Results: Pancreatic cancer cells cultured in fasting mimicking medium and ERS diet-mimicking medium impacted the proliferation pathway and the nutrients sensitive pathway decreasing the levels of phospho-ERK1/2 and phospho-mTOR. As compared to those cultured in standard medium. Consistently, xenograft pancreatic cancer mice subjected to modifies dietary approaches displayed significant retardation in tumor growth and a significant shift in microbiota profiles towards butyrate producer's microorganisms.

Conclusion: It is important to modulate dietary habits and apply new dietary intervention in order to modulate the composition and metabolism of mouse fecal microbiota which is one of the key organs involved in the chemotherapy response. All these results indicate that engineered dietary interventions may potentially reveal useful in fighting human cancers and could be supportive as a synergistic approach to improve the efficacy of existing drugs in pancreatic cancer therapy.

14. Effects of selective targeting of mitochondria in experimental cancer and chemotherapy-induced cachexia

Riccardo Ballarò^{1,2}, Marc Beltrà^{1,2}, Paola Costelli^{1,2}, Hazel Szeto³, Fabio Penna^{1,2}

²*Interuniversity Institute of Myology, Milano 20132, Italy.*

³*Mitochondrial Therapeutics Consulting, New York, NY 10016, USA.*

Cachexia is a syndrome frequently occurring in cancer patients. The main features are loss of muscle mass and function associated with negative energy balance. In this regard, cachectic tumor-bearing animals show altered mitochondria and reduced oxidative capacity in the muscle. Mitochondrial homeostasis could be further impaired by chemotherapy administration, contributing to muscle wasting.

The present study aimed at evaluating the effects of a mitochondrial-targeted compound (SS-31) on muscle wasting in mice bearing the C26 tumor in the presence or in the absence of chemotherapy [oxaliplatin + fluoruracil (OXFU)].

Reduced body weight, food intake, muscle mass and function were observed in the untreated tumor hosts. Lifespan in OXFU-treated C26 hosts was almost doubled with respect to untreated animals, however muscle wasting was exacerbated. SS-31 administration was able to counteract body weight loss, anorexia and the reduction of myofiber dimensions, while the protection against muscle mass depletion was only slight. As for markers of mitochondria, both treated and untreated C26 hosts showed that the expression of PGC-1 α , cytochrome c, SDH and cardiolipin levels were reduced compared to control animals, and not modified by SS-31. In OXFU-treated tumor-bearing mice, also the SDH total activity and ATP content were reduced. SS-31 increased SDH activity and ATP content in untreated C26 hosts. The modulations of the mitochondrial compartment in the C26-bearing mice were also associated with markedly decreased protein synthesis, that improved after administration of SS-31.

In conclusion, these results suggest that targeting mitochondria could be an effective strategy to counteract cancer cachexia, partially preventing the loss of body weight and food intake, improving muscle atrophy, muscle oxidative capacity and energy wasting in mice hosting the C26 tumor in the absence of

chemotherapy. Further investigation and treatment optimization is required in order to demonstrate a potential effectiveness of SS-31 in the chemotherapy-treated tumor-bearing mice.

15. L1CAM gene overexpression is associated with platinum-resistance in high-risk endometrial carcinoma

⁴Molecular and Translational Medicine Department, University of Brescia, Brescia 25121, Italy.

Introduction: L1 cell adhesion molecule (L1CAM) expression has been reported associated with high-grade disease and non-endometrioid histology, as well as poor prognosis, in endometrial carcinoma (EC). These high-risk EC types have frequently already spread outside the uterus when diagnosed and, after an extensive surgery, are often treated with chemo and radiation therapy. We hypothesized that L1CAM gene expression could discriminate, among poor outcome EC patients, those who do and who do not respond to adjuvant platinum-based chemotherapy.

Experimental model: Using an efficient multiplex qRT-PCR, we test L1CAM mRNA expression on 117 EC and 16 normal endometrial (NE) flash-frozen tissues, with HPRT1 and PPIA as reference genes.

Results: L1CAM mRNA was significantly overexpressed in EC compared to NE tissues ($P = 0.02$), significantly upregulated in G3 vs. G1-2 ECs ($P < 0.001$) and in non-endometrioid vs. endometrioid ECs ($P < 0.001$). Our analysis showed no difference in L1CAM expression of stage I-II vs. stage III-IV ECs ($P = 0.5$). Of the initial 117 EC patients, 47 received chemotherapy on adjuvant setting and were classified as platinum-sensitive and platinum-resistant patients, based on PFI > 12 months and < 6 months, respectively. L1CAM gene was significantly overexpressed in resistant vs sensitive EC ($P = 0.001$). Moreover, by means of a multivariate logistic regression model, we found L1CAM gene overexpression as an independent indicator of the probability to harbor a platinum-resistant EC ($P = 0.047$, OR = 3.5). In addition, univariate and multivariate survival analysis showed L1CAM gene upregulation associated with poor outcome, in terms of progression-free survival and disease-specific survival.

Conclusion: Our results suggest L1CAM gene expression as a potential prognostic marker and a predictive biomarker of platinum-response in high-risk EC patients.

16. Resveratrol counteracts ovarian cancer cell migration stimulated by interleukin-6 by limiting glucose uptake

Introduction: IL-6, a pro-inflammatory cytokine produced by cancer-associated fibroblasts, increases the proliferative and invasive properties of ovarian cancer cells. Glucose metabolism is altered in ovarian cancer cells and permits fast proliferation and survival. Resveratrol (RV) is a naturally occurring polyphenol with the potential to inhibit cancer cell migration.

Results: Here, we found that IL-6 enhances ovarian cancer cell migration, while RV and deprivation of glucose reduce cell motility. In particular, IL-6 stimulates glucose uptake along with cell migration, while RV abrogates this effect through the reduction of GLUT1 plasma membrane translocation and glucose internalization. Further, the cells exposed to IL-6 at the migration front show an increased expression of N-cadherin over E-cadherin, and this effect is reverted by RV exposure. Accordingly, the expression of TWIST1, a regulator of epithelial-to-mesenchymal transition (EMT), is reduced by RV and deprivation of glucose. Transcriptomic and microRNomic analyses revealed that RV up-regulates a subset of miRNAs that have several glucose metabolism regulators as targets. In particular, we found that RV abrogates the transcription of ZEB1, Hexokinase 2 and FOXM1.

Conclusion: Our data indicate that RV counteracts glucose metabolism negatively impinging on ovarian cancer cell migration induced by IL-6.

17. FXYD5 is a predictor of short-term survival in high-grade serous ovarian carcinoma

*Equal contribution.

Introduction: High-grade serous ovarian carcinoma (HGSOC) is generally associated with a very dismal prognosis. Nevertheless, patients with similar clinicopathological characteristics can have markedly different clinical outcomes. We aim to identify the molecular determinants influencing survival by comparing the gene expression patterns of two patient cohorts characterized by extreme overall survival.

Experimental model: We determined the gene expression profiles of 12 HGSOC long-term and 27 short-term survivors (training set) by microarray chips. By a generalized linear model with cross-validation, we generated a prognostic gene signature that was further evaluated on the entire "The Cancer Genome Atlas" (TCGA) ovarian cancer dataset. The resulting genes were then verified on an independent cohort of 29 HGSOC flash frozen samples (validation set) by RT-qPCR, and in a panel of 38 formalin fixed paraffin embedded HGSOC tissues by immunohistochemistry (IHC).

Results: We identified a ten-gene prognostic signature able to correctly assign 98% of patients of the training set within their survival class. By "in silico" validation on TCGA microarray dataset, we confirmed the overexpression in short term survivors of FXYD domain containing ion transport regulator 5 (FXYD5),

one of the 10 top score genes of the signature. The prognostic power of FXYD5 was also successfully validated, both at mRNA and protein level by RT-qPCR and IHC, respectively on the training and validation sets. Moreover, FXYD5 overexpression was significantly associated with platinum resistance and cancer progression.

Conclusion: We demonstrated the consistent overexpression of FXYD5 in HGSOC short-term survivors compared to long-term ones. FXYD5 may become a useful predictive marker for a more accurate selection of HGSOC patients for adjuvant treatments, and a possible target for antibody-drug conjugated anticancer agents, as recently demonstrated for thyroid cancer cell lines.

18. Claudin-7 downregulation is predictive of distant metastases in high-grade serous ovarian carcinoma patients

*Equal contribution.

Introduction: High-grade serous carcinoma (HGSOC) is the most frequent and lethal ovarian carcinoma histotype. Although the abdominal dissemination is considered the most common, distant metastases occur in about 30% of patients with newly diagnosed or recurrent HGSOC. No tumor marker can currently predict the risk of distant metastasis in HGSOC. Tight-junction protein claudin-3, -4 and -7 are frequently dysregulated in HGSOC and functionally related to cancer progression to a metastatic disease. Here we analyze claudin-3, -4 and -7 expression as markers of distant metastasis.

Experimental model: Claudin expression was evaluated in 105 primary HGSOC tissues, 14 normal ovarian and 26 normal fallopian tube epithelia by quantitative RT-PCR and immunohistochemistry, and correlated with clinicopathological features. Gene set enrichment analysis was performed on microarray-generated gene expression data to investigate key pathways in patients with distant metastasis.

Results: Claudin-3, -4 and -7 expression levels are decreased in HGSOC compared to normal tubal epithelium, currently considered alternative source of such tumors. Decreased expression of claudin-7 is seen in tumors from women who develop distant recurrence ($P = 0.016$), mainly by hematogenous route ($P = 0.025$). The estimated reduction in the probability of distant disease is of 39% per unit increase in the level

of claudin-7 (AUC 0.659, $P = 0.03$). Genes involved in hypoxia and angiogenesis processes result strongly associated to hematogenous recurrence ($P = 0.012$).

Conclusion: Claudin-7 decreased expression in primary tumor tissues is a significant predictor of distant metastasis in HGSOC patients.

19. Glutamine synthetase-negative multiple myeloma cells secrete glutamate and shape the bone marrow niche

Martina Chiu, Denise Toscani, Giuseppe Taurino, Fabrizio Accardi, Nicola Giuliani, Ovidio Bussolati

Department of Medicine and Surgery (DiMeC), University of Parma, Parma 43121, Italy.

Altered metabolism, a hallmark of cancer, also impacts on non-cancer cells of tumor microenvironment, driving them towards a pro-tumor behavior. In multiple myeloma (MM) patients, bone marrow glutamine (Gln) is lowered, while glutamate (Glu) and ammonium increase. In most MM patients, Glutamine Synthetase (GS), the enzyme that catalyzes Gln synthesis from Glu and ammonium, is lowered in neoplastic plasma cells. GS is also down-regulated during normal osteoblast differentiation from mesenchymal stromal cells (MSC). Since bone lesions of MM patients are characterized by impaired osteogenesis, we hypothesize that MM cells negatively affect osteoblasts through the peculiar low-Gln, high-Glu bone marrow microenvironment and the manipulation of GS expression in niche cells.

Human MM cell lines (HMCLs) and immortalized MSC were grown in Glu-free α MEM and used in mono- or co-cultures. Gene expression was assessed at either mRNA and protein level. Amino acid levels were determined with a colorimetric test (extracellular) and LC-MS/MS (intracellular).

Analysis of a dataset of 323-sample plasma cell dyscrasias indicated that GS expression is downregulated during MM progression, with less than 20% MM patients with GS-positive CD138⁺ cells. Also most HMCLs, but not MM1.S and U266, have a negligible GS expression. While both low- and high-GS HMCLs exhibited a high consumption of Gln and a comparable glutaminolysis, low-GS HMCLs exploited roughly 50% of Gln to secrete Glu. Consistently, the activity of the Glu exchanger xCT was higher in low-GS MM cells. GS is strongly induced in MSC when co-cultured with MM cells.

These preliminary results are consistent with the hypothesis that low GS expression, Gln addiction and Glu secretion of MM cells are functional to osteoblastic differentiation impairment in the BM niche.

20. Evaluation of the interaction among HPV16 E6 and E7 oncoproteins and the DNA damage sensor 53BP1 in 2D and 3D epithelial cultures by the proximity ligation assay

Barbara Azzimonti, Diletta Francesca Squarzanti, Rita Sorrentino, Manuela Miriam Landini, Andrea Chiesa.

University of Piemonte Orientale (UPO), School of Medicine, Department of Health Sciences, Via Solaroli 17, Novara 28100, Italy.

Introduction: Human papillomaviruses (HPV) group several viruses are able to infect squamous stratified epithelia and cause benign papillomas, warts and anogenital lesions. They also correlate to oropharyngeal

and anogenital malignancies, mainly promoted by the high risk (HR) α -HPV16 E6E7 oncoproteins. Despite scientific progresses and the development of vaccines, these tumors are still common and represent one of the major causes of women's death. Host's cell replication fidelity depends by the DNA damage response (DDR). Unlike from other DNA viruses, HR-HPVs encourage cells proliferation without inactivating the DDR: the mechanisms at the basis haven't been clarified yet. During HPV16 infection, E6 binds and degrades p53 through the E6AP LXXLL domain. Similarly, E7 competes with E2F1-pRb interaction, thus inactivating pRb, and promoting the linking the pRb-like proteins CBP/p300 and p107, that also harbor a LXXLL sequence. Unfortunately, E6 E7 role in the DDR activation is not elucidated yet.

Experimental model: To gain new information, we reproduced an *in vitro* 3D HPV16-E6E7 infected epithelium, already characterized for HPVs studies, and checked for cellular and viral markers, among them HPV16E6E7 oncoproteins and the double strand breaks sensor 53BP1; we then made a Co-IF for E6 and E7 with 53BP1. Since E6 and E7 both interact with LXXLL containing proteins, we analyzed 53BP1 BRCT2 domain and we explored the binding hypothesis via the *in situ* PLA technique in 2D in CaSki and E6E7HPV16 keratinocytes and in the 3D model.

Results: The *in vitro* infected epithelium resembles the *in vivo* tissue. E6E7HPV16, both in basal and differentiated strata, induce a 53BP1 increase in nuclear foci. After highlighting E6 and E7 co-expression with 53BP1 and a LKVLL sequence within the 53BP1 BRCT2 domain, we demonstrated the binding in all the employed cellular models.

Conclusion: Our results add new information on HPV16 oncoproteins capability in overcoming cellular defense strategies.

21. Iron metabolism regulates cancer related skeletal muscle wasting

Erica Mina, Elisabeth Wyart, Myriam Hsu, Paolo Ettore Porporato

Molecular Biotechnology Centre, Department of Molecular Biotechnology and health sciences, University of Torino, Torino 10126, Italy.

Introduction: Cancer associated cachexia is a syndrome characterized by a significant weight loss, due to metabolic changes affecting skeletal muscle and adipose tissue²⁰¹⁸. Given the importance of iron in controlling energy metabolism, we speculated that decreased iron availability occurring in cancer might contribute to skeletal muscle atrophy.

Experimental model: *In vitro* experiments are performed with C2C12 myotubes, while *in vivo* experiments are conducted using Colon-26 carcinoma bearing BALB-C mice.

Results: Interestingly, using Colon-26 carcinoma bearing mice, we found strong alterations in protein and gene expression of iron homeostasis key players in skeletal muscle, notably a downregulation of transferrin receptor 1 (TFR1, the main importer of iron) and an increase of the iron exporter Ferroportin. Coherently, we observed a decreased iron content in both skeletal muscle and spleen while serum iron is increased, suggesting a global mobilization of iron. To further confirm our hypothesis, we created iron-deprived models *in vitro* using several iron chelators (Desferoxamine, BPS) or by TFR1 knockdown with siRNA and, in line with our *in vivo* observations, iron depletion in C2C12 myotubes directly promoted atrophy. Finally, we were able to prevent myotube atrophy by restoring iron transport.

Conclusion: Taken together, these results highlight a previously unknown role for altered iron homeostasis in cancer-induced muscle wasting and provide a potential new therapeutic target.

22. Liquid biopsy applications in lymphomas

Mahmoud¹, Syed Hasan Mosavi¹, Sreekar Kogila¹, Simone Favini¹, Denise Peroni¹, Marta Castagno¹, Silvia Rasi¹, Valeria Spina², Andrea Patriarca¹, Gloria Margiotta Casaluci¹, Luca Nassi¹, Davide Rossi², Gianluca Gaidano¹

¹*Division of Hematology, Department of Translational Medicine, Amedeo Avogadro University of Eastern Piedmont, Novara 28100, Italy.*

²*Oncology Institute of Southern Switzerland, and Laboratory of Experimental Hematology, Institute of Oncology Research, Bellinzona 6500, Switzerland.*

Liquid biopsy is an emerging tool across many types of cancers. This technique consists in the analysis of biomarkers released by tumor cells in the peripheral blood. In lymphomas, the most studied biomarker is circulating tumor DNA (ctDNA), shed into the bloodstream (e.g., plasma) by tumor cells undergoing apoptosis.

Analysis of plasma ctDNA analysis allows serial monitoring of the disease genotype over time and the assessment of the entire tumor heterogeneity at different anatomic sites. Consistently, ultra-deep targeted next generation sequencing of ctDNA from diffuse large B-cell lymphoma (DLBCL) patients correctly identified DLBCL-associated mutations. Moreover, plasma ctDNA genotyping also allows for the recovery of mutations that are undetectable in the tissue biopsy, conceivably because, due to spatial tumor heterogeneity, they are restricted to clones that are anatomically distant from the biopsy site. In Hodgkin lymphoma (HL), the rarity of neoplastic cells in the biopsy has so far limited genomic studies. By using a highly sensitive and robust deep next-generation sequencing approach for ctDNA, the current knowledge of HL has been refined. In addition, similarly to DLBCL, also in HL a fraction of mutations has been detected only in ctDNA but not in the tissue biopsy.

Regarding disease monitoring during the course of treatment, CT/PET scans do not capture all patients designated to relapse. This gap may be filled by ctDNA analysis providing higher sensitivity and ease of sample collection in a radiation free manner. In DLBCL, the 2.5-log drop of ctDNA concentration after two cycles of treatment is an independent predictor of response. Similarly, in HL the 2-log drop of ctDNA after two courses of chemotherapy associated with complete response and complemented the results obtained by the CT/PET scan. Incorporation of both CT/PET and ctDNA monitoring into clinical trials may guide future personalized risk-directed approaches of treatment.

*Equal contribution.

Introduction: The current shift of therapy of chronic lymphocytic leukemia (CLL) towards novel targeted agents mandates the identification of new molecular predictors. The aim of this study is to identify new molecular predictors in FCR treated patients and to assess the biological features underlying chemo-refractoriness to FCR.

Experimental model: A retrospective multicenter cohort of 287 untreated CLL receiving first-line therapy with FCR was subjected to a targeted NGS approach in 24 most recurrently mutated genes in CLL. The entire non-canonical NF- κ B pathway was assessed by Western blot and by real-time PCR.

Results: *SF3B1* and *NOTCH1* were the most frequently mutated genes identified in 13.9% and in 13.6% of patients respectively, followed by *TP53* in 9.4% and *ATM* in 6.9%. *BIRC3* was mutated in 3.1% of patients. By univariate analysis adjusted for multiple comparisons, only *BIRC3* mutations (median PFS of 2.2 years; $P < 0.001$) and *TP53* mutations (median PFS of 2.6 years; $P < 0.0001$) identified patients who failed early FCR. By multivariate analysis, *BIRC3* mutations maintained an independent risk of progression, with a HR of 2.8 (95%CI 1.4-5.6, $P = 0.004$). In addition, *in vitro* studies showed that fludarabine-induced apoptosis in *BIRC3* mutated cells was comparable to samples harboring *TP53* mutations. Western blotting analysis of the non-canonical NF- κ B pathway showed that *BIRC3* mutated cells was significantly enriched of non-canonical NF- κ B target gene and addicted of MAP3K14 overexpression.

Conclusion: *BIRC3* mutations identify a very poor prognostic subgroup of patients that fails FCR similar to patients harboring *TP53* abnormalities. If validated, *BIRC3* might be used as a new molecular predictor to select high-risk patients for novel frontline therapeutic approaches. From the biological point of view, *BIRC3* mutations enhance the non-canonical NF- κ B signaling pathway promoting survival, proliferation and chemo-refractoriness.

24. Peptide nucleic acid-based targeting of microRNAs: possible therapeutic and diagnostic applications for glioblastoma

Roberto Gambari

Department of Life Sciences and Biotechnology, Ferrara University, Ferrara 44124, Italy.

Introduction: MicroRNAs (miRNAs) are small noncoding RNAs regulating gene expression by sequence-selective targeting of mRNAs, leading to translational repression or mRNA degradation. Low miRNA expression is associated with accumulation of target mRNAs; high miRNA content causes low expression of target mRNAs. In cancer, microRNAs are associated with tumor onset and progression.

Experimental model: Targeting oncomiRNAs and metastamiRNAs with biomolecules interfering with their biological activity is of interest and peptide-nucleic acids (PNAs) might be useful. PNAs are DNA analogues in which the sugar-phosphate backbone has been replaced by *N*-(2-aminoethyl) glycine units, hybridize to RNA with high efficiency, are resistant to proteinases and nucleases, and have been proposed as excellent tools for alteration of gene expression. We have developed novel delivery strategies for PNAs targeting miRNAs, based on the use of PNAs linked to a poly-arginine R8 peptide tail for efficient cellular delivery. As far as cancer-related model systems, we focused on PNAs targeting miR-221 and miR-222 in glioblastoma cells.

Results: In a first study, a combined treatment of U251, U373 and T98G glioma cell lines was performed with different anti-miRNA PNAs (against miR-221, miR-222 and miR-155). Increased pro-apoptotic effects were obtained with the co-administration of both anti-miR-221 and anti-miR-222 PNAs, or anti-miR-221 and anti-miR-155 PNAs. In a second study, we demonstrated synergistic effects of co-administration of corilagin and a PNA targeting miR-221. In a third approach we performed a combined treatment of glioma U251 cells with the pro-apoptotic pre-miR-124 and the PNA targeting miR-221, showing induction of apoptosis at very high levels.

Conclusion: PNAs might be a relevant therapeutic tool for anti-cancer miRNA-therapy based on inhibition of oncomiRNA and metastamiRNAs, as well as mimicking tumor-suppressor miRNAs (funded by AIRC IG13575 and Horizon 2020 Project ULTRAPLACAD).

25. Liquid biopsy-based colorectal cancer diagnosis: analysis of a limited panel of miRNA in mice bearing colorectal carcinoma tumor xenografts and in Human plasma samples

³Pathology, IRCCS Regina Elena National Cancer Institute, Rome 00144, Italy.

Introduction: Due to their high stability in body fluids, circulating tumor microRNAs are proposed as promising biomarkers useful for early tumor diagnosis, prognosis, monitoring, and to predict therapeutic response, in non-invasive liquid biopsy. We investigated the release of miR-141-3p, miR-221-3p and miR-222-3p previously associated to colorectal cancer (CRC).

Experimental model: We employed droplet digital PCR to quantify the amount of miRNAs released in: (1) supernatants of three human CRC cell lines (HT-29, LoVo and Ls174T); (2) in plasma of nude mice inoculated with the same three cell lines, in order to obtain tumor xenograft models; (3) in plasma isolated from a heterogeneous group of CRC patients.

Results: MicroRNAs miR-221-3p and miR-222-3p (but not miR-141) in cellular supernatants were proportional to the cellular levels. Interestingly, all three miRNAs are released in plasma of xenografted mice. Using plasma samples from CRC patients, we found that only in 57% of the cases it was possible to identify a differential expression of at least one of the miRNAs with respect to control subjects.

Conclusion: Our data demonstrate that, despite the three selected miRNAs are not only present in CRC cells and tissues but are also released in extracellular environments, they are not informative for a high proportion of CRC patients. NGS allowed to expand the number of miRNAs differentially expressed in CRC samples. A novel set, constituted of 12 miRNA was demonstrated to be of diagnosis relevance in 94% of CRC patients samples (funded by AIRC IG13575 and Horizon 2020 Project ULTRAPLACAD).

26. Sensitivity to asbestos is increased in patients with mesothelioma and pathogenic germline variants in BAP1 or other DNA repair genes

Introduction: Malignant Pleural Mesothelioma (MPM) is a rare, aggressive cancer caused by asbestos exposure. A genetic predisposition has been suggested to explain the occurrence of multiple cases in the same family and the observation that not all individuals highly exposed to asbestos develop the tumor. Germline variants in *BAP1* are responsible for a rare cancer-prone syndrome (*BAP1*-TPDS) that includes mesothelioma in its cancer constellation. *CDKN2A* and several DNA repair genes have been reported as further predisposing genes.

Results: We searched for *BAP1* germline variants in 25 new probands with suspected *BAP1*-TPDS and we found a new pathogenic germline variant that affects splicing: c.783+2T>C. We calculated that the prevalence of the truncating variants in patients with familial MPM and MPM and other tumors is 7.7% (3/39). Cumulative asbestos exposure was assessed quantitatively in our cohort of patients to compare patients carrying pathogenic variants in *BAP1*, *CDKN2A* and DNA repair genes ($n = 14$) to patients without variants in 94 cancer predisposing genes ($n = 67$). We showed that patients with variants in *BAP1*, *CDKN2A* and DNA repair genes had a lower asbestos exposure than non-mutated patients ($P = 0.00002$).

Conclusion: Our results suggest that other genes could be involved in the genetic predisposition to mesothelioma. These data support the hypothesis of an increased asbestos sensitivity in patients with germline variants in *CDKN2A*, *BAP1* or DNA repair genes. According to the concept of BRCAness, patients with germline mutations in genes involved in homologous recombination repair may respond to drugs (e.g., PARP inhibitors) that induce synthetic lethality, similarly to patients with familial ovarian cancer and *BRCA1/BRCA2* inherited mutations.

27. Resveratrol reverts the EMT phenotype induced by lysophosphatidic acid in ovarian cancer cells through restoration of autophagy

Alessandra Ferraresi¹, Christian Seca¹, Chiara Vidoni¹, Carlo Girone¹, Ji Hee Ha², Danny N. Dhanasekaran², Ciro Isidoro¹

²Stephenson Cancer Center and Department of Cell Biology, The University of Oklahoma Health Sciences Center, Oklahoma City, OK 73104, USA.

Introduction: Ovarian cancer emerges as a highly aggressive metastatic disease characterized by a high grade of lethality due to its asymptomatic nature and the late diagnosis, when cancer cells already spread in distant organs. Cancer progression is facilitated by pro-invasive factors, released by ovarian cancer cells and CAFs, that promote the Epithelial-to-Mesenchymal transition (EMT). Lysophosphatidic acid (LPA), a bioactive phospholipid abundantly present in ascitic fluid and plasma of ovarian cancer patients, stimulates the invasiveness of cancer cells. Resveratrol (RV), a natural-occurring polyphenol, is attracting the interest of many researchers due to its several anti-cancer properties. Of note, RV is a strong autophagy inducer.

Results: We found that LPA elicits cell migration in a panel of ovarian cancer cell models characterized by different grades of malignancy. In parallel, LPA induces EMT through the inhibition of autophagy in the cancer cells at the migration front. Interestingly, RV restores autophagy and halts ovarian cancer cell motility even in the presence of LPA.

Conclusion: Our findings indicate that restoration of autophagy by RV prevents LPA-induced tumor invasion and suggest that there is a functional cross-talk between autophagy and EMT phenotype.

28. Spiperone, an antipsychotic, induces colorectal carcinoma cell death by a calcium-mediated apoptosis

Colorectal cancer (CRC), one the most common malignancies, with increasing incidence and mortality rate worldwide, requires novel therapeutic strategies for its treatment. As developing new drugs is a time- and cost-intensive process with unexpected side effects, drug repositioning provides an effective strategy for accelerating drug development. Some antipsychotics currently used in human therapy reported potential anti-tumoral activity, thus in this study we intended to investigate their activity against CRC and CRC-stem cells (CRC-SCs).

We screened a panel of commercially available psychotropic drugs for their antitumoral activity on HCT116 cell line. Regardless for their receptor specificity, the viability data showed that this cell line was sensitive to just some drugs, especially spiperone, with an IC_{50} of 4 $\mu\text{mol/L}$. Spiperone was also highly toxic for CRC-SCs, inducing cell death by both apoptosis and necrosis with an $IC_{50} < 6 \mu\text{mol/L}$. To verify its mechanism of action, we investigated the role of spiperone on Ca^{2+} homeostasis in HCT116 by using the Fura-2 probe. We observed that it increases cytoplasmic Ca^{2+} in CRC cells in a dose dependent manner. Experiments performed in the absence of extracellular Ca^{2+} demonstrated that spiperone increased cytoplasmic Ca^{2+} originating from endoplasmic reticulum (ER); this was further confirmed by the induction of ER depletion with 2,5-tBHQ (specific SERCA inhibitor) followed by spiperone treatment resulted in an accentuated store operated Ca^{2+} entry response. Restoration of extracellular Ca^{2+} in the presence of spiperone further increased cytoplasmic Ca^{2+} , suggesting that this drug is also active on plasma membrane Ca^{2+} channels.

Concluding, our data suggest that the anti-tumoral activity of spiperone might be due to Ca^{2+} movements through ER and plasma membrane channels. Further experiments are needed to better clarify the mechanism of action of spiperone in Ca^{2+} signalling and its possible repurposing as an antineoplastic drug.

29. Circulating tumor cells in patients with non small cell lung cancer: pilot study, initial results

⁵Department of Health Sciences, Università del Piemonte Orientale, Novara 28100, Italy.

Introduction: Lung cancer is the main cause of cancer mortality worldwide and the number of new cases is still rising. Early detection might be paramount to diagnose curable stages. There is growing interest about isolation of circulating tumor cells (CTC). This pilot study aimed at isolating epithelial putative CTCs in peripheral blood of early stage lung cancer patients using Smart BioSurface CTC assay, a nanoparticle-

coated slide that quickly immobilizes living nucleated cells, thus avoiding pre-selection and any change in cell structure and biology.

Experimental model: Twenty-two patients undergoing surgical lung resection have been included in the preliminary study. Blood sample was collected from patients and the white blood cells fraction was let adhere on SBS-CTC slide. The cells were stained with anti-CD45 and anti-pan-CK antibodies. Positive cells (putative CTCs) were detected with an automated fluorescence microscope, isolated by laser capture microdissection and characterized for gene mutations.

Results: All patients were positive for at least 1 epithelial cell (putative CTC)/mL of blood, though no correlation between the number of epithelial cells and the stage of the disease was observed. NGS analysis revealed gene variants associated with tumors in all patients, of whom 13 patients had mutations in genes that are specifically associated with lung cancer. One patient carries BRAF V600E mutation, that has been identified also in the tissue biopsy.

Conclusion: Epithelial cells are present in the blood of lung cancer patients. Further analyses of the genotype and phenotype are in the process to determine whether these cells are indeed CTCs.

30. Benefit sharing and globalisation of industry sponsored clinical trials for breast cancer research

Anil Babu Payedimarri, Gianluca Gaidano

Department of Translational Medicine, University of Eastern Piedmont, Novara 28100, Italy.

Introduction: The burden of cancer is the greatest and rising most rapidly in low-income and middle-income countries (LMICs). The survival of breast cancer is especially poor in LMICs due to late stage presentation and inadequate access to therapy. Whereas low-income countries (LICs) suffer from a generalized lack of access to cancer care, in middle-income countries (MICs) such services and facilities may exist. However, highly-priced innovative medicines are often only affordable for certain subsets of the population, and good outcomes remain biased toward those who can pay. We carried out comprehensive analysis of the geographic distribution of breast cancer clinical trials involving at least one LMICs clinical site and trials evaluating costly innovative medicines.

Methodology: Data were extracted from clinicaltrials.gov registry (as of 30 Jun 2018). Advanced search filters used: (1) condition/disease: breast cancer; (2) study type: Interventional studies; (3) phases: I to IV; (4) funder type: industry. Countries were classified by income according to the World Bank (Fiscal year 2019).

Results: We analysed 1,746 trials. The fraction of phase III trials involving MICs sites was 55.36% (155/280) in which Lower-MICs (L-MICs) were 27.14% (76/280) and Upper-MICs (UMICs) were 54.64% (153/280). Smaller proportions of Phase I and II trials were conducted in MICs i.e. 5.92% (26/439) and 16.23% (161/992). Phase IV trials that involve MICs were 31.43% (11/35). No trials were conducted in LICs. L-MICs countries with the highest number of trials were India ($n = 63$) and Ukraine ($n = 56$) followed by Philippines ($n = 23$), Egypt ($n = 17$), and Pakistan ($n = 10$). For U-MICs, Russian Federation ($n = 141$), Brazil ($n = 113$), China ($n = 112$), followed by Mexico ($n = 88$) and Turkey ($n = 66$).

Conclusion: Our analysis of the case of industry sponsored clinical trials with new, innovative medicines for breast cancer confirms previous observations with rarer blood cancers, that such trials are increasingly

globalized, i.e., delocalized to countries that do not have the means to ensure (universal) access to high-cost medicines. Although substantial numbers of anti-cancer medicines are nowadays included in national lists of LMICs, their affordability and accessibility at country-level are often far from ensured. The relevance of benefit sharing in international research is still poorly understood. A legal framework formulating benefit-sharing requirements in international research is necessary.

31. *TP53* analysis in hematological malignancies

Ahad A. Kodipad, Silvia Rasi, Clara Deambrogi, Simone Favini, Denise Peroni, Sruthi Sagiraju, Ramesh Adhinaveni, Sreekar Kogila, Fary Diop, Chiara Favini, Riccardo Moia, Lorenzo De Paoli, Gloria Margiotta Casaluci, Elena Crisà, Andrea Patriarca, Gianluca Gaidano

Division of Hematology, Department of Translational Medicine, Amedeo Avogadro University of Eastern Piedmont, Novara 28100, Italy.

Introduction: Chronic lymphocytic leukemia (CLL) is the most common type of adult leukemia in the Western World. *TP53* disruption (e.g., 17p del and/or *TP53* mutations) is associated with chemo-refractoriness and is now used in the clinical practice as a predictive biomarker. Moreover, also in myelodysplastic syndrome (MDS) *TP53* seems to be associated with an inferior outcome. Based on these observations, the objective of the project is to characterize *TP53* mutations in a prospective cohort of CLL and MDS patients to better define the frequency and the clinical implications of *TP53* mutations.

Experimental model: The study is based on the analysis of 53 CLL and 26 MDS patients. The mutational analysis of the *TP53* gene was performed using genomic DNA extracted from tumor cells. Peripheral blood was collected for CLL patients, while bone marrow for MDS patients. The *TP53* gene was analyzed by Sanger sequencing from exons 2 to 11.

Results: In the CLL group 5/53 (9.4%) cases showed *TP53* mutation. All mutations were missense and were reported in the IARC database. All *TP53* mutations predicted functional consequences and were all reported as pathogenic mutations. At diagnosis, *TP53* mutations associated with advanced age ($P = 0.031$), advanced Binet stage ($P = 0.021$) and higher $\beta 2$ -microglobulin levels ($P = 0.018$). In MDS 2/26 (7.7%) patients harbored *TP53* mutation. These two mutations were missense and were validated by the IARC database. Both of *TP53* mutated patients were treated with azacitidine but progressed early after treatment start.

Conclusion: In this prospective CLL cohort, *TP53* mutations reflect the mutation profile already reported, with the novel finding of the correlation between *TP53* and higher $\beta 2$ -microglobulin levels. In MDS, *TP53* seems to be associated with an advance disease and with early progression after therapy. Longer follow up is needed for univariate and multivariate survival analysis stratified according to *TP53* mutations.

32. Epigenetic changes in ovarian cancer cells subjected to starvation or to the caloric restriction mimetic Resveratrol

Letizia Vallino¹, Alessandra Ferraresi¹, Chiara Vidoni¹, Claudia Lora, Giovanna Chiorino², Alessandra Galetto³, Ciro Isidoro¹

³Oncology Unit, Department of Translational Medicine, Università del Piemonte Orientale “A. Avogadro”, Novara 28100, Italy.

Introduction: Biological processes are regulated through epigenetics, including chromatin remodelling (methylation, acetylation, etc.) and non coding RNAs. The correct balance of these mechanisms is crucial for the maintenance of cellular homeostasis and its dysregulation is correlated to many disorders such as cancer. Nutrient availability has a great impact on the metabolic pathways involved in cancer cell proliferation. Incubation in Earle’s Balanced Salt Solution (EBSS), a culture medium containing 1% glucose in absence of serum and amino acids, mimics the condition of starvation. Resveratrol (RV), a dietary polyphenol acting as a protein (caloric) restriction mimetic makes the cells unable to uptake nutrients for their metabolism.

Results: Here, we report on the changes of the miRNAs in ovarian cancer cells subjected to amino acid starvation or to RV. In this fasting condition, cancer cells promote autophagy as a pro-survival mechanism and eventually exit the cell cycle to undergo a dormant state. RV has a major impact on miRNome involved in autophagy and apoptosis compared to the one observed in EBSS-treated cells.

Conclusion: Our data support the view that RV treatment can be more effective than nutrient starvation, thus it can substitute it in order to induce a dormant-like state in cancer cells.

33. *KMT2D* mutations and *TP53* disruptions are poor prognostic biomarkers in MCL receiving high-dose therapy: a fil study

Introduction: In recent years, the outcome of mantle cell lymphoma (MCL) has improved, especially in younger patients, receiving cytarabine-containing chemoimmunotherapy and autologous stem cell transplantation. Nevertheless, a proportion of MCL patients still experience early failure. The aims of the study are to identify biomarkers anticipating failure of intensive chemotherapy in MCL.

Experimental model: We performed target resequencing and DNA profiling of purified tumor samples collected from patients enrolled in the prospective FIL-MCL0208 phase III trial (NCT02354313, high-dose chemoimmunotherapy followed by autologous transplantation and randomized lenalidomide maintenance).

Results: Mutations of *KMT2D* and disruption of *TP53* by deletion or mutation associated with an increased risk of progression and death, both in univariate and multivariate analysis. By adding *KMT2D* mutations and *TP53* disruption to the MIPI-c backbone, we derived a new prognostic index, the “MIPI-genetic”. The “MIPI-g” improved the model discrimination ability compared to the MIPI-c alone, defining three risk groups: (1) low-risk patients (4-year PFS and OS of 72.0% and 94.5%); (2) intermediate-risk patients (4-year PFS and OS of 42.2% and 65.8%); and (3) high-risk patients (4-year PFS and OS of 11.5% and 44.9%).

Conclusion: Our results: (1) confirm that *TP53* disruption identifies a high-risk population characterized by poor sensitivity to conventional or intensified chemotherapy; (2) provide the pivotal evidence that patients harboring *KMT2D* mutations share the same poor outcome as patients harboring *TP53* disruption; and (3) allow to develop a tool for the identification of high-risk MCL patients for whom novel therapeutic strategies need to be investigated.

34. *In vitro* and *in vivo* activity of biomimetic magnetic nanoparticles for drug delivery in presence of gradient magnetic field

Maria Prat¹, Francesca Oltolina¹, Ana Peigneux Navarro², Donato Colangelo¹, Concepcion Jimenez-Lopez²

¹ Laboratory of Histology, Department of Health Sciences, Università del Piemonte Orientale “A. Avogadro”, Novara 28100, Italy.

² Departamento de Microbiología, Facultad de Ciencias, Universidad de Granada, Fuentenueva, Granada 18071, Spain.

Nanotechnology and nanoparticles (NPs) have become very attractive for their applications in different fields, comprising biology, medicine and oncology. In this context, magnetite nanoparticles are even more interesting as they can be manipulated by an external magnetic field, besides being multifunctional platforms.

Herein, we describe a drug delivery system based on biomimetic magnetic nanoparticles (BMNPs) synthesized in presence of MamC protein from *Magnetococcus marinus* MC-1. MamC controls the

morphology and size of the crystals (~40 nm), that are paramagnetic at room and body temperature. Because of this protein, BMNPs have a negative surface charge at physiological pH values that allow an efficient coupling with different molecules.

These BMNPs were functionalized with the chemotherapy drug doxorubicin (DOXO) and their ability to respond to an externally applied gradient magnetic field (GMF) was studied both *in vitro* and *in vivo*. Naïve BMNPs were cytocompatible on 4T1 cells, while the DOXO-BMNPs were toxic starting from short exposure times when a GMF is applied. This allowed a faster interaction between BMNPs and cells (Perls Blue Staining) as well as a faster delivery of the DOXO to cell nuclei (confocal analysis). When DOXO-functionalized or not functionalized BMNPs were i.v. injected in mice bearing 4T1 cells-induced tumors, the application of the magnet on the tumors for 1 h reduced their size. Moreover, the presence of DOXO on BMNPs enhanced this effect.

All together, these data suggest that tumor attack by combined strategies (chemotherapeutic drug and magnetic field) could represent a promising approach for cancer therapy. Future steps will be the possibility to apply an alternating magnetic field to BMNPs to induce hyperthermia, to which tumor cells are more sensitive than healthy cells, and to enhance a more efficient localized release of the drug at the tumor site.

35. Novel diacylglycerol kinase alpha inhibitors for X-linked lymphoproliferative disease 1 therapy

Suresh Velnati^{1,2}, Elisa Ruffo^{1,3}, Alberto Massarotti⁴, Maria Talmon⁵, Sai Sandeep Varma Konduru^{1,2}, Annamaria Antona¹, Alessandro Gesu⁴, Luigia Grazia Fresu⁵, Andrew L Snow⁶, Daniela Capello¹, Alessandra Bertoni¹, Gian Cesare Tron⁴, Andrea Graziani^{1,3}, Gianluca Baldanzi^{1,2}

⁵Department of Health Sciences, School of Medicine, University of Piemonte Orientale, Novara 28100, Italy.

⁶Department of Pharmacology and Molecular Therapeutics, Uniformed Services University of the Health Sciences, Bethesda, MD 20814, USA.

Background: X-linked lymphoproliferative disease 1 (XLP1) is a primary immunodeficiency due to mutations in the SH2D1a gene, encoding SAP. SAP deficiency perturbs TCR signalling and results in a constitutive diacylglycerol kinase alpha (DGK α) activity that impairs CD8⁺ T cell restimulation induced cell death (RICD). Indeed, pharmacological inhibition of DGK α in XLP1 animal models limits CD8⁺ T cell expansion and interferon- γ production, suggesting the development of DGK α inhibitors for XLP1 therapy.

Experimental model: To find new DGK α inhibitors, we used a 2D/3D *in silico* approach based on chemical homology with the two commercially available DGK α inhibitors (R59922 and R59949). The library was screened for inhibitory activity at 100 μ mol/L. Active compounds were tested at concentration from 0.1 to 100 μ mol/L to estimate the IC₅₀. Furthermore, we tested the most active compounds in RICD assay using SAP silenced lymphocytes as XLP1 model.

Results: Out of the resulting 127 compounds, ritanserin (serotonin antagonist) and compound01 (uncharacterized molecule) were highly specific for DGK α and showed superior potency compared to R59022 and R59949. In cellular models of XLP-1, both ritanserin and compound01 restored RICD of SAP-deficient CD8 $^{+}$ without significant toxicity. Moreover, compound01 doesn't perturb serotonin signalling. Thus, we executed compound optimization of compound01 that yielded compound02-07 (synthesized compounds). All those compound01 derivatives are highly specific to DGK α without perturbing serotonin signalling.

Conclusion: Concluding our work allows us to propose a pharmacological model for the rational design of DGK α inhibitors and may contribute to the development of innovative therapies for diseases characterized by RICD resistance such as XLP-1.

Abstract

Aim: Breast cancer (BCA) in women is a leading cause of mortality and morbidity; distant metastases occur in ~40% of cases. Here, as an alternative to ionizing radiation therapy and chemotherapy and their associated side effects, we explored a new combination approach using capecitabine (CPBN) and aminolevulinic acid (ALA)-based photodynamic therapy (PDT). We had previously developed a combination PDT approach in which 5-fluorouracil (5FU), a differentiation-promoting agent, increases the levels of protoporphyrin IX (PpIX) in cancer cells when given as a neoadjuvant prior to aminolevulinic acid (ALA). However, 5FU can be toxic when administered systemically at high levels. We reasoned that CPBN, a known chemotherapeutic for BCA and less toxic than 5FU (because CPBN is metabolized to 5FU specifically within tumor tissues), might work equally well as a PDT neoadjuvant.

Methods: Murine 4T1 BCA cells harboring a luciferase transgene were injected into breast fat pads of female nude mice. CPBN (600 mg/kg/day) was administered by oral gavage for 3 days followed by intraperitoneal ALA administration and PDT with red light (633 nm) on day 4. Tumor growth and regression were monitored *in vivo* using bioluminescence imaging. Histological changes in primary tumors and metastases were assessed by immunohistochemistry after necropsy.

Results: CPBN pretreatment of 4T1 tumors increased cellular differentiation, reduced proliferation, raised PpIX levels, enhanced tumor cell death, and reduced metastatic spread of 4T1 cells post-PDT, relative to vehicle-only controls.

Conclusion: The use of CPBN as a non-toxic PDT neoadjuvant for treatment of BCA represents a novel approach with significant potential for translation into the clinic.

INTRODUCTION

Breast cancer (BCA) is the most common type of malignancy in women, with 1.7 million new cases diagnosed worldwide each year^[1] and it is also a leading cause of mortality among women, accounting for over half a million deaths annually^[1-3]. The main cause of death is not the primary tumor, but distant metastases that create significant morbidity. Although 80% of BCA patients receive adjuvant chemotherapy, ~40% of those patients relapse and ultimately die due to metastatic disease^[4]. While 5-year survival rates of BCA patients are increasing overall due to advanced therapeutic techniques, relatively low survival rates and poor prognoses are still observed in patients with metastatic BCA^[4]. BCA cells metastasize mainly to the lung, liver, brain and bone; metastases to the skin (cutaneous metastasis) occur in ~20% of cases^[4]. Local relapse and chest wall metastases occur at a rate of 5%^[4]. The chest wall tumors are notable because they can be very painful, and are hard to treat due to their resistance to chemotherapy^[5,6]. Ionizing radiation therapy (RT) has been successfully used for the treatment of cutaneous chest wall metastases; however, multiple rounds of therapy are required and are typically associated with side effects such as radiation dermatitis, blistering and chronic ulcers. An alternative to RT, constituting a safer treatment that might be given either alone or together with chemotherapy, is urgently needed.

Photodynamic therapy (PDT) is a non-mutagenic, non-scarring treatment modality for cancer. PDT employs a photosensitizer (PS) and visible light in the presence of oxygen to kill tumor cells^[7-9]. During PDT, two steps provide dual selectivity. First, the cancer cells accumulate and retain PS to a greater extent than normal cells. Second, focusing the light source onto the tumor further enhances tumor specificity. The PS is activated, triggering cell death by releasing free radicals^[8]. In the early history of PDT, the PS was given systemically and carried a high risk of increased skin phototoxicity (sunburn). To reduce toxicity and improve tumor selectivity, a newer mechanism of PDT that uses a prodrug, aminolevulinic acid (ALA) instead of the pre-formed PS, was developed^[10,11]. ALA, given systemically, orally or topically, is taken up and enzymatically converted into protoporphyrin IX (PpIX) within mitochondria. PpIX is then activated by strong visible light to generate reactive oxygen species that kill the cancer cells^[9,12,13]. Skin cancers are easily illuminated from the surface using red light that penetrates up to 1 cm into tissue. PDT is now successfully used in Europe to treat superficial basal cell carcinoma and squamous cell carcinoma (SCC)^[14]. PDT has several advantages over other modalities: (1) unlike surgical excision, PDT is non-scarring (and may actually inhibit fibrosis^[15,16]); and (2) unlike RT, PDT can be repeated multiple times and because PDT targets mitochondria rather than DNA, there is minimal risk of genetic mutations.

Although PDT is currently employed mostly for skin cancers, it carries tremendous potential to shrink or eliminate BCA and its associated metastases; this research area has only been explored in a preliminary fashion^[17,18]. Up until now, the need for specialized equipment and better-standardized protocols has delayed the acceptance of PDT as a main line of treatment for BCA and its metastases. In a recent clinical trial in China, ALA-PDT used in combination with RT to treat cutaneous BCA metastases, showed a better complete response (50% vs. 20%) and a reduced time to clearance (110 days vs. 175 days) vs. RT alone^[19]. It was also shown that lowering the photosensitizing drug dose and the light fluence rate can improve the clearance

of BCA chest wall lesions^[19]. Here, we seek to apply a different combination therapy PDT approach to BCA. Using pre-clinical murine models and subsequent clinical trials in patients with skin cancer, we have established that certain neoadjuvant agents can significantly improve PpIX levels and distribution within tumors when combined with ALA-PDT^[9,20]. In this study, we explore an approach that combines two FDA-approved drugs [capecitabine (CPBN) and ALA] and a standard light source used in dermatology, to deliver a safer, more efficacious, and more convenient treatment for localized BCA tumors and metastases in mice.

The rationale for our approach is based upon several relatively new scientific principles. In the past, several PDT regimens have been explored with different PS molecules, routes and doses of PS, and various wavelengths, illumination protocols and oxygen concentrations (hypoxia *vs.* normoxia), in attempts to improve PDT responses^[7-9]. However, since cell physiology (particularly the state of tumor differentiation) plays an important role in PDT outcome, we considered biomodulation with neoadjuvants given prior to PDT as another avenue for optimization^[9]. Towards this goal, we pioneered a concept called “differentiation-enhanced” or “combination PDT”. Thus, cancer cells of different tissue origins, when pre-treated with differentiation promoting agents, show elevated accumulation of PpIX and enhanced cell death after ALA-PDT^[9]. Three such agents, methotrexate^[21,22], vitamin D (calcitriol)^[23] and 5-fluorouracil (5-FU)^[24] were shown to improve tumor responses in skin, prostate and BCA models when used as neoadjuvants for PDT. Pretreatment with any of these agents resulted in 3- to 5-fold upregulation of mitochondrial PpIX production^[9]. The effects on PpIX levels were selective for tumor cells and did not occur in adjacent skin^[24,25]. We recently worked out the molecular mechanisms for this effect. Coproporphyrinogen oxidase, a heme enzyme located upstream of PpIX, is upregulated; ferrochelatase located downstream of PpIX, is decreased; and the net effect favors PpIX buildup^[23,26]. An important feature of these neoadjuvants is that they drive cancer cells toward a more highly differentiated state, as determined by the elevated expression of E-cadherin in tumors. Using a BCA model (MDA-MB-231 cells implanted in breast fat pads of nude mice), we showed that pretreatment with calcitriol (the active form of Vit D) prior to ALA-PDT resulted in an enhanced therapeutic response relative to ALA-PDT alone^[25]. Using topical 5-FU, we recently completed a clinical trial in patients with actinic keratosis (AK; pre-SCC), and showed that combination PDT with topical 5-FU significantly enhanced the PDT efficacy as determined by increased clearance of the AK lesions^[20].

A major reason for PDT treatment failure is the heterogeneity of PpIX distribution within the target tissue. Some microanatomical pockets, located deep inside the tumor, produce minimal PpIX due to poor PS penetration and suboptimal physiological response, thereby escaping PDT photodamage^[26]. When 5-FU is given as a neoadjuvant prior to ALA, PpIX levels are raised in the vast majority of tumor cells, resulting in enhanced cell death following PDT in both skin tumors and in murine breast tumors^[24]. However, the systemic dose of 5-FU required to achieve this effect is quite high and might be toxic in humans. In the current study, in order to circumvent toxicity, we used an alternative drug that is FDA-approved for treatment of metastatic BCA^[27-29]. CPBN is a precursor form of 5-FU that is selectively converted into the active end product, 5-FU, primarily in cancer cells. CPBN is converted to 5-FU in three enzymatic steps requiring carboxylesterase, cytidine deaminase (CDA), and thymidine phosphorylase (TYMP)^[28,30]. Cancer cells have relatively high levels of CDA and TYMP, explaining the increased sensitivity of cancer cells to CPBN, and the low adverse effects of this drug on non-tumoral tissues^[28]. To test and develop a combination approach with CPBN and PDT, we used a mouse BCA model (the 4T1 cell line; a triple-negative BCA equivalent to human stage IV) that has already been previously utilized in many studies of BCA^[31,32]. The long-term goal of our study was to develop a better mechanistic understanding of the CPBN-PDT approach, for possible translation of this concept to the clinic for treating localized BCAs.

METHODS

Cell culture

4T1, a murine breast carcinoma line (a triple-negative breast cancer and stage IV human BCA equivalent) and Bioware® Brite Cell Line 4T1-Red-FLuc, were purchased from animal type culture collection and Perkin

Elmer Inc., respectively, and cultured as per the instructions provided by the source/vendor.

4T1 murine breast tumor model

Murine 4T1 cells (0.5×10^6) and 4T1-Red-Fluc cells (0.005×10^6) were resuspended in the growth medium and injected into breast fat pads of female nude mice. Visible/palpable tumors developed in 3-5 days post injection. All experimental procedures involving mice were preapproved by the Institutional Animal Care and Use Committee of the Cleveland Clinic.

Pretreatment with CPBN

CPBN (Sigma Aldrich, 600 mg/kg/day) was dissolved in 5% gum arabic-sodium citrate solution (vehicle) and was given by oral route (gavage) once daily for 3 days. Control mice received vehicle solution only. On day 4, ALA was administered through intraperitoneal route (IP; 200 mg/kg in phosphate buffered saline) for 4 h and the mice were either exposed to red light (633 nm) for PDT, or euthanized for tumor harvest and histological and immunohistochemical analyses^[23,24]. The dose of oral CPBN chosen for our study (600 mg/kg/day for three days) was based upon 80% of the maximum tolerated dose determined in nude mice by Kolinsky *et al.*^[33], maximum tolerated dose 700 mg/kg/day when given for 7 days. Note that dose translation between CPBN (Xeloda®) doses used in humans^[34,35] and biologically equivalent doses in mice is not straightforward, and typically involves body surface normalization methods^[36,37].

Imaging of tumor growth/regression and metastases using *in vivo* imaging system (IVIS® spectrum)

4T1 tumor bearing mice were injected with *D*-luciferin (IP; 150 mg/kg; Perkin Elmer Inc.) and imaged under continuous isoflurane anesthesia using the *in vivo* imaging system (IVIS spectrum; Perkin Elmer Inc.) following the manufacturer's instructions. Bioluminescence imaging signals were recorded as bioluminescence units (BLUs, photons/s/cm²/sr), and used to analyze tumor growth/regression and metastases to distant sites using Live Imaging Software^[25]. Digital images were captured 5 min after *D*-luciferin injection, along with a radiance calibration standard scale, at each weekly time point during tumor growth/regression experiments. Tumor-associated signals (emitted light units) from each region of interest (ROI) were normalized per this radiance standard scale.

Treatment with PDT

Mice were anesthetized using intraperitoneal ketamine and xylazine. Anesthetized mice with 4T1 tumors (\pm CPBN pretreatment and after 4 h of ALA), were exposed to 100 J/cm² of 633 nm light using a LumaCare® xenon source (LumaCare). The light source was calibrated using a FieldMate® laser power meter (Coherent). Mice were either imaged at different time points to analyze the therapeutic response and metastases to distant sites or sacrificed and tumors harvested at 24 h post PDT for histological and immunohistochemical analyses^[23,24].

Imaging of PpIX in 4T1 tumors by confocal microscopy

Tumor cryosections (10 μ m) were placed on glass slides, briefly air dried, mounted under coverslips with Vectashield (Vector Laboratories), and viewed on a confocal microscope (Leica Microsystems; 40 \times magnification; excitation at 635 nm and image collection at 650-780 nm). Quantitation of relative PpIX levels from digital photomicrographs was performed using IP Lab software^[23,24].

Histology, immunohistochemistry and cell death analyses

The 4T1 tumors and distant metastatic sites were harvested at different time points, fixed in formalin, paraffin-embedded and sectioned (5 μ m) following a standard protocol. Hematoxylin and eosin staining, immunofluorescence staining, and cell death analysis [terminal-deoxynucleotidyl transferase dUTP nick end labeling (TUNEL)] were performed as described^[23,24].

Figure 1. Analyses of protoporphyrin IX (PpIX) in murine breast tumor model. (A) Photograph of a nude female mouse with 4T1 subcutaneous tumors in breast fat pad; (B) hematoxylin and eosin (H&E) stained 4T1 tumor section showing histological details of the murine breast carcinoma shown in (A); (C) confocal micrographs of frozen sections of 4T1 tumors after oral treatment with vehicle (top) or capecitabine (CPBN) (bottom) followed by aminolevulinic acid; red signal is mitochondrial PpIX; (D) quantitation of PpIX-specific fluorescence from confocal micrographs shown in (C); integrated fluorescence intensity was measured using IPLab software. Mean SEM (18 images from 6 tumors) from three independent experiments is shown. $*P = 0.0001$

Statistical analyses

Statistical analyses were performed using a two-sided *t*-test to compare differences between PpIX levels, expression of markers by immunohistochemistry, cell death and tumor bioluminescence. $P \leq 0.05$ was considered statistically significant.

RESULTS

Experiments were designed to test our hypothesis that oral CPBN, given as a differentiation-promoting agent (instead of administering its final product 5-FU [Anand, 2017 #100; Maytin, 2018 #114]), may enhance the PS levels, subsequent cell death response and will impact distant metastases following ALA-PDT in a murine 4T1 breast tumor model.

Combination of oral CPBN before ALA enhances PpIX levels in 4T1 tumors

To study if oral CPBN can successfully replace its relatively toxic final product 5-FU for the purpose of promoting differentiation prior to ALA-PDT, a murine breast tumor cell line (4T1) equivalent to stage IV human triple negative breast carcinoma was injected in the breast fat pad of female nude mice to generate a murine breast tumor model [Figure 1A and B]. Following the injection of 4T1 cells, mice with visible and palpable 4T1 breast tumors [Figure 1A] were given either CPBN or vehicle (orally by gavage, once a day for 3 days), followed by intraperitoneal ALA administration on the 4th day. Tumors were harvested and frozen sections were analyzed by confocal microscopy using excitation and emission settings that allow visualization of PpIX-specific fluorescence. In the 4T1 tumors from mice treated with oral CPBN, PpIX was more abundant and also present throughout the tumor at much higher levels, as compared with vehicle treated (control) tumors [Figure 1C; bottom *vs.* Top]. Digital quantification of the PpIX fluorescence signal from confocal images confirmed this observation by showing a statistically significant increase of ~4-fold in PpIX levels in CPBN treated tumors [Figure 1D].

CPBN pretreatment enhances differentiation, inhibits proliferation and enhances cell death following PDT

5FU, a chemotherapeutic drug and the final product of CPBN metabolism specifically converted in the tumors due to high levels of CDA, and TYMP^[28,30], is known to downregulate DNA synthesis through

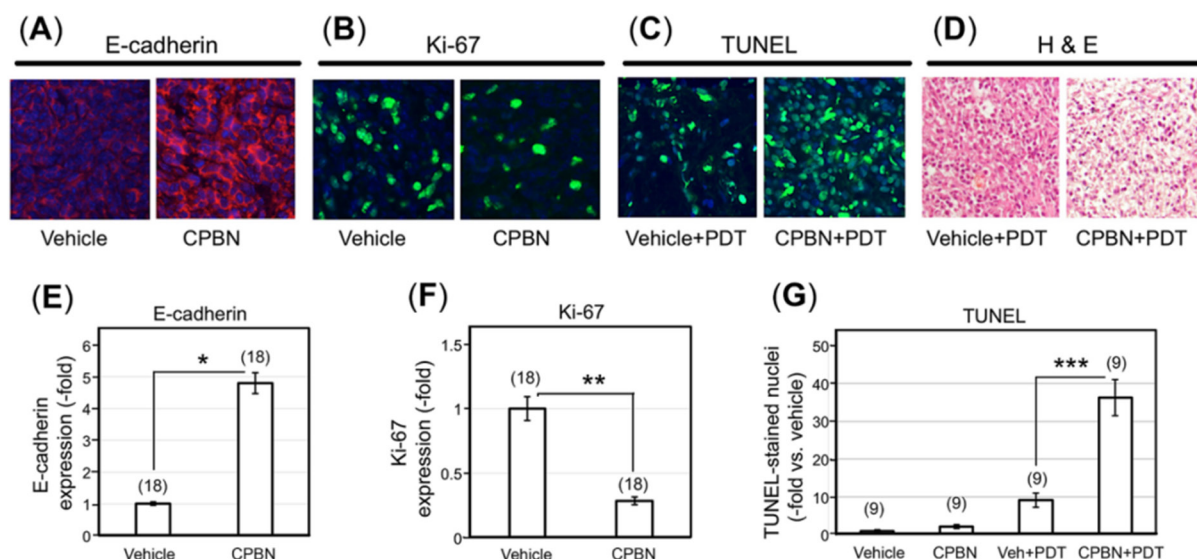

Figure 2. Physiological and cell death responses to capecitabine pretreatment and photodynamic therapy in murine breast tumor model. Photomicrographs showing 4T1 tumor sections immunohistochemically stained for (A) E-cadherin (E-cad), a marker of differentiation; (B) Ki67, a marker of proliferation, following vehicle or capecitabine (CPBN) treatment; (C) Cell death analysis by terminal-deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) labeling of apoptotic nuclei at 24 h post photodynamic therapy (PDT), following vehicle or CPBN pre-treatment. Nuclei in images shown in (A-C) were stained with 4',6-diamidino-2-phenylindole (DAPI); (D) hematoxylin and eosin (H&E) staining of tumor sections showing enhanced cell death at 24 h post PDT in tumors pretreated with CPBN or vehicle alone. Graphs show quantitation of changes in (E) E-cadherin signal; (F) Ki67 signal; and (G) TUNEL positive nuclei per high power field. All graphs show Mean \pm SEM from multiple images (number of images shown in parentheses) from three independent experiments. P values from an unpaired two-sided t -test are shown: * $P = 1.57 \times 10^{-11}$; ** $P = 1.20 \times 10^{-8}$; *** $P = 6.02 \times 10^{-9}$.

inhibition of thymidylate synthase (TS) and *de novo* synthesis of thymidylate acid^[38]. In addition to its anti-proliferative effect, 5-FU induces epithelial cell differentiation^[9]. The physiological effects of CPBN pretreatment on the 4T1 tumors were analyzed by immunostaining of tumor sections for expression of E-cadherin and Ki67, markers of differentiation and proliferation, respectively [Figure 2]. As anticipated, relative to vehicle treated tumors, CPBN pretreatment led to a 5-fold increase in differentiation [E-cadherin expression; Figure 2A and E]. In the same set of tumors, CPBN pretreatment resulted in a 70% reduction in cell proliferation [Ki67 expression; Figure 2B and F].

To assess the effects of combination therapy upon 4T1 intratumoral cell death, CPBN + PDT treated tumors along with vehicle- and CPBN-treatment controls were harvested 24 h after PDT and histological sections were analyzed by TUNEL assay and by hematoxylin and eosin staining. TUNEL is a technique in which cleaved inter-nucleosomal DNA fragments are enzymatically labeled in dying cells. CPBN pretreated tumors showed an approximately 4-fold increase in TUNEL positive nuclei, relative to their vehicle treated PDT controls by 24 h post PDT [Figure 2C and G]. Histomorphological details of CPBN-PDT induced cell death in 4T1 tumors were analyzed by comparing hematoxylin and eosin stained sections from tumors treated with CPBN + PDT or with PDT alone [Figure 2D]. At 24 h following PDT, all tumors displayed numerous apoptotic cells with shrunken, pyknotic nuclei, intracellular vacuoles, and large areas of cell loss (empty spaces), but these features were more pronounced in the CPBN pretreated tumors, similar to quantitation of cell death features by hematoxylin and eosin reported previously^[25,39].

Non-invasive visualization and monitoring of tumor growth and regression after PDT using IVIS

Using the IVIS Spectrum® device, growth and/or regression of orthotopic 4T1 breast tumors in nude mice from different treatment groups (vehicle, CPBN, vehicle + PDT and CPBN + PDT) was monitored non-invasively. A genetically modified version of 4T1 cells (4T1-red-fluc Bioware® Brite cell line), which had been stably transduced with the red-shifted firefly luciferase gene from *Luciola Italica* (Red-FLuc), was

used to monitor the effect of vehicle or combination PDT on tumor growth and regression. These cells were implanted in mammary breast fat pads of nude mice and tumor growth was followed non-invasively by IVIS. The bioluminescent images were captured on: (1) a day after implantation; (2) prior to PDT (pre-PDT); (3) one-week and (iv) two-week post PDT. Growth/regression after PDT was quantitated using BLUs from individual ROI from images captured at different time points during an experiment. [Figure 3A](#) shows representative examples of nude mice carrying 4T1 breast tumors imaged just before, one week, and two weeks after PDT, along with vehicle- or CPBN-only treatment groups that did not receive PDT. The bioluminescence signal (pseudo-colored rainbow scale) represents the radiance (photons/s/cm²/sr) emitted from 4T1 tumors due to the reaction between luciferin substrate (delivered via i.p. injection) and luciferase enzyme (expressed in the 4T1 cells).

In the vehicle-only group of mice, the luciferase signal increased continually to 4.6-fold by 2 weeks, reflecting unrestricted growth of 4T1 cells [[Figure 3A](#); top left set of images, and [Figure 3B](#)]. In a CPBN-treated group of mice that received only CPBN (600 mg/kg/day) once daily for 3 days, the luciferase signal by week 2 was increased by 13.6-fold as compared to the pre-PDT signal [[Figure 3A](#), top right set of images, and [Figure 3B](#)]. The ~4-fold induction in growth of 4T1 tumors following CPBN treatment, relative to the vehicle only group, was an unanticipated observation. CPBN, a chemotherapeutic drug approved for the treatment of BCA in humans with anti-proliferative physiological effects, should have reduced the tumor growth, but we note that the incongruent finding might possibly be due to a smaller number of mice ($n = 4$) in this particular treatment group. In the vehicle + PDT group, the rise in bioluminescent signal (2.5 and 9-fold over baseline at weeks 1 and 2, respectively) reflected continued growth and inadequate response of 4T1 tumors to PDT alone [[Figure 3A](#), left bottom set of images, and [Figure 3B](#)]. In contrast, the last group of mice that received CPBN + PDT was the only treatment group that showed no tumor growth [[Figure 3A](#), right bottom set of images, and [Figure 3B](#), fourth set of bars]. Thus, the combination of CPBN with PDT showed a much better therapeutic response than PDT alone. Our observation of tumor bioluminescence was only possible up to two weeks post-treatment. At weeks 3 and 4, the signal was often blocked or reduced due to a combination of crust on the dying tumor, increased tumor size, and probably uneven uptake of luciferin due to tumor hypoxia and cell death. We are currently studying the mechanistic details of these effects, with special interest in regulation of apoptotic cell death following CPBN-PDT.

Distant 4T1 metastases: bioluminescent, histological and immunohistochemical analyses after PDT treatments

The 4T1 BCA line used in this study has been shown to metastasize widely to distant organs (lymph node, lung, liver, bone, spleen and skin) at later stages of tumor development^[40-42]. Here we investigated the effect of CPBN-PDT on distant metastases in nude mice, using luciferase-expressing 4T1 cells implanted at a single site on the animal. Metastatic spread to lung, lymph nodes, spleen and skin was observed at three weeks after implantation of the primary tumor site into the ventral breast fat pads [[Figure 4](#)]. In addition to the obvious signal at the site of injection, 4T1 cells were also observed to spread in the abdominal cavity and at other distant sites, reflecting likely metastases of tumor cells to lungs, lymph nodes and spleen [[Figure 4](#)]. Signals from some specific anatomical locations corresponded to cervical, axillary, sciatic and inguinal lymph node sites. Cutaneous metastases were also seen both visually on the skin (data not shown), and confirmed by IVIS imaging that revealed luminescent signals originating from cutaneous metastatic lesions [[Figure 4C](#), rightmost mouse].

To analyze the effect of combination therapy upon BCA metastases, mice from different treatment groups were examined for the incidence of distant metastases. The mice from three treatment groups, i.e., vehicle, CPBN and vehicle + PDT showed a similar incidence of metastases ranging from 60%-65% [[Figures 4A-C and 5A](#)]. By contrast, mice from the CPBN + PDT treatment group showed significantly less metastatic spread [[Figure 4D](#)], corresponding to only a 17% incidence of metastases [[Figure 5A](#)]. The metastatic tumor

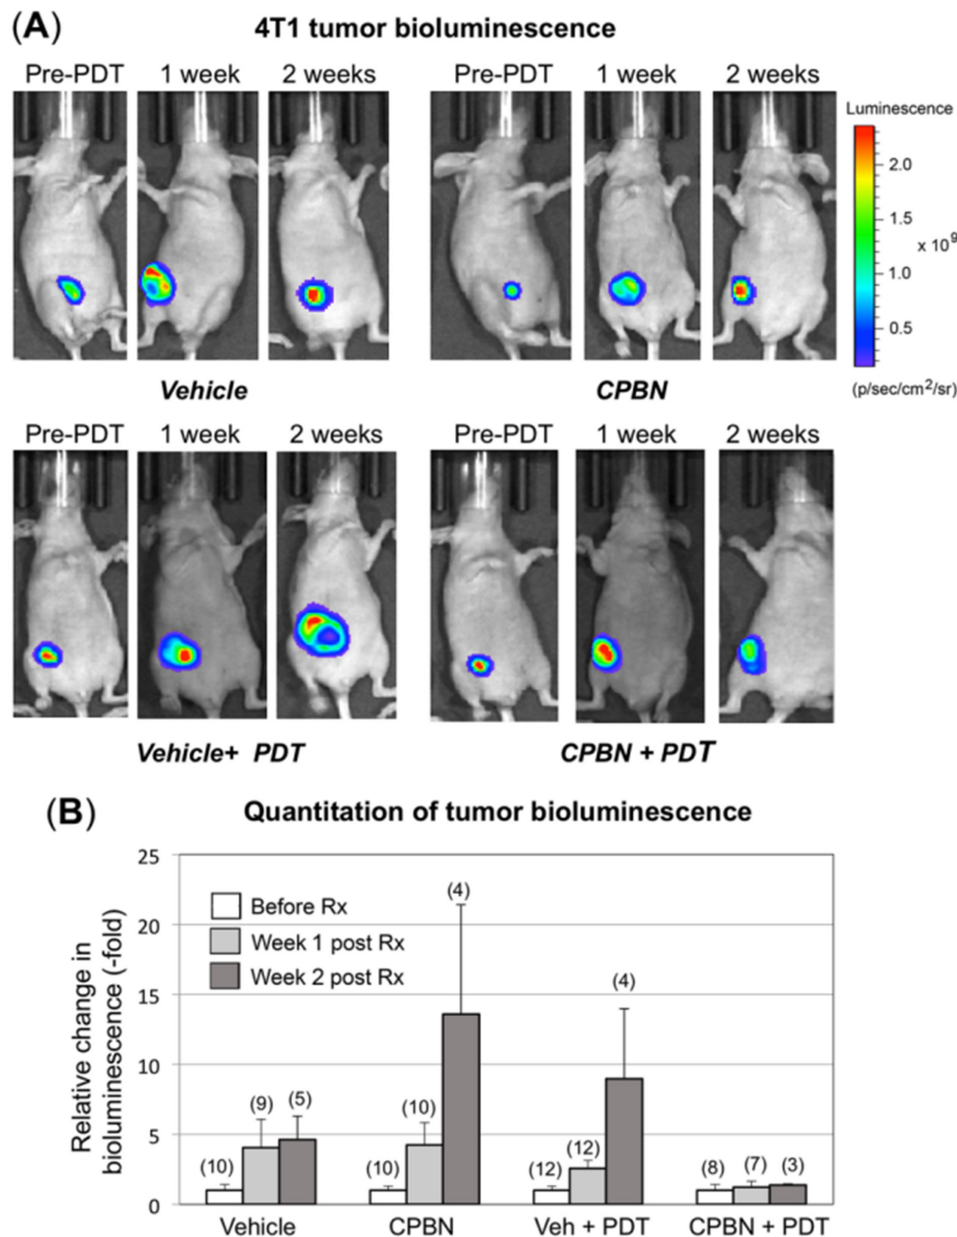

Figure 3. Monitoring of therapeutic responses to capecitabine and/or photodynamic therapy (PDT) in murine breast tumor model using an in vivo imaging system (IVIS). 4T1 murine breast cancer cells (stably transfected with luciferase) were implanted in the breast fat pad of nude mice and monitored for bioluminescence signals originating from tumors, using an IVIS instrument. (A) Tumor growth or shrinkage after 1 or 2 weeks of vehicle- or capecitabine (CPBN)-only, ALA + PDT or CPBN + PDT, was monitored by injection of luciferin, and measurement and quantitation of luminescence output using Live imaging software as described^[25]. A typical radiance scale, common to most of the bioluminescent images, is shown in (A); (B) quantitation of bioluminescent light units, relative to pre-PDT tumor luminescence from each treatment group, is shown as fold increase. Bars representing mean (\pm SEM), from the number of mice shown in parentheses on top of the bars (pooled from four independent experiments) are shown. The differences observed in the relative bioluminescence between vehicle + PDT and CPBN + PDT at one ($P = 0.14$) and two ($P = 0.20$) weeks post PDT, were not statistically significant

load among mice from different treatment groups was compared by analyzing cumulative bioluminescence originating from different ROIs on each mouse. Mice from vehicle-only, CPBN-only, PDT-only treatment groups, showed a similar metastatic load [Figure 5B]. However, the CPBN + PDT treatment group showed a significantly reduced metastatic load of only 14% [Figure 5B].

To further confirm that the bioluminescence observed in Figure 4 did indeed represent tumor metastases, various organs were necropsied and stained with hematoxylin and eosin. Our histological and

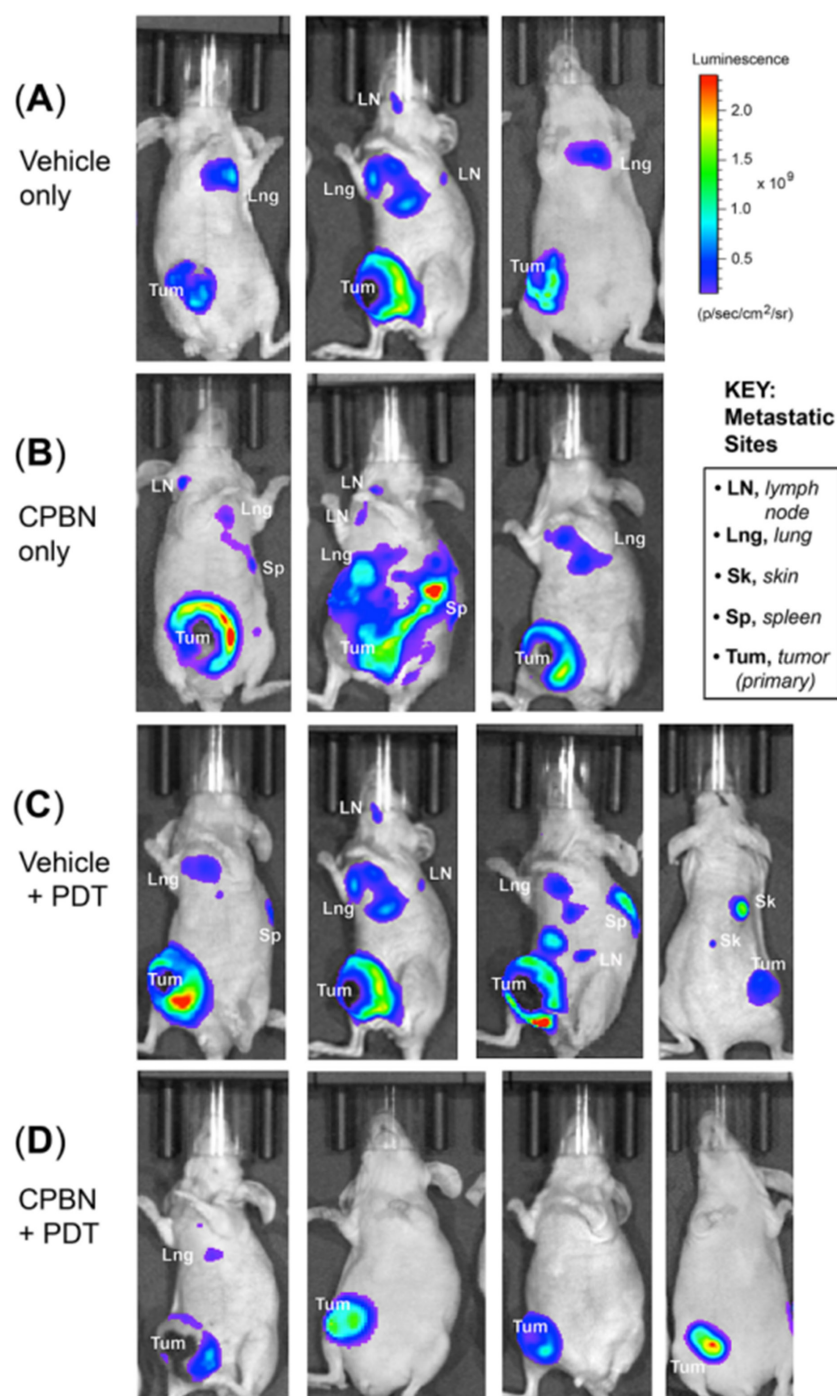

Figure 4. Monitoring of distant metastases of breast tumor cells in nude mice treated with conventional or combination photodynamic therapy (PDT). 4T1 murine breast carcinoma cells were implanted in the breast fat pad of nude mice, and distant metastases were monitored by bioluminescence signals originating from metastatic sites using an *in vivo* imaging system instrument. Metastatic spread of 4T1 tumor cells (3 weeks post PDT) in mice representing (A) vehicle only; (B) capecitabine (CPBN) only; (C) vehicle + PDT; and (D) CPBN + PDT are shown. Observed organ sites of metastases, including lymph nodes (LN), lung (Lng), spleen (Sp) and skin (Sk) are indicated. Note the significant reduction in the incidence of metastases in CPBN + PDT treated mice

immunohistochemical analyses were only able to reveal 4T1 metastases in the lungs and skin, possibly due to the difference in sensitivity of detection between IVIS and hematoxylin and eosin methods. IVIS is an *in vivo* optical imaging system capable of detecting signal from as few as 3 cells implanted in a mouse^[43], as compared to a few hundred cells required to form a tumor nest that can be detected histologically by

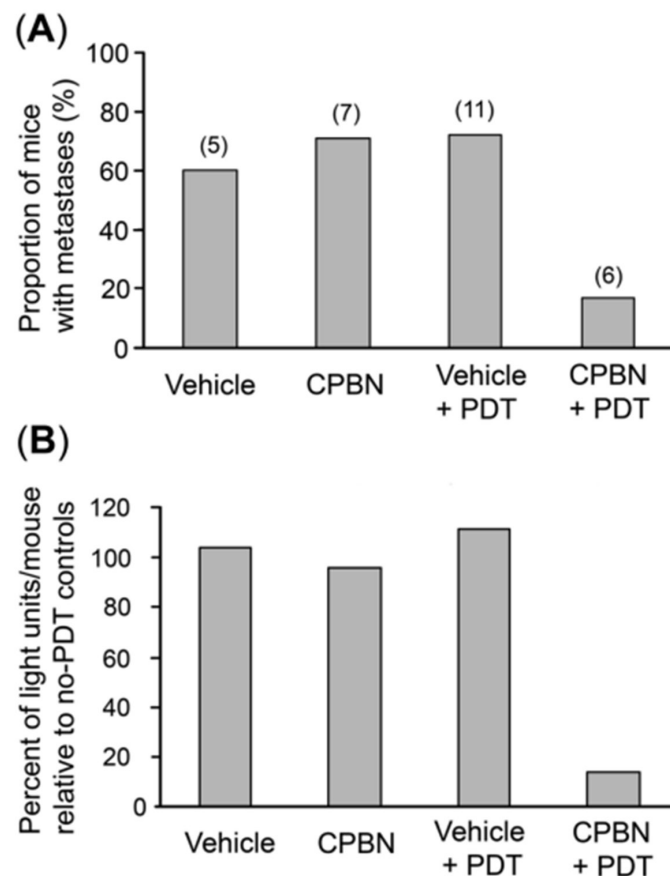

Figure 5. Analyses of incidence of metastases, and total metastatic load, in nude mice with 4T1 breast tumors. Mice from four different treatment groups [vehicle only, capecitabine (CPBN) only, vehicle + photodynamic therapy (PDT) and CPBN + PDT] were quantitatively analyzed as follows. (A) Incidence of metastases by week 3. Note that the first three treatment groups showed 60%-70% of mice with metastases, whereas the CPBN + PDT treatment group showed only 17% of mice with metastases; (B) metastatic tumor load per mouse, calculated by comparing the cumulative bioluminescence units (BLUs) from each mouse with the average cumulative BLUs from no-PDT controls. The metastatic load of 14% in CPBN + PDT group is much lower than the other three groups (96%-111%)

hematoxylin and eosin. [Figure 6A](#) clearly shows the presence of metastatic tumor nests (marked with dotted lines) in the lung of a mouse that was positive by IVIS imaging. Keratin 14 (K14, a marker for epithelial breast tumors at ectopic sites; [Figure 6A](#)), was expressed only within tumor nests in the lungs of tumor-bearing mice and not in the lungs from control mice [[Figure 6A](#); bottom]. Comparing this to the primary tumor (which also stained strongly for K14; [Figure 6B](#)), the pattern of K14 expression was interesting, in that the most intense expression was observed in the tumor periphery, with far fewer positive cells in the central/stromal (hypoxic) tumor regions ([Figure 6B](#); top vs. bottom), possibly due to hypoxia and necrosis in the center and the proliferative nature of the tumor periphery, respectively. This observation further supports the assertion that the primary breast tumor was the origin of the K14-positive, metastatic tumor nests in the lungs. Histology of cutaneous metastatic lesions also clearly confirmed the presence of metastatic carcinoma in skin ([Figure 6C](#); righthand image marked with dotted lines). Further exploration of how CPBN-PDT exerts its inhibitory effect on 4T1 metastatic spread is underway.

DISCUSSION

In this study we have shown, in a murine model of BCA, that pretreatment with CPBN prior to ALA-mediated PDT causes selective enhancement of PpIX levels within 4T1 tumors, and improves the treatment outcome of PDT by enhancing tumor cell death. We also showed, using histological and

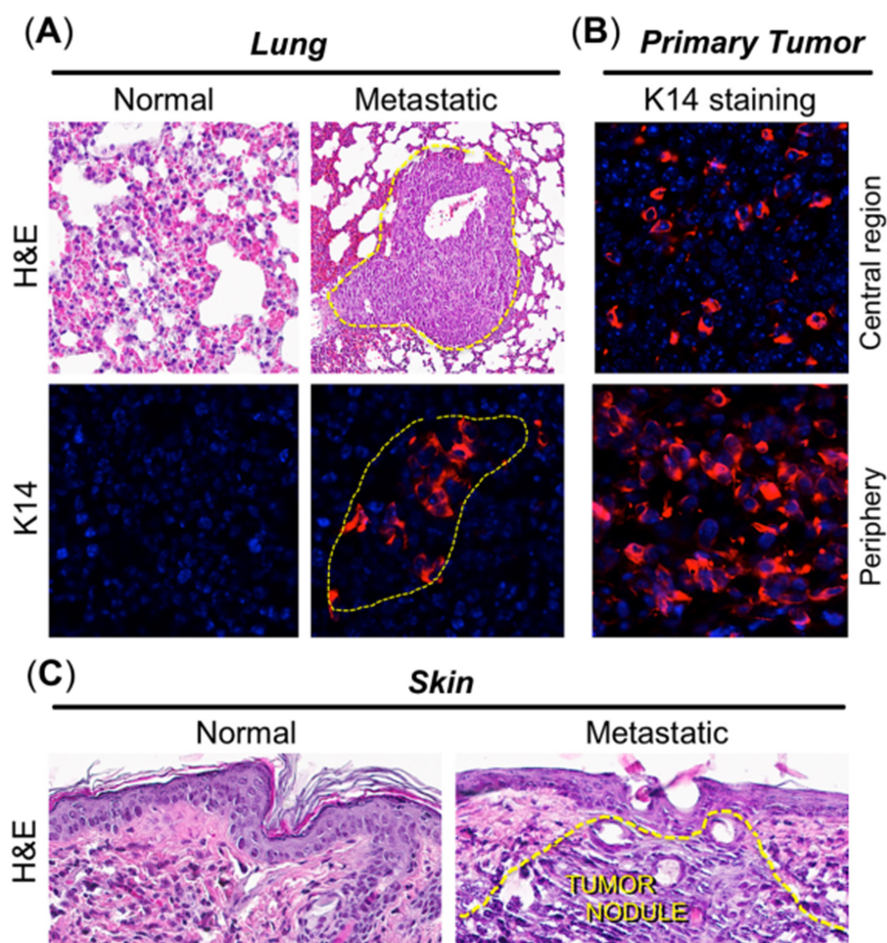

Figure 6. Histological and immunohistochemical analyses of distant metastases in the 4T1 breast tumor model. Tissue biopsies from organs positive for bioluminescence, along with primary tumors, were harvested three weeks after photodynamic therapy. By histological analyses, metastases were detectable in lungs and skin only. (A) Metastatic nodules were visible in lungs via hematoxylin and eosin (H&E) staining, and by immunostaining with antisera to keratin 14 (K14; red color), as delineated by dotted yellow lines; (B) positive K14 staining in primary breast tumor, to confirm that lung tumor nests originated from the primary breast tumor. K14 staining was weaker in the tumor center (top panel) than in the tumor periphery (bottom panel), possibly due to hypoxia and necrosis in the center *vs.* proliferation at the tumor periphery; (C) a cutaneous metastasis, detected visually and by *in vivo* imaging system, revealed obvious infiltrating tumor cells when stained with H&E (right panel, dotted yellow lines)

immunohistochemical analyses, that the CPBN-PDT combination enhances the differentiation state of 4T1 carcinoma cells within the tumors. Finally, using *in vivo* bioluminescent monitoring, we showed that the combination approach appears more effective than ALA-PDT alone, retarding the growth of the primary tumor, and also reducing metastatic spread.

The observed beneficial effect of neoadjuvant CPBN on the therapeutic outcome of PDT may involve several underlying mechanisms that we previously identified in studies with other differentiation-promoting drugs such as methotrexate, vitamin D and 5-FU^[9]. The first apparent mechanism, an inhibition of tumor cell proliferation [Figure 2B and F], is an anticipated effect of 5-FU since the latter inhibits TS and induces growth arrest by mis-incorporation of FU into DNA^[38]. The second mechanism, enhanced differentiation of tumor cells, is a less understood effect whose basis is unclear since the induction of growth arrest is often associated with induction of differentiation. The third mechanism, enhancement of PpIX accumulation, is actually now fairly well understood from our previous work^[24]. PpIX is produced by enzymatic conversion of ALA through the heme biosynthetic pathway. 5-FU, the final product of CPBN metabolism, has been

shown to exert its effects on PpIX levels in murine and human SCC tumors by upregulating the levels of two rate-limiting enzymes of the heme pathway, coproporphyrinogen oxidase (upregulation) and ferrochelatase (down regulation), in a way that favors accumulation of higher PpIX levels inside the tumor cells' mitochondria^[24]. The ultimate consequence of elevated PpIX levels following CPBN pretreatment, is a significant increase in tumor cell death after PDT. This is due not only to higher PpIX concentrations within individual cells, but also to a more homogeneous distribution of high PpIX throughout the tumor [Figure 1C]. Following PDT, the loss of tumor cells through apoptosis was demonstrated via TUNEL and hematoxylin and eosin staining; thus, apoptosis clearly contributes to better outcomes such as retardation of tumor growth in the CPBN-PDT treatment group. Our data regarding inhibitory effects of the CPBN-PDT regimen upon metastases are particularly exciting. Although our sample sizes were relatively small and the data should be considered somewhat preliminary, the CPBN-PDT combination appears to be more effective at preventing metastatic spread than either CPBN or PDT alone [Figures 4 and 5].

The clinical implication of this study is the possibility that a new combination approach might bring PDT closer to the forefront of options available for management of BCA. Mainline treatment options available for BCA today include RT, surgery, chemotherapy, biological therapy (targeted agents), and hormonal therapy. As approaches to BCA disease management have evolved, the focus has shifted toward breast preservation, placing less emphasis on surgical and ablative approaches. In this setting, PDT, represents a promising treatment and management strategy for the following reasons: (1) Unlike RT, PDT does not cause fibrosis and scarring; (2) PDT can be repeated many times since it targets mitochondria rather than DNA, and thereby poses minimal risk for inducing mutations and secondary tumors; (3) PDT has already been successfully tried as a means to control recurrent BCA, especially for recurrences on the chest wall (which are extremely resistant to chemotherapy for unknown reasons). Thus, a recent clinical trial from China used ALA-mediated PDT in combination with RT for BCA metastases of the chest wall, and showed that the alternating use of PDT and RT improved the complete response rate, and reduced the time to clearance, when compared to RT alone^[19]. Increased use of PDT as a tissue-sparing adjunct for RT, would reduce the amount of radiation-induced fibrosis and vascular damage (scarring, ulceration, dermatitis) suffered by BCA patients, thereby representing a meaningful advance in clinical oncology; (4) it might be possible to boost the efficacy of PDT, by using neoadjuvant CPBN, to the extent that CPBN-PDT becomes useful as a monotherapy. At the very least, CPBN-enhanced PDT would be more effective as an RT-sparing approach when used together with RT; (5) future clinical translation of a CPBN-PDT approach is likely to be relatively easy, since CPBN (trade name Xeloda) is already a well-established, FDA-approved agent for the treatment of metastatic BCA.

In conclusion, based on our previous work showing that a combination of 5-FU given prior to PDT, leads to enhanced ALA-mediated PpIX levels and greater tumor cell death following PDT in several different epithelial cancers, we hypothesized here that CPBN might be a useful alternative to 5-FU as a neoadjuvant with PDT for BCA. Because 5-FU might be quite toxic at the high systemic levels required to modulate PpIX levels in BCA tumor, we reasoned that CPBN, a precursor to 5-FU, might serve as a safer yet equally effective alternative. In this study, we compared the responses of 4T1 tumors when treated with either conventional ALA-PDT, or with ALA-PDT preceded by oral CPBN. Our results revealed the following major findings: (1) CPBN-enhanced PDT can be used to significantly increase the accumulation of PpIX in murine breast tumors, and therefore represents a non-toxic alternative to 5-FU; (2) the pretreatment of 4T1 tumors with CPBN causes increased differentiation and decreased proliferation; (3) CPBN-enhanced PDT improves photodynamic killing of the breast tumor cells; (4) a combination regimen using CPBN and PDT significantly reduces distant metastases in the 4T1 tumor model. In summary, this treatment combination has the potential to be an effective therapy for BCA metastases, and potentially for other types of cancer. A more extensive version of this preclinical study would be immensely exciting and provide an additional rationale for designing a clinical trial based upon this concept.

DECLARATIONS

Acknowledgments

We thank Dr. Tayyaba Hasan (Massachusetts General Hospital) and Dr. Brian Pogue (Dartmouth Medical Center) for their longstanding collaborations with us through an NIH Program Project that they co-direct.

Abstract

Retrograde trafficking is a well-regulated, multi-component pathway that can result in endosomal trafficking to the trans-Golgi network, the perinuclear space, or the nucleus. Either clathrin or the retromer complex can travel with proteins endocytosed from the plasma membrane, guided by Rabs (including 5, 6, 7, 9, 22A), interacting with a host of sorting nexin proteins, and fusing with Golgi-specific anchors to allow transport of activated receptor tyrosine kinases to a potential end within the nucleus. Amplification in these constituents is common in cancer, leading to increased retrotranslocation and a reduction in degradation of receptor tyrosine kinases, an event highly associated with cancer metastasis. Here, we review the role of retrograde trafficking in altering transmembrane receptor localization and activity and the relationship to metastasis, focusing on all four members of the ErbB family, with comparison to other receptor tyrosine kinases including the insulin receptor and fibroblast growth factor receptor, as well as other transmembrane proteins dysregulated in metastasis. By examining how these receptors are being alternatively trafficked and the cancer-associated events resulting from this process, we hope to identify novel therapeutic targets.

Keywords: Retrograde trafficking, receptor tyrosine kinase, metastasis, nuclear receptor

INTRODUCTION

Retrograde transport is a process that involves secretory trafficking pathways from endosomes to the trans-Golgi network (TGN), the Golgi to the endoplasmic reticulum (ER), and within the perinuclear space, designed to maintain a steady-state localization of proteins^[1-4]. Upon internalization of a receptor, toxin, or other constituent subject to intracellular trafficking, cargo is transported to the early endosomes. There, cargo can be recycled to the plasma membrane (with or without passing through the recycling endosome), transferred to a late endosome en route to the lysosome for degradation, or subject to retrotranslocation to the trans-Golgi^[5]. Within the Golgi proteins can undergo post-translational modifications, be distributed to their appropriate cellular localization (e.g., polarized membrane), or sent to the ER for re-folding or ER-assisted degradation (ERAD). In this review, we focus on retrograde trafficking, not for the purposes of protein homeostasis, but rather examining how activated receptor tyrosine kinases are trafficked towards the nucleus upon internalization, where a host of signal transduction, DNA binding, and transcription result in metastatic events. In multiple kinase receptor families, including the ErbB family, this alternative trafficking results in endosomally-captured active receptors in the perinuclear space and nucleus. This trend is not specific to solely receptor tyrosine kinases, as we also discuss the retrotranslocation of other transmembrane proteins, such as the interleukin-2 receptor (ILR2) and the transforming growth factor β (TGF- β) receptor. In addition to perinuclear localization, retrotranslocation is frequently associated with the upregulation and constitutive activation of the phosphatidylinositol-3-OH kinase (PI3K)/protein kinase B (AKT) pathways, known drivers of cancer metastasis. Taken together, we present the concept that retrotranslocation of activated proteins, particularly receptor tyrosine kinases, augments AKT signaling and increases nuclear transcription, resulting in cancer metastasis.

MEDIATORS OF RETROTRANSLOCATION

Internalization

Internalization of cargo, the first conserved step of retrograde trafficking (receptor tyrosine kinases require activation, toxins do not) occurs in two primary formats - clathrin-mediated endocytosis (CME) or retromer-assisted. Toxins (such as shiga, ricin, or cholera) and many receptor tyrosine kinases are subject to retrotranslocation from the early endosome in clathrin-coated endosomes, while transmembrane receptors such as wntless, β -secretase (BACE1), and TGN38 interact with the retromer complex from the early endosome^[6-11]. Trafficking constituents such as mannose 6 phosphate receptor and Vsp10 are directed from late endosomes via the retromer complex^[12-14].

CME occurs when clathrin triskelions form a bilayered coat of polyhedral lattices surrounding an inner coat of clathrin adaptors. Adaptors are then responsible for interacting with the cytoplasmic domains of membrane-bound receptors, and in some instances, even appear to promote the binding of clathrin directly to the receptor^[15]. Clathrin can interact not only with the cytoplasmic domain of receptors, but also with post-translational modifications, and at the interface between endosomes and the TGN^[3,16]. It has been demonstrated that clathrin is frequently required for retrograde trafficking, both for endogenous cargo and plasma-membrane-localized proteins^[3,17].

The retromer

In contrast to clathrin-mediated retrotranslocation, proteins can also be trafficked via the retromer complex. The retromer is a three-protein complex consisting of Vsp26, 29, and 35, capable of binding the cytoplasmic domain of transmembrane proteins located in endosomes without interacting with clathrin. Once bound, the retromer interacts with a dimer of sorting nexin (SNX) family members (either SNX1/2 and SNX5/6) to induce membrane curvature and direct retrograde trafficking away from lysosomal degradation^[1,18]. This trimer interacts with GTPases; Rab5 when interacting with the early endosome or Rab7 with the late endosome^[2]. SNX proteins directly interact with the membrane, with a Bis/amphiphysin/Rvs domain to sense

and stabilize membrane curvature and a PX domain capable of interacting with phosphoinositides (PtdIns) to determine the localization of early endosomes^[18-20]. Alteration of SNX proteins can directly affect receptor tyrosine kinase activity, as loss of SNX1 activity is correlated to a reduction in lysosomal degradation of epidermal growth factor receptor (EGFR)^[21-23].

Rab GTPases and retrotranslocation

Whether cargo enters the system via CME or SNXs, it will be found associated with Rab GTPases. The Rab family of proteins - highly specialized in location and function, are frequently amplified but not mutated in metastatic cancers, leading to increased availability of retrograde trafficking vesicle fusion components, thereby promoting unabrogated receptor signal transduction and uninhibited nuclear colocalization^[24-27].

Rab proteins are GTPases involved in vesicular transport, providing membrane identity and tethering vesicles prior to fusion^[26,28]. They are capable of interacting with other coat components, motor proteins including kinesins and myosins, and soluble *N*-ethylmaleimide-sensitive factor attachment protein receptors (SNAREs)^[26]. Despite strong homology among the family members, each Rab confers a unique function to the vesicles they mediate in response to specific activators^[29]. Two Rabs in particular are known mediators of retrotranslocation: Rab22A which acts in early endosome-TGN trafficking, and Rab6A which is involved in Golgi-ER transport.

Rab22A is involved in clathrin-independent endocytosis, associating with both early and late endosomes, but not lysosomes. When bound to GTP and active, Rab22A is capable of binding to early endosome antigen 1 (EEA1; a marker unique to the endosomal sorting complex where most transmembrane receptors pass through during endocytosis), directing the activator for Rab5 to promote early endosome fusion, a necessary step in retrotranslocation^[30]. Rab22A expression is increased in lung, liver, ovarian, renal cell carcinoma, and melanoma^[30,31]. Rab22A is also commonly overexpressed in breast cancer and associated with decreased patient survival. A HIF1 α -dependent Rab, Rab22A is responsible for generating hypoxia-induced vesicles, that when present promote breast cancer cell invasion through cytoskeletal alterations^[32]. Using miRNAs to suppress the expression of Rab22A, studies have demonstrated that miR-373 can inhibit ovarian cancer, miR-203 inhibits osteosarcoma, and miR-204 inhibits renal cell carcinomas, all in a Rab22A-dependent manner^[31,33,34].

Rab6A is a GTPase associated with highly dynamic vesicles subject to retrograde transport from the Golgi to the ER^[35]. Part of the recycling endocytic pathway, Rab6A is known to function within the cis- and trans-Golgi, involved in both intra-Golgi and coat protein complex-1 (COP-1)-mediated Golgi-ER transport^[36-38]. Frequently dysregulated and associated with poor prognosis in cancer, it also presents with increased expression in human epidermal growth factor 2 (HER2+; ErbB2) breast cancer patients^[35,39].

One of the primary functions of the Golgi is to aid in post-translational modifications (such as glycosylation) of proteins, particularly for activation of receptor tyrosine kinases, which allows for ligand binding, receptor trafficking, and internalization^[40]. As previously discussed, a key element of retrotranslocation is the ability of vesicles to fuse with the TGN, instead of trafficking for lysosomal degradation. GOLPH3, a resident Golgi protein, localizes to the TGN and can directly interact with the retromer complex through Vsp35. Responsible for driving cell proliferation, tumor development, and anchorage independent growth both *in vitro* and *in vivo*, GOLPH3 is an oncogene amplified in more than 30 percent of lung, ovarian, and breast cancer cases (as high as 56 percent of lung cancers). Previously demonstrated in yeast that the retromer complex is involved in mammalian target of rapamycin (mTOR) signaling, high expression levels of mTOR have been similarly observed in GOLPH3-amplified human tumor tissues, resulting in increased pAKT activity^[40]. Not only is increased pAKT associated with high metastatic potential in breast cancers, but mutations in an anchor protein such as GOLPH3 could result in endosomal retention of receptors by inhibiting their transition out of endosomes, leading to prolonged signal transduction and metastasis^[41,42].

An event frequently observed in cancers such as breast, pancreatic, and lung is the localization of activated receptor tyrosine kinases in the perinuclear space^[43-45]. While not all of these receptors have been shown to pass through the Golgi, they do appear to be subject to retrotranslocation as many of them are found in the nucleus, including fibroblast growth factor receptor (FGFR), members of the ErbB family, and TGF- β receptor, all of which will be further discussed below^[41,46,47].

Here, we explore a range of transmembrane receptors associated with cancer and metastasis, examining their endogenous trafficking pathways, conditions in which this trafficking may be altered, and the relationship between retrotranslocation, nuclear localization, and metastasis.

INSULIN RECEPTOR

The insulin receptor (InsR) is a receptor tyrosine kinase known to traffic to the perinuclear space (rather than the TGN) and colocalize with SNARE proteins through a targeting motif in the carboxy terminus^[48]. This perinuclear colocalization occurs in a subset of storage vesicles near the Golgi, driven by the high rates of intravesicular cycling associated with InsR, as only 2-5 percent of the receptor is maintained at the cell surface^[49,50]. Intracellular InsR promotes the constitutive activation of AKT, resulting in glucose transporter 4 translocation, enhanced anchorage-independent growth, and altered acinar structure formation^[50-52].

FGFR

FGFR is a receptor tyrosine kinase highly involved in epithelial to mesenchymal transition (EMT) and tumorigenesis, promoting signal transduction through mitogen-activated protein kinase (MAPK) and β -catenin activity^[53]. Stimulation with ligand FGF1 results in receptor retention in Rab5-positive endosomes in the perinuclear space (undetermined if in the Golgi apparatus) and promotes trafficking to the nucleus, an event modulated by importin- β ^[46,54]. When bound to the ligand FGF2, FGFR is capable of inducing c-Jun and cyclin D1 mRNA expression by acting as a transcription factor at the FGF2 promoter, an event similar to that seen in EGFR^[54-56]. Nuclear FGFR is highly associated with AKT-driven breast cancer metastasis to the lung and pancreatic cancer cell invasion^[57,58]. Importantly, neither the FGF ligands nor FGFR contain a canonical nuclear localization sequence (NLS)^[55], indicating that the nuclear localization is a result of retrotranslocation driving activated receptors from endosomes in the perinuclear space toward the nucleus.

ERBB RECEPTORS

EGFR

ErbB1, also known as HER1 or EGFR is a single pass transmembrane receptor tyrosine kinase subject to significant post-translational modifications, which affect both its activation and trafficking. Upon binding a ligand, EGFR is subject to homo/heterodimerization, transphosphorylation, and is primarily trafficked to the lysosome^[59,60]. It is also capable of retrotranslocation, recycling, and other trafficking pathways, all of which are highly dependent on the localization of EGFR within the cell and additional signal transduction pathways activated in the cell^[61-63].

EGFR can bind a range of ligands, including epidermal growth factor (EGF), TGF- α , heparin-bound-EGF (HB-EGF), β -cellulin (BTC), epiregulin (EPR), and amphiregulin (AR). Upon binding a ligand, ErbB receptors dimerize and are subject to internalization and trafficking. Ligand binding triggers membrane invagination within at least 30 s, a transient process that resets within approximately 15 min after exposure. All ligands promote the transport of EGFR from the plasma membrane to EEA1-positive endosomes, though AR is slightly less efficient at this^[62,64]. EGF, HB-EGF, and BTC promote EGFR trafficking to the lysosome for degradation, while TGF- α and EPR binding primarily promote EGFR recycling^[62]. EGFR-EGF binding promotes activation of multiple signaling pathways including MAPK, PI3K, phospholipase C (PLC γ), and AKT, leading to a host of potentially oncogenic activities when left unregulated. EGFR has been implicated

in organ morphogenesis, maintenance and repair pathways, tumor progression, and metastasis through upregulated EGFR signaling^[65]. EGFR signaling is potentiated by phosphorylation of tyrosines found in the cytoplasmic domain, whose activation is determined by ligand and dimerization partner. Phosphorylated tyrosines act as docking sites for many proteins and interactors, such as Src homology 2 or phosphotyrosine binding domain-containing proteins, including growth factor receptor-bound protein 2, Src-homology and collagen, PLC γ , PI3K subunit p85, GTPase activating protein, Cbl, and adaptor protein-2 (AP-2). EGFR phosphorylation remains active in endosomal vesicles, where EGFR is hyperphosphorylated, allowing for continued signal transduction^[66-70]. Signaling through PLC has been shown to be preferentially activated when at the cell surface, while MAPK signaling continues to occur while in intracellular vesicles^[71].

PI3K signaling is also preferentially activated in endosomes, as Vieira *et al.*^[66] demonstrated PI3K activation is unnecessary for internalization and instead plays a role in endosomal trafficking of EGFR. Similarly, Garay *et al.*^[67] indicated preferential AKT signaling when EGFR is internalized in clathrin-coated vesicles rather than at the plasma membrane through siRNA against clathrin.

Vesicular EGFR alternatively trafficked away from the lysosome (demonstrated with a SNX1-directed siRNA) results in augmented AKT signaling in non-small-cell lung cancer^[72], and we have previously demonstrated that endosomally retained and mislocalized EGFR is capable of upregulating AKT activity, resulting in increased metastatic potential, as well increased nuclear localization of transcription factor TAZ (transcription co-activator with a PDZ-binding domain), an event associated with cancer stem cells^[42,73]. AKT is involved in driving EMT through disassembly of cell-cell junctions and upregulation of SNAIL, confirmed by loss of EMT phenotype in prostate cancer cells when treated with AKT inhibitors^[74]. AKT1 kinase activity and AKT2 overexpression are associated with ovarian, breast, and thyroid cancers - three cancer types commonly hallmarked by high EGFR expression^[75-81]. While AKT activation is strongly associated with the inhibition of apoptosis, at least one study has found endocytosed EGFR that does not traffic to the lysosome correlates with an induction of apoptosis^[82]. More work to determine the mechanisms of these events will be required to fully understand these processes.

Though EGFR is primarily targeted to the lysosome to prevent constitutively activated signal transduction, when stimulated by EGF, it has been shown that a fraction of EGFR will be transported to the Golgi and the ER, carried via COP-I vesicles en route to trafficking to the nucleus^[83,84]. Studies have shown that after 20 min of EGF stimulation, 10 percent of EGFR colocalizes to the Golgi and remains phosphorylated, even in the presence of protein synthesis inhibitors, indicating that the retrograde trafficking observed is not due to post-translational modifications^[85].

Upon translocation to the Golgi, the amino-terminal domain of EGFR sits within the lumen of the Golgi, leaving the carboxy-terminal domain exposed in the cytoplasm to interact with importin β -1 via the NLS^[84]. All ErbB family members can enter the nucleus, with full-length, phosphorylated EGFR entering via the Sec61 translocon and interacting with importin α - β 1 complexes^[43,86,87]. EGFR is capable of transactivational activity, but lacks a DNA-binding domain, providing a need for transcription co-factors^[88]. Upon entry into the nucleus, EGFR can associate with transcription co-factors such as signal transducer and activator of transcription 3 (STAT3) to co-regulate inducible nitric oxide synthase expression and E2F1 to promote cell cycle progression, as well as the proliferation marker Ki-67^[88-90]. Nuclear EGFR interactions with proliferating cell nuclear antigen (PCNA) also promote cell cycle progression, while increasing PCNA phosphorylation and the DNA damage response^[91,92]. Nuclear EGFR has been found to be associated with more than 40 percent of breast cancer tumors and 35 percent of esophageal squamous cell cancers, correlated to shorter overall survival in patients and increased metastatic potential, respectively^[93,94]. Nuclear EGFR also contributes to cetuximab and gefitinib resistance, likely due to the restricted access of the therapeutics to the target protein^[41,85]. Finally, the role of retrotranslocated EGFR as a transcriptional co-factor further exemplifies its kinase-independent function, highlighting the need for therapeutically targeting this process.

We have previously demonstrated the localization of EGFR in the nucleus when interacting with the oncogenic adaptor glycoprotein mucin1 (MUC1). Notably, when in the presence of MUC1, EGFR is able to bind to chromatin and act as a co-transcriptional activator by colocalizing to the transcriptional start sites with phosphorylated RNA polymerase II^[56]. EGFR has also been shown to interact with cyclin D1 in the nucleus and cyclin D1 expression is increased in EGFR-dependent mouse models and breast cancers^[56,95-97]. Also seen in MUC1-expressing, EGFR-driven breast cancer mouse models were high rates of lung metastases (96 percent showing distinct pulmonary foci and the remaining 4 percent unspecified adenocarcinomas). Alternatively, in the absence of MUC1 and nuclear EGFR, no lung metastases were observed. Taken together, nuclear EGFR, particularly in the presence of MUC1, promotes EGFR transcriptional activity, increases cyclin D1 expression, and drives metastasis.

To elucidate the mechanism by which MUC1 promotes nuclear localization of EGFR, we have also demonstrated MUC1 and EGFR colocalize in EEA1-positive endosomes that are retained in the perinuclear space and actively are trafficked away from the lysosome. This allows for signal transduction to remain unattenuated, resulting in a MUC1-dependent increase in breast cancer cell migration rates, an effect completely eliminated by the introduction of a retrograde trafficking inhibitor, Retro-2. Inhibiting retrotranslocation of EGFR, even in the presence of MUC1, results in a reduced migratory phenotype through cytoskeletal rearrangement and reduction of focal adhesion kinase (FAK)-positive structures^[41].

EGFR is a pleiotropic signal transducer with a highly conserved activation and endocytosis pathway. However, during cancer, a high correlation is observed between retrograde trafficking and nuclear localization, resulting in increased metastatic events, both *in vitro* and *in vivo*.

ErbB2 receptor

ErbB2 (HER2, Neu2) is another member of the ErbB family, well-studied for its role in driving cancer through increased cell proliferation, resistance to apoptosis, and migration. A transmembrane protein found on the basolateral surface of cells, ErbB2 lacks the ability to bind ligands, therefore relying on other receptors for dimerization. While EGFR is primarily driven to the lysosome as part of its endogenous trafficking, ErbB2 is resistant to downregulation of itself or its heterodimerization partner, instead subject to rapid recycling through CME^[98].

ErbB2 activation is dependent upon heterodimerization with another ErbB receptor, as it lacks a ligand-binding domain to allow for self-activation. It can also become active through extensive overexpression, which promotes the formation of ErbB2 heterodimers responsible for enhancing the signal transduction associated with their dimer partner, an event seen in colon, gastric, prostate, and breast cancers^[59,61,99]. ErbB2 overexpression in breast cancer is so well-characterized that it is responsible for an entire classification: HER2+; studies have shown it is amplified in more than 20 percent of breast cancer tumors, making it a strong predictor of survival and time to relapse^[100,101].

Upregulation of ErbB2 is known to promote lymph node metastasis, as well as significantly increase metastasis rates to the brain, liver, and lung^[102]. Like all members of the ErbB family, ErbB2 can enter the nucleus, where it can interact with promoters, including matrix metalloproteinase 16, p53-related protein kinase, and cyclooxygenase-2 (COX-2). The COX-2 gene is known to drive metastasis in cancer cells and co-expression of these two proteins has been reported in colon, cholangiocarcinoma, and breast cancers^[103]. Exploring further, Edwards *et al.*^[104] reported that prostate tumors with increased HER2 copy number also had increased levels of COX-2 expression while Thorat *et al.*^[105] and Glynn *et al.*^[106] demonstrated that COX-2 levels are highest (if not statistically significant) in HER2+ breast cancer (vs. luminal A/B and triple negative breast cancers) and that positive COX-2 expression in HER2+ patients is directly correlated to increased phosphorylation of AKT and poor survival outcomes^[104-106].

ErbB2 overexpression is seen in a variety of cancers and is strongly associated with metastatic events and inhibited degradation of activated receptors. Lacking intrinsic ability to self-phosphorylate, ErbB2 receptors bind with other members of the ErbB family to induce activation and potentiate signal transduction, frequently resulting in increased COX-2 and AKT activity due to nuclear localization, events commonly seen in metastasis.

ErbB3 receptor

ErbB3 is a catalytically inhibited member of the ErbB family, bearing a mutated tyrosine kinase domain and relying on heterodimerization partners for phosphorylation. As such, ErbB3 frequently presents with decreased levels of ubiquitination in comparison to EGFR, emphasizing the inefficiency of ErbB3 to be targeted to the lysosome^[107]. Heterodimers between ErbB2 and ErbB3 lead to strong activation of the MAPK and PI3K/AKT pathways, promoting survival and proliferation by ErbB2 and ErbB3, respectively^[108-110]. Through these signaling pathways ErbB3 activity is associated with loss of cellular differentiation and increased expression of MUC1 in carcinomas, as well as driving proliferation in ErbB2-positive breast cancer cells lines^[108,111]. ErbB3 is subject to significantly slower rates of endocytosis than EGF-bound EGFR due to the anti-internalization regions within the C-terminus, allowing for longer periods of receptor activation (when in a heterodimer)^[71,112]. This delayed trafficking results in perinuclear accumulation, thereby allowing nuclear localization via retrotranslocation^[113]. Once in the nucleus, ErbB3 presents in an activated, uncleaved format, capable of associating with the Cyclin D1 promoter to drive cell proliferation, similar to the mechanism seen in EGFR^[54,56,114]. Clinical data has shown in prostate cancer, nuclear localization of ErbB3 present in 100 percent of hormone-refractory samples and 40 percent of hormone-sensitive samples, in contrast to the negligible amount seen in normal prostate tissue, directly associated with disease progression risks^[115]. Nuclear ErbB3 also presents at higher frequency in prostate cancer metastases (particularly bone) than in primary tumor sites^[116], indicating that retrotranslocated ErbB3 is likely involved in the metastasis of prostate cancers.

ErbB4 receptor

The fourth and final member of the ErbB family, ErbB4 maintains homology to ErbB1- capable of binding ligands (EPR, HB-EGF, BTC, and neuregulins 1-4) and a tyrosine kinase domain capable of catalytic activation^[112,117]. Once bound to a ligand, ErbB4 promotes signal transduction through a host of pathways, including PLC γ , PI3K, and STAT^[118].

Post-activation, ErbB4 is subject to dual-protease cleavage in both the extracellular domain and the transmembrane domain, resulting in an active, cleaved cytoplasmic domain capable of nuclear translocation (upon binding to neuregulin). ErbB4 activity is highly associated with poor prognosis and increased metastasis in Ewing sarcoma, activating PI3K-AKT and altering FAKs to drive invasion^[119]. Expression of ErbB4 also increases in colorectal cancer as disease stage progresses, indicating a potential role in driving cancer progression, though its expression is associated with improved prognosis in estrogen-receptor positive breast cancers^[120,121]. Highly enriched in neuronal plaques of patients with Alzheimer disease, nuclear localization can lead to transcriptional activation of genes that regulate neurodegeneration^[118]. To achieve nuclear localization, it is possible that active, cleaved ErbB4 reaches the Sec61 translocon in the ER and is processed while avoiding ERAD-ubiquitin-associated proteolysis, in a mechanism similar to EGFR nuclear translocation^[86,118].

In addition to the tyrosine kinase receptors described above, at least two non-tyrosine kinase receptors, ILR2 and TGF- β receptor, also undergo retrotranslocation in cancer.

ILR2

Found in fibroblasts, epithelial, and neuronal cells, ILR2, upon ligand binding is internalized and targeted for degradation through acidification, similar to EGFR and the transferrin receptor^[59,122,123]. ILR2 has also

demonstrated an ability to undergo endocytosis in the absence of clathrin or AP-2 at relatively uninhibited rates, likely due to the nature of the receptor to promote T-cell proliferation - a system that would benefit from redundancies^[122].

When undergoing non-CME, ILR2 is internalized through detergent-resistant membrane domains, similar to the mechanism employed by cholera toxin^[124,125]. Upon entry into the cell, vesicles containing ILR2 are found in the glycolipid rich areas of the cell, particularly in the perinuclear spaces and near the organelle responsible for glycolipid modification, the Golgi^[124]. Retention of the receptor in the perinuclear space is common in cancer, as ILR2 expression can be a predictor of patient survival and is significantly reduced at cell surface levels in advanced ovarian cancers^[126,127].

TGF- β RECEPTOR

TGF- β is a secreted ligand involved in modulating cellular growth and arrest, differentiation, and immune responses, capable of binding to type I or type II single-pass transmembrane receptors^[47,128-130]. Unlike other receptors presented in this review, TGF- β receptor can be internalized with or without ligand binding, resulting in either CME-assisted recycling or non-CME degradation^[47].

When subject to CME, TGF- β receptor is sorted into EEA1-positive vesicles where it acts to activate SMAD2 and potentiate TGF- β signal transduction. Activated receptors localize to the perinuclear space and remain in endosomes, a phenotype also seen with the transferrin receptor and which we have previously shown to occur with EGFR in breast cancer^[41,47]. Alternatively, TGF- β receptor can also be sorted via lipid rafts to interact with SMAD7. In either scenario, SMAD signaling nuclear translocation require internalization of TGF- β receptor^[131,132].

Taken together, a range of transmembrane proteins are subject to retrotranslocation. While some localize to the perinuclear space and can be internalized into the nucleus, such as InsR, FGFR, TGF- β receptor, and ILR2, others can enter the Golgi, such as ErbB family members, and remain active and promote metastasis. ErbB receptors also localize to the nucleus, resulting in transcriptional activity of cancer genes and pathways.

THERAPEUTIC TARGETING OF RETROTRANSLOCATION

Given the metastatic and oncogenic activity associated with nuclear localization of activated receptor tyrosine kinases driven by retrograde trafficking, it is important to explore potential mechanisms by which retrotranslocation could be inhibited as a therapeutic target.

It has been demonstrated that introduction of retrograde inhibitors can drastically reduce the cytotoxic effects of toxins like ricin, cholera, or shiga, which rely on retrograde trafficking to be distributed throughout cells. A compound designated Retro-2 works to inhibit toxin trafficking from the early endosome to the trans-Golgi interface, actively protecting cells from ricin toxicity 2-3 fold *in vitro* and almost 50 percent of mice from airborne exposure to the ricin toxin (in comparison to the 11 percent that survived in the absence of retrograde inhibition)^[133]. Retro-2 does not inhibit plasma membrane budding or endosome formation; rather it inhibits transport of endosomes to the TGN without affecting Golgi morphology (or that of EEA1 or Rab11). Endocytic degradation and recycling pathways also remain unaltered. However, SNARE proteins syntaxin 5 and 6 were subject to alterations in localization, indicating Retro-2 may work to inhibit retromer trafficking of endosomes or inhibit interactions of endosomes with the Golgi^[133].

We have previously demonstrated the importance of retrograde trafficking in promoting a migratory phenotype in association with the presence of MUC1^[41]. Treatment of breast cancer cells *in vitro* with the retrograde trafficking inhibitor Retro-2 led to the inhibition of MUC1-driven migration and re-introduction

of EGFR trafficking to the lysosome for degradation. Given this, a potential therapeutic option may be to inhibit retrograde trafficking of EGFR, possibly through the use of Retro-2, though no studies have yet examined the effects in humans.

Alternative to inhibiting retrograde trafficking, current research has demonstrated an effort to capture the retrotranslocation mechanisms of toxins and repurpose them for drug delivery. Using the non-toxic subunit B of Shiga-like toxin, various attempts at conjugating therapeutics, incorporating nanoparticles, or developing fusion proteins have been attempted (reviewed in Luginbuehl *et al.*^[134]).

Should inhibition of retrograde trafficking prove untenable in patients, a secondary approach to inhibition of the oncogenic activity driven by nuclear receptor tyrosine kinases would target receptors within the nucleus. Nuclear EGFR has been shown to associate with promoter regions of a variety of proteins, including cyclin D1, activated STAT3, E2F1, DNA-dependent protein kinase, and other nuclear targets, while nuclear ErbB2 is capable of interacting with COX-2, all resulting in increases in tumorigenesis, proliferation, metastasis, chemoresistance, and radioresistance^[106,135]. ErbB2-EEA1 complexes are capable of nuclear transport, and given the high affinity of EGFR-MUC1 complexes in EEA1 positive vesicles in the perinuclear space of cells after extended exposure to EGF ligand, it is feasible that EGFR endosomal machinery is promoting nuclear localization of EGFR in a similar mechanism^[41,87,136].

Radiation treatment of cells is known to drive EGFR to the nucleus as part of the DNA-repair pathway mechanism, and studies have shown that treatment of irradiated cells with cetuximab will inhibit EGFR trafficking to the nucleus in both lung carcinoma and breast cancer cell lines^[137]. Radiation treatment, along with neuregulin stimulation or trastuzumab will also promote retrograde trafficking of ErbB2-ErbB3 dimers to the nucleus, visible by super-resolution confocal microscopy as demonstrated by Pilarczyk *et al.*^[138]. Nuclear import might also be inhibited by targeting the importin- β 1 molecule through treatment with small molecule inhibitors such as Karyostatin1A to disrupt importin interactions with the GTPase Ran^[139].

Treatment of cells with 1,25-dihydroxyvitamin D was found to prevent EGFR from entering the nucleus by promoting intracellular localization of inactive, unphosphorylated EGFR, even if bound to a ligand, to early endosomes. By doing so, 1,25(OH)₂D₃ downregulated the oncogenic activity associated with nuclear EGFR without targeting vesicles to the lysosome^[140]. This treatment could feasibly be used to target two processes associated with cancer progression - inhibit nuclear targeting of EGFR and convert endosomally localized EGFR to an inert state, essentially nullifying the need for lysosomal degradation.

CONCLUSION

Retrograde trafficking of transmembrane proteins, with an emphasis on receptor tyrosine kinases, results in alternatively trafficked activated receptors accumulating in the perinuclear space of cells. The primary effect of these undegraded, endosomally-retained, actively signaling receptors is the unabrogated transduction of the PI3K/AKT pathway - resulting in upregulation of cancer metastasis. Not only that, but for those receptors that transit through the Golgi or come in sufficient proximity to a nuclear pore, active receptors can now act as transcriptional activators to a host of oncogenic activities. Seen in cancers ranging from Ewing sarcoma to breast to prostate and more, it is clear this ubiquitous mechanism of translocation is responsible for trafficking receptors to the wrong place at the wrong time, driving cancer metastasis. Future therapeutics may choose to inhibit retrograde trafficking to prevent mislocalization or focus instead on targeting receptors after their localization has already been altered. Given current treatment plans for many cancers now involve adjuvant therapies, the most efficient method for overcoming metastasis-promoting retrograde trafficking may involve some combination of both.

DECLARATIONS

Acknowledgments

We would like to thank Dr. Kel-Eton S and Dr. Odoonce Y for their insightful discussion and commentary.

Authors' contributions

Written and edited manuscript: Maisel SA, Schroeder J

Availability of data and materials

Not applicable.

Financial support and sponsorship

None.

Conflicts of interest

Both authors declared that there are no conflicts of interest.

Abstract

Breast cancer is a common malignancy among women. Due to the improvement of social awareness and advances in imaging technologies, significant achievements are obtained at its diagnosis and treatment each passing day. A 54-year-old, multiparous and postmenopausal woman, who presented with a palpable lymph node in the right supraclavicular region and a right adnexal mass but had no findings from the breast examination, is reported in this article. Following advanced assessment, metastatic carcinoma was identified in the lymph node biopsy and the adnexal mass. During the exploration for the primary origin, microinvasive breast cancer was diagnosed following mammographic imaging and an excisional biopsy from the right breast. Microinvasive breast cancer, which did present itself with clinical findings with metastases despite the lack of local findings, was discussed with the review of the literature.

Keywords: Microinvasive breast cancer, imaging, ovarian metastasis

INTRODUCTION

In the United States, one in every eight women has the risk to experience breast cancer in her lifetime. Breast cancer is one of the most common cancers and it is often stated as the second cause of cancer related

deaths among women^[1]. Microinvasive breast cancer makes 0.7%-2.4% of all cases, it is a rare subgroup of breast cancer. The term of “microinvasive breast cancer” was used by Logios in 1982. Later, the World Health Organization defined it as an invasive carcinoma of the breast with no invasive focus measuring more than 1 mm^[2]. The prognosis of microinvasive breast cancer is open for discussion, since it is rare and difficult to diagnose. Generally, it is known that their clinical behavior is between invasive carcinoma and carcinoma *in situ*. Lymph node metastasis, which is one of the most important prognostic factors of breast cancer, is rare among microinvasive breast cancers (0%-25%) and there is an expectation of better clinical course^[3]. On the other hand, although there are very few in the literature, there are reported cases of aggressively progressive microinvasive breast cancers that presented clinical findings with lymph node involvement and distant organ metastasis^[4].

In this article, we present a case of microinvasive breast cancer that presented clinical findings with supraclavicular lymph node involvement and ovarian metastasis without any findings from breast examination. We found it to be interesting, due to the rarity of such cases.

CASE REPORT

A 54-year-old patient (Gravida 4, parity 3, 3 years since menopause, gave birth to her last child 20 years ago) was visited due to the complaint of a palpable lymph node at the right supraclavicular region. Due to the finding of a metastatic carcinoma at the lymph node after thin needle aspiration biopsy, she was investigated with imaging and systemic examination in order to find the primary focus. Systemic examination only demonstrated a palpable lymph node, which was 2 cm × 3 cm in size, at the right supraclavicular region. No other abnormal clinical finding was detected. A solid, mobile mass was found at the right adnexal region during gynecologic examination. The mass was 6 cm × 7 cm in size. Pelvic ultrasonography of the left adnexa and the uterus was normal regarding the patient's age. The lesion, which seemed to be originating from the right ovary was measured to be 65 mm × 72 mm in size. No free abdominal fluid was present. Ultrasonography of the upper abdomen and the physical examination of the breast was normal. Cervical smear, endometrial sampling, endoscopy of the gastrointestinal system, routine biochemical tests and complete blood count resulted in the normal range.

Apart from elevated CA15-3 concentration (157 IU/mL) and erythrocyte sedimentation rate (72 mm per 30 min); no abnormal blood parameters were present. Bilateral mammography was reviewed as Breast Imaging Reporting and Data System - 4B for the right breast (possible malignant findings), and therefore excisional biopsy (surgical margin clear of disease) was performed. Following radiological examinations showed no residual lesions. Pathological examination resulted as: microinvasive breast carcinoma, nuclear grade II. Immunohistochemistry results were as follows: p63 (+) at myoepithelial cells, estrogen receptor (ER) (+) for about 5%-10% of the cells at the ductal carcinoma *in situ* (DCIS) focus, progesterone receptor (PR) (-) for the cells at the DCIS focus.

Positron emission tomography-computerized tomography (PET-CT) showed increased F-18 fluorodeoxyglucose (FDG) uptake at both supraclavicular lymph nodes, especially more prominent on the right cervical level. In addition, increased uptake of FDG was also present at the lymph nodes in thorax and abdomen. The mass lesion, whose margins were not distinguishable from the uterus, was located in the right adnexal region and showed increased F-18 FDG uptake. These radiological findings in the right adnexal region supported the diagnosis of primary gynecological malignancy.

The case was reviewed in the gynecological oncology council of our institution. The decision was to perform diagnostic laparotomy in order to confirm the primary focus. The patient underwent surgery. A firm, solid mass with lobulated margins and 6 cm × 7 cm in size was observed during laparotomy ([Figure 1](#): macroscopic appearance of the tumor located at the right adnexal region). The contralateral ovary

Figure 1. Macroscopic image of the tumor located in the right ovary

and genital structures, pelvic structures, organs of the upper abdomen were in normal appearance. Frozen examination of the mass from the right adnexal region was reported as malignant metastatic tumor. Due to this result staging surgery was performed.

The paraffin sections of the removed mass were examined by our pathology department and the diagnosis of metastatic carcinoma at the right ovary was confirmed (Figure 2: the microscopic image of the metastatic tumor located at the right ovary). The morphology of the metastatic tumor was reported as lobular carcinoma and it was concurrently examined with the histopathology of the previously removed excisional biopsy material from the right breast. After the examination, the ovarian mass was diagnosed as a metastasis of the primary breast cancer. The immunohistochemical findings at the ovarian tumor are as follows: ER positive, PR negative, Pax8 negative, Wilms' tumor 1 negative, gross cystic disease fluid protein-15 focal positive, GATA3 positive, epithelial membrane antigen positive, Ber-Ep4 positive; these findings supported the diagnosis for a malignant epithelial tumor but excluded a primary ovarian carcinoma. The lesion at the right breast, which appeared as a single focal lesion in imaging studies, was removed with clear margins. Therefore, no secondary surgery for local control was considered. After the abdominal surgery, the patient received the following chemotherapy treatments: 8 cycles of herceptin and docetaxel and subsequently 8 cycles of trastuzumab and pertuzumab. She undergoes examination every three months and has been disease - free for 12 months as this report is written.

DISCUSSION

At the present day, more patients are diagnosed with microinvasive breast cancer due to the broad usage of mammography. Most of the microinvasive breast cancer cases (80%) do not have palpable masses in the breast and are diagnosed with mammography^[2]. Nevertheless, microinvasive breast cancers constitute only a small part of invasive breast cancers (0.7%-2.4%) and confusion is still present about their prognosis^[1]. According to many studies, microinvasive breast cancers are reviewed in a spectrum between the early invasive breast cancer and *in situ* carcinoma of the breast, and excellent survival expectations are reported^[1-4]. However, in some cases, local and distant recurrences are reported during follow-up despite this high prognostic expectation^[5,6]. Involvement of axillary lymph nodes, which is a very important prognostic factor during the treatment and follow-up of breast cancers, is reported to be between 0 and 25 percent of microinvasive breast cancer cases^[3]. Involvement of axillary lymph nodes is crucial regarding local and

Figure 2. Microscopic image of the tumor H&E × 100

distant recurrences, as it is with invasive breast cancers. Expectation of five-year survival in microinvasive breast cancer is 95.2%-95.9% when there is axillary lymph node involvement; whereas the five-year survival rate is 100% for axillary lymph node-negative cases^[3-7]. Axillary lymph nodes were negative for tumors in our case.

In spite of the advancements in its diagnosis and treatment, breast cancer continues to be fatal. Because of the fact that it can spread both locally and distantly simultaneously, breast cancer is considered to be a systemic disease from the beginning.

Three point five to ten percent of the breast cancer cases present findings with distant metastasis at the moment of diagnosis^[8,9]. Microinvasive breast cancer presented clinical findings with supraclavicular lymphadenopathy and adnexal mass. Positive ER (which was focally 5%-10% positive in this case), negative PR and increased expression of human epidermal growth factor receptor 2 (HER2) may be the molecular features that are responsible for such aggressive spreading of the tumor^[10]. One to seventeen percent of all malignant ovarian tumors are metastatic. Breast, gastric and colon cancers are the most common cancers that metastasize to the ovary^[11]. Contrary to our case, 70% of the metastatic ovarian tumors are bilateral. Distinction of primary and metastatic tumor is essential for determining the treatment approach and prognosis. Tumors metastasizing to the ovary from non-genital organs are associated with poor prognosis. Five-year survival rate for primary ovarian cancer is 40%, whereas in case of metastasis from non-genital organs the rate becomes 12%-24%, and the mean survival is 15 months^[11,12]. Survival depends on the prognosis of the primary tumor and when the tumor presents findings with metastases before itself, the prognosis is poorer^[12].

Debulking surgery has a role in patients with metastatic ovarian tumors that originate from non-genital organs, however it is not established that which patients are going to benefit from this technique of surgery^[12,13]. Yet we consider it worthwhile, because it reduces the required amount of time for final diagnosis and the tumor burden prior to chemotherapy. The patient undergoes regular clinical controls and has been disease free for 12 months.

Concerning the diagnosis and management of primary ovarian tumors, serum CA 125 levels are among

important markers. Still, it is difficult to tell the same for metastatic tumors^[13,14]. Except elevated CA 15-3 levels, other tumor markers (CA 125, CA 19-9, carcino-embryonic antigen, alpha-fetoprotein) were in normal range in our case.

As patient history, laboratory findings and physical examination, radiological examination is also an important means while detecting the primary focus of the tumor. In addition to ultrasonography, mammography, magnetic resonance imaging and CT; PET-CT is also very helpful. Especially during the postmenopausal period, when the ovaries are non-functional, the diagnostic power of PET-CT is higher^[11]. Mammography manifested the findings for breast cancer rather clearly. The expectation for broad involvement of lymph nodes and presence of distant metastases was low at the stage of microinvasive breast cancer, therefore the possibility of the right ovarian mass being a second primary malignancy was considered. Although the imaging methods were very revealing regarding the extensiveness of the lesion, they were inadequate for the distinction between primary and metastatic tumor. Consequently, final diagnosis was established with laparotomy^[15]. Presence of an adnexal mass, while there is a diagnosis or possibility of breast cancer, should be evaluated carefully regarding increased risk of malignancy.

Distant organ metastasis is beyond expectation at the moment of diagnosis for microinvasive breast cancers. Nevertheless, ovarian metastasis should be kept in mind provided there is involvement of regional lymph nodes and the tumor is histologically lobular type^[8,9,16]. Despite the fact that it was not tested at our case, if the immunohistochemistry of the breast tumor is negative for hormone receptors and shows findings like increased expression of Ki-67 and HER2, it should be alarming for increased metastatic potential^[4,10,16].

Microinvasive breast cancers constitute a rare subgroup of invasive breast cancers. Since their histological features are better acknowledged and imaging technologies are more enhanced, more patients are diagnosed with the disease in recent years. While it presents a fair survival expectation, systemic spread and metastases may occur in very early phases of microinvasive breast cancers, when it is accompanied with regional lymph node involvement and poor prognostic immunohistochemical factors. Hence, testing for immunohistochemical and molecular markers may provide more information regarding the biology and behavior of this tumor^[10]. Metastases from non-genital organs to the ovary are associated with poor survival. Due to the expediting effect on the process of diagnosis and treatment, laparotomy and laparoscopy should be performed promptly as definitive methods. Multidisciplinary approach is the most important principle for the diagnosis and treatment of a malignancy that presents itself with metastases, also for the investigation of the primary focus.

DECLARATIONS

Authors' contributions

Wrote the manuscript: Kurt S, Timur HT

Provided data regarding the patient's treatment in the department of Obstetrics and Gynecology: Kurt S, Timur HT, Saatli HB

Provided information about the patient's treatment in the department of General Surgery: Sevinc AI

Provided the pathological findings and other information from the department of Pathology: Ulukus EÇ

Availability of data and materials

Not applicable.

Financial support and sponsorship

None.

Conflicts of interest

All authors declared that there are no conflicts of interest.

Ethical approval and consent to participate

The consent form was signed by the patient herself. We foresee no ethical issues regarding the publication of this case report.

Abstract

Postpartum involution is the process by which the lactating mammary gland returns to the pre-pregnant state after weaning. Expression of tumor-promotional collagen, upregulation of matrix metalloproteinases, infiltration of M2 macrophages, and remodeling of blood and lymphatic vasculature are all characteristics shared by the involuting mammary gland and breast tumor microenvironment. The tumor promotional nature of the involuting mammary gland is perhaps best evidenced by cases of postpartum breast cancer (PPBC), or those cases diagnosed within 10 years of most recent childbirth. Women with PPBC experience more aggressive disease and higher risk of metastasis than nulliparous patients and those diagnosed outside the postpartum window. Semaphorin 7a (SEMA7A), cyclooxygenase-2 (COX-2), and collagen are all expressed in the involuting mammary gland and, together, predict for decreased metastasis free survival in breast cancer. Studies investigating the role of these proteins in involution have been important for understanding their contributions to PPBC. Postpartum involution thus represents a valuable model for the identification of novel molecular drivers of PPBC and classical cancer hallmarks. In this review, we will highlight the similarities between involution and cancer in the mammary gland, and further define the contribution of SEMA7A/COX-2/collagen interplay to postpartum involution and breast tumor progression and metastasis.

Keywords: Postpartum involution, postpartum breast cancer, Semaphorin 7a, cyclooxygenase-2, collagen, metastasis

BREAST CANCER METASTASIS AND POSTPARTUM BREAST CANCER

In the United States, breast cancer remains the second leading cause of cancer related death in women, with the majority of these deaths resulting from metastatic disease. Breast cancer is a heterogeneous disease with five identified molecular sub-types: luminal-A, luminal-B, HER2-enriched, basal-like, and normal-like^[1]. Treatments for hormone receptor positive and HER2 amplified cases include targeted therapies that, while initially successful, often result in the development of resistance, thereby increasing the likelihood of metastasis^[2]. Breast cancers lacking estrogen receptor, progesterone receptor, and HER2 amplification are defined as triple negative breast cancers (TNBC) and account for 15%-20% of breast cancer diagnoses. Patients with TNBC not only have lower survival rates due to increased early metastasis, but also lack a targeted therapeutic option^[3,4]. This evidence underscores the necessity of novel models for the identification of molecular drivers of breast cancer progression, therapy resistance, and metastasis.

Multiple epidemiological studies highlight the effect of pregnancy on breast cancer risk. While first pregnancy at an early age confers a lifelong protective effect against breast cancer, all women who have given birth undergo a transient period of increased risk^[5-9]. Previously, women diagnosed within five years of most recent childbirth were found to be at higher risk for developing metastatic breast cancer than nulliparous women^[5-12], a risk that persists even after adjustments have been made for variability in hormonal receptor status, HER2 status, age, histological grade, tumor size, node status, and year of diagnosis^[10,13]. More recent results have revealed that the probability of metastasis is increased for women diagnosed with breast cancer between 0-5 and 5-10 years postpartum. Thus, we now define breast cancers diagnosed within 10 years of most recent childbirth as postpartum breast cancer (PPBC)^[10,13]. By this definition, PPBC accounts for over half of all breast cancers diagnosed in women under age 40 in two independent cohorts^[10,13]. Since patients with PPBC have significantly worse outcomes, regardless of numerous clinical parameters, it has been hypothesized that pro-tumorigenic changes in the breast tissue following pregnancy may persist for an extended period and accelerate PPBC progression. Consistent with this hypothesis, Asztalos *et al.*^[14] identified a breast cancer associated genetic signature in the normal breast tissue of parous women that persists for up to 10 years after childbirth. Further evidence of a postpartum tumorigenic signature is supported by multiple pre-clinical models, where implantation of tumor cells into rodent mammary glands after weaning facilitates tumor cell growth, invasion, and metastasis. Additional studies of the mammary gland after lactation have revealed that these phenotypes are driven, in part, by mammary and tumor specific increases in pro-inflammatory cyclooxygenase-2 (COX-2), fibrillar collagen, semaphorin 7a (SEMA7A), bone marrow derived stromal and macrophage populations, lymphangiogenesis, and circulating estrogens^[15-22]. In this review, we will explore some of the mechanisms by which post-lactational changes in the mammary gland facilitate breast cancer progression and metastasis, with a focus on the roles of collagen, COX-2, and SEMA7A in cell death, extracellular matrix (ECM) and vascular remodeling, and macrophage infiltration.

PRO-TUMORIGENIC ROLES OF INVOLUTION ASSOCIATED PROGRAMS

For a detailed review of the events that occur during embryonic and adult mammary gland development, see Macias and Hinck^[23]. Briefly, mammary gland development begins during embryogenesis where ectodermal placodes invade into the mammary mesenchyme to form a rudimentary ductal tree^[24]. This primitive structure persists until puberty where upregulation of growth hormone and estrogen coordinate ductal morphogenesis to form the extensive epithelial ductal network that fills the mammary fat pad. Mammary epithelial structures are bi-layered, meaning they consist of both luminal cells and basally restricted myoepithelial cells that contact the basement membrane^[25]. Full differentiation of the mammary

gland is not achieved until pregnancy, where progesterone and prolactin coordinate differentiation of the alveolar structures that are responsible for milk storage and secretion; in addition, continued branching morphogenesis occurs to prepare the gland for lactation^[23,26]. During lactation, oxytocin stimulates the contraction of myoepithelial cells in response to suckling, resulting in milk delivery via the nipple^[27]. When lactation ends, the gland must cease milk production and return to the pre-pregnant architecture through postpartum involution.

Postpartum involution involves the upregulation of tumor-promotional factors in the mammary epithelium and surrounding stroma. As primary components of the mammary ECM, collagen proteins, and the fibroblasts that produce and remodel them, have been extensively studied for their role in breast tumor progression and metastasis^[28,29]. The 28 types of collagen proteins share a triple α -helix as part of their structure, and they can be broadly classified as fibrillar or non-fibrillar based on their assembly^[30]. For additional information on collagen and its assembly, see Mouw *et al.*^[30]. In this review, we will focus on fibrillar collagen, as this is the most abundant form in the mammary gland^[31]. Collagen I expression is both spatially and temporally regulated, and its tight control is essential for the proper mechanosignaling required for normal mammary gland development and function^[31]. In fact, dysregulation of the primary collagen I receptor, $\alpha_2\beta_1$ integrin, can alter mammary ductal branching and promote tumor formation^[32,33]. The contribution of collagen to tumor progression is emphasized by the prognostic value of collagen I mRNA in clinical outcomes of breast cancer^[34] and evidence that increased collagen density promotes local breast cancer invasion and distant metastasis^[35]. One way that collagen deposition is regulated during involution is by the pro-inflammatory enzyme COX-2.

COX enzymes were first identified as the targets of inhibition by aspirin and other non-steroidal anti-inflammatory drugs (NSAIDs)^[36]. COX enzymes exist in two isoforms, both of which bind to cell membranes where they catalyze the metabolism of free arachidonic acid (AA) to prostaglandins (PGs) via phospholipase A2^[37,38]. First, COX enzymes rapidly catalyze the formation of an unstable intermediate, prostaglandin G2 (PGG2), from AA. PGG2 is then rapidly converted to prostaglandin H2 (PGH2) via COX-mediated peroxidase activity. Finally, specialized prostaglandin synthases result in the conversion of PGH2 to specific, biologically active PGs^[37-39]. Though initially believed to function identically, later investigations revealed important differences between COX-1 and COX-2^[40]. COX-1 is constitutively expressed as a regulator of tissue homeostasis^[41], whereas COX-2 is not normally expressed in adult tissues, with the exception of the central nervous system^[42], kidneys^[43], and male reproductive organs^[40,44]. Unlike COX-1, COX-2 expression is regulated by mitogens, hormones, and cytokines, and it is also correlated with cancer progression^[45,46]. However, it is the product of COX-2 activity - PGE2 - that serves as the active effector of pro-tumorigenic signaling. Once synthesized, PGE2 can bind to specific E-prostanoid receptors on the cell surface to activate pathways associated with survival and inflammation^[47]. COX-2/PGE2 signaling has been described in multiple models of cancer, including oral, breast, prostate, and colorectal, with documented roles in tumor initiation, invasion, immune evasion, cell survival, metastasis, vascular remodeling, cancer stem cells, and drug resistance; for further review, see Hashemi Goradel *et al.*^[46] and Stasinopoulos *et al.*^[48]. In addition to the feedback between COX-2 and collagen deposition in involution and in breast cancer^[18], we have also published a connection between COX-2 and tumor cell invasion through expression of the neuronal guidance protein, SEMA7A^[49].

SEMA7A, or CD108w, was first recognized for its expression on lymphocytes^[50]; however, a role for SEMA7A in cancer was later identified through its association with Plexin-C1, the receptor for the viral homolog of SEMA7A. Engagement of Plexin C1 by viral semaphorin inhibits dendritic cell adhesion and motility via alterations to the actin cytoskeleton^[51]. Similarly, in melanoma, SEMA7A/Plexin-C1 engagement inhibits cell migration via inactivation of the cofilin pathway^[52]. Cofilin activation, which normally generates free actin filaments required for cell migration^[53] is considered a major component of the metastatic cascade^[54]. SEMA7A/Plexin-C1 mediated cofilin inactivation led to the identification of Plexin-C1 as a novel tumor

suppressor^[53]. Consistent with this finding, Plexin-C1 expression is frequently lost in melanoma^[53]. Conversely, during development, SEMA7A signals through its other known receptor, β 1-integrin, to promote axon outgrowth via activation of the mitogen activated protein kinase (MAP-K) pathway^[55]. Unlike Plexin-C1, SEMA7A-mediated activation of β 1-integrin has been shown to promote cancer progression. Our lab and others have shown that SEMA7A- β 1-integrin binding promotes cell migration, invasion, metastasis, and neo-vasculogenesis of the blood and lymphatic vessels^[49,56-58]. SEMA7A has also been implicated in multiple models of fibrosis (reviewed below), supporting additional roles in inflammation and fibrillar collagen deposition. The expression of SEMA7A, COX-2, and collagen during postpartum involution and their known roles in facilitating tumor progression suggest these molecules and their interplay may be important drivers of PPBC.

PRO-TUMORIGENIC MECHANISMS OF CELL DEATH DURING INVOLUTION

Programmed cell death is essential for preventing the aberrant cellular phenotypes that arise when cells acquire DNA damage and mutations. Resistance to cell death may, consequently, result in the propagation of potentially harmful mutations that allow cells to bypass checkpoints meant to prevent unregulated growth and division. Resistance to cell death is thus defined by Hanahan and Weinberg^[59] as one of the original hallmarks of cancer. For a detailed review of cell death and cancer, see Ichim and Tait^[60]. In tumor cells, resistance to cell death plays an important role beyond tumor initiation, affecting drug-resistance, recurrence, and metastasis. Despite continuous advances in targeted chemotherapy, treatment efficacy tends to decline over time as a result of the ability of tumor cells to suppress apoptotic pathways, upregulate DNA repair, and genetically adapt to escape death. Tumor cells with repopulating capacity may also acquire the ability to resist death in response to chemotherapy, thereby constituting a major mechanism of cancer recurrence. Mechanisms by which tumor cells resist chemotherapy are further summarized by Al-Dimassi *et al.*^[61]. Active survival signals from the mammary ECM are required to override the default programming of normal adherent cells to die. When these cells become detached, they die in the absence of ECM signaling by a specialized form of programmed cell death called anoikis^[62]. Anoikis-resistance is a critical requirement for the successful metastasis of circulating tumor cells, a feature that may be shared by some of the cells that survive involution^[63]. Postpartum involution is characterized by two major waves of apoptosis, culminating in the death of over half of the mammary epithelium^[64]. As a minority of mammary epithelial cells (MECs) survive this process, postpartum involution represents an excellent model for studying the mechanisms by which cells acquire resistance to cell death in apoptotic environments. In this section, we will review the major mechanisms regulating cell death during postpartum involution and potential contributors to cell death resistance during tumorigenesis.

Postpartum involution occurs in two primary phases. In the first, or reversible phase, accumulation of milk protein, a process known as milk stasis, results in the detachment and shedding of secretory alveolar epithelial cells to the lumen. Milk stasis induces the first wave of cell death, in part, through the local expression of leukemia inhibitory factor (LIF). LIF is a primary activator of the master apoptotic regulator of involution - signal transducer and activator of transcription 3 (STAT3)^[65]. Other important activators of STAT3 at the onset of postpartum involution include transforming growth factor- β (TGF β), Janus kinase-1 (JAK-1), and Snail2 (SLUG)^[66-68]. Activation of STAT3 promotes postpartum mammary gland involution by shifting the balance of pro- and anti-apoptotic signals in favor of programmed cell death. STAT3 coordinates the first wave of epithelial apoptosis through activation of pro-apoptotic Bcl-2 family members, upregulation of PI3K inhibitory subunits, and downregulation of MAP-K survival signaling^[66]. STAT3 further promotes cell death during involution by mediating the formation of triglyceride-containing vacuoles. Triglycerides within these lysosomal-like vacuoles become metabolized into free fatty acids which interact with and distort lysosomal membranes. This results in the leakage of cathepsin proteases into the cytosol, and ultimately, lysosomal-mediated programmed cell death^[69]. The role of STAT3 in regulating apoptosis during involution has recently been comprehensively reviewed by Hughes and Watson^[66]. STAT3 has a well-defined role in

cancer progression, with over 40% of breast cancers presenting with constitutive STAT3 activation. Because STAT3 activates multiple signaling pathways, aberrant activation can promote multiple changes associated with cancer, including altered cell cycle dynamics, EMT, angiogenesis, and interestingly, resistance to cell death^[70,71]. Therapies targeting STAT3 may, thus, be of important therapeutic value for PPBC patients. For more about the role of STAT3 in breast cancer, see Segatto *et al.*^[70].

Removal of the overwhelming number of dead cells from the gland requires the Rac-1 mediated switch of MECs from a secretory to a phagocytic phenotype - a process which is essential for proper remodeling in the second phase of involution^[72]. Despite the massive wave of cell death that occurs during the first phase, if suckling resumes within this window (48-72 h, in mice), involution can be reversed, and lactation can proceed. This reversibility is due, in large part, to the expression of tissue inhibitors of metalloproteinases (TIMPs)^[73]. TIMPs preserve the reversibility of gland regression by delaying irreversible tissue remodeling events through the inhibition of matrix metalloproteinases (MMPs)^[74]. Interestingly, TIMP expression may also serve as an additional mechanism to regulate epithelial apoptosis, as TIMP3 has been implicated in the regulation of cell death in a tumor necrosis factor (TNF)-dependent manner^[75]. The number of compensatory mechanisms that exist to activate apoptosis underscore the importance of postpartum involution to future rounds of successful lactation. At approximately day three of involution in mice, downregulation of TIMPs results in activation of the MMPs that degrade the mammary ECM, causing MECs to lose contact with their underlying basement membrane^[73]. In the absence of pro-survival signaling from the ECM, detached MECs die by anoikis, thus comprising the second wave of cell death^[62,73]. Similar to the first phase, clearance of dead cells during the second phase of involution is largely mediated by phagocytic MECs, with additional limited support from professional phagocytes. Milk fat globule epidermal growth factor 8, which works by recognizing phosphatidylserine on the outer leaflet of the plasma membrane of dying cells, is also critical for apoptotic cell clearance during the second phase^[76].

What allows some cells to die and others to live during involution remains largely unanswered. To date, more than 50 mammary specific knockouts have been generated that exhibit alterations in postpartum involution - either delayed or premature - that are consistent with the proposed role for each molecule in the process. For example, activation of pro-survival pathways, such as Akt1, and/or deletion of death inducing genes, such as Bax, results in delayed involution, while deletion of Akt1 and anti-apoptotic Bcl-x results in premature involution^[77-80]. See Radisky *et al.*^[80] for an extensive review of these models. As pro-survival signals progressively decline and pro-apoptotic signals increase during the first phase of involution, the mammary basement membrane and ECM become the primary mediators of cell survival^[81]. Yet, during the second phase, the basement membrane and ECM are degraded by proteases. Previously, SEMA7A mRNA expression was shown to increase in whole mammary extracts during the early phase of involution, and its expression was attributed to its immunomodulatory role^[82]. Recently, we published that SEMA7A is expressed on Epcam+ MECs during the remodeling phase of involution^[57]; however, the downstream mechanisms activated by epithelial SEMA7A are not well understood. Interestingly, SEMA7A is a ligand for β 1-integrin, which is the receptor for ECM molecules that normally facilitate epithelial cell attachment. It is therefore possible that SEMA7A may activate β 1-integrin signaling and provide a pro-survival mechanism to overcome anoikis. Furthermore, β 1-integrin mediates the activation of known survival pathways including MAP-K and AKT, which affects survival via stabilization of NF- κ B and expression of COX-2. Thus, SEMA7A may promote anoikis-resistance during involution via activation of β 1-integrin in a manner that is independent of ECM; however, additional investigation is required.

The role of COX-2 during involution has also largely been attributed to its role in the modulation of the immune milieu^[83]. Yet, COX-2 also contributes to cell survival mechanisms and collagen remodeling via PGE₂, which promotes cell growth and proliferation, modulates collagen expression levels, and upregulates proteinase expression. Studies investigating the effects of postpartum involution in TNBC progression

have revealed a feed-forward mechanism by which fibrillar collagen deposition during involution requires COX-2 expression. COX-2 further promotes increased fibrillar collagen^[18], which is directly associated with tumor progression and poor prognosis in breast cancer patients^[31,84]. Cooperation between fibrillar collagen and COX-2 may therefore contribute to the pro-tumorigenic nature of the involuting mammary gland. Similar to postpartum involution, wound healing is a biological process where cell death is accompanied by collagen remodeling. In the “phoenix rising” model of cell death, discovered in a model of wound healing and further characterized in cancer, dying cells send signals to stem and progenitor cells to increase their proliferation, thereby coordinating cell growth with death^[85,86]. In dying cells, activation of caspases 3 and 7 results in the release of calcium-independent phospholipase-2, which increases the production and release of AA from cell membranes. Ultimately, COX-2 and PGE2 synthase convert free AA to PGE2, which increases stem and progenitor cell proliferation to promote tissue regeneration^[85]. Though the phoenix rising model, to our knowledge, remains uninvestigated during mammary involution, there are numerous similarities between the wound healing program and postpartum involution, including apoptosis, clearance of damaged and dead cells, and activation of similar inflammatory programs. This suggests that this mechanism of coordinated cell death and tissue regeneration may be conserved in mammary development. Additionally, these mechanisms seem to be particularly important for the growth and survival of stem and progenitor cells in response to apoptotic stimuli, thus representing a mechanism of tumor recurrence in response to chemotherapy. The preceding data may help to further explain the role of collagen, COX-2, and SEMA7A in facilitating tumor progression following lactation.

EXTRACELLULAR MATRIX AND REMODELING DURING POSTPARTUM INVOLUTION AND CANCER

In their updated review of the hallmarks of cancer, Hanahan and Weinberg described the tumor microenvironment (TME) as a critical mediator of cancer progression due to its ability to supply cancer cells with signals that promote inflammation, induce angiogenesis, and confer resistance to cell death^[87]. The TME consists of all the cells, ECM molecules, vasculature, and proteins that surround a tumor. The cross-talk between these components and the tumor can affect tumor growth, survival, metabolism, metastasis, response to treatment, and recurrence. The contributions of the TME to cancer progression are comprehensively reviewed in a recent special issue of *Nature Reviews Cancer*^[88]. In this section, we will briefly discuss some of the similarities between the tissue microenvironment of the involuting mammary gland and the TME.

ECM fragments, which can be used as diagnostic markers of disease, are known contributors to cancer for their ability to participate in cell signaling events and modulate gene expression^[31,89]. An investigation of the tumor-promotional aspects of involution revealed that tumor cells co-cultured with ECM isolated from involuting rat mammary gland promoted tumor cell invasion, whereas tumor cells co-cultured with ECM isolated from nulliparous rat mammary glands did not^[90], suggesting that involution-derived ECM promotes tumor cell invasion and metastasis. In further support, orthotopic injection of breast cancer cells mixed with ECM isolated from the mammary glands of rats undergoing postpartum involution also confirmed that involution derived ECM promotes metastasis^[90]. Additional investigations have confirmed that the involution microenvironment mirrors the typical breast TME based on their shared availability of ECM fragments, dramatic increases in fibrillar collagen, and increased MMP activity^[90-92]. Specifically, studies of stromelysin-1 (MMP3), the primary active MMP during the tissue remodeling phase of involution, have characterized it as a potent mediator of EMT and other early oncogenic events in the mammary gland^[93]. Furthermore, elevation of fibrillar collagen results in increased collagen crosslinking and ECM stiffening - characteristics known to accompany breast tumor progression^[89,94-96]. Increased collagen deposition and cross-linking further promote tumor cell invasion and metastasis by providing a structural network for tumor cell migration^[97].

Transforming growth factor β (TGF β), well-known for its paradoxical role in breast tumor progression, is a primary regulator of collagen deposition in the mammary gland^[98]. At approximately 8 h post weaning, TGF β becomes activated and exerts tumor suppressive effects via activation of apoptotic programming^[73,99]. Conversely, when normal cells begin to take on tumorigenic phenotypes, TGF β promotes cancer progression by enhancing tumor cell survival and contributing to the maintenance of cancer stem cell populations^[100]. TGF β is also essential for wound healing, where it stimulates ECM deposition via fibroblast activation^[101]. Interestingly, TGF β dependent fibroblast activation during involution may be COX-2 dependent, as NSAID treatment decreases fibroblast activation *in vivo*. Furthermore, NSAIDs inhibit fibroblast mediated fibrillar collagen deposition during involution and in a model of PPBC^[15]. Additionally, TGF β is known to positively regulate SEMA7A in pulmonary fibrosis, where SEMA7A is critical for ECM deposition via activation of the PI3K/AKT pathway^[102]. Given its role in ECM deposition, SEMA7A expression during the second phase of involution suggests it may also play a role in mammary gland tissue remodeling^[57]. SEMA7A can affect ECM remodeling through its ability to recruit fibroblasts and immune cells to fibrotic sites, and it has been further implicated in fibrosis models in the liver, kidney, and in glial scar formation^[103-108]. Contradictory to this role, when endogenously expressed on fibroblasts, SEMA7A can maintain fibroblast homeostasis and reduce pro-fibrotic markers^[109], indicating context dependent roles for SEMA7A-mediated signaling. In cancer, fibrillar collagen coordinates upregulation of COX-2 on tumor cells, further promoting tumor cell invasion and metastasis^[7], and we have published that COX-2 drives SEMA7A expression^[49]. Thus, fibrillar collagen, COX-2, and SEMA7A may be a part of a feed-forward loop that ultimately results in cancer cell invasion and metastasis. Additional studies, however, are needed to better understand the hierarchy and cross-talk between these molecules in the context of postpartum involution and breast cancer progression.

Altering fibrillar collagen deposition provides a route for tumor cell migration and invasion, but also changes the signals received by cells from the surrounding environment. Signals from the ECM are communicated to cells by integrins. Integrins are heterodimeric ($\alpha\beta$) transmembrane receptors with 18 known α and 8 β integrin subunits, resulting in 24 possible heterodimeric integrin receptors^[110]. Proper expression and signaling of integrins is essential for cell survival and adhesion, and integrin dysregulation can promote cancer via activation of pathways that affect survival, EMT, and migration^[28,111-115]. Specifically, improper integrin signaling and expression can result in the loss of normal epithelial cell polarity and attachment, in addition to the over-activation of focal adhesion kinase and subsequent downstream signaling pathways that promote cell survival, migration, invasion, and ultimately metastasis^[116]. While some integrin pairs are highly specific in their substrate recognition, others can recognize a number of substrates from the ECM, as well as foreign molecules such as snake venom, viral particles, and pathogens^[117,118]. Alternative ligand-binding partners and/or differential integrin expression can elicit different signaling pathways; thus, when either ligand or integrin profiles are altered, cellular signaling pathways can become aberrantly activated or inhibited. Abnormal SEMA7A expression during involution and/or cancer may promote tumorigenesis via activation of β 1-integrin and downstream pathways. SEMA7A binds to β 1-integrin via the RGD binding site located on the SEMA domain; however, this site is buried in the crystal structure when SEMA7A is bound to Plexin C1. The ability to differentially regulate tumor progression could, therefore, be explained by binding of SEMA7A to its different receptors^[119,120]. Further, while SEMA7A binds to α 1 β 1-integrin on inflammatory macrophages^[121], the α -binding partner needed for SEMA7A-mediated breast cancer progression is unknown. As reviewed above, one consequence of SEMA7A- β 1-integrin signaling is fibrillar collagen deposition. Collagen can also activate integrins and modulate their associated signaling pathways, primarily through α 2 β 1 integrin, which is often upregulated on cancer cells of epithelial origin^[122]. Collagen binding to α 2 β 1 integrin on tumor cells promotes cellular invasion, which helps cells navigate through the collagen I rich mammary TME and distant metastatic sites, such as the bone^[122]. Interestingly, α 2 β 1 integrin has been shown to increase COX-2 expression in intestinal epithelial cells^[123], leading to activation of downstream signaling events associated with tumor promotion. While these results further support a link between COX-2 and collagen, α 2 β 1 integrin has also been recognized as a metastasis suppressor in breast cancer. The

complex interplay between integrins, collagen, COX-2, and SEMA7A is, thus, likely to be context-dependent, and additional studies are necessary to understand the role of this signaling axis in mediating tumor cell invasion and metastasis in breast cancer.

MACROPHAGES IN POSTPARTUM INVOLUTION AND PPBC

Macrophages are the phagocytic immune cells that mediate the removal of foreign pathogens, dead cells, and debris. Classically-activated macrophages, also known as M1 macrophages, are activated in response to pathogen-associated cytokines, most often IFN- γ and lipopolysaccharide. M1 macrophages are largely considered to be “anti-tumor” based on their expression of the pro-inflammatory cytokines, interleukin-1 (IL-1), IL-12, TNF- α , and inducible nitric oxide synthase - all of which have been shown to oppose tumor progression^[124,125]. In contrast, Th2 family cytokines induce the maturation of alternatively-activated, or M2 macrophages, and cause their release of anti-inflammatory mediators that support tumor cell survival^[21,126]. M2 macrophages promote tumor cell growth, invasion, and metastasis, via their secretion of IL-10, TGF β , and MMPs. Though the M1/M2 system is useful for broadly classifying macrophages, this taxonomy fails to capture the plasticity and diversity characteristic of this cell type. For the purpose of this review, however, we will use M1 and M2 to broadly classify anti- and pro-tumor macrophages, respectively. Multiple studies support the role of macrophages as critical mediators of metastasis^[21,127-129]. In models of gastric and breast cancer, M2 macrophages are recruited by tumor cells, where they activate MAP-K signaling to promote the motility of disseminating tumor cells^[127]. Further, macrophages appear to be critical for the migration of the majority of ductal carcinoma *in situ* cells, as only 10% are motile when macrophages are absent^[130]. The critical contribution of macrophages to tumor cell metastasis is further evidenced by studies in the MMTV-PyMT mouse model of breast cancer, where knockout of colony stimulating factor-1 (CSF-1), a secreted glycoprotein that induces the differentiation of hematopoietic stem cells to macrophages, correlates with a near complete elimination of tumor cell metastasis^[21,131]. Macrophages, therefore, represent a diverse population of cells that can promote or inhibit tumor progression based on the context of their environment.

Macrophages are the primary immune cells present during mammary gland postpartum involution, and because of their role in facilitating tumor metastasis, represent a potential contribution to the highly metastatic nature of PPBC. Though known primarily for their phagocytic capacity, macrophages only play a minimal role in the clearance of apoptotic cells during involution^[21,132,133]. Despite their limited role in phagocytosis, M2 macrophages are essential for the epithelial apoptosis and tissue remodeling characteristic of postpartum involution^[134]. At the peak of apoptotic cell clearance, macrophages exist at relatively low levels, as MECs represent the primary phagocytes. At day 6 of involution, however, the peak of mammary tissue remodeling, M2 macrophages exist at 6 times the level of those in the nulliparous mammary gland, while classically-activated M1 macrophages remain at consistent levels throughout pregnancy, lactation, and gland regression^[21]. F4/80, a general marker of mature mouse macrophages, marks more than the sum of M1 and M2 macrophages during involution, suggesting there are additional macrophage populations present in the involuting mammary gland^[20]. Our lab has recently identified a population of macrophages that also express the lymphatic endothelial marker, podoplanin (PDPN)^[57]. In culture, SEMA7A drives the expression of PDPN on macrophages and promotes their migration and adherence to lymphatic vessels^[57]. Because macrophages have proven to be a critical part of the metastatic cascade by facilitating intravasation into tumor associated blood vessels^[135], SEMA7A-mediated macrophage lymphatic mimicry may also facilitate intravasation into lymphatic vessels, providing another explanation for the high rates of metastasis associated with PPBC. This is further supported by the prognostic value of a combined genetic signature of CD68, PDPN, and SEMA7A in predicting decreased distant metastasis free survival in a cohort of 600 human breast cancer cases^[57]. SEMA7A further regulates macrophages by serving as a strong activation factor for monocytes, promoting both chemotaxis and secretion of inflammatory cytokines, in addition to upregulation of granulocyte-macrophage CSF (GM-CSF), supporting an additional role for SEMA7A in macrophage differentiation^[136].

Another important macrophage regulator during postpartum involution and breast cancer is COX-2. Previous studies in breast cancer models have shown that COX-2 expression increases with cancer stage, and its expression levels can indicate breast cancer progression, recurrence, and metastasis^[137]. Recently, COX-2 expressing tumor associated macrophages (TAMs) have been shown to promote the metastatic potential of breast cancer cells via secretion of IL-6 and subsequent activation of AKT signaling in cancer cells^[138]. Further, expression of COX-2 in stromal TAMs results in upregulation of COX-2 in breast cancer cells, thereby shifting polarization of local macrophages toward the M2 phenotype. In addition to its association with tumor promotional CD163+ TAMs, COX-2 expression in the stroma is further associated with increased collagen alignment in invasive breast cancer^[139]. TAMs are known to associate with dense regions of collagen in breast cancer in the same way M2 macrophages associate with fibrillar collagen during involution. In the MMTV-PyMT model, macrophages associated with fibrillar collagen have been shown by intravital imaging to migrate across collagen fibers, suggesting that one mechanism by which macrophages promote metastasis is by supporting the migration of tumor cells across collagen networks^[21,140]. SEMA7A, COX-2, and collagen all represent important effectors of macrophage-mediated tumor cell growth, survival, and metastasis. As macrophages are considered essential for successful metastasis, targeting the molecules responsible for alternative macrophage activation, survival, and chemotaxis may be critical for the successful treatment of metastatic disease.

ENDOTHELIAL VESSEL FORMATION

Blood and lymphatic vessels form two similar, yet distinct, organ systems that assemble into extensive networks throughout the body to support development and survival. Blood vessels provide tissues with oxygen and nutrients, while the primary functions of lymphatic vessels are immune cell trafficking and removal of excess interstitial fluid from tissues. Blood and lymphatic vessels are lined with blood endothelial cells and lymphatic endothelial cells, respectively, and are both surrounded by a thin layer of smooth muscle. Some lymphatic vessels have unique “button-like” junctions that differ from the more continuous “zipper-like” junctions of the blood vasculature and established lymphatic vessels. These specialized junctions are covered with a flap that opens and closes to allow fluid and cells to pass without affecting vascular integrity. Vascular networks are highly dynamic, expanding and retracting as tissues change in response to normal developmental processes or pathologies. Indeed, a widely accepted hallmark of cancer is the ability of tumors to induce angiogenesis, or the development of new blood vessels from existing vasculature^[59]. Tumors must acquire pro-angiogenic abilities in order to grow beyond 1-2 mm³^[141]; otherwise, the tumor will die by necrosis or apoptosis^[142,143]. In rat mammary tissues, we observe an overall net increase in lymphatic vessel density (LVD) during involution when compared to a lactation timepoint^[16]. In contrast, blood vessel density (BVD) drops dramatically after lactation, suggesting an initial period of regression before increasing in a manner similar to LVD^[144]. During involution, the highest vasculature densities peak at day 10, followed by a slight decrease in the fully regressed gland [Figure 1]. This is consistent with published studies from our group and others describing increased pro-angiogenic and pro-lymphatic signaling during postpartum involution, and in postpartum tumors compared to non-postpartum controls^[14,16,22,145]. Interestingly, fibrillar collagen, COX-2, and SEMA7A all have established roles in endothelial vessel formation. Studies using artificial collagen matrices have shown that collagen increases angiogenic responses from endothelial cells by providing the support needed for sustained endothelial cell growth and the formation of endothelial networks^[146]. Angiogenesis can also be regulated by mechanical stiffness within the small microvessel environment^[147], and breast tumors are often stiffer than neighboring normal tissues by up to 6-fold^[84,148]. For a more comprehensive review on collagen and angiogenesis, see Fang *et al.*^[149]. These studies demonstrate how the ECM in the TME can modulate vessel formation and alter the tumor’s blood supply.

If a tumor outgrows its blood supply and loses its access to oxygen, it can become hypoxic. Under normal oxygen content conditions, termed “normoxia,” the transcriptional regulator hypoxia-inducible factor-1

Figure 1. BVD and LVD during mammary gland development. BVD measured as number of blood vessels per millimeter and LVD measured as number of lyve-1 positive vessels per millimeter in nulliparous (N), pregnant (P), lactating (L), involuting (days 2-10) and regressed (R), mammary glands (data adapted from Lyons *et al.*^[16] and Ramirez *et al.*^[144]). BVD: Blood vessel density; LVD: lymphatic vessel density

(HIF-1) is unable to affect its targets; for further review of this topic, see Masson and Ratcliffe^[150]. HIF-1 is comprised of two subunits - ARNT/HIF-1 β , which is constitutively expressed, and HIF-1 α , which is an oxygen-sensitive subunit. During normoxia, HIF-1 α is hydroxylated by prolyl hydroxylase domain containing proteins, ubiquitinated by von-Hippel-Lindau protein, and rapidly degraded. During hypoxia, however, HIF-1 α is not hydroxylated and degraded, but instead, translocates to the nucleus, heterodimerizes with ARNT, and induces transcription of its target genes. HIF-1 affects a variety of targets, including pro-angiogenic genes like vascular endothelial growth factor-A (VEGF-A)^[151]. In breast cancer cells, COX-2 can induce inflammation-associated HIF-1 activity, resulting in the expression of pro-angiogenic genes^[48]. Further, HIF-1 and COX-2 maintain a positive feedback loop, as HIF-1 can also induce expression of COX-2^[152]. Utilizing NSAIDs to target COX-2 activity can inhibit angiogenesis, demonstrating the potential for therapeutic intervention^[152-154]. Corroborating our findings that SEMA7A may be involved in COX-2 associated pathways, HIF-1 can directly upregulate SEMA7A in endothelial cells^[155]. SEMA7A can elicit the release of pro-inflammatory cytokines and cause increased endothelial barrier permeability^[156,157]. SEMA7A can also promote angiogenesis in a hypoxia-independent manner in murine mammary carcinoma and in the cornea by stimulating macrophages to produce pro-angiogenic molecules, such as CXCL2/MIP-2^[158] and VEGF-A^[159].

In addition to their roles in angiogenesis of the blood vasculature, collagen, COX-2, and SEMA7A also have known roles in lymphangiogenesis. In breast cancer, increased LVD, lymph node involvement, and lymph vessel invasion are predictive of higher risk of metastasis; further, increased LVD and lymph node metastasis are commonly observed in PPBC^[16]. While the role of collagen in lymphangiogenesis has not been extensively characterized, one study has shown that collagen I increases lymphangiogenesis and angiogenesis in mouse embryoid bodies under hypoxic conditions^[160]. Therefore, it is plausible that other fibrillar collagens may contribute to lymphangiogenesis during mammary tumorigenesis. COX-2/PGE2 signaling also promotes production of pro-angiogenic VEGF-A and pro-lymphangiogenic VEGF-C and VEGF-D^[161]; further, lymphangiogenesis during wound healing is dependent on COX-2 activity^[162]. Moreover, COX-2 has been implicated in lymphangiogenesis in other cancer types, including cervical and gastric^[163,164]. We published that inhibition of COX-2 with celecoxib and NSAIDs results in decreased LVD, tumor cell

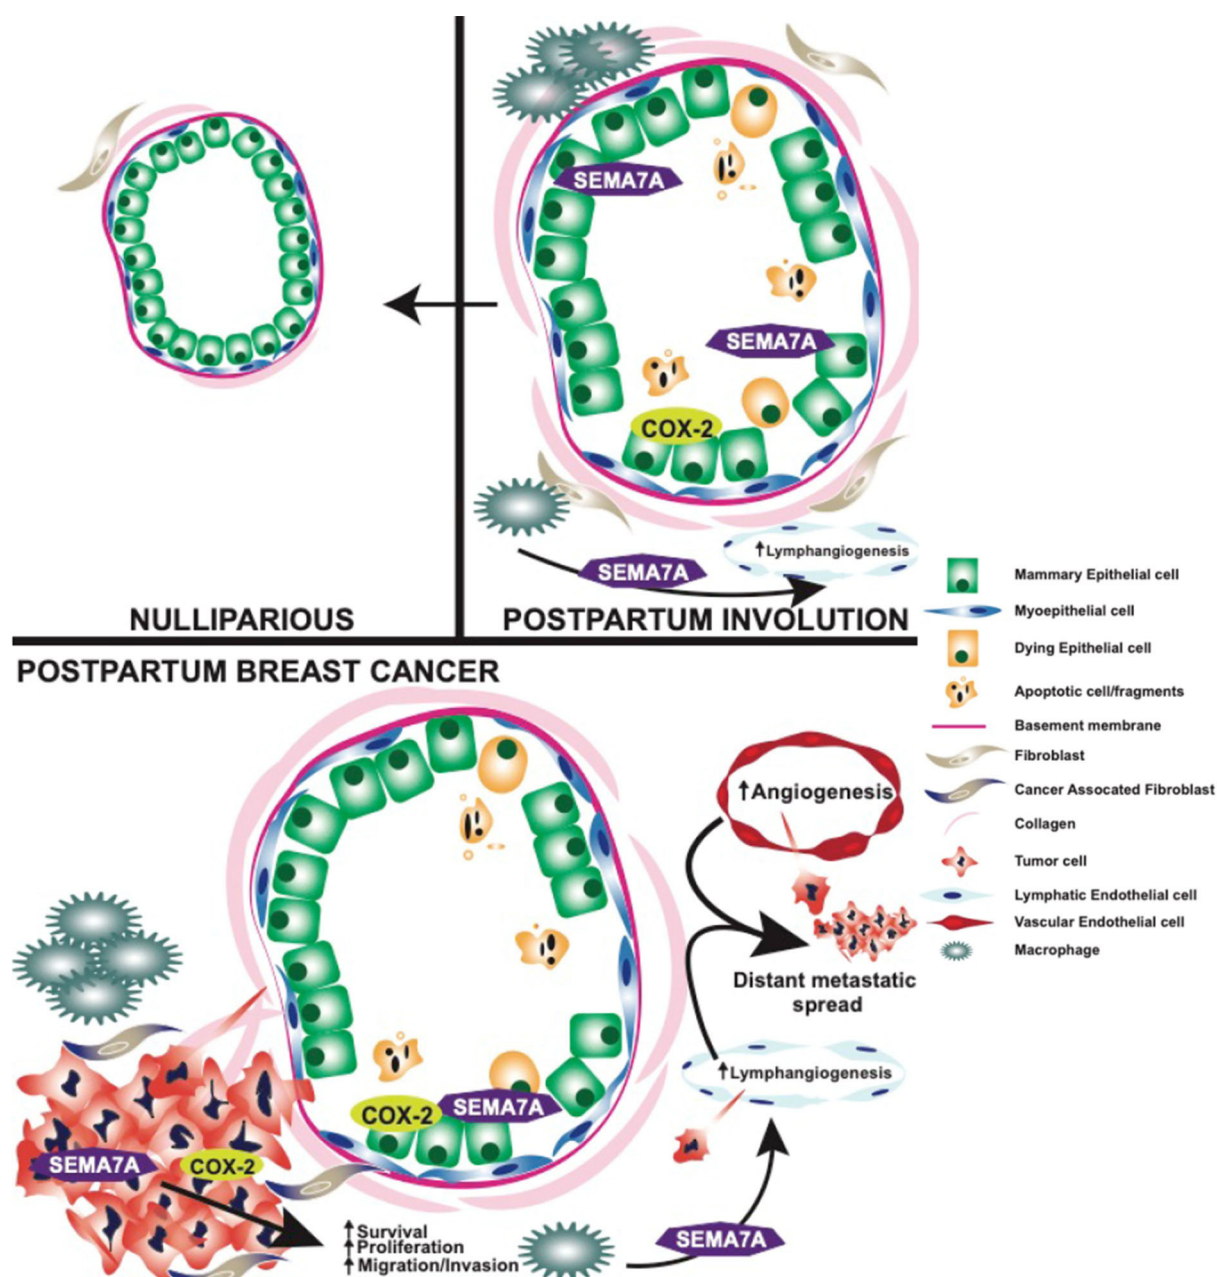

Figure 2. Graphical summary of pro-tumorigenic and metastatic roles of COX-2 and SEMA7A during postpartum involution and postpartum breast cancer. SEMA7A: Semaphorin 7a; COX-2: cyclooxygenase-2

invasion into lymphatics, and metastasis during PPBC^[16]. For more detailed information on COX-2 and lymphangiogenesis in breast cancer, see Lala *et al.*^[165]. Finally, SEMA7A has a functional role in lymphatic vessel modulation, as we recently published that SEMA7A promotes tumor-associated lymphangiogenesis via macrophage-mediated lymphatic vessel remodeling during postpartum involution and breast cancer^[57]. These findings suggest an additional mechanism by which SEMA7A, COX-2, and collagen promote tumor progression and metastasis.

CLINICAL RELEVANCE/CONCLUSION

Women with postpartum breast cancer face a disease that carries three times the rate of metastasis and death relative to women who have never been pregnant and those diagnosed outside of the postpartum

Figure 3. Distant metastasis free survival is decreased with high levels of expression of SEMA7A, COX-2, and COL1A1 signature. DMFS analysis using KmPlot ($n = 664$) * $P < 0.05$

window. One physiological event these women have in common is postpartum involution - a process that results in the upregulation and activation of tumor-promotional factors in MECs and the mammary stroma. Identification of the genetic engines that drive PPBC is critical to the development of targeted therapies for postpartum patients. In this review, we have highlighted potential roles for collagen, COX-2, and SEMA7A in driving some of the pro-metastatic aspects of involution [Figure 2]. Previously published results indicate overall survival is generally decreased for breast cancer patients with high collagen, COX-2, and SEMA7A expression, suggesting that these mechanisms are important mediators of breast cancer metastasis^[18,49]. Interestingly, while individual expression of each molecule does not predict for metastasis using KM Plotter analysis^[166], the combination of high SEMA7A, COX-2, and COL1A1 mRNA expression results in significantly decreased distant metastasis free survival for breast cancer patients in this dataset [Figure 3]. Thus, studies rooted in understanding the contributions of postpartum involution associated programs to breast cancer metastasis are likely to also be applicable to general breast cancer metastasis, and perhaps to other cancer types.

Based on the cooperation between SEMA7A, COX-2, and collagen, a multi-targeted therapy to affect the individual molecules and their interplay would likely be more effective than targeting one, alone. The potential of COX-2 as a therapeutic treatment has been investigated in multiple models of cancer. In fact, the COX-2 inhibitor, celecoxib, has been successful in the treatment of a specific type of colorectal cancer - familial adenomatous polyposis - in both adults and children^[167,168]. Targeting COX-2 in breast cancer, by celecoxib or other NSAIDs, may inhibit tumor cell dissemination by reducing the expression of tumor-promotional collagen. Targeting SEMA7A in conjunction with already established therapies, such as NSAIDs, may also increase the efficacy of these treatments in women with breast cancer. Ideally, the characterization of tumor-promotional factors in the postpartum mammary gland may also lead to preventative therapies aimed at reducing the risk for PPBC. NSAIDs may further represent a safe candidate for preventative therapy during involution via inhibition of COX-2 mediated collagen upregulation and alternative macrophage activation. The topics covered herein highlight both the potential contribution of the SEMA7A/COX-2/Collagen relationship to PPBC, and the importance of PPBC models to the discovery of new molecules and pathways that can be exploited as novel therapeutics.

DECLARATIONS

Acknowledgments

The authors would like to give special thanks to Alan Elder and Chloe Young for their critical contributions to the editing process and PA Masso-Welch for providing the raw data from published studies^[144] for Figure 1.

Abstract

Brain metastases risk at the time of diagnosis or during the course of disease is high in non-small cell lung cancer (NSCLC). Even the incidence of brain metastases has increased in recent years, due to detection of smaller asymptomatic lesions with MRI screening as well as improved survival as a consequence of developments in systemic therapies. In the last decade, there have been many trials in the management of NSCLC patients with brain metastases, questioning the role of adjuvant whole brain radiotherapy (WBRT) after surgery or stereotactic radiosurgery (SRS), WBRT, compared to best supportive care in patients not amenable to surgery, aggressive local therapies in solitary brain metastases, postsurgical cavity SRS, SRS in non-oligometastatic patients, cranial radiotherapy in patients with driver mutations, tyrosine kinase inhibitors, immune check point inhibitors and the impact of therapies on neurocognitive functions and quality of life. The main objective of this review is to provide an update on current trends in radiotherapy in the management of newly diagnosed brain metastases from NSCLC.

Keywords: Radiotherapy, whole-brain radiotherapy, stereotactic radiotherapy, stereotactic radiosurgery, brain metastases, lung cancer

INTRODUCTION

Brain metastases are the most frequent malign brain tumors. Lung cancer is the leading primary tumor composing 40%-50% of cases^[1,2]. In non-small cell lung cancer (NSCLC) brain metastases risk at the time of diagnosis is 15%-20%, even the risk increases to 50%-60% during their course of disease in patients with epidermal growth factor receptor (EGFR) mutation or anaplastic lymphoma kinase (ALK) rearrangement^[3,4].

Incidence of brain metastases has increased in recent years as a result of detection of smaller asymptomatic lesions with MRI screening as well as improved survival as a consequence of developments in systemic therapies. In addition to these, improvements in imaging technology, surgery, radiotherapy, targeted therapies, even immunotherapy and deep understanding of treatment related toxicities have resulted in evolvement of current trends in management of brain metastases^[5,6].

Although brain metastases is an indicator of poor outcome^[7,8], it's shown that a subgroup might have longer survival, e.g., EGFR mutated and ALK rearranged NSCLC^[4,9]. In this context, to assist the selection of personalized therapy several prognostic indices have been developed; e.g., recursive partitioning analysis, diagnosis-specific graded prognostic assessment (DS-GPA) and more recently graded prognostic assessment for lung cancer using molecular markers (Lung-mol GPA)^[10-12]. Optimal treatment planning should consider both patient (age, performance status, expected life span) and tumor related factors (number and volume of brain metastases, extracranial disease control, molecular subtype).

Historically, whole brain radiotherapy (WBRT) or best supportive care were the only treatment modalities for patients with brain metastases. The aim of WBRT was to treat both microscopic and macroscopic metastases. But treatment to whole brain parenchyme reduces distant in-brain recurrences with the cost of cognitive toxicity^[6]. In the last decade, there have been many trials in management of NSCLC patients with brain metastases, questioning the role of adjuvant WBRT after surgery or stereotactic radiosurgery (SRS), WBRT compared to best supportive care in patients not amenable to surgery, aggressive local therapies in solitary brain metastasis, postsurgical cavity SRS, SRS in non-oligometastatic patients, cranial radiotherapy in patients with driver mutations, TKI, immune check point inhibitors and the impact of therapies on neurocognitive functions (NCF) and quality of life (QOL).

The main objective of this review is to provide an update on current trends in radiotherapy in the management of newly diagnosed brain metastases from NSCLC.

Solitary metastasis: WBRT vs. WBRT plus surgery

Until Patchell *et al.*^[13] randomized trial of surgical resection followed by WBRT vs. WBRT only in patients with solitary brain metastasis, WBRT was the standard treatment. The findings of increased median survival (10 months vs. 4-6 months), decreased brain recurrences (20% vs. 52%), increased functional independence and lower risk of neurological deaths with surgery in conjunction to WBRT, lead to increased role of aggressive local therapies in selected patients with solitary and oligo brain metastases^[14-17].

Solitary metastasis: adjuvant WBRT plus surgery vs. surgery only

The success of aggressive local treatment and fear of long-term neurologic toxicity led the authors to question the role of adjuvant WBRT in oligometastatic patients. Patchell *et al.*^[18] randomized the patients with solitary brain metastasis after surgery to WBRT or observation. Postoperative WBRT reduced both local and distant brain failure rates significantly compared to observation arm (10% vs. 46%, $P < 0.001$), (14% vs. 37%, $P < 0.01$), respectively. Neurologic death rate was 3 times higher in the observation arm. But overall survival (OS) and survival with functional independence were the same^[18].

Solitary metastases: surgery vs. SRS

In the absence of head to head randomized data, most of the retrospective studies comparing surgery vs. SRS reported similar outcomes in brain control or survival in solitary resectable brain metastases^[19,20]. It's hard to make a decision when there is no indication for surgical decompression or need for histologic diagnosis. One small randomized study with 64 patients with solitary metastases, compared SRS to microsurgery plus WBRT. OS and 1 year local control were similar^[21]. Recently, in secondary analysis of EORTC 22952 trial in abstract form which randomized patients to SRS or surgery with or without adjuvant WBRT, it was reported that early control was better with SRS but late control favored surgery^[22].

Solitary metastasis: only SRS after surgery

Postoperative SRS vs. WBRT after resection of brain metastases

The absence of survival advantage and recognized neurotoxicity of adjuvant WBRT after surgery have led to postoperative SRS to surgical cavity^[6]. But there has been some challenges in the use of SRS without WBRT after surgical resection. First, the use has increased in trend although the data have been mainly derived from retrospective series^[23,24] and one prospective phase II trial^[25]. The results of these studies report around 80% local control in 1 year suggest similar control rates with adjuvant WBRT. The only randomised data on this subject has been available from Kepka's multicenter trial, which did not demonstrate the non-inferiority of postsurgical SRS compared to postsurgical WBRT in patients with solitary brain metastasis. The difference in neurocognitive failure at 6 months (primary end-point) was in favour of WBRT. Besides, although it was not the primary end-point; the patients in postsurgical SRS arm compared to postsurgical WBRT were found to have increased neurological deaths (66% vs. 31%, $P = 0.015$, HR: 2.51) and decreased 2 years overall survival (10% vs. 37%, $P = 0.046$, HR: 1.8), respectively^[26]. The second challenge is that there have been some reports on dural-based leptomeningeal recurrences along the surgical tract after postoperative SRS^[27,28]. Atalar *et al.*^[27] reported 13% leptomeningeal recurrence rate at a median of 5 months after SRS directed to postsurgical resection cavity. It's hard to define target volume for postoperative SRS. Tumor cell dissemination along the surgical tract is another challenge. Recently, Soliman *et al.*^[29] reported a consensus guideline on delineation of CTV for postsurgical cavity SRS.

Preoperative SRS

In the context of leptomeningeal recurrences after postoperative SRS, preoperative SRS followed by surgical resection in 48 h is evolving as a new paradigm. The theoretical benefits are decreased radionecrosis and decreased leptomeningeal recurrences as a result of better definition of target volume by delineation of intact metastasis, a smaller margin volume and sterilization of surgical bed^[6,30]. The results of preoperative SRS in 47 oligometastatic (1-3 brain metastases) patients before surgical resection have been reported by Asher *et al.*^[5] NSCLC patients were 37.2% of the cohort. The median dose was 14 Gy. The expansion margin of gross target volume to planned target volume was not used. There wasn't any difficulty during surgery or increased postoperative complication. In spite of the inclusion of relatively large lesions (median dimension 3.04 cm and median volume 8.49 cm³), local control rates were 97.8%, 85.6% and 71.8% at 6, 12 and 24 months, respectively. Six of the 8 local relapsing patients were the ones who had either significant dural attachment or adherence to dural veins which might make an implication on the need for higher doses in such cases instead of dose reduction. There wasn't any leptomeningeal failure which confirms the hypothesis of the study. The authors concluded that preoperative SRS might be a better treatment at least for "high risk" patients^[5]. A phase II trial is going on this subject^[31].

Oligometastases: WBRT alone vs. WBRT plus SRS boost

In line with the intensification of local therapy Radiation Therapy Oncology Group (RTOG) conducted a phase 3 trial (RTOG 9508) which randomized 331 patients with 1-3 brain metastases to WBRT vs. WBRT plus SRS. Lung cancer patients were 64% of the patient cohort. SRS boost in conjunction to WBRT showed survival benefit in patients with 1 metastatic lesion (6.4 months vs. 4.9 months, $P = 0.0393$). The addition of

SRS resulted in increased local control in all patients (82% vs. 71%, $P = 0.01$). There were improvement in survival, local control, performance status and decreased steroid dependence in NSCLC patients with 1-3 in post hoc analysis^[17]. In the secondary analysis, the patients were re-stratified according to GPA scoring system. There were 211 lung cancer patients out of 252 (84%) re-analysed patients. It was found that SRS boost after WBRT resulted in increased survival in patients with GPA 3.5-4.0 score (good prognosis); the median survival was 21 months in WBRT + SRS vs. 10.3 months in WBRT only. The benefit was irrespective of the number of metastases^[32].

Oligometastases: omitting adjuvant WBRT after surgery or SRS

The indication of adjuvant WBRT after surgery or SRS has been evolving. The rationale of omitting immediate WBRT after surgery or SRS with close follow-up lies on the availability to treat in-brain recurrences with salvage focal therapies or WBRT at relapse with the aim of avoiding neurocognitive dysfunction. To meet this challenge four phase 4 randomised trials and a metaanalysis was carried out^[33-37].

In this concept, the first randomized trial came from Japan (JRSOG-99 trial). The primary end point was the survival difference between SRS and WBRT plus SRS, but at interim analysis it was realized that sample size would be unachievable and accrual was terminated. Aoyama *et al.*^[33] reported same survival rates (8 months vs. 7.5 months, $P = 0.42$) and same neurologic death rates (19% vs. 23%) in spite of higher local recurrences (27% vs. 11%) and distant brain recurrences (64% vs. 41%) in 132 patients with 1 to 4 brain metastases treated with SRS alone vs. WBRT plus SRS. The authors claim that SRS alone might be a viable approach if the patient is compatible with close brain monitoring for the early detection of recurrence to have the ability for early salvage^[33]. In a secondary analysis, 88 NSCLC patients were poststratified by DS-GPA and survival was the primary end-point. Forty seven patients with favorable DS-GPA score (2.5-4.0) had better OS with the addition of WBRT (16.7 months vs. 10.6 months, $P = 0.04$)^[38].

From MD Anderson, Chang *et al.*^[34] reported the second randomized trial: 58 patients with 1-3 brain metastases were randomized to SRS alone vs. SRS followed by WBRT. The primary end-point of the study was decline in neurocognitive function measured by Hopkins Verbal Learning Test-Revised at 4 months compared to baseline but was terminated early due to high probability (96%) of inferior outcome in learning and memory at 4 months in SRS plus WBRT arm. Local and distant in-brain controls were higher in SRS plus WBRT arm compared to SRS only (100% vs. 67% and 73% vs. 45%, respectively). An addition of WBRT resulted in less need for salvage therapies (11% vs. 90%) but higher risk for neurological deaths in SRS plus WBRT group (HR: 2.1, 95% CI 0.8-6.0, $P = 0.15$) and median survival was higher in SRS only group (15.2 months vs. 5.7 months). Higher survival in SRS only group was explained by higher rate of local surgical salvage and ability of the patients to have systemic chemotherapy 1 month earlier and median 2 more cycles^[34].

EORTC 22952 phase III randomized trial was the third with the largest patient number, unique in enrolling both SRS and surgically resected patients. Besides, in contrast to other two studies, it included only patients with systemic disease under control. The design was more complex; randomizing adjuvant WBRT vs. observation after surgery or SRS in systemically controlled 359 patients with 1-3 brain metastases. The primary end-point was survival time with functional independence. The local (surgery: 27% vs. 59%, $P < 0.001$; SRS: 19% vs. 31%, $P = 0.04$) and distant brain recurrences (surgery: 23% vs. 42%, $P < 0.008$; SRS: 33% vs. 48%, $P = 0.023$), need for salvage therapy (16% vs. 51%) and neurological death rates because intracranial progression (28% vs. 44%) were decreased with addition of WBRT after surgery or SRS compared to observation but without difference in median duration of functional independence (9.5 months vs. 10 months, $P = 0.71$) and survival (10.9 months vs. 10.7 months, $P = 0.89$)^[35]. In secondary analysis of EORTC 175 NSCLC patients were re-analyzed to evaluate the benefit of WBRT on survival of patients with favorable prognosis (high GPA); there wasn't any significant survival difference between patients with high or low GPA scores^[39].

As seen from these three randomized controlled trials, intracranial control (both local and distant sites) was almost equal in both SRS and SRS plus WBRT groups but survival outcomes were conflicting though none of these trials were intended to address survival as the primary endpoint; both JRSOG and EORTC trials reported same survival rates with both treatment approaches, whereas MD Anderson trial reported higher survival in SRS only group. An individual patient data metaanalysis considering JRSOG, MD Anderson trials and only 199 patients treated with SRS plus or minus WBRT in EORTC was performed by Sahgal *et al.*^[40] It was reported that, in patients with single brain metastasis, overall survival was higher and distant in-brain recurrence was lower compared to the patients with 2-4 metastases. SRS alone resulted in survival advantage in patients ≤ 50 years of age compared to their age-matched control treated with SRS plus WBRT without increase in distant brain recurrences. But there was no significantly higher neurological death in patients ≤ 50 years treated with SRS only (39% vs. 22%). In patients > 50 years of age distant in-brain recurrence risk was significantly higher in SRS only group but this increased recurrence did not translate to any survival disadvantage. When the data was re-evaluated considering only NSCLC patients the results were similar. But the authors emphasize that firm conclusion concerning histology could not be done because of limited sample size and reflection of subset analysis. As a conclusion, the authors suggest that SRS might be the treatment of choice in patients ≤ 50 years with 1-4 metastases^[40].

Recently, Brown *et al.*^[37] have reported the effects of adjuvant WBRT on cognitive function in a randomized phase III (N0574-Alliance) trial in patients with 1-3 metastases. The primary end-point was the amount of neurocognitive decline at 3 months compared to baseline. The local control was increased at 1 year with addition of WBRT to SRS (85% vs. 51%). There wasn't any difference in terms of survival (10.1 months vs. 7.5 months)^[37]. Recently secondary analysis of N0574-Alliance has been reported in 126 NSCLC patients to determine if WBRT might be associated with prolonged survival in NSCLC patients with good performance status. The patients were scored according to DS-GPA scores. There was no significant differences in OS between SRS only or WBRT plus SRS groups in NSCLC patients with favorable DS-GPA scores. This study further supports the approach of SRS alone in the majority of patients with limited brain metastases^[41].

Neurocognitive impairment following WBRT after surgery or SRS vs. observation after surgery or SRS

The impact of adjuvant WBRT on NCF have been utilized in these previously mentioned 4 studies by different methods. JRSOG trial evaluated the Mini Mental State Examination (MMSE) results in SRS only and SRS plus adjuvant WBRT groups in long term. They revealed that the control of metastases increased the MMSE scores in 2-3 months after radiotherapy in both groups and but in late-term (36 months) deterioration of NCF in WBRT group was prominent. In the post hoc analysis, average time to neurocognitive decline was shorter in SRS only group compared to SRS plus WBRT group 7.6 months vs. 16.5 months, respectively. The authors claim that distant in-brain recurrence might have a bigger negative effect on neurocognition and control of metastases is the most important factor in stabilizing cognitive function^[42]. But it should be mentioned that MMSE has been accepted as having lower sensitivity in detection of NCF changes^[43]. Besides, the paucity of the data on neurocognition in this study prevents us from making a conclusion on the effect of WBRT on NCF^[34].

MD Anderson trial reported significant decrease in recall memory and learning at 4 months after WBRT plus SRS compared to SRS alone patients (52% vs. 24%) despite the decreased local and in-brain recurrences as described previously. The authors claimed that adverse effects of WBRT on neurogenesis in hippocampus might have a greater effect on neurocognition than in-brain recurrences and related salvage therapies seen more often in SRS only group^[34].

QOL analysis of EORTC 22952 trial declared a significant neurocognitive decline at 12 months and lower QOL scores in WBRT arm after surgery or SRS^[44].

Table 1. Summary of randomised trials comparing stereotactic radiosurgery to stereotactic radiosurgery plus whole brain radiotherapy

Study	Patient number	Lung cancer patients (%)	# of brain metastases	Type of test	Local relaps (%)		Distant relaps (%)		Median OS (month)		Neurologic death (%)		Decline in NCF/QOL	
					SRS	SRS + WBRT	SRS	SRS + WBRT	SRS	SRS + WBRT	SRS	SRS + WBRT	SRS	SRS + WBRT
JRSOG-99, Aoyama <i>et al.</i> [33] 2006	132	66	1-4	MMSE	27	11	64	41	8	7.5	19	23	Deterioration is earlier in SRS only group at 7.6 month at 16.5 month	
MD Anderson, Chang <i>et al.</i> [34] 2009	58	67	1-3	HVLT-R	33	0	55	27	15.2	5.7	SRS + WBRT risk for death HR: 2.1, 95% CI 0.8-6.0		24%	52%

Alliance N0574, Brown <i>et al.</i> [37] 2016	213	68	1-3	FACT-Brain ADL Index HVLT-R GPT, COWAT TMT-A and B	27	10	30	8	10.4	7.4	NA		NCF at 3 months 64% 92% $P < 0.001$ QOL change from baseline -0.1 -20 $P = 0.001$	

SRS: stereotactic radiosurgery; WBRT: whole brain radiotherapy; OS: overall survival; NCF: neurocognitive functions; QOL: quality of life; MMSE: Mini Mental State Examination; HVLT-R: Hopkins Verbal Learning Test-Revised; FACT: functional assessment of cancer therapy; ADL: activities of daily living; GPT: Grooved Pegboard Test; COWAT: Controlled Oral Word Association Test; TMT: Trail Making Test Part A and B

Alliance trial evaluated the amount of decline in neurocognitive function at 3 months compared to baseline with 6 different cognitive tests. The WBRT and SRS group showed significant decline compared to SRS alone group (92% vs. 64%, $P < 0.001$) at 3 months. Among long term survivors, cognitive decline rates in SRS only and SRS plus WBRT groups were 45% vs. 94% ($P = 0.007$) in 3 months and 60% vs. 94% ($P = 0.04$) in 12 months, respectively, despite the increased local control in 1 year with the addition of WBRT (85% vs. 51%). In each cognitive test there was higher deterioration in SRS plus WBRT group, reaching statistical significance for immediate memory (30% vs. 8%, $P = 0.004$), delayed memory (51% vs. 20%, $P < 0.001$) and verbal memory (17% vs. 2%, $P = 0.01$), respectively [37].

The summary of these four trials can be seen in Table 1. As a whole, adjuvant WBRT reduces distant brain recurrence approximately by 50% and increases local control approximately by 15%-30%, without any survival benefit [6]. Of note, as mentioned before, none of these trials were powered to evaluate survival difference. One explanation for the lack of survival benefit for adjuvant WBRT is the uncontrolled extracranial disease which is the proximate cause of death. But even the largest EORTC trial that enrolled only patients with systemic disease under control to eliminate the competing risk of death from extracranial disease and to be able to detect the survival advantage of WBRT if any, did not find any difference. Secondary analyses of JRSOG 99 showed survival benefits of WBRT among NSCLC patients with high DS-GPA scores (good prognosis). But, secondary analyses of EORTC and Alliance trials failed to confirm this result. On the other hand, efficacy of local salvage therapies in SRS only arm might also be attributed to the lack of survival benefit [6]. Taken together, in the absence of survival advantage and recognized neurotoxicity of WBRT the results of these 4 trials suggest that in single or 24 brain metastases, SRS alone might be the

preferred strategy in amenable patients willing to have frequent brain surveillance with MRI.

Similarly, the American Society for Radiation Oncology (ASTRO) does not recommend routine adjuvant WBRT in oligometastatic brain metastases in its choosing wisely initiative organisation^[45].

On the other hand there have been several opposers to this approach, because they claim that there should be a trade between the risk of neurocognitive dysfunction and the risk of in-brain recurrences which could adversely worsen cognitive function even more than WBRT that might not be reversed by salvage therapies^[46,47].

Solitary or oligometastatic or non-oligometastatic: WBRT only

Brain metastases from the primary tumors occur mainly by hematogenous route making the whole brain under the risk for micrometastatic disease. This concept has been the rationale of WBRT even in case of small solitary metastasis but recently has started to be questioned in the context of true oligometastatic brain disease^[33]. In patients with life expectancy less than 3 months and/or poor performance status, short course WBRT or best supportive care with corticosteroids are reasonable options^[48].

A phase III non-inferiority Medical Research Council trial (QUARTZ), comparing best supportive care alone and best supportive care plus WBRT in NSCLC patients with brain metastases not amenable to surgery or SRS, reported similar survival and QOL. Solitary metastasis rate was 30% but median number of metastatic lesions and distribution of patients among two treatment arms according to number of metastatic lesions were not available in the data^[49]. But there has been some debates on this article; 38% of the cohort had poor performance, the median survival was only 8 weeks which was much inferior compared to previous data^[7]. Besides, due to heterogeneity of prognosis in patients with brain metastases with different primaries the results can not be generalized^[6].

Hippocampus sparing WBRT

WBRT related neurocognitive complications have led to the development of new radiotherapy techniques; hippocampus sparing WBRT (HS-WBRT) is one of them. The rationale lies on that; new memory is composed by neural stem cells located in the subgranular zone of the hippocampus and there is a dose-response-related risk of decline in NCF due to radiation dose received by the HP^[50]. Until recently, there have been only 2 prospective data on this subject. The first one, single-armed phase II RTOG-0933 trial, reported no increased risk of recurrence with HS-WBRT and better preservation of cognitive function with this technique compared to historical controls^[51]. The second data is from Oehlke *et al.*^[52] the progression in the hippocampus avoiding area was 2 (10%) of 20 in 40 weeks. But recently, the preliminary results of a randomized trial (NRG-CC001) composed of 518 randomized patients to memantine and HS-WBRT arm vs. memantine and WBRT arm have been presented in the last ASTRO meeting. HS-WBRT has prolonged time to neurocognitive failure, decrease in neurocognitive function at 6 months was 59.5% vs. 68.2% (HR: 0.76, $P = 0.03$) favoring HS-WBRT without any difference in intracranial brain recurrences or overall survival ($P = 0.208$ and $P = 0.307$, respectively)^[53].

Memantine and WBRT

Memantine has been tested in prevention of cognitive dysfunction as a neuroprotective agent in a randomized placebo controlled trial (RTOG 0614) and shown to be effective in decreasing the rate and delaying the time to cognitive decline^[54]. There is an ongoing randomized clinical trial comparing memantine and WBRT with or without HS-WBRT^[55].

Non-oligometastatic: SRS without WBRT

There have been growing data on SRS without WBRT in patients with more than 3 brain metastases although the maximum number of metastases appropriate for SRS has not been established, yet^[49]. The

Japanese Leksell Gamma Knife Society reported the results of a prospective observational multicenter phase 2 (JLGK0901) study in which survival outcomes and treatment related toxicity of SRS without WBRT in 1,194 patients with single, 2-4 and 5-10 brain metastases were evaluated. Patients with solitary brain metastasis had the longest survival (median 13.9 months, 95% CI 12.0-15.6). In this non-inferiority study, overall survival, local failure, distant in-brain recurrences, neurological death and toxicity were found to be similar both in patients presenting with 2-4 and 5-10 metastases. There was not any survival difference in lung cancer patients with 2-4 or 5-10 metastases either^[56]. An update of this study which was planned to see the radiation related complications and changes in NCF in long-term reported that toxicity and MMSE scores were similar among the three groups^[57]. There have been two clinical trials recruiting patients with estimated study completion date of 2022. One of them led by National Cancer Information Center, is randomizing patients with 5-15 brain metastases to SRS or WBRT plus memantine. Overall and neurocognitive deterioration free survival are the primary endpoints^[58]. The other one is from Dana-Farber Cancer Institute and randomizing patients with 5-20 brain metastases to SRS or WBRT plus hippocampal sparing in available cases, the QOL is the primary end-point^[59].

SRS vs. fractionated SRS

In the absence of randomized trial comparing SRS vs. fractionated SRS (FSRS); FSRS might be the option with lower risk of radionecrosis in large lesions^[60].

TKI and radiotherapy

NSCLC patients having driver mutations (EGFR mutation and ALK rearrangement) in NSCLC have increased risks of brain metastases both at the time of diagnosis and during the course of the disease^[3,4]. TKI targeting EGFR and ALK pathways have resulted in encouraging intracranial control rates compared to chemotherapy^[61].

Withholding radiotherapy in asymptomatic patients with driver mutations

Recently reported three phase II trials advocate withholding radiotherapy (SRS or WBRT) until progression if small asymptomatic brain metastases are present in an EGFR mutation positive NSCLC patient^[62-64]. There are several explanations; first, targeted therapies have greater intracranial activity compared to historical chemotherapeutic agents. Secondly, prolongation of survival with these agents allows time for manifestation of neurocognitive side effects if radiotherapy is the treatment of choice^[65]. But patients should have the willingness to close surveillance with MRI, though the optimal interval is unknown. Contrary to these trials, recently, a retrospective multiinstitutional analysis reported inferior survival with up-front EGFR-TKI in EGFR mutant NSCLC patients with brain metastases, both up-front SRS and up-front WBRT were found to be associated with higher survival compared to up-front EGFR-TKI in multivariate analysis, (HR: 0.39, 95% CI 0.26-0.58 and HR: 0.70, 95% CI 0.50-0.98), respectively^[66]. The debate will be going on until a randomized trial's results, comparing up-front radiotherapy followed by EGFR-TKI to up-front EGFR-TKI followed by radiotherapy at progression in EGFR mutated NSCLC patients.

A retrospective analysis of NSCLC patients with brain metastases and ALK rearrangement, showed prolonged time to intracranial progression with up-front cranial radiotherapy adjunct to first generation ALK inhibitor (crizotinib) compared to patients without cranial radiotherapy, (13.2 months vs. 7 months, respectively)^[67]. Second and third generation ALK inhibitors have better blood brain barrier penetration kinetics which might change the indications for cranial radiotherapy in the near future^[61]. Updated ALEX trial comparing crizotinib vs. alectinib in stage IIIB/IV (asymptomatic brain metastases were allowed) reported median PFS 27.7 months with alectinib vs. 7.4 months with crizotinib (HR: 0.35, 95% CI 0.22-0.56), cranial response rates were 59% vs. 26% and complete cranial response rates were 45% vs. 9% in patients presented with brain metastases at the time of diagnosis, respectively^[68]. As a result of these striking results, postponing the cranial radiotherapy might be reasonable in ALK rearrangement positive patients if Alectinib was the treatment of choice in first line.

Sequencing of radiotherapy and TKI

It's recommended to withhold TKI during WBRT to decrease unexpected toxicity which was observed with concurrent use of erlotinib and WBRT^[69]. If SRS were the treatment of choice, similarly withholding TKI and resuming one day after SRS is usually recommended in the absence of data.

Immune checkpoint inhibitors and radiotherapy

Although the prospective data is lacking, the data on immune checkpoint inhibitors targeting the programmed cell death 1 pathway (PD1) in NSCLC patients with brain metastases has been growing. In a phase II trial it was reported that pembrolizumab showed 33% intracranial response rate^[70]. But nivolumab led to discontinuation of treatment in 58% of patients, because of progression of neurologic symptoms which might be the reflection of pseudoprogression or hyperprogression^[71]. A recent retrospective study reported higher OS in multivariate analysis that concurrent use of anti-PD1 and SRS resulted higher OS compared to sequential use ($P = 0.006$) or SRS alone ($P = 0.002$) or anti cytotoxic T-lymphocyte-associated protein 4 ($P = 0.045$). Concurrent use also reduced distant intracranial relapses^[72].

Sequencing of radiotherapy and immune checkpoint inhibitors

Several retrospective data have reported no increased toxicity with the concurrent use of immunotherapy and cranial radiotherapy in NSCLC, though prospective studies are needed to confirm this finding^[73]. There have been several clinical trials recruiting patients testing the efficacy of immunotherapy in combination with radiotherapy in NSCLC patients with brain metastases (NCT02978404, NCT02858869, NCT02696993)

CONCLUSION

Taken together, these trials suggest survival advantage of surgery or SRS in selected patients with solitary metastasis but no survival advantage of certain treatment option in oligometastatic patients; they differ only in terms of local or distant in-brain control. Besides, QOL assessments have inconsistent results and has yet to be defined. Optimal treatment planning should consider both patient (age, performance status, expected life span) and tumor related factors (number and volume of brain metastases, extracranial disease control, molecular subtype) by using new prognostic models which is in line with personalised medicine and tailored therapy approach rather than “one size fits all”. In light of today's knowledge, it is quite likely that the trade would be going on between doctors and patients, considering QOL as an outcome of neurocognitive function that might be deteriorated either by symptomatic brain recurrence(s) or treatment related morbidity.

Surgical cavity directed SRS seems to be effective in local control and preservation of NCF compared to WBRT but the optimal sequencing (postoperative or preoperative) should be defined.

In non-oligometastatic patients the role of SRS has been evolving, the results of randomized studies might help in decision making.

Targeted therapy and immune checkpoint inhibitors have resulted in increased intracranial activity compared to chemotherapy, but the evidence is not strong enough to defer local therapy and the use as up-front therapy. Also, there are ongoing trials exploring the technique and the methods to spare the NCF.

Abstract

Brain metastasis is a major cause of death in patients with solid cancers. Breast cancer cells have high tendency to migrate towards brain. Cancer cells within brain are characterized by severe aggressiveness and inaccessibility. Currently, breast cancer and its metastasis are the second leading cause of death among women. Tumor microenvironment and blood brain barrier (BBB) represent great obstacles in targeting breast cancer and its metastasis. Chemotherapy is a safer treatment modality for brain metastasis compared with risky surgical resection and brain radiotherapy. Unfortunately, conventional chemotherapy lack penetration of BBB and suffer from multiple resistance mechanisms. Current treatment technologies for brain metastases of breast cancer have limited long-term success and numerous side effects, illustrating the urgent need for novel smart strategies. Various novel drug entities and nanosystems have been employed to improve diagnosis and targeted treatment of breast cancer and its metastasis. Immunotherapy agents and small tyrosine kinase inhibitors have been shown to reduce tumor size and increase survival in patients with breast cancer, but still poorly penetrate BBB. Tailored sized nanoparticles to some extent crossed brain tumor barrier and enhanced drug accumulation in tumors by taking advantage of enhanced permeability and retention. Furthermore, various active targeting strategies have been adopted to improve accessibility to brain malignancies. Therefore, to achieve enhanced antitumor therapy against

breast cancer and its brain metastasis, multi-talented delivery systems are urgently needed for optimal treatment. This review focuses on the various active and passive targeting technologies for the treatment of breast cancer brain metastases in the past decade. A comprehensive summary and examples along with pros and cons of each system will be discussed. Different treatment modalities and nanotechnology facilities will be demonstrated to aid in designing the optimal smart, safe, targeted and effective systems to combat brain metastases of breast cancer.

Keywords: Active targeting, passive targeting, brain metastasis, breast cancer

INTRODUCTION

Despite the recent pharmaceutical and medical advances in treatment and diagnosis of different carcinogenic tissues and their metastases, brain and central nervous system (CNS) primary and metastatic tumors remain a tough hurdle to overcome due to physiological and anatomical barriers represented by blood brain barrier (BBB) and the aggressiveness and continuous adaptive evaluation of this tumor tissue.

As systemic therapy of metastatic breast cancer advances, survival rates of patients are enhanced. On the other side, the incidence of brain and CNS complications increases^[1]. In historical series, the risk of developing brain metastasis has been estimated among women with stage IV breast cancer to range from 10% to 16% among living making it the second most common cause of metastatic brain tumor after lung cancer (10%-25%)^[2-4]. The development of breast cancer brain metastases (BCBM) tends to vary by the subtype. Forty-six percent of patients with advanced triple negative breast cancer, and up to thirty-seven percent of patients with HER2-positive breast cancer relapse due to intracranial metastases, despite control of the peripheral tumors^[5-8].

Treatment options are limited and usually involve multimodality approaches that include surgery, radiotherapy, radiosurgery, and rarely systemic therapy, depending on the number of CNS lesions^[9,10]. The unpredictable extent of therapeutics that can reach tumor vasculature of BCBM has been the challenge in developing effective treatments for these patients^[11,12]. BBB has always been a challenge to drug delivery to brain tissues^[13-16]. However, during brain metastases, the structure and integrity are altered forming a “Blood Brain Tumor Barrier” (BBTB)^[17]. The leaky structure of BBTB is an appealing strategy to target brain tumors^[18]. Approaches to deliver drugs into the brain are being extensively studied [Figure 1].

Beside the common technologies including viral vectors and nanoparticles, novel non-invasive techniques such as ultrasound alteration and magnetic stimulation have been studied to temporally open the BBB to enhance brain drug uptake. In this review, we discuss passive and active targeting BCBMs.

BBB AND DRUG DELIVERY

The BBB, as a morphologic and physiologic barrier, protects the brain tissue from the peripheral vasculature, protecting normal brain function by impeding most compounds from transiting from the blood to the brain^[13,16,18]. There is a common misconception about the nature of BBB as a protective barrier or sac protecting the brain underneath it. Perhaps, the term BBB was the main reason of such misconception. The BBB is mainly a fortified special vascular structure in the brain different from the common vascular structure in the rest of the body. Mainly, the brain capillary endothelial cells (BCECs) form the BBB, besides other cell types such as pericytes, astrocytes, and neuronal cells; playing an important role in the function of the BBB^[19]. BCEC have tight junctions that prevent paracellular transport of small and large (water soluble) compounds from the circulation to the brain except for some very small or gaseous molecules, such as water and carbon dioxide^[17,19,20]. The components of the BBB continuously adapt in response to various physiological changes in the brain^[21] [Figure 1].

Figure 1. The vascular and structural components of the blood brain barrier (BBB) and the blood brain tumor barrier

Similarly, BCECs restrict drug distribution into the brain by limiting drug diffusion from blood to brain. In addition to these physical barriers, cells, like pericytes, and astrocyte foot processes, express several drug metabolizing enzymes that inactivate drugs reducing the distribution of active drugs to the brain. Thus, complicating barrier mechanisms & the presence of both drug-uptake and drug efflux mechanisms such as multidrug transporters including P-glycoprotein (ABCB1/MDR1) and ABCG2. Some compounds pass the BBB by passive non-saturable diffusion, some by active transport; others are actively excluded, and still, others enter through endocytosis^[12].

BRAIN METASTASES OF BREAST CANCER

The occurrence of brain metastases depends on how breast cancer cells adapt to and survive in foreign environments^[22]. Specific homing molecules mediate organ-specific metastasis formation on the heterogeneous tumor cell surface^[23]. Investigating throughout the metastatic cascade is one area of research that can lead to the development of effective treatment.

Research has shown that at the time of initial diagnosis of primary cancer, circulating tumor cells can be found in the bloodstream of patients^[24]. Breast cancer stem cells are characterized by the ability to self-renew along with their high level of resistance to radiation and chemotherapeutic agents^[25]. After detachment of tumor cells from the primary lesion, invasion into the CNS and bypassing the BBB occur, followed by sustained proliferation towards the formation of brain metastases^[26,27]. Studies have suggested that brain metastases originate from cells as a primary mass or lymph nodes or from other visceral metastases^[28].

Disruption of the BBB was shown to involve mediators of extravasation through non-fenestrated capillaries. A number of mediators have been identified to assist breast cancer cells crossing the BBB, including cyclooxygenase-2, heparin-binding epidermal growth factor-like growth factor, and the $\alpha 2$, 6-sialyltransferase ST6GALNAC5^[29-34].

The recently identified extracellular (circulating or exosomal) miRNAs were shown to mediate the ability of metastatic breast cancer cells to target the distant brain endothelium and vasculature^[35]. The metastatic BC cells in brain express high levels of anti-plasminogen activator serpins as a shield to escape from the reaction of brain stroma, conferring the adherence of infiltrating breast cancer cells to the surface of capillaries and the growth on the vasculature^[36].

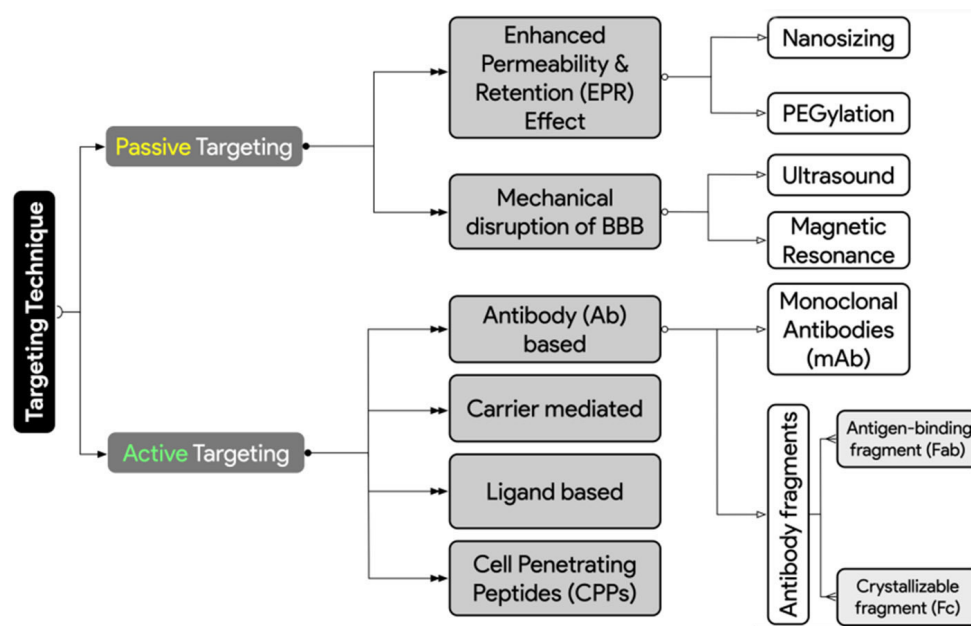

Figure 2. Different adopted strategies for actively and passively targeting brain metastases of breast cancer to overcome the blood brain barrier (BBB) hurdles

Brain metastases of breast cancer are also subject to the limited permeability characteristics of the BBB in spite of the formation of the BBTB with altered integrity. MRI data have shown that not all brain metastases display elevated BBTB permeability^[37]. The changes in BBTB vascular permeability are usually not homogenous throughout the lesion^[38,39]. It was noticed that brain metastases from HER2+ breast cancers infiltrate brain tissue crossing the endothelial cells without disrupting the BBB, unlike the brain metastases from triple negative or basal-type breast cancers that often disrupt the BBB^[8,40] [Figure 1].

TARGETING BRAIN METASTASES

Although, there are no FDA-approved systemic treatments for BCBM to date^[41], patents and studies in the past years have shown promising progress and well-established techniques to overcome the BBB/BBTB^[42]. There are two general strategies adopted to facilitate crossing the BBB; invasive and non-invasive techniques^[43]. The invasive techniques rely primarily on disrupting the BBB integrity by direct intracranial drug delivery through intracerebroventricular, intracerebral or intrathecal administration, osmotic pumps or biochemical means^[43]. But all these approaches are severely limited by poor distribution into brain parenchyma^[44]. On the other hand, non-invasive methods include drug moieties modifications through the transformation of the drug into lipophilic analogs, prodrugs, chemical drug delivery, carrier-mediated drug delivery, receptor/vector-mediated drug delivery and intranasal drug delivery^[43,45].

Diffusion of substances into the brain can be divided into paracellular and transcellular. Generally, BBB targeting strategies can be categorized into passive (transcellular lipophilic pathway) and active targeting (mainly; transcytosis)^[46]. Figure 2 summarizes the targeting techniques covered in this article.

Passive targeting

Enhanced permeability and retention phenomenon

Passive targeting depends mainly on the preferential accumulation of drug molecules into tumor cells^[47]. Enhanced permeability and retention (EPR) phenomenon based on the nanometer size range of the nanoparticles and two fundamental characteristics of the neoplastic tissues, namely, the leaky vasculature and impaired lymphatic drainage. EPR was first described by Maeda and Matsumura^[48]. The selective high

local concentration of nanosized anticancer drugs in tumor tissues enhances the therapeutic effect with minimal side effects in both preclinical and clinical settings^[49].

Various important factors such as circulation time, targeting and the capability to overcome BBB are heavily reliant on the shape, size and the surface area of these particles. In passive diffusion, lipid solubility, molecular weight, and the presence of tight junctions greatly affect the degree of permeation^[50,51].

Conventionally, a particle must be at least 10 nm in diameter to avoid clearance by first-pass renal filtration and the optimal size range of 100-180 nm will ensure longer circulation time, increased accumulation within the tumor mass and lower renal clearance^[52,53]. Moreover, surface characteristics also play a very important role in determining the extent of internalization of these nanoparticles into cells. Relatively, the surface can be modified by the polymer composition, thus governing an extra amount of hydrophobicity or hydrophilicity to these particles^[51]. [Supplementary Table 1](#) illustrates some of the papers using passive targeting technology in targeting BCBM.

Nanotechnology as a tool for targeting EPR

Nanotechnology paved the road towards safer and more likely effective cancer treatment strategies that can overcome some of the hurdles for drug delivery. Nano-medicines primarily aim to improve the circulation time of the conjugated or entrapped (chemo-) therapeutic drugs^[54]. Examples of nanoparticles commonly used include: polymeric particles, polymeric micelles, dendrimers, and liposomes. Nanoparticles represent versatile tools to encapsulate various types of drugs, either hydrophilic or hydrophobic moieties altering their physicochemical parameters and pharmacokinetics profile^[55].

Beside increasing drug-site contact time, some polymers used in nanoparticles formulations such as polylactic-co-glycolic acid (PLGA) have high cell adhesion property, increasing the drug concentration gradient at the adhesion site by longer drug carrier contact time with the targeted cells^[56].

However, nanoparticles can show some serious adverse effects^[57]. Adverse effects of nanoparticles depend on individual factors such as genetics, existing disease conditions, exposure, nanoparticle chemistry, size, shape, agglomeration state, and electromagnetic properties^[57]. The key to understanding the toxicity of nanoparticles is their size; nanoparticles are smaller than cells and cellular organelles, which allow them to penetrate these biological structures, disrupting their normal function^[57]. Examples of toxic effects include tissue inflammation, and altered cellular redox balance toward oxidation, causing abnormal function or cell death^[57]. Furthermore, a major drawback is the difficulty in scaling up the formulation and its transformation to clinical use, due to high cost and instability during storage. The NP materials must be biocompatible and safe when administered^[58].

Liposomes

Liposomal (Liposome: lipid vesicle in Latin) nanocarrier systems are vesicular lipid bilayer colloidal spheres formed by self-assembly^[59]. Without the use of surface modification by a hydrophilic polymer such as polyethylene glycol (PEG), the biological half-lives of liposomes are very short due to several factors including the tendency of the liposome to exchange lipid materials with cell membranes and their uptake by phagocytes. Mohammad *et al.*^[60] noticed increased survival rates in animals treated with liposomal irinotecan (nal-IRI) that sustained the accumulation of irinotecan and its active metabolite in the brain metastases lesions, unlike non-liposomal irinotecan whose distribution in the CNS was hampered by BBTB and various efflux proteins. The size of nal-IRI was between 100-110 nm, which enhanced its preferential accumulation within tumor due to EPR through the leaky vasculature of the tumor^[60]. Drawbacks of liposomes involved their rapid uptake by the Reticulo-Endothelial System (RES) and consequent removal from circulating blood.

PEGylation

The main pharmacokinetic outcomes of PEGylation include: changes occurring in overall circulation life-span, tissue distribution pattern, and elimination pathway of the parent drug/particle^[61]. PEG mainly protects these particles from being phagocytosed by natural particle eliminating mechanisms, mainly organs of the RES^[62].

Pegylated nanoparticles are characterized by hydrophilic surfaces that circumvent opsonization and decrease their clearance by macrophage, which results in prolonged circulation^[51]. PEGylation has been shown to alter the pharmacokinetics of doxorubicin considerably; the total clearance was significantly reduced^[63]. In the early 1990's, PEGylated polymeric vesicles were introduced by Yokoyama *et al.*^[64], which represented an important milestone in the synthesis of long-circulating liposomal formulations (STEALTH® liposomes). Liposomal formulations are the first novel controllable carrier systems to be sold in the market for cancer (Doxil®, PEGylated liposomal formulation encapsulating doxorubicin(PLD)^[65-67]. PLD showed reduced cardiotoxicity and prolonged activity.

Anders *et al.*^[68] encapsulated doxorubicin in pegylated liposomes (PLD) that achieved 20 folds higher concentration of doxorubicin within intracranial tumors compared to non-liposomal doxorubicin, whose distribution was compromised by BBTB. Moreover, co-administration of PLD and BBB permeable ABT-888, an inhibitor of a poly (ADP-ribose) polymerase, showed better survival as compared to non-liposomal doxorubicin and ABT-888.

Nektar™ Therapeutics has several patents on PEGylation bioconjugation aiming to modify the pharmacokinetic profile^[69-75]. Adkins *et al.*^[76] formulated NKTR-102, an Irinotecan-PEG conjugate linked with a hydrolysable ester bond, whose polymer moiety resulted in prolonged circulation and subsequently increased tumor localization. The innovative nature of this PEGylated system is the adoption of the three-dimensional (3D) branching technology in the PEGylation to provide superior pharmacokinetics and pharmacokinetic parameters. The 3D propriety Nektar PEG technology offers weeks of half-lives compared to days in conventional PEG^[76]. The preferential accumulation of NKTR-102 within brain metastases via EPR, its reduced clearance and ability to escape P-glycoprotein mediated efflux resulted in continuous release of the active metabolite SN38 and better therapeutic efficacy.

Nektar™ Therapeutics is not the only pharmaceutical company relying on innovative PEGylation technologies for passively targeting brain metastases of breast cancer. Other companies, such as 2-BBB, is investing heavily on the use of PEGylation bioconjugated with liposomal vesicular carrier systems to passively target brain metastases of breast cancer^[77]. BBB adopts a propriety G-Technology® for targeting the brain. 2-BBB's G-Technology® empowers sustained delivery of systemically administered therapeutics to the brain with high safety and efficacy profiles. The G-Technology® uses PEG and glutathione bioconjugated to active pharmaceutical ingredients loaded liposomal vesicular structures. Polyethylene glycol (PEG) is attached to the liposomes to provide a prolonged circulation time in the blood stream with sustained half-life pharmacokinetic profile. Glutathione is bioconjugated to the PEG molecules to offer targeted safe and effective delivery of the therapeutics across the BBB^[78].

2-BBB has adopted its G-Technology® in developing two lead clinical programs targeting multiple indications of brain cancers and neuroinflammatory diseases. 2-BBB's lead product 2B3-101 (glutathione PEGylated liposomal doxorubicin) combines the G-Technology® with the existing chemotherapeutic agent doxorubicin for the possible treatment of brain metastases and glioma. It has completed a Phase I/IIa trial treating patients with various forms of brain cancer. 2-BBB's second promising lead product is 2B3-102. 2B3-102 is a glutathione PEGylated liposomal methylprednisolone. It applies the anti-inflammatory glucocorticoid methylprednisolone to combat acute and chronic neuro-inflammation associated with several CNS

indications including acute relapses of multiple sclerosis, optic neuritis, neuromyelitis optica and uveitis. 2B3-201 has completed a Phase I clinical trial in healthy volunteers^[77].

2-BBB is a clear example of industry-driven research aiming at developing innovative passive targeting technologies to brain and brain metastases. They use triple passive targeting techniques to offer optimal safety and efficacy profiles, Glutathione passively targeting the cancerous intracellular reductive environment, PEGylation and liposomal vesicular carrier system^[77].

Nucleic acid

RNA interference (RNAi) is an endogenous pathway for post-transcriptional silencing of gene expression that is triggered by double-stranded RNA, including endogenous microRNA (miRNA) and synthetic short interfering RNA^[79]. MicroRNA-122 mediated RNAi brings new prospects^[80]. Zhang *et al.*^[81] miRNA-1258 in BMBC cells inhibited heparanase which regulates many molecules involved in angiogenesis and metastasis of the tumor.

Advanced physically manipulated systems to disrupt BBB

Another modality of addressing BBB passively is advanced physically manipulated systems that can be tightly mediated by stimuli to treat diseases specifically and with a controlled dosage of drugs. Physical manipulation can be achieved based on ultrasound, electricity, magnetism and photonic emission technologies^[82]. Davalos *et al.*^[83] applied pulsed electric fields into brain tissue of an animal, to cause temporary disruption of the BBB in a volume of brain tissue near the source of the pulsed electric fields over a specified time interval.

The use of focused ultrasound (FUS) combined with circulating microbubbles is a non-invasive method that increases the permeability of BBB and improves outcomes of trastuzumab; this technique was used by Park *et al.*^[84] to improve outcomes with trastuzumab in a breast cancer brain metastasis model. Similarly, FUS in combination with microbubbles was able to temporarily disrupt the BBB enhancing the anti-tumor efficacy of the two anti-HER2 agents combination therapy^[85]. Moreover, reversible disruption of the BBB by bursts of low frequency MRI-guided ultrasound enhances the brain delivery of monoclonal antibody - Herceptin (trastuzumab) in mice^[86,87].

Active targeting

Active targeting was proposed for improved targeting efficacy^[47]. These strategies consist in incorporating affinity molecules or taking advantage of influx transport systems expressed within the BBB/BBTB depending on specific interactions of ligand-receptor and antibody-antigen^[47,88,89]. Also, several ligands have been studied and utilized to shuttle nanoparticles, antibodies, and drugs across the BBB and into the brain cells^[90] [Figure 1]. Supplementary Table 2 summarizes recent studies of actively targeted treatments for BCM.

Receptor-mediated transcytosis/ligand-based

An overexpression of receptors or antigens in cancer acts as a potential target to achieve efficient drug uptake via receptor-mediated endocytosis^[47]. Moreover, receptor-mediated transcytosis (RMT) allows for BBB transport of various macromolecules after initial binding of a targeting ligand to a receptor expressed on the brain endothelial cells^[91]. Tumor-targeting ligands such as peptides and antibodies may effectively aid certain cytotoxic agents (either biological or synthetic) to deliver to the tumor cells, thereby improving therapeutic efficacy while limiting the exposure of normal tissues to the cytotoxic agents^[92]. The transferrin receptor, the low-density lipoprotein receptor-related protein 1 (LRP-1), the insulin receptor and the nicotinic acetylcholine receptors are examples of receptor expression on the BBB.

AngioChemTM Inc. developed a series of aprotinin polypeptides (Angiopeps)^[93]. Angiopep-2, a 19-amino-acid peptide, is one of the promising vectors designed to target the LRP-1 receptor, to mediate transcytosis across the BBB. It is derived from the human Kunitz domain^[94]. Angiopep-2 can facilitate brain-targeted drug delivery through LRP-1-mediated transcytosis. Regina *et al.*^[95] demonstrated that a conjugate between angiopep-2 and an anti-HER2 mAb results in a new chemical entity, ANG4043. ANG4043 retains *in-vitro* binding affinity for the HER2 receptor and antiproliferative potency against BCBM rat model. This study showed increased uptake in brain endothelial cells and enhanced BBB permeability compared to poor brain penetration of anti-HER2 mAb alone. Similarly, Thomas *et al.*^[96] showed that ANG1005 shows significantly improved delivery to brain and brain metastases of breast cancer compared to free paclitaxel in mice bearing BCBM.

On the other hand, Orthmann *et al.*^[97] formulated rigid and fluid liposomes entrapping Mitoxantrone and equipped with a 19-mer angiopeptide as a ligand. Angiopeptide bearing fluid liposomes showed *in vitro* the highest cellular uptake and transcytosis. They were significantly better than the corresponding ligand-free fluid liposomes and ligand-bearing rigid vesicles however; the improvement was mainly depending on liposomal fluidity while the targeting contributed only to a minor degree. In 2016, Orthmann *et al.*^[98] encapsulated oxaliplatin (OxP) in liposomes then bound angiopep-2 to the vesicular surface. They determined that the newly developed OxP liposomes significantly improved the treatment of subcutaneously and intracerebrally growing breast cancer, but the targeted angiopep-equipped liposomes showed no superior effect *in vivo*.

Melanotransferrin (hMTf) is another target to the LRP-1 receptor, which was shown to deliver doxorubicin across BBB^[99,100]. In order to overcome the trastuzumab inability to cross the BBB and treat brain metastases of HER2+ breast cancer, BT2111, a novel bioconjugate of trastuzumab was developed by BiOasis Inc., on the hMTf (p97) TranscendTM vector platform^[101]. This platform is an example of an actively targeted immunotherapy, aiding in enhancing the immunotherapy targetability, ability to cross the BB and clinical efficacy via the use of the targeting moiety hMTf.

Another complex process involves binding to a primary, tumor-specific receptor activating endocytosis; using “Tumor-penetrating peptide”^[102]. The prototypic peptide of this class, iRGD (CRGDKGPDC), contains the integrin-binding RGD motif^[103]. The integrin-binding RGD sequence motif binds to $\alpha v \beta 3$ and $\alpha v \beta 5$ integrins, which are specifically expressed in tumor endothelial cells^[102]. Hamilton *et al.*^[104] demonstrated that a single dose of iRGD had a significant effect on metastatic tumor progression and nonproliferative cancer cell retention when applied early in course of tumor development. Proteolytically processed iRGD also exerts anti-metastatic activity by binding to neuropilin-1 and activating an endocytic bulk transport pathway through tumor tissue. The iRGB platform offers an innovative dual targeting tool to target the tumor portion via the integrins and the RGB motif^[103].

Carrier-mediated transcytosis

Naturally, carrier-mediated transcytosis (CMT) enables spontaneous internalization of small biomolecules^[105,106]. CMT takes advantage of the immunological surveillance system of the brain, using circulating phagocytic cells such as monocytes or macrophages as Trojan horse to deliver drug molecules into the brain^[107]. Such cells have a tendency to endocytose colloidal materials, for example, nano or microparticles, liposomes, and subsequent exocytosis to release drug and/or colloidal materials to external media^[108]. Fidler and colleagues provided evidence that macrophages of blood monocyte origin can infiltrate experimental brain metastases while the BBB is intact.

In 2012, Choi *et al.*^[109] reported the first successful demonstration of the active delivery, using macrophages, of nanoparticles to brain metastases. Activated macrophages not only cross the BBB but they envelop the

metastatic cells delivering the loaded nanoparticle to less than a cell width away from the nearest metastatic cell^[109].

Cell penetrating peptides

Cell-penetrating peptides (CPP), that show great capacity in BBB transport, have the ability to transport protein or peptides into cells in a nonspecific, receptor-independent manner and non-immunogenic when compared with antibodies^[110]. Considering their smaller size (up to 30 amino acids in length), cationic and/or amphipathic CPPs have a greater potential to penetrate the BBB than other transport systems. Short peptides, as targeted drug delivery vehicles, appear to have some advantages owing to their small size, efficient tissue penetrability, and minimal toxicity and immunogenicity.

The first CPP, trans-activator of transcription (TAT), derived from human immunodeficiency virus-1, can be efficiently taken up from the surrounding media^[111]. Morshed *et al.*^[112] used PEGylated gold nanoparticle conjugated to TAT peptide as well as doxorubicin. This formulation offered extensive accumulation of particles throughout diffuse intracranial metastatic microsatellites. Moreover, it was shown to destabilize a brain capillary monolayer increasing its permeability. Fu *et al.*^[113] combined brain metastatic breast carcinoma cell (231-BR)-binding peptide BRBP1, a cell penetrating peptide TAT, and a proapoptotic peptide KLA. The composite selectively homed to the tumors in vivo where it induced cellular apoptosis without significant toxicity on non-tumor tissues. Angiopep-mediated targeting also can be considered as one of the most promising ways to reach the CNS for the treatment of brain cancer or brain metastases^[114].

Conclusion and future directions

There is a global need for effective and safe pharmaceutical chemotherapeutic agents that have the potential to target tumors like BCBM.

Conventional chemotherapy, radiation therapy and immunotherapy offers promising options for treating brain metastases, which is traditionally treated with surgery.

In 2005, the chemotherapy temozolomide (Temodar®) was approved to treat glioblastoma (GBM) patients. However, over 50% of GBM tumors generate a DNA repair protein (methylguanine methyltransferase) that effectively combats and neutralizes temozolomide chemotherapy. There are two FDA approved immunotherapies for brain and nervous system cancers and metastases. Bevacizumab (Avastin®) and Dinutuximab (Unituxin®). Several other immunotherapies are being used to treat different types of brain cancers in clinical trials. However, there are no FDA-approved systemic treatments specific to BCBM to date^[41]. Improved insights into the microenvironment and metastatic cascade processes have resulted in the development of several novel chemotherapeutic and immunotherapeutic drugs and strategies^[35,36,38,39,54]. Such novel chemotherapeutic and immunotherapeutic strategies adopt active and passive targeting strategies to enhance the clinical treatment effects.

Surveying the published research papers and patents also revealed a major drawback in the methodology design, which is the lack of standardization of efficacy and safety profiles. Various sophisticated nano-systems and conjugates have been studied to either actively or passively target BCBM. However, most of these complex delivery systems fail to reach the market due to high cost, instability and difficulty of scaling up. In addition, majority of the reagents used in the formulation of such novel therapeutic systems to improve the stability; are not included in the FDA approved inactive ingredient database. The main question of this review is to query the preferential advantage of either active or passive targeting in combating brain metastases of breast cancer. Such question is a major ongoing debate as revealed by the recent patents and papers portfolio.

Passive targeting could be a cheaper, long-term effective and safe technique to target tumor cells without triggering resistance for active targeting moieties. Numerous significant downsides in active tumor-targeted drug delivery were identified^[115-120]. Interestingly, passive targeting can be tailored and designed via simple ideologies and techniques such as simple PEGylation, size modifications or even shape customization. It was shown that slender shape and particles modifications such as drifting from the conventional spherical particulate structures, can yield high effectual passive targeting^[121].

Active targeting shows significant results in combating cancer initially with long-term degraded efficacy profile, most potentially attributed to multidrug resistance^[119]. Additionally, the marginally augmented efficacy of active targeting strategies does not substantiate the extremely higher cost, difficulty in clinical application and the high complexity level of the carrier system^[54,78,115-120,122,123]. Interestingly, passive targeting can be tailored and designed via simple ideologies and techniques such as simple PEGylation, size modifications or even shape customization.

Multiple researchers suggested the preferential long-term advantage of passive targeting over active targeting such as Lammers *et al.*^[122] and Rosenblum *et al.*^[123]. Such researches highlighted the need for future realistic and scalable efforts to address some of the conceptual drawbacks of drug targeting to tumors such as resistance, and that strategies should be developed to overcome these deficiencies. Such research presented evidence that passive targeting yield very comparable results to active targeting on the short term and superior results on the long term^[54,78,115-120,122,123].

Some of the main drawbacks of engineered nanotechnologies, either active or passive, are the poor robust and cost-effective toolbox to characterize nanomaterials and to quantify exposure in test systems (dosimetry), lack of standard techniques and methods for test, hazard, and risk assessment strategies and lack of specific safety assessment strategies in evaluating nanotoxicities. However, passive targeting offers less problematic strategy compared to active targeting engineered nanotechnologies in terms of nano-safety and its quantitative characterization^[124].

Passive targeting could provide an applied direction for the advance of novel management tackles and therapeutics for brain metastases of breast cancer for researchers worldwide, paving the road to affordable, scalable, stable, efficient and safe management strategies. Such observations were evident from the multiple passive targeting products under Phase II and Phase III clinical trials from multiple pharmaceutical firms such as Nektar Therapeutics, BiOasis Inc. and 2-BBB. Such companies have invested heavily into the development of new formulations that combat brain barriers, targeting the brain and accumulates in tumor tissue rather than normal cells, to enhance the nano-safety profiles to chemotherapeutics. This may not be only attributed to their need to expand their portfolio to increase their commercial value for possible products buyouts and licensing by big pharmaceutical firms, but the safety and efficacy potential of such passively targeted nanotherapeutics in the treatment strategies of brain metastases of breast cancer compared to current conventional modalities and research-driven active-targeting initiatives.

Such conclusions have driven the industry to invest heavily on passive targeting compared to active targeting. A major focus by industry is the successful transformation of such novel technologies from bench to bedside with reasonable cost, scale-up abilities and formulation robustness and reproducibility, which are achievable via passive targeting technologies compared to active targeting. Active targeting ligand post-insertion and labeling techniques need to be extensively researched for ease of application for active targeting to gain industrial momentum. Conclusively, patents and products under development should focus on simple passively targeted bioconjugate structures, which are easily synthesized with high yield, reduced cost and high stability profile of the final formulation.

Abstract

The carcinogenic mechanism proposed considers that stem cells committed to repair tissues and differentiated cells, acquire different metabolic properties, if there is an associated GABA deficiency suppressing a control system of the endocrine pancreas. This control system mediated by GABA, released with insulin, normally turns off glucagon and somatostatin release when insulin is released. A consequence of the GABA deficiency in pancreas and adrenals is a hybrid insulin-glucagon-somatostatin message, received by new mitotic stem cells displaying then a hybrid metabolic rewiring. This gives them a selective metabolic advantage over differentiated cells that become insulin resistant and only receive the glucagon- somatostatin part of the hormonal message. Indeed, their insulin receptors are desensitized by the persistent leakage of insulin resulting from the GABA deficiency that fails to close the insulin release mechanism. Thus differentiated cells are simply rewired to be plundered by stem cells. The metabolic advantage gained by stem cells blocks their own differentiation and maintains their mitotic capacity. Inevitable mutations of mitotic cells follow, the immune system is unable to eliminate a geometrically increasing number of altered stem cells, a selection of the most aggressive but metabolically successful population takes place when cancer is declared.

INTRODUCTION

Since the early observations of Warburg on cancer metabolism showing the lactic acid increase even in the presence of oxygen (Warburg effect)^[1,2], until the seminal works of Mazurek and Eigenbrodt^[3] and Eigenbrodt *et al.*^[4] on pyruvate kinase (PK) M2 blockade in tumors, much progress has been made on metabolic rewiring processes in cancer^[5,6]. An increasing number of works are interestingly gathered in special issues on cancer metabolism^[7]. However, they deserve to be included in a more general frame proposing a mechanistic explanation for metabolic rewiring processes in cancer. In parallel, there is great interest for diets, natural products and life styles that would decrease cancer incidence. Presumably, the idea is that a diet might influence metabolism and the epigenetic control of genes that have been implicated in cancer incidence. It is for example shown that a simple dietetic mixture: curcuma and poly unsaturated fatty acid, gives protection against a carcinogen (Dimethyl Benz Anthracene) in animal models^[8]. There are several observations linking nutrition and cancer, reminding that nutrition has evidently metabolic consequences that may change the incidence of diseases, including cancer.

Paradoxically, even viral or cellular oncogenes that initially pointed toward a viral or genetic cause for cancer, reinforced the metabolic cancer model, because the genes that were up-regulated by the viral or cellular oncogenes encoded for proteins supporting the different steps of signaling pathways similar to the one activated by insulin, via tyrosine kinase receptors. With insulin signaling, glycolytic metabolism evidently came back on the stage. However, a general frame that would explain the metabolic rewiring process in cancer, its effects on stem cells and differentiated cells remained to be proposed; this was started in previous works^[9-13] and is continued in this presentation.

A surprisingly low number of metabolic “switch compounds” control the direction of major metabolic pathways in a network of enzymes that support the different metabolic finalities reached by a cell in response to its receptors. The cascades of signals that follow coordinate the enzymes and the pathways direction towards a specific metabolic finality responding to a physiological situation. Schematically, the finalities to reach are: (1) the catabolic production of nutrients (glucose and ketone bodies) when food gets scarce; (2) the production of energy, with a possible selection of the energetic source (glucose, fatty acids, eventually ketone bodies); (3) the anabolic synthesis of new constituents for new mitotic cells, which requires energy and the substrates for making these constituents. In addition, anabolic hormones increase glycogen and lipid tissue stores when food is available. These metabolic finalities are controlled by the ON or OFF status of major enzymes, activated or inhibited by phosphorylation via their respective protein kinases or phosphatases, themselves controlled by “switchboard” kinases and phosphatases activated by specific receptors. In previous works we have analyzed the phosphorylation status of key enzymes in given physiological situations covering the finalities considered. A coherent set of phosphorylation of these enzymes was associated to the action of catabolic hormones (glucagon, epinephrine and cortisol). The phosphorylation status was opposite for anabolic hormones such as insulin or IGF. The conclusion was that in cancer, enzymes such as PK and pyruvate dehydrogenase (PDH) remained phosphorylated and blocked in their catabolic configuration, even if the cell had switched from catabolism to anabolism; as if the action of a switch board phosphatase had failed. In such condition, the cell had to rewire its metabolic pathways in order to by-pass the PK and PDH “bottle necks”, the resulting metabolism was favorable to its development at the detriment of other differentiated cells that become their nutritional reservoir; this perverted finality seems to be a starter for cancer. We shall first consider the status of major control switches, for the three major metabolic finalities and then analyze the unique hybrid configuration of these switches in cancer, showing how pathways are reconnected in mitotic stem cells, or in differentiated cells. It will become apparent that a non-coherent

mixed hormonal signal is received by new mitotic cells with new receptors, while differentiated cells with desensitized insulin receptors, resistant to insulin, will respond preferentially to catabolic hormones and to growth hormone (GH). We have in earlier works considered that a failure of the endocrine pancreas, would explain the aberrant hybrid hormonal signaling that supports cancer metabolism. Indeed, insulin secreting beta cells in the pancreas possess a major GABA control system that normally turns off glucagon releasing alpha cells and somatostatin releasing delta cells, when beta cells release insulin and GABA. The released GABA also closes via auto receptors of beta cells, the release of insulin. Thus a GABA deficiency would not only fail to turn off glucagon release when insulin is released, sending a dual hybrid glucagon-insulin message, but also maintain a steady leakage of insulin that desensitizes with time, insulin receptors. New mitotic stem cells with new insulin receptors, not yet desensitized for insulin will then respond to both insulin and glucagon, while other differentiated cells constantly submitted to an insulin leakage become resistant to insulin. The stem cells will have to rewire their metabolic pathways in response to the hybrid message; they gain a special metabolic advantage over differentiated cells that are simply plundered, since they only respond to the catabolic component of the hybrid message.

The carcinogenic mechanism proposed considers that stem cells committed to repair tissues after a variety of injuries and differentiated cells develop different metabolic features, if there is an associated GABA failure in the endocrine pancreas^[9,10]. The pancreatic GABA deficiency hypothesis that fully explained the observed metabolic rewiring in cancer was initially published in reference 9; the hypothesis was confirmed and strengthened by a set of epidemiological observations that were gathered in reference 10. These observations also included the more controversial role of some pesticides that may affect GABA, a point that was not particularly appreciated. The metabolic advantage given to stem cells by the pancreatic deficiency blocks their differentiation and maintains their mitotic capacity; while differentiated cells are plundered. Inevitable mutations follow, while the immune system becomes unable to eliminate a geometrically increasing number of altered stem cells, a selection of the most aggressive and metabolically successful population starts cancer. Presumably, this metabolic trigger for carcinogenesis starts years before cancer appears, correcting the GABA pancreatic failure, or neutralizing eventual auto-antibodies against glutamate decarboxylase (GAD), or suppressing its inhibition, might delay or avoid cancer. When cancer is declared present therapies might be backed-up by a metabolic treatment aiming to reverse the rewiring process that gave to tumor cells their metabolic advantage.

METABOLIC SWITCHES ORIENT PATHWAYS TOWARDS DIFFERENT METABOLIC FINALITIES

We represented in [Figure 1](#), the endocrine pancreas, with its beta, alpha and delta cells that secrete respectively insulin, glucagon and somatostatin (STH). The GABA release from beta cells inhibits alpha and delta cells (via GABA A receptors) when insulin is released; and puts an end to insulin release (via GABA B auto receptors). GABA also inhibits epinephrine release from adrenals. We describe with different colors the pathways that operate for the different metabolic finalities that a cell is susceptible to reach, and give in the corresponding colored boxes the status (increase +, decrease -, or 0 not relevant) of the selected switches. First finality: The production of nutrients; triggered by catabolic hormones, glucagon, epinephrine, and cortisol (yellow pathways and yellow box [Figure 1](#)). When food gets scarce, the pancreas senses the drop of blood glucose, hyperpolarized beta cells retain GABA, no longer spilled over alpha cells and their relative depolarization triggers the release of glucagon. The action of glucagon on liver glucagon Gs coupled receptors, or that of epinephrine on beta adrenergic receptors in muscles, stimulates adenylate cyclase and the synthesis of cAMP. The latter, activates PKA serine kinase then Src tyrosine kinase, eliciting in fine, via specific protein kinases, the phosphorylation of a set of enzymes that are ON or OFF after phosphorylation. Glycogen phosphorylase a, is ON, supporting glycogenolysis, while PK and PDH are OFF closing the entry of the citric acid cycle, this spares oxaloacetate (OAA) at the start of the neoglucogenic pathway; pyruvate carboxylase (Pcarb) and phosphoenolpyruvate carboxykinase (PEPCK) are both activated. The blockade of PK by phosphorylation, avoids a reconversion of phosphoenolpyruvate (PEP) into pyruvate (PYR). Muscle

proteolysis provides amino acids, the transamination of alanine feeds with PYR the neoglucogenic route. Since cAMP inhibits Fructose 2-6 bis phosphate (Fru2-6 bisP), it cancels the inhibition of neoglucogenesis and blocks glycolysis; glucose is now produced. We have to add that hypoglycemia decreases glycolysis in erythrocytes, which form less 2-3 DPG. Thus, oxygen is retained by hemoglobin and less is delivered and reduced by other cells, their NADH/NAD ratio increases, closing their citrate condensation that starts the Krebs cycle, more OAA goes to neoglucogenesis. Glycogenolysis is activated as well (phosphorylated phosphorylase a, is ON), while phosphorylated glycogen synthase is OFF. The other nutrient are ketone bodies; we know that PKA and Src activate a protein LKB1 by phosphorylation, it will stimulate AMP kinase, which inhibits acetyl CoA carboxylase (ACC) at the start of the fatty acid synthesis pathway. The inhibition of ACC decreases the product malonyl CoA, which is an inhibitor of the mitochondria carnityl transporter of fatty acids, allowing then fatty acid to enter in mitochondria. There, beta oxidation forms acetyl CoA, then ketone bodies, acetoacetate, particularly in liver. The malonyl CoA inhibition of the fatty acid transporter blocks the degradation of fatty acid when their synthesis is activated and vice versa. The ketone bodies are delivered to other cells, where they give back acetyl CoA by the reverse pathway (thiolase operating in both directions).

Second finality: the production of energy, and selection of glycolytic or fatty acid sources of acetyl CoA. Even when glucagon, epinephrine and cortisol are released for making glucose and nutrients, muscles can reverse the situation and keep their glycolytic pathway operational, with little or no neoglucogenesis; on the other hand, glycogenolysis is still possible (Figure 1 red pathways and red box). This muscle exception is presumably linked to the fact that muscles have to be ready for escaping predators. How are the effects of cAMP on neoglucogenesis cancelled? Muscle activity is associated to the movement of charges along T tubules until reticulum sacs with ryanodine receptors in the depth of the muscle, the depolarization releases calcium in the cytosol initiating muscle contraction. Calcium will also stimulate a phosphodiesterase (PDE) converting cAMP into AMP, which restores the synthesis of Fru2-6 bisP, the allosteric activator of glycolysis, and inhibitor of neoglucogenesis. In parallel, calcium stimulates calcineurin phosphatase, which dephosphorylates an inhibitor (I1) of a major phosphatase PP1 that gets activated, leading in fine to the dephosphorylation and activation of PK and PDH, which opens the glycolytic supply of acetyl CoA to the Krebs cycle. The citrate condensation starts, (the NADH/NAD ratio decreases via oxygen reduction). Then, since ATP is low and AMP elevated, the inhibition isocitrate dehydrogenase by ATP is cancelled and the citric acid cycle "turns", which decreases the citrate efflux from mitochondria and closes the fatty acid synthesis route (via ATP citrate lyase and ACC). The elevated AMP activates AMP kinase, which inhibits ACC; a low level of malonyl CoA may now open the beta oxidation of fatty acid and the fatty acid source of acetyl CoA, when glucose is missing. Well, exactly the same glycolytic energetic finality (red pathway Figure 1) will eventually operate in anabolism when insulin is released; because insulin elicits the activation of a phospholipase that splits phosphatidyl inositol (4-5) Bis P (PIP2) into diacyl glycerol (DAG) and inositol 1,4,5 Phosphate (IP3). The latter, will act on IP3 receptors of the reticulum, releasing calcium in the cytosol. Calcium stimulates as described above, a PDE neutralizing the inhibitory effect of cAMP on Fru2-6 bisP synthesis, and activates calcineurin, then PP1, PK and PDH, which stimulates glycolysis and opens the glycolytic entry of the Krebs cycle. But here is a new regulator to consider: DAG. If the level of DAG is low, presumably when DAG is converted into monoacyl glycerol, the glycolytic route forms acetyl CoA as above (Figure 1 second red box). However, if DAG increases, it will activate protein kinase C (PKC) and the latter elicits the synthesis of a new inhibitor of PP1 known as CPI 17, which keeps PK and PDH phosphorylated and inhibited, and closes the glycolytic supply of acetyl CoA. The fatty acid source of acetyl CoA will have to be opened. Since AMP is elevated, it stimulates AMP kinase, which inhibits ACC and the fatty acid synthesis pathway. With malonyl CoA being low, fatty acid beta oxidation is now permitted, opening the fatty acid supply of acetyl CoA, (Figure 1 black pathway and black box). The third finality: the anabolic synthesis of new constituents depends essentially on Insulin and IGF. It is represented by the green pathways, plus the glycolytic red pathway, and green box for switches. The effect of insulin on its tyrosine kinase receptor elicits anabolism: The synthesis of glycogen, of fatty acids and triglycerides (TAG), of

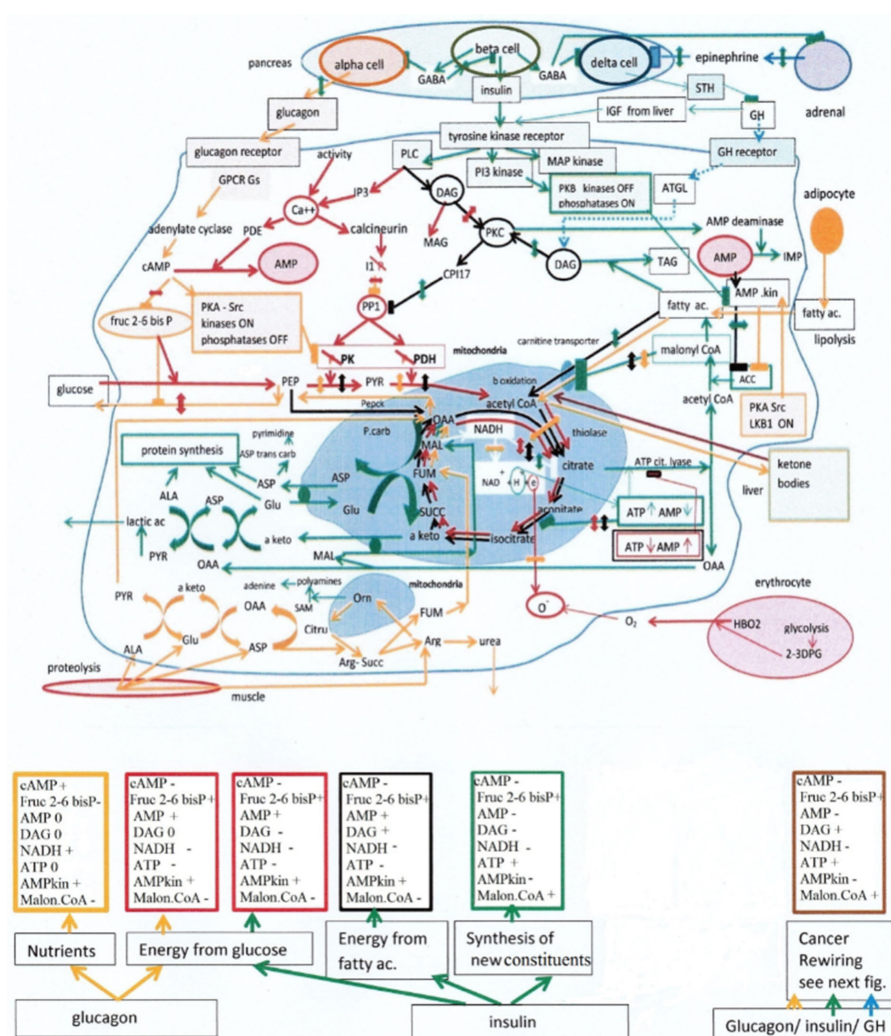

Figure 1. Top: endocrine pancreas, the alpha cell releases glucagon; it is turned off by GABA co-released with insulin from beta cells. In this way when anabolic insulin is ON catabolic hormones are OFF, GABA also inhibits epinephrine release from adrenals. Moreover, GABA turns off somatostatin release from delta cells, which stimulates growth hormone and IGF. The cell below the pancreas displays different metabolic finalities that can be reached; these are controlled by a few “switch compounds” themselves controlled by the endocrine pancreas. These compounds are listed in the boxes below the cell. The yellow pathways represent the nutrition finality forming glucose and ketone bodies; it is activated by catabolic hormones that control the switch compounds in the yellow box (+ is increase, - decrease, 0 no change or not relevant). The second and third metabolic finalities represented by the red pathways is the production of energy from glucose, in the case of glucagon or insulin, note in the corresponding red boxes the difference for diacylglycerol DAG. The next finality is the production of energy from fatty acids it is represented by the black pathways and the black box for switch compounds. The last finality represented by the green pathways and green box for the switches, is the anabolic synthesis of new constituents, it is essential for mitotic cells. The last box in brown shows for comparison the switches for mitotic tumor cells, specially studied in Figure 2. DAG: diacyl glycerol; PK: pyruvate kinase; PDH: pyruvate dehydrogenase; GH: growth hormone

proteins. Insulin also inhibits the opposite effects: glycogenolysis, neoglucogenesis, lipolysis and proteolysis mediated by catabolic hormones. Insulin stimulates glucose uptake, facilitating the incorporation of the glucose transporter. The influx of glucose in cells is also regulated by different affinities of liver glucokinase lower than the equivalent brain enzyme hexokinase; which serves the brain first with glucose. In parallel, insulin activates the MAP kinase mitotic and PI3kinase routes, supporting mitosis and cell survival (recall that each step of these pathways was up-regulated by viral or cellular oncogenes). We have mentioned above, the downstream stimulation by insulin, of a phospholipase C that generates IP3 and DAG. We recall that IP3 elicits the release of internal calcium, activating a PDE hydrolyzing cAMP, which cancels the inhibition of Fruc 2-6 bisP synthesis, leading to an increased glycolysis. Moreover, calcium helps the incorporation of glucose transporters in cells that have no constitutive transporter in their membrane. But the stimulation

of PKC by DAG will then stimulate AMP deaminase that converts AMP into IMP; which decreases AMP and the stimulation of AMP kinase, cancelling its inhibitory effect on ACC and fatty acid synthesis that gets activated. Moreover, insulin-mediated PKB effects are opposite to those of PKA that stimulated AMP kinase. One may then expect that the inhibition of AMP kinase (low AMP and inhibition by PKB) will open the fatty acid synthesis pathway; the malonyl CoA intermediate increases, closing the fatty acid carnityl transporter and the beta oxidation source of acetyl CoA. It is thus necessary to open back the glycolytic source of acetyl CoA that had been closed via DAG PKC stimulation forming the CPI17 inhibitor of PP1, which blocked PK and PDH. Now that the synthesis of fatty acids and triglycerides is activated by insulin, DAG will be converted into triglycerides and decrease, suppressing the stimulation of PKC by DAG and the CPI17 inhibition of PP1, which opens back PK and PDH and the glycolytic source of acetyl CoA (red pathway [Figure 1](#)), while the full anabolic effects of insulin take place. Note that the efflux of citrate from mitochondria is facilitated by the blockade of isocitrate dehydrogenase by ATP (the ATP/AMP ratio is elevated). When energy is missing, this ratio decreases, the citrate efflux from mitochondria declines, closing the citric supply to the fatty acid synthesis route, while the citric Krebs cycle starts turning again; the acetyl CoA may come again from fatty acid beta oxidation or from glucose, depending on the level DAG, as indicated in the corresponding black or red boxes.

Well, one of the keys for understanding the rewiring process taking place in cancer is the fact that tumor cells do maintain the synthesis of fatty acids and triglycerides, which automatically closes the fatty acid source of acetyl CoA, but tumor cells are unable to open back the glycolytic source of acetyl CoA; as if they were unable to decrease its DAG blocker, in spite of its conversion into triglycerides. A new supply of DAG kept PKC and CPI 17 stimulated, inhibiting PP1, then PK and PDH, which closes the glycolytic source of acetyl CoA. With these two sources of acetyl CoA blocked, the only possible way for tumor cells to get acetyl CoA and survive, comes from ketone bodies provided by liver cells. It is then essential to find out what keeps DAG elevated, in spite of its consummation by the active lipid synthesis pathway? Remember that carcinogenic phorbol-esters act similarly to DAG on PKC; this is discussed in the next section.

A CARCINOGENIC METABOLIC REWIRING PROCESS DESCRIBED IN STEM CELLS AND DIFFERENTIATED CELLS

We have again represented in [Figure 2](#), the endocrine pancreas but here is a blockade of GABA release, which might be the consequence of auto-antibodies against GAD that synthesizes GABA; remember that diabetes Type 1 is provoked by such antibodies that kill beta cells^[14,15]. The GABA deficiency may have other causes, vitamin B6 deficiency (it is the co-factor of GAD) or a GAD mutation as in Stiff person syndrome, or result from pesticides and compounds that affect GABA uptake (betel nut addictions) and metabolism^[10]. The most compelling fact in support of the hypothesis is that smoking (a major risk factor for numerous cancers, including pancreatic) impairs the GABA system. In brain, the increase of glutamate and decrease of GABA prolongs the activation of the dopaminergic rewarding sensation elicited by nicotine. In the periphery, the effects of smoking increase the systemic levels of epinephrine and norepinephrine. Whatever is the cause of the pancreatic GABA deficiency, it leads to an abnormal release of glucagon even when insulin is released, sending to cells a hybrid catabolic - anabolic message. There is also an effect on beta cells that become unable to terminate insulin release, a constant leakage of insulin will occur and desensitize insulin receptors, recalling much aspects of type 2 diabetes or metabolic syndrome. The GABA deficiency should increase somatostatin release from delta cell, but this is counteracted by an increased epinephrine release from adrenals due to the GABA deficit; thus, epinephrine strongly inhibits the delta cell and STH release, increasing the action of GH. It is not the same for alpha cells that are stimulated by epinephrine.

Below the GABA deficient pancreas, three cells are represented: the top one is a stem cell rewiring its metabolic pathways into a carcinogenic mode after receiving the hybrid hormonal message from the deficient pancreas, the cell below is a liver differentiated cell, rewiring its metabolism while receiving the hybrid hormonal message after becoming insulin resistant. The bottom cell is of a muscle fiber also receiving

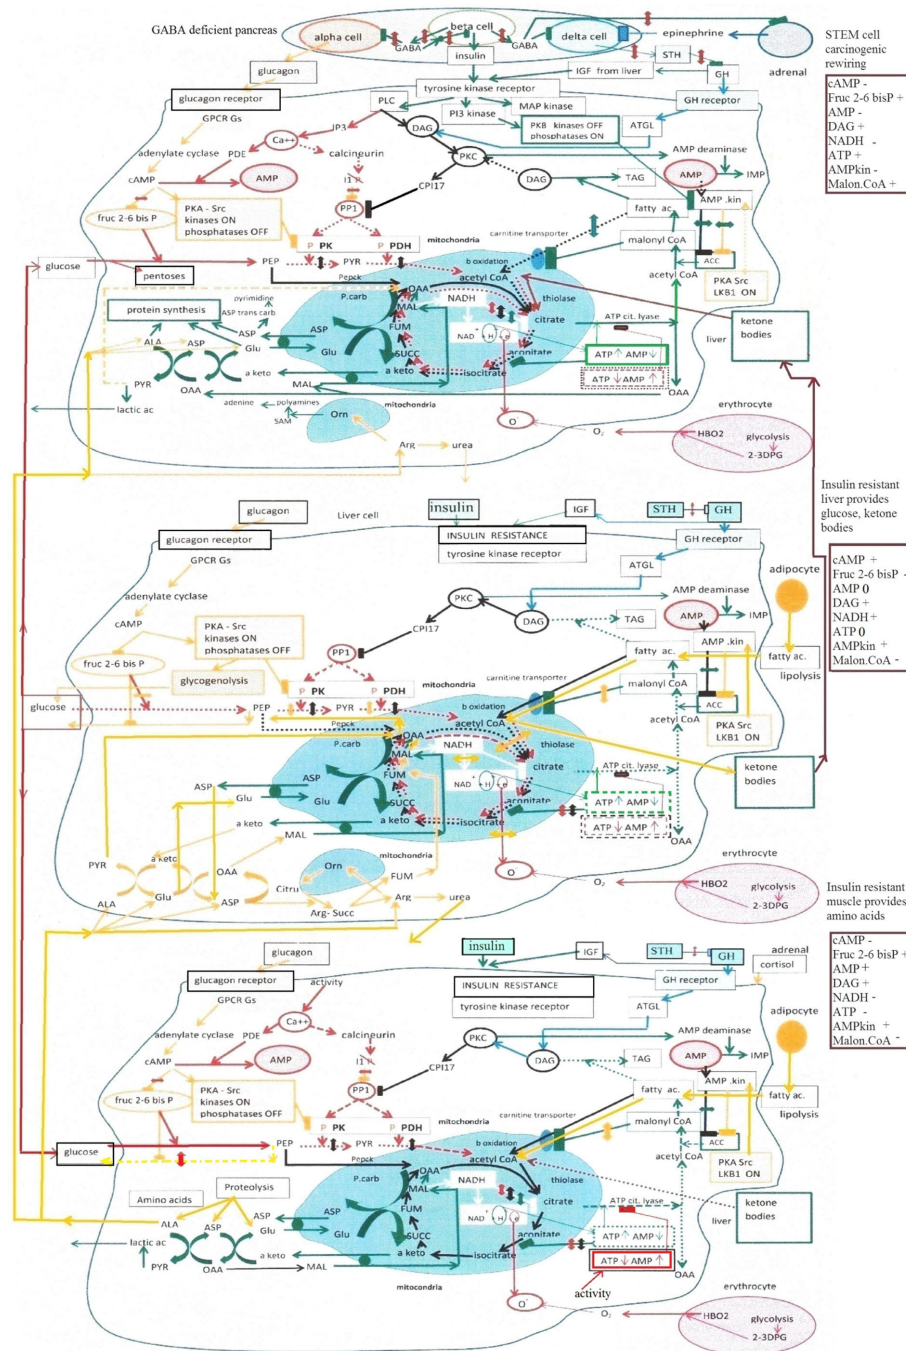

Figure 2. Top: endocrine pancreas with its GABAergic controls OFF. This leads to a leakage of insulin rendering differentiated cells resistant to insulin; in addition, GABA fails to block glucagon release when insulin is released, sending a hybrid catabolic-anabolic hormonal message. The GABA deficiency increases epinephrine release from adrenals, which inhibits delta cells and somatostatin, activating growth hormone. The first cell is a new mitotic stem cell with new insulin receptors it receives the dual catabolic - anabolic message. PKA, Src are activated closing pyruvate kinase and pyruvate dehydrogenase and the glycolytic supply of acetyl CoA; but the increase of IP₃ and calcium mediated by insulin, boosts glycolysis until the pyruvate kinase bottle neck, by increasing the fructose 2-6 bis Phosphate activator. Indeed, calcium stimulates a phosphodiesterase that decreases cAMP, cancelling its inhibitory effect on fructose 2-6 bis Phosphate synthesis. Note that growth hormone activates the production of DAG via ATGL, which stimulates PKC and CPI17, inhibiting PP1 phosphatase, which maintains the glycolytic bottle neck, in spite of the conversion of DAG into triglycerides. Insulin elicits fatty acid synthesis by inhibiting via PKB, AMP kinase, which suppresses the inhibition of acetyl CoA carboxylase; the automatic increase of malonyl CoA closes the fatty acid transporter and the fatty acid source of acetyl CoA. Since the glycolytic source of acetyl CoA was off as well, the stem cell becomes dependent of ketone bodies reconverted into acetyl CoA to feed their citrate condensation, and support the synthesis of fatty acid and lipids for new mitotic cells. Note the supply of amino acids the synthesis of proteins, the transamination, and the release of lactic acid. The next cell is a liver cell resistant to insulin; it receives the catabolic glucagon part of the pancreatic message and is programmed for making glucose and ketone bodies. The fatty acid synthesis is OFF (ACC inhibition by AMP kinase) while fatty acid supplied by adipocytes, form acetyl CoA by beta oxidation, the decreased citrate condensation inhibited by NADH, leaves more acetyl CoA for the ketogenic pathway. The increased NADH comes from a lower oxygen supply and reduction. PKC-CPI17 is stimulated by DAG coming from ATGL stimulated by growth hormone. Muscle, provides amino acids supporting neoglucogenesis, note the transamination the urea cycle. The bottom cell is a muscle cell, also insulin resistant, while receiving the catabolic message (through epinephrine). Muscle activity releases calcium in the cytosol stimulating a phosphodiesterase hydrolyzing cAMP, which cancels the inhibition of fructose 2-6 bis Phosphate formation, activating glycolysis. The glycolytic bottle neck, is maintained because the inhibitor CPI17 of PP1 is again formed via PKC stimulation by DAG, produced by ATGL activated by growth hormone. The citrate condensation is not inhibited by NADH (the latter decreases since lactic acid and myoglobin pull more oxygen). The citric acid cycle turns, activity lowers the ATP/AMP ratio. Cortisol activates proteolysis providing amino acids to the liver. Dotted lines are interrupted pathways. Blocks adjacent to each cell indicate the switch compound levels. DAG: diacyl glycerol; PK: pyruvate kinase; PDH: pyruvate dehydrogenase; GH: growth hormone; ATGL: adipose triglyceride lipase

the hybrid hormonal message with insulin resistance. The full lines are operational pathways; the dotted lines are pathways that have been closed. Each block adjacent to the cell gives the expected switch status in cancer: [Figure 2](#).

In the top stem cell, glucagon activates via GPCR Gs receptors, adenylate cyclase and PKA-Src signaling as for the nutritional finality, but insulin elicits the formation of IP₃ and DAG. The release of calcium mediated by IP₃ activates the PDE hydrolyzing cAMP into AMP, the associated increase of Fruc 2-6bisP stimulates glycolysis, while calcium triggers the incorporation of glucose transporters in the membrane, rendering the cell avid for glucose. But the increased DAG stimulates PKC and the synthesis of the CPI17 inhibitor of PP1^[16], which maintains the phosphorylation of PK and PDH and closes the glycolytic source of acetyl CoA. Accumulated above this bottle neck, PEP will be converted into OAA. Then, PKC will stimulate AMP deaminase and 5' nucleotidase^[17,18], which decreases AMP and the stimulation of AMP kinase; but here, AMP kinase is already directly blocked by PKB that is activated by the insulin signal. This blockade of AMP kinase cancels its stimulation by PKA-Src via LKB1. The inhibition of AMP kinase activates ACC, eliciting the synthesis of fatty acid, while the malonyl CoA intermediate increases and turns off the beta oxidation of fatty acids, which closes the fatty acid source of acetyl CoA. With the two sources of acetyl CoA closed, the only possible supply of acetyl CoA are ketone bodies provided by liver cells. Acetoacetate is taken up and reconverted back into acetyl CoA (via beta hydroxybutyrate dehydrogenase, ketoacyl CoA transferase and thiolase that are reversible). With OAA coming from PEP above the bottle neck via PEPCK, and acetyl CoA provided by ketone bodies, the citric Krebs cycle starts. The ketone bodies supply was the only way for these cells to survive. The citric condensation reaction is activated; since oxygen reduction pulls electrons from NADH converted to NAD, which removes the NADH brake over the citrate condensation reaction. Note that the release of lactic acid generates an acid gradient around the cell, pulling oxygen from erythrocytes via the Bohr Effect. The ATP/AMP ratio being elevated isocitrate dehydrogenase is inhibited favoring the citrate efflux from mitochondria, which feeds via ATP citrate lyase, and ACC, fatty acid synthase; and the synthesis of fatty acids, then triglycerides, to make new membranes for mitotic cells. The conversion of DAG into TAG should decrease DAG and put an end to the stimulation of PKC and CPI17 and to the inhibition of PP1 that closed the glycolytic source of acetyl CoA. But this does not occur in this case, because growth hormone activated by the decrease of STH mediated by epinephrine, stimulates an enzyme: adipose triglyceride lipase (ATGL) that forms more DAG, maintaining in this way the stimulation of PKC and CPI17, which closes the glycolytic acetyl CoA supply, via PP1 inhibition that fails to activate PK and PDH; (recall once more that phorbol ester carcinogens stimulate PKC as DAG). The release of epinephrine that blocked STH release from delta cells and increased GH is a consequence of the GABA deficiency that increases epinephrine release from adrenals.

Another point to mention is that the inhibition of AMP kinase discussed above, suppresses as well the inhibition of mTOR, which liberates a factor (eIF4E) from its binding protein phosphorylated by mTOR; this factor eIF4E will then initiate the synthesis of proteins. Amino acids are provided by muscle cells, and processed via the transaminases and the mitochondria shuttle, feeding also the synthesis of adenine and pyrimidine bases. The transamination chain forms pyruvate and in fine lactic acid. In addition, the avid uptake of glucose supports the pentose phosphate pathway, forming necessary nuclear components (ribose 5P) for mitotic cells. The box adjacent to the top cell gives the status of switches for this stem cell that rewires its metabolism into a carcinogenic way.

The next cell in [Figure 2](#) is a differentiated liver cell rendered resistant to insulin; this is due to the leakage of insulin resulting from the pancreatic GABA deficiency. However, this cell responds to the glucagon part of the hybrid pancreatic message. The Gs coupled glucagon receptor is activated, adenylate cyclase forms cAMP, and PKA-Src are operational; cAMP inhibits the formation of Fruc 2-6bis P, closing glycolysis while opening neoglucogenesis. In parallel, PKA-Src will phosphorylate and inhibit PK and PDH closing the entry of the citric acid cycle. The cell receives amino acids from muscle proteolysis; the amino acids follow the

transamination chain as indicated, forming pyruvate that feeds, via Pcarb and PEPCCK the neoglucogenic pathway. There is also an activation of the urea cycle. In parallel to neoglucogenesis, glucose is also produced by glycogenolysis (phosphorylase a, is ON). The transaminations are interacting as indicated in Figure 2, with the mitochondria shuttle. Note that PKA-Src activates LKB1, which stimulates AMP kinase, this closes the fatty acid synthesis pathway (AMP kinase inhibits ACC). Now fatty acids provided by adipocyte lipolysis, get transported in the liver cell mitochondria since malonyl CoA is low, their beta oxidation forms acetyl CoA. With the NADH being elevated, the citrate condensation is inhibited. Thus, acetyl CoA in excess will follow the ketogenic route giving acetoacetate. Note that growth hormone stimulates ATGL and DAG formation, which stimulates PKC and the CPI17 inhibitor of phosphatase PP1, maintaining the inhibition of PK and PDH, which closes the glycolytic entry of the citric acid cycle. The stimulation of PKC should activate AMP deaminase, decreasing AMP and the stimulation of AMP kinase, but AMP kinase is already efficiently activated by LKB1, which maintains the inhibition of the fatty acid synthesis pathway. Note also that the ATP/AMP ratio that controls the citrate efflux via the inhibition of isocitrate dehydrogenase by ATP is not operational here, since the above reaction, the citrate condensation, is already inhibited by an elevated NADH/NAD ratio. Presumably a low supply of glucose decreases 2-3DPG in erythrocytes, less oxygen is delivered and reduced by the liver cell and fewer electrons are pulled away from NADH, which inhibits the citrate condensation reaction. Probably, less lactic acid is released by liver cells, since pyruvate feeds the neoglucogenic route, rather than lactate dehydrogenase, which locally decreases the Bohr Effect and oxygen supply to the liver. This liver cell is programmed to feed the above stem cell with nutrients, glucose and particularly ketone bodies, while receiving amino acids from muscle, and fatty acids from adipose tissue.

The bottom cell in Figure 2 is a muscle cell; again, it is resistant to insulin like other differentiated cells, and receives the catabolic part of the hybrid pancreatic message. For muscles, epinephrine rather than glucagon, activates via Gs coupled beta adrenergic receptors, adenylate cyclase and PKA-Src. But here, there is a muscle specificity that has to maintain glycolysis as discussed earlier. Muscle activity releases calcium from internal stores, stimulating a PDE that hydrolyses cAMP, this cancels the inhibition by cAMP on Fruc2-6 bis P formation; the increase of this allosteric activator of glycolysis at the phospho fructokinase 1 step, boosts glycolysis, while calcium stimulates the membrane incorporation of the glucose transporter. In addition, the alpha epinephrine receptors of Go or Gi type are predominant in muscle limiting the increase cAMP, via Gs coupled beta adrenergic receptors. Calcium should also activate calcineurin phosphatase and neutralize the inhibition of PP1 by I1 in order to open back PK and PDH by de-phosphorylation, but here the activation of PKC by DAG forms the CPI 17 inhibitor of PP1 closing the glycolytic acetyl CoA supply. This DAG is formed by ATGL stimulated by GH; we explained above that the GABA deficit elicits the release of epinephrine that blocks efficiently delta cells, decreasing STH, which stimulates GH and ATGL. As occurred for the liver cell, the LKB1 stimulation of AMP kinase inhibits ACC and closes the fatty acid synthesis route, which automatically opens the beta oxidation of fatty acids into acetyl CoA. But in contrast to the liver cell, the citrate condensation is operational in muscle. It is activated by the decrease of NADH resulting from the increased reduction of oxygen. Indeed, the lactic acid released supports the Bohr Effect, which liberates more oxygen from oxy- hemoglobin in acid conditions. Moreover, muscle myoglobin pulls more oxygen into the muscle. The condensation of acetyl CoA coming from fatty acids, and OAA provided by PEP, above the PK bottle neck, forms citrate. The efflux of citrate will not feed the fatty acid synthesis, we have seen that the pathway was closed (via the activation of AMP kinase by LKB1) thus citrate will be processed by the Krebs cycle. Muscle activity consumes ATP and forms AMP; since ATP is lowered, it does not inhibit isocitrate dehydrogenase, the citric acid cycle “turns”. Another essential point is that cortisol stimulates proteolysis in muscle; indeed, glucagon increases ACTH release and the release of cortisol from adrenals. Note that the amino acids will feed the liver cell forming glucose, and the stem cell synthesizing its proteins; follow the interaction of the amino acids with the transaminases and mitochondrial shuttle, and the lactic acid release for both stem cells and muscle supporting locally a Bohr Effect. In liver cells, pyruvate will preferentially follow the neoglucogenic route, and less goes to lactate dehydrogenase.

CONCLUSIONS AND PERSPECTIVES

An overview of the carcinogenic mechanism proposed, considers that stem cells receive an anabolic message: “divide and make the constituents for new cells” in order to replace altered cells by whatever cause. These stem cells will then have to synthesize fatty acids and lipids for making new membranes. Fatty acid synthesis automatically closes via malonyl CoA, their beta oxidation, and shuts the fatty acid source of acetyl CoA. Since there is an associated pancreatic GABA failure, there is a catabolic message sent in parallel to insulin, and glucagon cuts the glycolytic supply of acetyl CoA as well, by eliciting the phosphorylating of PK and PDH. Normally this occurs in neoglucogenesis and should be reversed by the anabolic insulin message; but here, this does not occur. Insulin did stimulate via IP₃ and calcium the PDE that hydrolyses cAMP, which boosted glycolysis by increasing Fruc2-6 bisP, and calcium did stimulate glucose uptake by incorporating transporters in the membrane, but the end of glycolysis remains OFF, closing the glycolytic supply of acetyl CoA. The persistent blockade of the de-phosphorylation of PK and PDH and their inhibition, comes from an elevated DAG that maintains the stimulation of PKC and CPI 17 inhibitor of PP1, which fails to activate PK and PDH. What kept DAG elevated is again a consequence of the GABA failure. Indeed, the GABA deficiency increases epinephrine release as well, which turns off STH and thus activates GH; the latter will stimulate ATGL, which increases DAG that stimulates PKC, closing the glycolytic source of acetyl CoA. Since the two sources of acetyl CoA, from fatty acids, and from glycolysis are blocked, the mitotic stem cell will have to get acetyl CoA from ketone bodies, reconverted into acetyl CoA by the reversible ketogenic pathway. This is possible if liver cells are maintained in catabolism to form ketone bodies. Well, this is again a consequence of the GABA failure, because a persistent leakage of insulin desensitizes their insulin receptors, rendering differentiated cells resistant to insulin, while responding to glucagon. Adipocytes provide fatty acids that will form in the liver these ketone bodies. As for the muscles, which are also insulin resistant, they receive the catabolic message through epinephrine and cortisol, the beta oxidation of fatty acids operates in muscles, but since the citric acid cycle Krebs cycle “turns” in muscles, acetyl CoA condenses with OAA coming via PEPCK and forms citrate, rather than ketone bodies. In muscles an intense proteolysis takes place, they provide amino acids to stem cells for making their proteins, and to liver for neoglucogenesis. The adipocytes respond preferentially to the catabolic component of the hybrid pancreatic message (they become insulin resistant) and provide fatty acids to liver and muscle. The amino acids processed by the transamination chain form pyruvate, and lactic acid is released by stem cells and muscles. In liver, a large part of this pyruvate feeds the neoglucogenic route.

Thus, the new mitotic stem cells that have not been chronically desensitized for insulin receive the dual hybrid message and the metabolic advantage they gain over the differentiated cells that are plundered, opens the road for these stem cells to cancer. Their differentiation is blocked, their number increases geometrically, inevitable mutations select the most aggressive population, the immune system fails to eliminate such cells.

A comment of some perspectives might be useful; the finding that diabetes type 1 result from the auto-immune destruction of beta cells by anti-GAD antibodies is certainly a major discovery, particularly if we consider that GABA is an essential regulator in the endocrine pancreas. These anti-GAD antibodies were detected in most cases, and were even implicated in type 2 diabetes. An interesting attempt to prevent diabetes using a “GAD vaccination” for preserving beta cells, did not yet give the expected results. Presumably, the network of anti-GAD antibodies and anti-idiotypic antibodies is an equilibrium that is difficult to displace. There is still some condition to be found and hopefully a preventive vaccination will someday become efficient. This question is particularly relevant here, since we suspect that the GABA deficiency of beta cells in the pancreas is the starting point of a metabolic rewiring process of stem cells and differentiated cells that leads to the carcinogenic transformation of stem cells. Hence, preserving the pancreatic GABAergic system^[19] may not only prevent diabetes but presumably cancer as well. It would be interesting to look for eventual anti-GAD antibodies in cancer as it was done for diabetes. One may also

hope that neutralizing these antibodies would give protection. The GABA deficiency may have other causes, a vitamin B6 deficiency for example, since it is the co-factor for GAD. Indeed, conditions that inhibit GAD or neutralize vitamin B6 (pesticides, amines and others) have been found to be carcinogenic^[10]; this is also the case for diseases that genetically affects GAD. In Stiff person syndrome for example, the neurological symptoms prevail, but the cancer incidence is more elevated. It would be an interesting perspective to look for anti-GAD antibodies long before cancer develops and eventually find out procedures for neutralizing them, and develop “an anticancer vaccination”. It is certainly a difficult project, particularly if we consider the difficulty encountered for the diabetes type 1 vaccination attempt. Checking GABA metabolism and preserving this control system of the pancreas that depends of vitamins (B6) and nutrition, might decrease cancer incidence, particularly if its alteration by pesticides and other compounds that affect GAD is avoided. Moreover, it might be an interesting perspective to explore the pancreatic GABA system in relation to cancer, using noninvasive imaging methods for GABA as those developed for brain.

The other more practical perspective is to try to normalize the rewiring process that was presented in detail, even though many parts were deduced, and require more experimental work. A few compounds such as isocitrate, lipoic acid and others, gave encouraging results in animal cancer models (the list of compounds is given in previous publications)^[5,11,13,20]. However, only a small number of potentially useful compounds were tested, in spite of the fact that many more should be given for normalizing the complex rewiring processes associated to cancer. One would gain to suppress the metabolic advantage given to stem cells by cutting their supply of ketone bodies; or to block the effect of GH on ATGL, which increases DAG, inhibitors of ATGL have been developed^[21]; or to control the cAMP and AMP ratio, and AMP kinase^[22]; or the mitochondria citrate efflux^[23]; or to decrease the DAG activation of PKC, there are several PKC inhibitors discussed in reference^[13]; or to inhibit the fatty acid synthesis pathway. A final remark concerns the direct effects of GABA on pancreatic ductal adenocarcinoma and presumably on other cancers. Apparently, GABA B receptor activation mediates a decrease of adenylate cyclase that attenuates the progression of pancreatic cancer^[24]. This does not contradict the fact that a GABA deficiency of Beta cell fails to terminate insulin release, which desensitizes insulin receptors, while glucagon is released, leading to the described metabolic rewiring process that initiates cancer.

The best mixtures that will reverse the rewiring process still remain to be compared, in animal cancer models, then in properly built clinical trials. It is also essential to find an adequate diet and control the amino acid supplied, in order to attenuate the effects of the metabolic rewiring process in cancer; and then develop a metabolic treatment with non-toxic mixtures that would normalize cancer metabolism. In our opinion, this would be useful for backing up, if necessary, present cancer therapies.

Abstract

Ovarian cancer (OC) is a serious condition that often presents at advanced stages and has high mortality rates, with the current mode of early-stage screening lacking sensitivity and specificity. OC often presents asymptotically, which renders early diagnosis difficult. Furthermore, many patients lack significant risk factors or family history of the disease. Five-year survival rates differ between patients with OC among racial, ethnic, and social groups as a result of different social barriers. This review article aims to present the currently existing data regarding health care disparities among OC patients of different ethnic, demographic, and socioeconomic backgrounds, and what next steps should be taken to better understand and eventually eliminate these potentially devastating health care disparities. Increasing data support the notion that a combination of genomic, socioeconomic status, social factors, and cultural differences lead to differential treatments and therefore health care disparities. While genomic and biological factors are important, language barriers, geographic and travel barriers, differences in comorbidity likelihood between populations, and different treatment plans seem to have a greater impact on 5-year survival rates of patients from diverse backgrounds. Language barriers limit a shared-decision model of care. Transportation limitations and geographic differences can lead to limited follow-up and insufficient care in resource and equipment restrictive settings. Patients with these barriers also tend to have a higher incidence of comorbidities that raise the mortality rate of OC. Further research needs to explore effective

INTRODUCTION

Ovarian cancer (OC) is the most lethal gynecologic malignancy and tends to develop as a result of atypical cells in the epithelium of the distal fallopian tubes^[1]. Worldwide each year there are an estimated 200,000 women diagnosed with OC and 125,000 deaths from the disease^[2]. In the United States, the American Cancer Society estimated that in 2017, there would be 22,440 new cases of OC and 14,080 deaths associated with the disease^[3]. One in 78 American women will develop OC in their lifetime^[2]. Five-year survival rates vastly differ among early stage and late-stage disease. For instance, with advanced stage III and IV disease, in which disease has spread beyond the pelvis to lymph nodes or the abdominal cavity or lungs, the mortality rate is around 70% whereas in early stages when the disease is confined to the ovaries or pelvis mortality rates are much lower at around 10%-40%^[1,4,5]. Early diagnosis of OC when the disease is limited to the ovaries is difficult because, in early-stages, patients tend to be asymptomatic. This is further complicated by the lack of screening or diagnostic tests, which aid in early diagnosis^[1,4-6]. Early diagnosis is prudent since the mortality rate after treatment or interventional therapy of early-stage OC is much lower^[1,5,6]. By the time patients develop symptoms, such as abdominal pain or swelling, the vagueness of these symptoms often complicates and delays diagnosis. These symptoms tend to be attributed to aging, menopause, dietary changes, stress, depression or gastrointestinal issues. Patients with more apparent symptoms such as a pelvic mass, abdominal pain, bloating, abdominal swelling, early satiety or urinary symptoms often have a more advanced disease, with symptoms usually due to the development of large mass and ascites^[7]. This is further complicated by the fact that screening tests for OC, such as tumor markers or imaging, often lack both sensitivity and specificity. As a result, a physician's ability to detect OC in its early-stages is limited by the low-performance measures of these currently available screening tests^[5], leaving most patients undiagnosed. Patients with lack of access to tertiary medical care are more susceptible to late-stage diagnosis, associated with far higher mortality rates^[1,5,8]. The current standard is to test for high levels of cancer antigen 125 (CA-125), an ovarian cell glycoprotein^[5]. However, high levels of CA-125 tend to be correlated with late-stage OC^[5]. Eighty percent of patients with late-stage OC have elevated values of CA-125, whereas only 10% of patients with early-stage OC have elevated values of CA-125^[5]. Furthermore, certain histologic types of OC, such as mucinous or endometrioid type tumors may not have elevations in CA-125. Another factor limiting the utility of CA-125 screening is that high levels of CA-125 can be seen in a variety of other benign gynecologic and non-gynecologic malignant conditions. Non-malevolent conditions such as endometriosis, fibroids, and pregnancy can result in elevations in CA-125^[4]. Other malignant conditions, which can result in elevations in CA-125, are breast, pancreatic, lung, gastric and colorectal cancers^[4]. Additional diagnostic techniques such as ultrasound evaluation for masses, may aid in diagnostic precision but also lack sensitivity and specificity. Consideration of other risk factors for OC such as genetic susceptibility, strong family history, and nulliparity may influence the detection of OC in patients^[1,9]. At present, the standard tests and techniques to screen for this devastating disease are ineffective, and studies show that routine screenings are not recommended for the general population^[4,8-10].

Standard treatment for OC is a combination of surgery and chemotherapy^[4]. Surgical exploration is performed if there is sufficient suspicion for OC based on an initial evaluation. The goal of surgery is to confirm if malignancy is present and if so to proceed with surgical staging and cytoreduction. Per National Comprehensive Cancer Network (NCCN) guidelines, adjuvant therapy, which consists of platinum-taxane based combination chemotherapy, is necessary in most cases and depends on the stage of the disease^[5]. Women with clinical suspicion of OC should be referred to a gynecologic oncologist for counseling and surgical treatment. Evidence shows that prognosis is improved when a gynecologic oncologist performs surgical staging and cytoreduction^[1,2,6]. Unfortunately, despite initial therapy, the majority of women with

advanced-stage OC will relapse and require additional treatment. The likelihood for recurrence depends on many factors, including distribution of disease at initial presentation, the success of initial surgical cytoreduction, rapidity of CA-125 resolution, and treatment response after primary therapy^[5]. However, a predictive marker for recurrence has not been prospectively verified. Patients should be followed closely by a gynecologic oncologist to detect these signs of recurrence. The management of patients with relapsed disease varies based on the platinum-free interval or months since last platinum treatment. Platinum free interval has been shown to correlate with progression-free survival and overall survival, as well as response to subsequent treatment. The complexity of managing patients with relapsed disease underscores the importance of treatment plans to include a gynecologic oncologist. Mortality rates for advanced stage disease are around 70%, and these rates differ between patients with OC among racial, ethnic, and social groups could be a result of different social barriers^[1,4,5].

EPIDEMIOLOGY OF OC

OC is the sixth most common cancer in women and the seventh most common cause of cancer death^[11]. There is substantial geographic variation in OC incidence and mortality. Higher rates are seen in the United Kingdom, Northern Europe, Australia, and the USA, with lower rates observed in Asia, China, and Africa^[11]. A recent study examining the international assessment of OC incidence and mortality confirmed these findings, demonstrating the lowest incidence of OC in China, and the highest in Russia and the United Kingdom^[12]. Similarly, other studies have confirmed that countries with a predominantly Caucasian population such as Europe, the US, Canada, and Australia, have a higher incidence of OC and that the incidence is lower in countries with other ethnic groups such as Asia, Brazil, and Mexico^[12]. These findings are consistent with the fact that within the USA, rates of OC are higher among white women than black women^[11]. Incidence rates of OC in the US are also lower in Asian/Pacific Islanders, American Indians/Alaskan Natives that are also consistent with previous international studies. In the US the incidence rate per 100,000 women of OC is 13.5 in whites compared to 9.9 in Asian/Pacific Islanders, 10.6 in American Indians/Alaska Natives, and 10.0 in blacks and 11.6 in Hispanics^[12]. In other terms, compared to black and Hispanic women, the risk of OC is 40% greater in white women^[2]. The exact reason for this racial disparity in incidence is unknown however racial disparities in certain risk factors for OC may account for this variation. For instance, this variation in geographic incidence rates of OC may be attributed to genetic risk factors, such as the higher incidence of OC among women with Ashkenazi Jewish ancestry^[13]. Among women with OC with Ashkenazi Jewish ancestry, 40% have a mutation in *BRCA1* or *2* when diagnosed with OC^[2]. Other risk factors for OC such as obesity, endogenous or exogenous hormonal exposure, parity, and dietary factors such as smoking, alcohol use, caffeine consumption are highly related to cultural habits and lifestyle practices that differ across different ethnic groups and may account for this geographical variation^[2,12]. Racial discrepancies of rates on gynecologic surgery such as tubal ligation and hysterectomy, which are known protective factors against OC, may also account for some of these variations in OC incidence^[2]. Similarly, rates of breastfeeding and combined oral contraceptive pill use, also known protective factors against OC, are highly related to cultural practices and may differ across ethnic groups. Overall the incidence of OC has gradually declined in most developed countries such as North America and Europe since the 1990's^[14]. Conversely, less developed countries with recent economic growth and lifestyle changes have seen increases in incidence rates^[14].

DISPARITIES IN THE SURVIVAL AND EXPERIENCE OF OC PATIENTS

The overall difficulty of early detection, early diagnosis, and the subsequent optimum treatment for patients with OC is exacerbated by the social disparities that exist in underserved communities. These disparities, in turn, lead to differences in survival rates and treatment. The existing literature supports the hypothesis that the risk of all-cause mortality in African American OC patients is roughly 1.3 times higher when compared to Caucasian women with OC, even when the access to care is equal^[15]. The mortality rates have increased

specifically for African American populations over time^[15,16]. A study conducted by Srivastava *et al.*^[16] demonstrated that from 1992 to 2008 the 5-year survival rates for Caucasian women rose from 40.7% to 45%, yet 5-year survival rates for African American women declined over that same time period from 47.9% to 40.3%. A similar study found that the 5-year survival rate for African American women had fallen to 36% from 2006 to 2012, while all races combined had a 45% 5-year survival rate, with Caucasian women having the highest 5-year survival rate at 46%^[16]. This variation in survival rates appears to be due to a decreased likelihood of receiving guideline-recommended care^[17]. Other studies have suggested that after controlling for factors like socioeconomic status (SES), patients with the same stage of OC have similar survival rates^[3,18]. Studies suggest that patients of a lower SES are receiving care less in line with NCCN guidelines and have decreased access to preventative medicine and genetic testing, which could contribute to delayed presentation. However, most studies are limited by their inability to detect if a patient's SES and a delay of presentation to the clinic are correlated, which could, in turn, affect 5-year survival rates^[3,18]. The current literature on the different survival rates of OC between diverse populations and the frightening statistics facing our underserved communities introduces a series of compelling questions. Why are patients with low SES presenting to the clinics with a more advanced disease? What preventative factors (i.e., the difference in the fund of knowledge, access, communication and financial resources) impact these differences in survival? Are there certain factors that are creating more disadvantages for patients who are underserved than other factors? What can be done to effectively mitigate these disparities? Studies have tried to control for such factors, with little success in large part because a multitude of critical contributing confounding variables is at work, not just one sole factor that is key in precluding underserved communities from attaining equal outcomes^[18,19]. Currently there is a need for increased randomized control studies and interventional studies that could shed more light on the impact of these social determinants of health, however the challenge is to isolate certain variables in these studies and have a sample size large enough to draw impactful conclusions.

GENOMIC DISPARITIES AMONG OC PATIENTS

The lifetime risk of developing OC is low, at 1.5%, and the vast majority of patients who develop OC comprise sporadic cases with no significant family history of the disease^[1]. In contrast, the remaining group of patients with deleterious genomic germline mutations (i.e., *BRCA1* and *BRCA2* genes) carry a much greater lifetime risk for breast cancer and OC (i.e., 50%-85% and 20%-40%, respectively)^[1,20-23]. Patients with a known genetic susceptibility to OC are typically followed closely with a combination of pelvic examination, ultrasound imaging, and CA-125 testing in order to detect abnormalities at early curable stages. These patients are also typically offered risk-reducing surgery, which consists of removal of the fallopian tubes and ovaries at the completion of childbearing in order to prevent the onset of disease. Patients in underserved communities may have lack of access to this type of preventive medical care. Among these OC patients with deleterious germline mutations, a significantly decreased overall survival and the worse prognosis is reported in OC patients from underserved populations^[24-26]. Bandera *et al.*^[27] reported an increased OC risk, associated with a worse survival rate, in underserved communities after controlling for confounding variable. Factors, such as medical comorbidity risk, and prevalence of *BRCA1* and *BRCA2* mutation, pointing instead to other contributing etiologic factors, such as quality of care and delay in care, to explain the significantly poorer outcome. Although a higher incidence of unmanaged medical comorbidities (i.e., hypertension, coronary artery disease, and diabetes) may be associated with an increased OC risk, these medical comorbidities alone cannot explain the poor outcomes in underserved populations^[16,27-29].

PUBLIC HEALTH, SOCIAL DISPARITIES, AND LANGUAGE BARRIERS AFFECT OUTCOMES IN OC PATIENTS

High adiposity and inflammatory diets consisting of high sugar intake are associated with an increased risk of developing OC^[16,27-30]. A systematic review of 28 studies reported a statistically significant, association between obesity [body mass index (BMI) 30 kg/m² or more] and OC^[31]. Another large prospective study

found that the risk of death from OC was higher in women with the greatest BMI (35-40 kg/m²) compared with those of normal weight (BMI 18.5-24.9 kg/m²)^[32]. African American and Hispanic women have a disproportionately higher rate of obesity and have higher BMI (> 40) which may correlate with a higher incidence mortality of OC^[16,27,28,33]. A correlation also exists between obesity and socioeconomic position, suggesting that more overweight and obese people are from underserved populations with poorer access to healthcare^[34]. In addition to limited access to quality healthcare, obese patients may be more difficult to diagnose with OC due to greater difficulty in assessing vague symptoms and limited utility of current diagnostic approaches in these patients. Studies indicate that women who were considered overweight and obese had symptoms such as abdominal swelling and discomfort months before the diagnosis of OC^[35]. Healthcare providers can impact meaningful change through education to patients of the positive impact of a low inflammation diet. Similarly, patient education regarding weight loss through healthy diet and exercise can meaningfully impact patient's health and reduce risk factors for OC.

Patients with a limited English proficiency have lower health literacy rates, less access to healthcare systems, and poorer outcomes^[36]. Many of these patients use ad-hoc medical interpreters, such as staff, friends or family members, who are not officially licensed to serve as an interpreter for a clinical interaction. The use of an ad-hoc interpreter leads to miscommunication and is ineffective and result in poor patient outcomes. One study confirmed that the use of an ad-hoc interpreter leads to a higher rate of error than using no interpreter at all^[37]. Schwei *et al.*^[36] reported that patients rarely, if ever, request interpreter services. Even the use of trained medical interpreters may result in impaired physician-patient communication. Kamara *et al.*^[38] analyzed 24 audio recordings of cancer genetic counseling consultations from 13 different patients and six different counselors conducted in Spanish with the assistance of 18 telephone interpreters at two large public hospitals^[38,39]. The primary causes of impaired communication through the use of interpreters were erroneous hypothetical explanations, and misinterpretation by the interpreter, resulting in a significant departure from the shared-decision model of healthcare^[37,38,40]. The interpretations did not assist patients in their decision-making process. Furthermore, physicians found that even with the use of interpreters it was difficult to understand the decision of a patient. There were instances in which interpreters did not interpret a patient's response or question, a marked departure from a high-quality mutual discussion, and a shared-decision model of healthcare^[36-38,40]. Therefore, patients often consented to the provider's recommendations regardless of their comprehension of the treatment plan and limiting patient autonomy. Low English proficiency patients are more likely to have a limited health literacy and increased dissatisfaction with the health system overall^[36-38,40]. These data suggest that public health, social disparities, and language barriers negatively impact outcomes in OC patients.

GEOGRAPHIC AND TRAVEL FACTORS THAT IMPACT OC PATIENTS

Disparities also exist in patients' geographic environments, impacting patient outcomes. Patients from lower socioeconomic communities have access to fewer clinics, with fewer resources and compromised diagnostic capability^[19,29]. Sakhuja *et al.*^[19] reported that African American OC patients lived in geographic areas that had fewer oncology centers and fewer centers with ultrasound, and fewer subspecialists^[1,5,19,29]. Statistics have consistently shown that patients with OC are best treated by a gynecologic oncologist and that tertiary care medical centers have the resources and capabilities to better serve these patients. Lack of access to subspecialty care negatively impacts survival from OC. Hence, the likelihood of a patient presenting to a physician with insufficient clinic resources is statistically much greater in a lower socioeconomic setting. Moreover, OC patients who are presented to general hospital clinics have greater odds of late-stage diagnoses and increased mortality rates than those who present to subspecialty clinics^[18,19].

Srivastava *et al.*^[16] reported that only 22% of Caucasian and 14% of African American OC patients would be willing to drive more than 20 miles for treatment, which also correlates with data suggesting that the larger the distance between a patient and their gynecologist, the greater the mortality rates^[16,41,42]. Guidry *et al.*^[43] surveyed 593 cancer patients in Texas, of which 38% of the Caucasians surveyed, 55% of

the African Americans, and 60% of the Hispanic respondents reported that they had poor access to a vehicle^[16,41,43]. The net result to the underserved communities was geographic and transportation barriers, greater reschedules, no-shows, delayed care or missed or delayed medication use^[16,41]. Hence, these geographic and transportation factors lead to delivery of substandard care and negatively, impact survival rates^[19,29,41]. Across 25 different studies, patients reported that transportation was a major barrier to their healthcare^[41]. These data indicate that geographic and travel factors have a negative impact on OC patient outcome.

DIFFERENT OC PATIENTS RECEIVE DIFFERENT TREATMENT

Patients from different socioeconomic backgrounds and cultures experience a difference in quality treatment. African American women from underserved communities overall have lower 5-year survival rates from OC than their Caucasian counterparts, attributed to treatment delays^[16]. Bristow *et al.*^[44] reported that despite equitable access to healthcare, patients who hailed from lower SES status were less likely to receive treatment adhering to the NCCN guidelines^[29]. Furthermore, a clear difference exists between populations regarding access to quality of healthcare, impacting the outcome of an OC patient. To understand the source of healthcare disparities is the key in order to pursue strategies to correct these disparities and eventually create initiatives to eliminate them.

An increasing body of literature suggests that patients from a lower SES receive substandard care, in large part from a general lack of proper facilities and equipment to carry out standard procedures^[1,16,29,44]. Unfortunately, patients from underserved communities, have poorer access than affluent communities to high-quality healthcare^[19,29]. African American and Hispanic patients were less likely to receive accurate staging for OC than Caucasian patients^[29]. African American patients with OC also tend to receive less proactive treatment plans than Caucasian patients^[16,19]. A study conducted at a large, high volume medical center showed that African American OC patients were less likely to undergo surgery than Caucasian OC patients overall, 61% and 77% respectively, and less likely to undergo chemotherapy^[16,19,29]. Furthermore, underserved patients are much less likely to enroll in clinical trials and experimental treatments. In a study that analyzed over 400 clinical trials from The Gynecologic Oncology Group (GOG) from 1985 to 2013, 83% of participants were Caucasian, and only 8% African American, and 2.2% Hispanic^[29,42,45]. As compared with the expected Centers for Disease Control projections for minority participation in clinical trials, actual African American participation was 15 times lower than expected for ovarian GOG trials^[45]. The GOG also reported that the rate of participation for African American patients has been decreasing over time, demonstrating that participation from African American communities has decreased 2.8 times from 1994-2002 to 2009-2013^[45]. There are many possible explanations for poor participation by minority groups in clinical trials include lack of access to centers, which offer these trials, lack of understanding regarding the purpose and potential benefits of these trials, and lack of means such as transportation to effectively participate in these trials. Due to decreased levels of education, patients may have diminished understanding of how the treatment works and therefore cannot understand how these treatments are different from previous ones and might have decreased efficacy. Additionally, cultural and spiritual differences in these communities could also contribute to the disparity. Members of these communities have been spurned by healthcare institutions and other institutions in the past, which could result in an overall distrust in providers or healthcare institutions. All of these aspects stack the odds against minority communities from receiving proper treatment.

Armstrong *et al.*^[46] reported that only 37% of patients received genetic counseling prior to testing for the *BRCA1/2* gene, and of those that did receive counseling, most were Caucasian women (69%) who were married (76%), with high income (55%) and with a college degree (81.4%)^[1,46]. African American women have a much lower rate of testing particularly in limited-resource settings, which is important because they have a similar or higher incidence of *BRCA* mutation than their Caucasian counterparts^[1,20-23]. It is estimated that roughly 12.4% of African American patients with breast cancer under 50 carry the

mutation^[1]. Limited resource settings are less likely to have a genetic counselor, and therefore patients are less likely to receive counseling support. All patients with OC should receive genetic counseling according to the NCCN guidelines. By undergoing genetic testing and genetic counseling, care providers can have a better understanding of the type of tumor that a patient is presenting with^[21,38]. If the patient has a known *BRCA1* or 2 mutation, then a provider has increased indications of what targeted therapies may work^[1,20-23,26]. A *BRCA1* or 2 mutation may result in errors with homologous recombination mechanisms in the DNA repair system, consequently there are downstream genes that are more likely to be mutated as well. These downstream genes have been studied extensively and as a result, target-therapies have been developed targeting these mutations. Additionally, patients who receive genetic counseling and genetic testing have increased understanding of their cancer, which can help make more informed decisions when it comes to their care^[21,38]. They have increased understanding about the progression of disease, their risks of developing cancer and their risks of passing this mutation onto their offspring. By providing this information, the decision-making model is shifting from one of paternalism to a shared-decision model, and allows for patients to be much more cognizant of early signs of developing cancer to begin treatment earlier, engage in more preventative treatment measures, and make care decisions in a timely manner that are in line with their values^[1,38]. However, in this case patients with decreased SES and therefore decreased access to genetic testing and counseling providing care teams have less information on base treatment, which essentially limits patient involvement in their own care^[1,19]. Proper genetic counseling prior to testing is a critical component of delivering this test and understanding the results.

Peres *et al.*^[47] reported that women taking an aspirin regimen for cardiovascular diseases or a daily nonsteroidal anti-inflammatory drug for arthritis had a decreased risk of developing epithelial OC, which stood at 44%, and 26%, respectively. However, a significant disparity still exists between the compliance rates for Caucasian and African American populations (44% vs. 29%, respectively) for these regimens^[48]. Decreased compliance with these medications reduces the protective factor of these agents against OC. African American and Hispanic women are much less likely to use oral contraceptives, a known reducer of OC risk^[1,49]. These data indicate that patients from underserved communities receive less preventive care than other patients.

CONCLUSION

Eliminating healthcare disparities is critical in order to ensure optimal outcomes in all patients with OC. Identifying what the healthcare disparities are is critical to their elimination. A paradigm shift, which leads to redistribution in the allocation of healthcare resources to create more equality across populations, will eliminate healthcare disparities.

Future research must focus upon the underlying genetic components that contribute to healthcare outcomes. Research that will elucidate tumor and population-specific molecular modifications to genes and proteins may positively impact the outcomes of patients with OC. The contribution of changes in dietary considerations (i.e., low sugar), language barriers, and geographic differences to the elimination of healthcare disparities requires additional research.

Physicians can impact the elimination of healthcare disparities through patient education (i.e., dietary practices), effective use of interpreters, and outreach to resource-poor communities with less access to high-quality healthcare. Population data demonstrate that the allocation of important equipment and resources (i.e., ultrasound machines, special genetic counselors) to support community primary care physicians, and the number of obstetric and gynecological specialists in the community will favor a lower incidence of late-stage diagnosis of OC^[19]. Patients hailing from lower SES and underserved communities may be at an additional disadvantage when they are excluded from promising investigational clinical trials. Hence,

the concept of the mobile clinic may bring high-level care directly to communities obviating the need for patients to travel long distances to find high-quality healthcare^[19].

In the short-term and long-term, a robust and sustainable solution is the creation of an inclusive culture that supports the elimination of healthcare disparities and discrimination among different racial, ethnic and social groups^[50]. The net result would be the replacement of patient isolation in underserved communities with access to quality healthcare, including access to promising clinical trials to treat cancer.

Abstract

Aim: Bisphosphonates are used as an adjuvant treatment in breast cancer bone metastasis patients, often simultaneously with chemotherapeutic agents. Interestingly, their sequential combination has been reported to have synergistic anti-tumor effects on bone metastases in preclinical models. We studied the effects of doxorubicin (DOX) and zoledronic acid (ZOL) and their combination on established bone metastases in the MDA-MB-231(SA) GFP bone metastasis model.

Methods: Tumor burden and osteolytic bone lesions were quantitated by fluorescence imaging and radiography, respectively. The mice were randomized in four groups receiving vehicle, DOX, ZOL or both DOX and ZOL in a sequential combination on day 14. Serum marker of osteoclast number was followed weekly, and blood ionized calcium was measured at sacrifice. Bone and tumor area, apoptosis and proliferation of tumor cells were analyzed from histological sections.

Results: ZOL prevented hypercalcemia and osteolytic lesion progression, whereas DOX induced apoptosis in the MDA-MB-231(SA)GFP cells. However, neither of the treatments alone nor in sequential combination were able to reduce tumor burden in bone. Furthermore, no additive effects on tumor cell apoptosis were observed in the

combination group.

Conclusion: No additive effects in combination of DOX and ZOL were observed in this aggressive model of breast cancer bone metastasis.

Keywords: Combination treatment, breast cancer, bone metastasis, MDA-MB-231(SA), doxorubicin, zoledronic acid

INTRODUCTION

Despite major advances in the treatment of primary breast cancer within the past decades, treatment of advanced breast cancer with bone metastases is still palliative in nature, as no curative treatments are available. Inhibitors of bone resorption, such as zoledronic acid (ZOL) or denosumab are used as adjuvant treatment in breast cancer patients with bone metastases, often simultaneously with chemotherapeutic agents such as doxorubicin^[1,2]. In these patients bisphosphonates decrease bone pain and skeletal-related events, but do not increase the overall survival^[3]. However, before the formation of bone metastases, bisphosphonate treatment in combination with standard chemotherapy may prevent the occurrence of bone metastases in postmenopausal, early stage breast cancer patients^[4]. Many preclinical studies in established experimental breast cancer bone metastasis models have reported direct anti-tumor effects of bisphosphonates alone, such as increase of apoptosis in intraosseous tumors and improved survival^[5-7], but we have reported no effects on survival in a model of established bone metastases^[8].

Bisphosphonates seek and incorporate into the hydroxyapatite in bone matrix. Therefore, it has remained an unanswered question how tumor cells in soft tissues can be exposed to effective concentrations of bisphosphonates. It is also possible that what was believed to be a direct anti-tumor effect is indeed, indirect. It has been shown that macrophages take up bisphosphonates in cytotoxic quantities, and tumor growth in soft tissues can be inhibited due to the lack of tumor-associated macrophages^[9,10].

Some exploratory preclinical studies investigating the effects of combinations of aminobisphosphonates and chemotherapeutic agents have suggested additional benefits. Sequential treatment with doxorubicin (DOX) followed by a single dose of ZOL 24 h later was reported to decrease tumor volume and proliferation and to increase apoptosis as well as mouse survival with established bone metastases with MDA-MB231/BO2 breast cancer cells^[11]. In addition, a single cycle of sequential administration of DOX and ZOL in a very early phase, 2 days after cancer cell inoculation, was reported to decrease intraosseous tumor area in an intracardiac mouse model using MDA-MB231 cells with green fluorescent protein (GFP)^[12]. Three additional studies by the same group with MDA-MB436 breast cancer cells showed synergistic effects on tumor volume reduction with the weekly administration of DOX and ZOL in combination, both on bone metastasis and primary tumor^[13-15]. In these studies, the combination treatment reduced the intraosseous tumor area and increased survival compared to DOX or ZOL monotherapy. The mode-of-action of the combination is not understood, but increased uptake of ZOL by tumor cells was observed with the sequential combination^[14]. Because of the varying results of anti-tumor effects of bisphosphonates, we felt a need to investigate these effects in a fairly aggressive and widely used model of breast cancer bone metastases, utilizing the human MDA-MB231(SA) GFP cells in nude mice. The treatment schedule was otherwise the same as used by Ottewell *et al.*^[13], but the treatment was started 3 days earlier to accommodate the more aggressive model.

METHODS

Compounds and cell line

DOX (Sigma-Aldrich, Saint Louis, MO, USA) was dissolved in saline (0.9% NaCl, Baxter, Deerfield, IL, USA) to concentration of 0.5 mg/mL. ZOL (Zometa®, Novartis Pharma GmbH, Basel, Switzerland) infusion

concentrate (0.8 mg/mL) was diluted in saline to obtain the concentration of 0.02 mg/mL. Saline was used as a vehicle control. MDA-MB231(SA)GFP^[8] were authenticated using short tandem repeat analysis (GenePrint10 system, Promega, Madison, WI, USA) at Institute for Molecular Medicine Finland (FIMM, Helsinki, Finland).

***In vivo* study**

The animal experiment was approved by the Animal Experiment Board of Finland and performed according to European Union directive 2010/63/EU. Five-week-old female athymic nude mice (Hsd: Athymic nude-nu, Harlan Laboratories B.V./Envigo, Horst, The Netherlands) were used. The mice were housed in groups of five in Scantainer™ (Scanbur, Karlslunde, Denmark) and fed an autofluorescence-reducing chlorophyll-free purified diet (AIN-76A, Special Diets Services, Witham, UK). The animals were weighed three times per week and daily during the last five days. On day 0, 10⁵ MDA-MB231(SA)GFP breast cancer cells were inoculated into the left cardiac ventricle of the animals, as described previously^[16,17]. The mice were anesthetized with 4 mg/kg xylazine (Rompun Vet 20 mg/mL, Bayer Animal Health GmbH, Leverkusen, Germany) and 75 mg/kg ketamine (Ketalar 10 mg/mL, Pfizer, NY, USA) intramuscularly (im) for inoculations and imaging procedures. Buprenorphine (Temgesic, Invidior UK Ltd, Slough, UK) was used as analgesic at 0.1 mg/kg subcutaneously (s.c.) and was administered once before the intracardiac inoculations and twice a day during the last five days of the study. The mice were randomized into four treatment groups (*n* = 8) on day 14 based on tumor growth and osteolytic lesion size as well as body weight. Tumor growth and osteolytic lesion size were measured by fluorescence imaging and X-ray analysis, respectively, on study day 14 and at sacrifice. The mice were sacrificed on day 25, except the 2-3 mice per group, which were sacrificed earlier due to weight loss over 20% or paraplegia. All the mice were included in the endpoint analyses. The mean day of sacrifice was very similar in all groups ranging from 24.13 in the DOX group to 24.63 in the ZOL group.

The control group received vehicle 5 mL/kg s.c. on day 15 and intraperitoneally (i.p.) on days 15 and 22. The DOX group received half of the maximal tolerated dose, DOX 2.5 mg/kg i.p. on days 15 and 22. The ZOL group received a single dose of ZOL 0.1 mg/kg s.c. on day 15. The DOX + ZOL group received DOX (2.5 mg/kg i.p.) on days 15 and 22 and a single dose of ZOL (0.1 mg/kg s.c.) 24 h after the first dose of DOX, i.e., on day 16 (schedule of the combination group dosing is shown in [Figure 1](#)).

Blood samples were collected from saphenous vein to 100 µL Microvette serum tubes (Sarstedt AG&Co, Nümbrecht, Germany), on days 1, 9, 17 and 24. Terminal blood samples were obtained by cardiac puncture. Five intact animals of the same strain and age were sacrificed on day 25 in order to obtain the baseline level for blood Ca²⁺ (ionized calcium). Femur and tibia were collected for histomorphometric analyses.

Fluorescence imaging

Metastatic growth of disseminated breast cancer cells was followed by fluorescence imaging using the LT 9 GFP imaging system LT-MACIMSYSPUSC (Lighttools Research, Encinitas, CA, USA) on days 10, 14 (randomization), and after sacrifice. Autofluorescence was reduced using the chlorophyll-free diet. The animals were anesthetized and imaged in both the ventral and dorsal position. The imaging settings (exposure 2.34 s, gain 6.7 and offset 238) were the same for all animals. The area of fluorescence was determined from the images using MetaMorph™ software (Molecular Devices, Sunnyvale, CA, USA).

Radiography

Development of bone lesions was monitored by radiography on days 10, 14 (randomization), and prior to sacrifice. The animals were anesthetized and radiographed (31 kV, 10 s, 2× magnification) in a prone position using the faxitron specimen radiographic system MX-20 DC-2 and Specimen Radiography Beta 2.0.0 software (both from Faxitron Bioptics, LLC, Tucson, AZ, USA). Lesion number and area were determined in tibias and femurs and the resulting data were analyzed using MetaMorph™ software.

Figure 1. Dosing schedule of the doxorubicin (DOX) + zoledronic acid (ZOL) group

Histomorphometric analyses

After fixation in 10% neutral buffered formalin and decalcification in 10% ethylenediaminetetraacetic acid for two weeks, the bone samples were processed to paraffin blocks. Four μm thick midsagittal sections were obtained from the left hind limb (tibia and femur) and stained with hematoxylin, eosin, Orange G and phloxine B (HE + Orange G)^[16], tartrate-resistant acid phosphatase (TRAP)^[6], Ki-67 (primary antibody clone SP6, Nordic BioSite AB, Täby, Sweden) and terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) methods (*in situ* cell death detection kit, APTM, Roche Diagnostics GmbH, Basel, Switzerland). Tumor area as well as trabecular and cortical bone areas were analyzed from the HE + Orange G stained slides as follows: first, micrographs were taken with a Leica DM4000 B Research Microscope (Leica Microsystems, Wetzlar, Germany), then brightness and contrast were optimized using the same settings for all images. Next, the tumor area was quantitated by drawing and bone area was quantitated by color thresholding using MetaMorphTM software as described^[18]. Areas expanding 5 mm from the articular surfaces of femur and tibia were analyzed. From a TRAP stained section, the number of osteoclasts at the tumor-bone interface in distal femur and proximal tibia was counted as described^[18], the whole section was analyzed using the MetaMorphTM software. Apoptotic cells in tumor were manually counted as TUNEL stained cells with apoptotic morphology as described^[6]. The whole tumor area was analyzed using a 20 \times objective Leica DM4000 B Research Microscope.

Biomarker analyses

Ca^{2+} concentration (corrected to pH 7.4 by the internal algorithm of the instrument) in whole blood was determined using a blood gas analyzer (ABL835 Flex blood gas analyzer, Radiometer Medical ApS, Bronshøj, Denmark) immediately after terminal bleeding. A comparison to the normal level of ionized calcium was performed using the values obtained from five intact animals of the same strain, sex and age. Serum tartrate-resistant acid phosphatase 5b (TRACP 5b) activity as a marker of osteoclast number was measured in serum samples obtained on days 1, 9, 17 and 24 using the MouseTRAP kit (IDS, Boldon, UK).

Statistical analyses

Statistical analysis was performed with SPSS (version 14.0). All statistical analyses were performed as two-sided tests and $P < 0.05$ was considered statistically significant. The normality of residuals and homogeneity of variances were examined using Kolmogorov-Smirnov and Levene's tests, respectively. If these assumptions were fulfilled as such or after appropriate transformation, one-way ANOVA followed by Dunnett t -test was used. If the assumptions were not fulfilled even after transformation, the non-parametric Kruskal-Wallis test followed by Mann-Whitney U -test was used. Fischer Exact test was used for comparison of proportions.

RESULTS

Effects of DOX and ZOL on body weight and tumor characteristics

Body weight of the mice decreased during the last five days of the study due to the disease progression. Although the weight loss was more pronounced in the DOX treated groups, statistically significant differences compared to vehicle group in the body weight change from day 0 were not observed [Figure 2B].

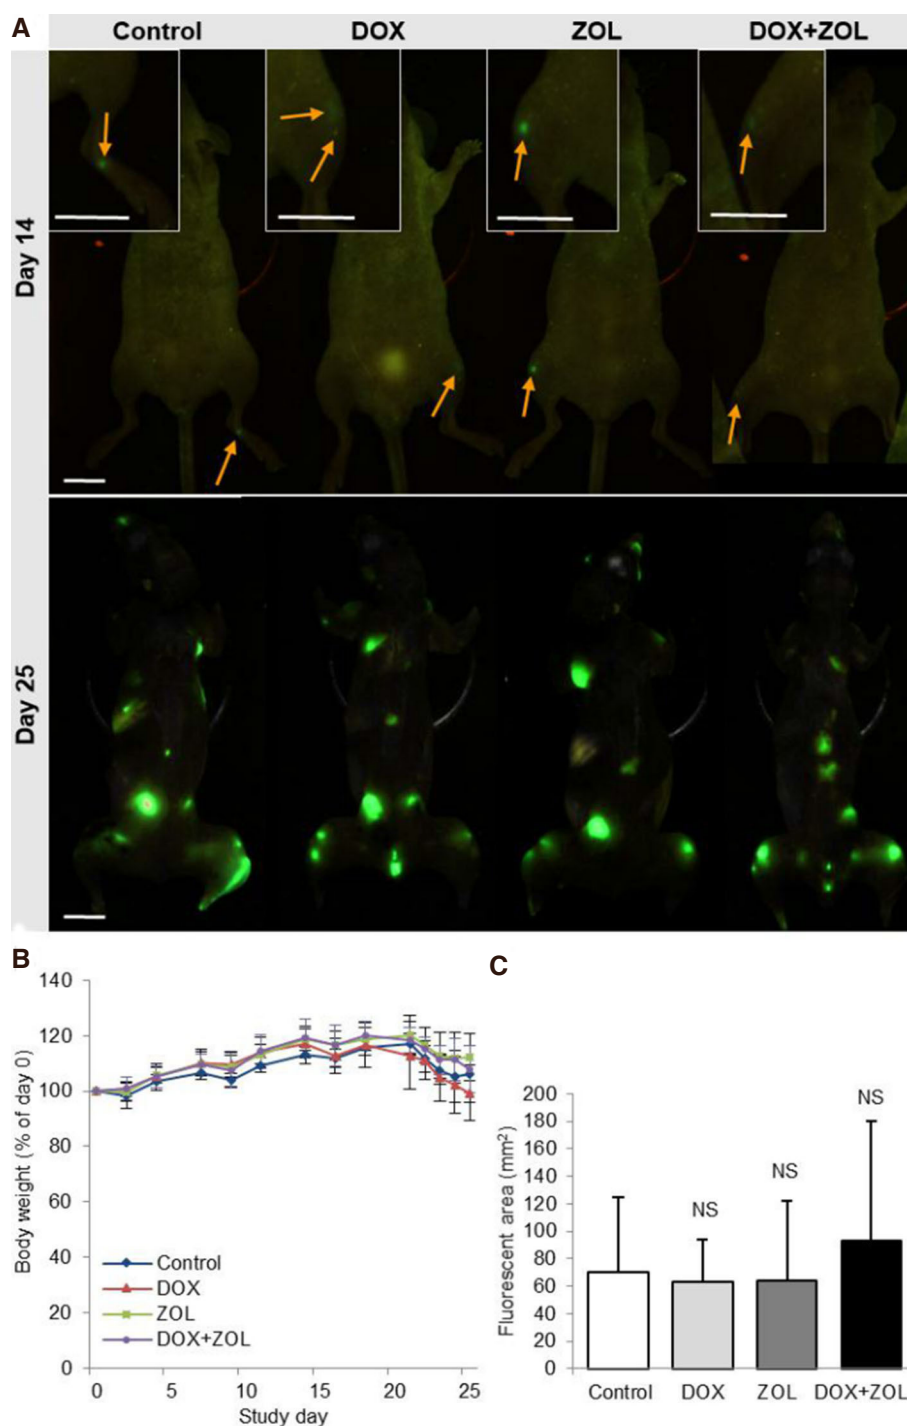

Figure 2. Body weight and MDA-MB231(SA) tumor burden. Whole body tumor burden was analyzed by fluorescence imaging. A: Representative images showing established metastatic foci before treatment (day 14) and at sacrifice (day 25); B: body weight during the study relative to body weight at the day of tumor cell inoculation. Significant differences in body weight at sacrifice relative to baseline were not observed; C: whole body tumor burden did not differ between the groups as measured by fluorescent imaging. Data are expressed as mean \pm SD, $n = 8$ animals. Scale bars 10 mm, arrows tumor foci *in vivo*. NS: non-significant; DOX: doxorubicin; ZOL: zoledronic acid

Anti-tumor effects of DOX, ZOL, and their sequential combination were studied by (1) measuring whole body tumor burden by fluorescence imaging; and (2) tumor area in bone by histomorphometry [Figures 2C and 3D, respectively]. According to fluorescence imaging at sacrifice, none of the treatments affected the

Table 1. The number of bone and soft tissue metastases were counted from green fluorescent protein images taken from dorsal and ventral sides of each animal

	ANOVA	$P = 0.884$			

DOX: doxorubicin; ZOL: zoledronic acid

whole body tumor burden [Figure 2C]. Furthermore, there was no difference in the numbers of metastases to bone or soft tissue sites between the treatment groups, based on fluorescence imaging [Table 1].

In accordance to these results, none of the treatments decreased the tumor area in bone analyzed from histological sections [Figure 3D]. All sections except sections from one animal in the DOX + ZOL group, contained tumor tissue. In many sections the tumor filled the entire intraosseous area. A thin layer of tumor on the periosteal surface resulting from disruption of the cortical envelope was sometimes observed. The anti-tumor effects were further examined by counting the number of apoptotic tumor cells and the proliferation index in histological samples [Figure 3E and F]. Even though the intraosseous tumor area was not affected, the number of apoptotic cancer cells analyzed by TUNEL staining was increased in the DOX and DOX + ZOL groups [Figure 3E]. However, the sequential combination of DOX and ZOL did not increase the amount of apoptotic cells compared to DOX alone.

Effects of DOX and ZOL on bone

The effects of DOX and ZOL on bone were studied by measuring osteolytic lesion areas observed in X-ray images and trabecular bone area in histological sections. All mice in the control and DOX groups, 12.5% of the mice in the ZOL group, and 42.9% of the mice in the DOX + ZOL group had osteolytic lesions at sacrifice [Figure 4A]. The proportion of mice with osteolytic lesions was significantly lower in both groups treated with ZOL compared to the control group ($P < 0.001$ for ZOL and $P = 0.026$ for DOX + ZOL). Osteolytic lesion area measured from X-ray images was radically lower in the ZOL and DOX + ZOL groups compared to the control group [Figure 4B]. ZOL also increased trabecular bone area by a factor of 2 analyzed by histomorphometry and DOX + ZOL by a factor of 1.5 compared to control. However, in the DOX + ZOL group statistically significant difference to the control was not reached [Figure 4C].

Effects of DOX and ZOL on TRACP 5b and Ca^{2+} concentration in the blood

Because breast cancer patients with bone metastases often have hypercalcemia and increased serum TRACP 5b has also consistently been reported in these patients, we measured Ca^{2+} in blood and serum TRACP 5b from the mice. In addition, osteoclasts were counted at tumor-bone interface of TRAP-stained sections. We found that ZOL alone rapidly decreased serum TRACP 5b values as early as two days after dosing, on day 17. Both the ZOL and DOX + ZOL groups showed decreased TRACP 5b on day 24 compared to the control group [Figure 5B]. The number of osteoclasts was 25%-50% lower at the tumor-bone interface in the ZOL and DOX + ZOL treated groups compared to the vehicle group [Figure 5C], but the differences were not statistically significant ($P = 0.595$ and 0.142 , respectively). Both groups also had lower blood Ca^{2+} compared to the control group (5d). The blood Ca^{2+} in ZOL and DOX + ZOL groups was similar to the baseline Ca^{2+} measured from five healthy animals of same age, sex and strain (1.268 mmol/L, SD 0.0205), whereas the control group had higher blood Ca^{2+} compared to the healthy animals ($P = 0.038$). In the DOX group 4/8 animals were above the range of healthy mice (> 1.29 mmol/L), but the group average did not differ from the control group.

Figure 3. Intraosseous tumor area, apoptosis and proliferation. Tumor burden in bone was analyzed in histological sections of the left hind leg. Apoptotic tumor cells were stained using the TUNEL method and stained cells with apoptotic morphology were counted. Proliferation index was analyzed from Ki-67 stained sections. A: Representative images of HE + Orange G stained sections showing tumors in bone at sacrifice (day 25); B: representative images of the TUNEL stained sections; C: representative images of the Ki-67 stained sections; D: intraosseous tumor area did not differ between the groups; E: apoptotic tumor cells relative to tumor area were increased in both groups receiving DOX, but not in the ZOL group; F: proliferation index did not differ between the groups. Data are expressed as mean \pm SD, $n = 8$ animals. Scale bars 1 mm (A); 50 μ m (B and C). ***Significantly different from control group ($P < 0.001$); NS: non-significant; T: tumor; M: marrow; Tr.B.: trabecular bone; HE: hematoxylin-eosin; TUNEL: terminal deoxynucleotidyl transferase dUTP nick end labeling; DOX: doxorubicin; ZOL: zoledronic acid

DISCUSSION

Direct anti-tumor effects of bisphosphonates on established tumors in bone have been reported in many preclinical studies^[5-7]. Decrease in tumor growth has been observed also in a model with defective osteoclasts^[19]. However, findings have not been positive in all models, and clear clinical proof has been lacking. Additive or synergistic effects when combined with chemotherapeutic agents observed in some preclinical models of bone metastases as well as primary tumors have further fueled the interest in the anti-tumor actions of bisphosphonates. Several clinical studies with combination of neoadjuvant

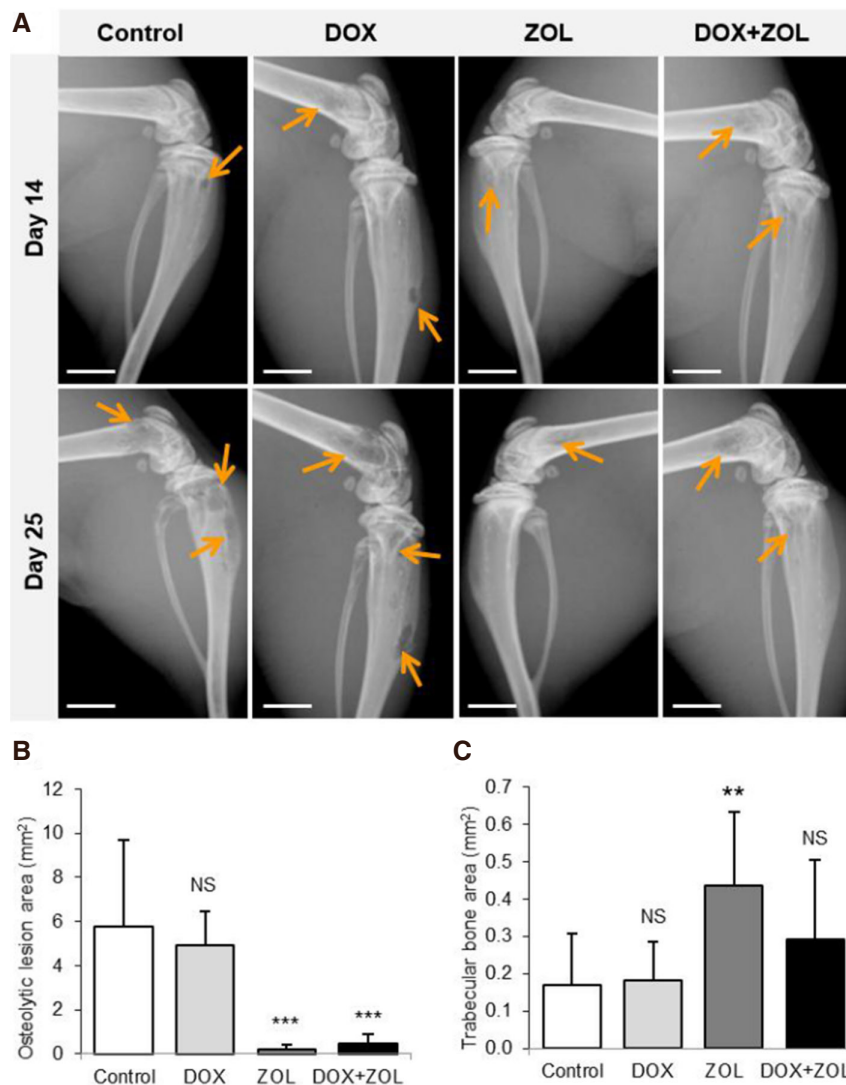

Figure 4. Osteolytic lesions, trabecular bone volume and the number of osteoclasts at the bone-tumor interface. Osteolytic lesion area was analyzed from X-ray images of both hind limbs, trabecular bone area and the number of osteoclasts in the bone-tumor interface in midsagittal histological sections of the left hind limb. A: Representative images showing established osteolytic lesions before treatment and at sacrifice; B: osteolytic lesion area was decreased in the ZOL and DOX + ZOL groups as measured by radiography; C: trabecular bone area was increased in the group receiving only ZOL, but the effect was not statistically significant in the DOX + ZOL group. Data are expressed as mean \pm SD, $n = 8$ animals. Scale bars 2 mm, arrows osteolytic lesions. **Significantly different from control group ($P < 0.01$); ***significantly different from control group ($P < 0.001$); NS: non-significant; DOX: doxorubicin; ZOL: zoledronic acid

chemotherapeutic agent and ZOL have been reported. A retrospective analysis of sequential treatment showed benefit in a patient subgroup of postmenopausal women with estrogen receptor negative breast cancer^[20]. Subsequent randomized controlled trials have suggested benefit, but failed to show statistically significant results^[21-23]. This study aimed to examine whether a sequential combination of DOX and single dose ZOL has synergistic effects in the widely used MDA-MB-231(SA) bone metastasis model.

Aminobisphosphonates, such as ZOL, inhibit the mevalonate pathway and thus protein prenylation, resulting in inhibition of many subsequent cellular processes and induction of apoptosis in *in vitro* studies, but the results of *in vivo* studies are less conclusive^[24]. ZOL alone did not affect tumor burden, proliferation or apoptosis, which is in line with previous findings, including models using MDA-MB231 cells or its sublines^[5,8,11,12]. It is also in line with clinical data of ZOL not increasing overall survival in patients with

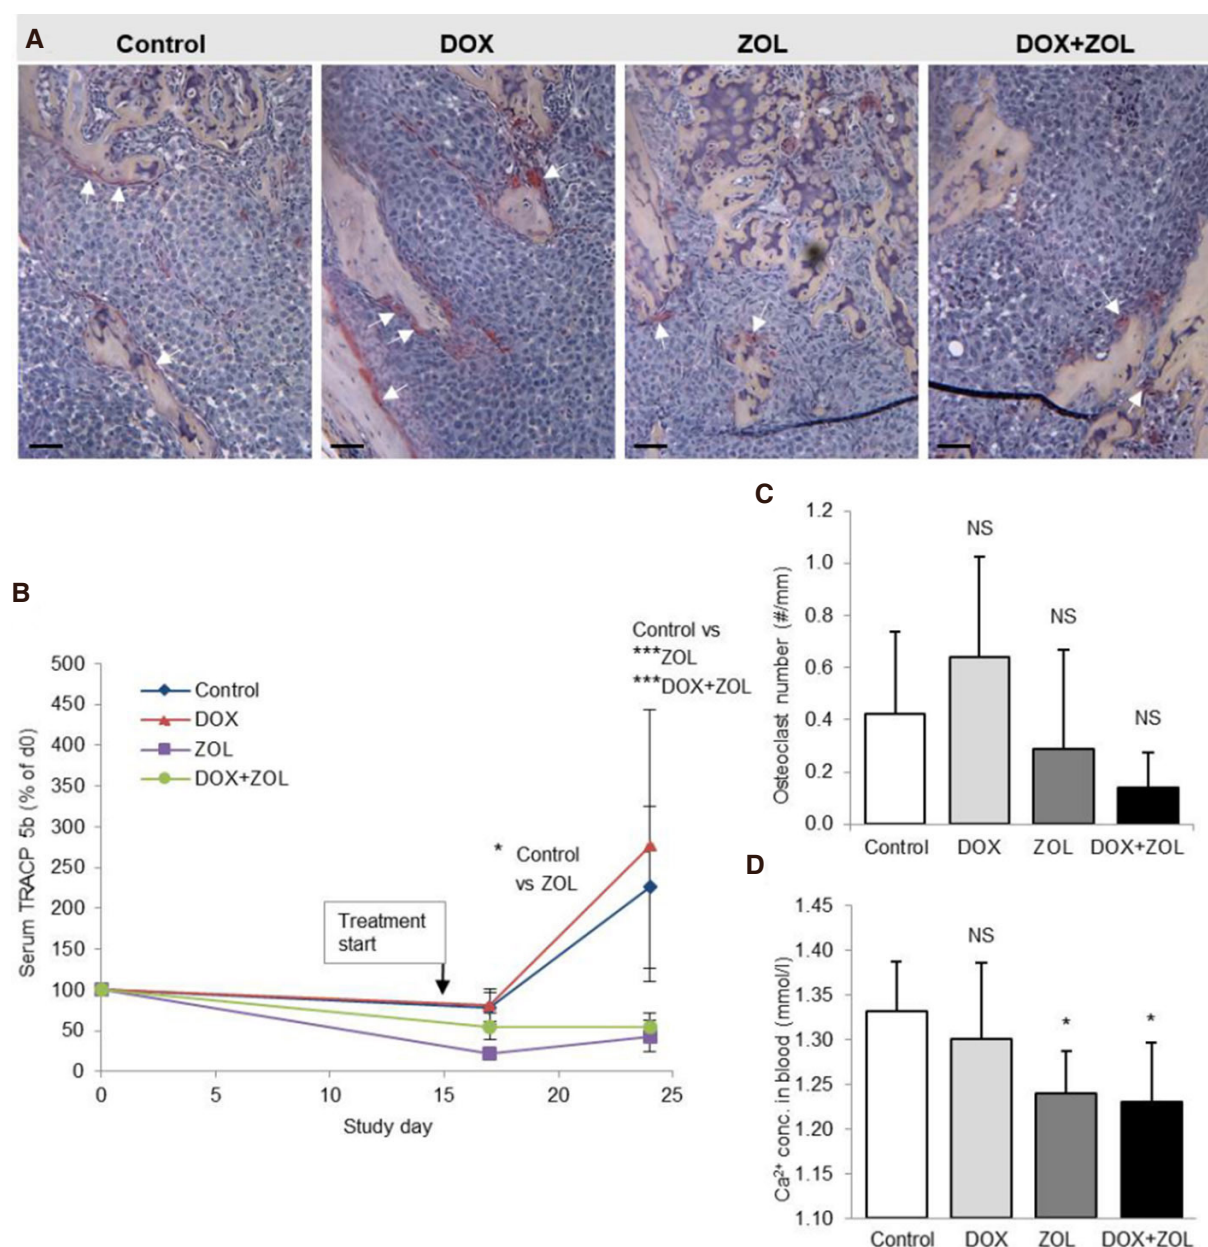

Figure 5. Osteoclasts and blood Ca²⁺. Osteoclasts were counted from TRAP stained sections and serum TRACP 5b activity was measured at three time points (before inoculation of cells, days 17 and 24) as a systemic marker of osteoclast number. Blood Ca²⁺ was measured from terminal blood samples for detection of hypercalcemia. A: Representative images of the TRAP staining; B: statistically significant changes were not observed in the number of osteoclasts at tumor-bone interface; C: serum TRACP 5b was decreased in the ZOL group already on day 17 and in the ZOL and DOX + ZOL groups on day 24 compared to the control group; D: hypercalcemia was prevented in the ZOL and DOX + ZOL groups. Data are expressed as mean \pm SD, $n = 7-8$ animals. Scale bars 50 μ m, arrows osteoclasts. *Significantly different from control group ($P < 0.05$); ***significantly different from control group ($P < 0.001$); NS: non-significant; TRAP: tartrate resistant acid phosphatase; TRACP 5b: tartrate resistant acid phosphatase 5b; DOX: doxorubicin; ZOL: zoledronic acid

established bone metastases^[3]. DOX on the other hand did increase the number of apoptotic cells, as expected. We did not observe any other significant effects with DOX on tumor growth or proliferation index, which may have been due to a suboptimal dose of DOX. Higher doses of DOX are able to decrease tumor burden in the same model^[25]. However, the dose in this study was set at a low level to enable observation of possible synergistic effects. Likewise, Ottewell *et al.*^[11] used a suboptimal dose of DOX and observed synergistic effects on tumor volume and number of apoptotic cells in bone. They did not observe any effects of DOX alone on apoptosis by caspase-3 staining or on tumor burden in the intravenous MDA-

MB231BO2 or intracardiac MDA-MB231 models. In contrast, we observed clear induction of apoptosis with DOX alone, but we did not observe any potentiation of apoptosis induction with the sequential combination. Furthermore, the sequential DOX + ZOL treatment did not decrease tumor area in our study, despite of increased apoptosis of cancer cells induced by DOX. The absence of any observed decrease in the GFP positive area representing total tumor burden supports the histological data.

The metastatic behavior between cell sublines can be strikingly different. Sublines of the MDA-MB231 cells derived through *in vivo* selection for bone metastases behaved differently, some formed metastases in adrenal glands and others in bone, some were fast with a high frequency and others were slow with a low frequency of metastases^[26]. However, the bone or adrenal metastatic sublines of the MDA-MB231 had similar growth rate when inoculated subcutaneously demonstrating that the cells were not generally more aggressive. Importantly, the bone metastatic subline cells exclusively induced osteoclast mobilization and recruitment^[26]. The MDA-MB231(SA) model is more aggressive and progresses faster than the MDA-MB231BO2 model, as the median survival time is 25 days in the former^[8] and 60 days in the latter^[11], with the same number of inoculated cells. However, the different inoculation route is likely to play a role in the disease progression. It is possible that more cells are seeded to the bone marrow through the intracardiac route, than through the intravenous route, where the cells have to pass through the lung capillaries first. The MDA-MB231(SA) cells have been found to express, e.g., more serine and interleukin-11 compared to the parental MDA-MB231 cells^[27,28], whereas the MDA-MB231BO2 cells were found to have decreased expression of the miRNA30 family regulating several osteomimicry genes, compared to the parental cells^[29]. Although the history of the two sublines is very different, the BO2 subline being derived through *in vivo* selection and the cells from San Antonio having occurred spontaneously, a common finding for both MDA-MB231(SA) and -BO2 sublines compared to the parental line is the strong downregulation of miRNAs 200a and 429^[28,29]. These miRNAs are involved in the epithelial-to-mesenchymal transition^[30]. Positive effects on tumor growth and survival have also been observed in a model of MDA-MB436 intratibial tumors using intensive, weekly sequential administration of DOX + ZOL^[14]. The MDA-MB436 cells are triple negative like MDA-MB231 cells, and both represent the claudin-low subtype.

As expected, ZOL efficiently prevented the progression of osteolytic lesions as both monotherapy and in combination with DOX. However, trabecular bone area was not statistically significantly higher in the DOX + ZOL group compared to the control group. The lesions visible in X-ray images present mainly lesions in cortical bone, whereas the reduction of trabecular bone is typically not so clearly observed in the X-ray images. This could partly explain the difference in radiography and histological data. Furthermore, a lesion has lost 50% of the bone volume by the time it is visible with planar X-ray imaging. MicroCT analysis would provide volumetric information of both cortical and trabecular compartments. Unfortunately, this imaging modality was not available for this study. Furthermore, there were no statistically significant differences in the numbers of osteoclasts at the tumor-bone interface between the groups. The variation of osteoclast number measurement was high, affected by the variable amount of measurable tumor-bone interface in the samples. The reason for not observing significant reduction in numbers of osteoclasts at the tumor-bone interface might be that the ZOL-induced reduction in the number of osteoclasts has been reported to be transient, observed three days after ZOL dosing to mice, but non-observable already five days after ZOL administration due to the formation of new osteoclasts^[31]. Consistently, serum TRACP 5b was decreased three days post-dosing compared to the control group. Serum TRACP 5b remained low at later time points in the groups treated with ZOL, suggesting that the osteoclasts may have been smaller^[32], or that the number of osteoclasts along normal bone surface at tumor-free areas was lower. Indeed, Brown *et al.*^[12] have reported decreased number of osteoclasts in tumor-free bone but not in tumor-bearing bone 13 days after administration of ZOL. Very importantly, however, the function of the osteoclasts at the tumor-bone interface was inhibited, as shown by the decreased osteolytic lesion area in the ZOL and DOX + ZOL groups, the increased trabecular bone area in the ZOL group, and the prevention of hypercalcemia in the ZOL and DOX + ZOL groups.

High variation was a problem in this study and may have masked treatment effects on osteoclast number. Larger groups and more sensitive methods, such as μ CT and luciferase labelled cells could have helped in reducing the variation. Intraosseous tumor area can only be analyzed by histology, which was restricted to analyzing the midsagittal sections in order to standardize the analysis. However, analyzing several levels could have reduced the variation. In order to further clarify the reasons underlying the insensitivity of the MDA-MB231(SA) tumors in bone to the combination treatment, as well as the unresponsive portion of patient population, the ZOL uptake of the MDA-MB231(SA) cells after DOX administration requires investigation. Longer treatment schedules with repeated cycles of sequential combinations would better present the clinical situation, but such studies are unfortunately not possible in this model due to the time frame of disease progression. Furthermore, the strong bone forming ability of the young, fast growing mice used in this model presents a major difference to the elderly breast cancer patients. New bone formed after the ZOL administration is not protected by ZOL, and is thus vulnerable to cancer induced degradation. This could have mitigated the effects of ZOL in this study, but because the treatment period is so short, the amount of new bone formed in that time period is not likely to influence the results.

In summary, we examined the anti-tumor effects of a single dose of ZOL alone and in sequential combination with DOX on established bone metastases in the intracardiac MDA-MB231(SA) model. DOX induced apoptosis in the tumor cells and ZOL prevented tumor-induced bone destruction. However, anti-tumor effects of ZOL were not observed, nor additive or synergistic effects of the sequential combination of DOX and ZOL.

DECLARATIONS

Abstract

Epithelial-mesenchymal transition (EMT) is a plastic and reversible process, essential for development and tissue homeostasis. Under pathological conditions, EMT causes induction of tumor growth, angiogenesis and metastasis. According to its reversible nature, the EMT program is associated with vast epigenetic changes. Targeting the epigenetic network that controls the EMT pathway in disease progression is a novel promising strategy to fight cancer metastasis. The impact of alterations in histone methylation in cancer has led to the identification of histone methyltransferases and demethylases as promising novel targets for therapy. Specifically, the lysine specific demethylase 1 (LSD1, also known as KDM1A) plays a pivotal role in the regulation of EMT. Here we present an overview of the causative role of LSD1 in the EMT process, summarizing recent findings on its emerging functions in cell migration and invasion in breast cancer.

Keywords: Lysine specific demethylase 1, KDM1A, epithelial-mesenchymal transition, breast cancers, metastasis, invasion, LSD1-complex

INTRODUCTION

Breast cancer is the most frequent cancer in women worldwide. It has a predictable incidence of 246,660 new cases (29% of all sites cancers) and 40,450 estimated deaths (14% of all sites) in 2016 in the United States^[1].

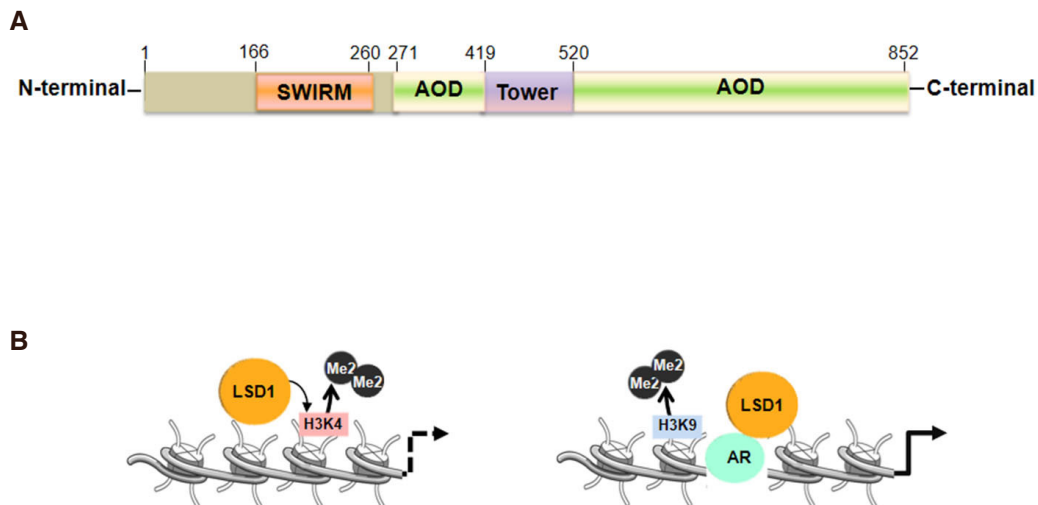

Figure 1. Lysine specific demethylase 1 (LSD1) protein domains and structure. A: In orange the SWIRM domain, in green the AOD domains and in yellow the Tower Domain; B: LSD1 selective substrate specificities: LSD1 represses promoter and enhancer activities through the demethylation of histones lysines, H3K4 or in cooperation with the androgen receptor (AR), activates transcription through Histones H3K9 demethylation

The major causes of death in breast cancer patients are the result of metastasis in distant organs^[2]. Metastasis is a complex biological process, which occurs through a series of steps: (1) rising of a locally invasive and migratory behavior, (2) arriving to the blood vessel and into the circulation via the blood flow, (3) halting in the distant organ, (4) surviving the initial stress, and (5) reinitiating outgrowth in distant stroma^[2,3]. Metastasis involves a multitude of molecular signals^[3]. Single cells leaving the primary tumor undergo epithelial to mesenchymal transition (EMT), consisting in the loss of epithelial polarity and the achievement of a mesenchymal morphology^[4]. The opposite process, the mesenchymal to epithelial transition, takes place when metastatic cells switch back to an epithelial state in order to colonize secondary sites^[5].

The mechanism of EMT is currently a major focus in metastasis research. The knowledge of its mechanisms is still fragmentary and more in-depth studies are needed in order to improve therapeutic approaches and influence, in the long-term, control of breast cancer outcome^[6,7].

According to the reversible nature of EMT-associated processes, epigenetic mechanisms, such as DNA methylation and histone modifications, exert a great influence on the EMT program^[8-11]. Particularly, wide ranges of studies demonstrate that the lysine specific demethylase 1 LSD1, also known as KDM1A, plays a pivotal role in the EMT regulation^[12-15].

High levels of LSD1 expression in various tumors, including breast cancer, are correlated with poor prognosis^[16-19]; several works reported that the ablation of LSD1 in breast cancer cells inhibits the invasion capabilities and suppresses their metastatic potential^[20-22].

LSD1 is classified as an amine oxidase that uses FAD as the co-factor for its enzymatic action^[23]; LSD1 is composed by three major domains: an N-terminal SWIRM (small alpha-helical domain), for protein stability; a central protruding Tower domain and a C-terminal amine oxidase like domain [Figure 1A]; LSD1 is able to demethylate mono and di-methylated lysine 4 and 9 of the histone H3 (H3K4, H3K9)^[23-27]. Exerting its activity LSD1 can function as co-repressor, removing H3K4 methylation on gene promoters and enhancers, or co-activator, by removing H3K9 methylation, indicating that substrate specificity and the binding to different interactors define its biological outcome [Figure 1B]^[12]. Furthermore, LSD1 regulates methylation dynamics of non-histone proteins^[16,28-33].

This review summarizes recent advantages in understanding the mechanisms through which LSD1 controls EMT in breast cancer, and discusses how these findings could be used to establish a new approach for therapeutic intervention in breast cancer.

LSD1 MODULATE THE EMT PROCESS BY ITS PARTICIPATION IN DIFFERENT COMPLEXES

In human cancers, EMT contributes to tumor progression and invasion of surrounding tissues and confers chemo-resistance. Morphological and phenotypic changes are orchestrated by transcriptional reprogramming in which several transcription factors, known as EMT-TF^[34], have a role in silencing of epithelial genes (e.g., E-cadherin, Occludin) and in the activation of mesenchymal genes (e.g., N-cadherin, Vimentin, Fibronectin)^[35]. EMT is characterized by reprogramming of epigenetic marks: following the induction of the EMT by the transforming growth factor beta (TGF- β), a global increase of trimethylation in H3K4 and H3K36 histones and a decrease in the dimethylation of H3K9 are observed^[34]. McDonald *et al.*^[35] demonstrated that these epigenetic modifications depend largely on LSD1, and that loss of LSD1 functions affects EMT-driven cell migration and chemo-resistance.

Taking in consideration different studies, it is clear that LSD1 may function as enhancer or inhibitor of EMT functioning in a cell type-specific fashion, probably due to the cells genetic background and depending on its interacting partners^[36]. A number of studies have described LSD1 as a critical player in epigenetic reprogramming during EMT. Two independent reports demonstrated that LSD1 physically associates with SNAIL1 (snail family transcriptional repressor 1) in breast cancer cells^[15,34,37]. The members of the SNAIL family of zinc finger transcription factors (Snail, Slug and Smuc) control the invasive phenotype and metastasis in several types of cancers, included breast cancer. In the EMT pathway, SNAIL family proteins repress the expression of epithelial genes, such as E-cadherin (CDH1), through an LSD1-dependent molecular mechanism. It has been shown that LSD1, interacting with Snail, leads to CDH1 repression^[15,34] [Figure 2A]. In particular, it has been defined that the N-terminal SNAG domain of Snail is essential and responsible for the interaction and recruitment of LSD1 to gene promoters. Notably, SNAG domain of Snail1 resembles a histone H3-like structure, thus, it acts as a pseudo-substrate “hook” for LSD1 to recruit it together with CoREST to the Snail1 target gene promoters [Figure 2A]. The inhibition of the Snail/Slug-LSD1 interaction, using pharmacological LSD1 inhibitors or a cell-permeable peptide corresponding to the SNAG domain of Slug, suppresses motility and invasiveness of breast cancer cells^[34].

Notably, high expression of LSD1 or ERR α associates with breast cancer poor prognosis, decreased survival, cancer progression and metastasis, and LSD1 has been found to protect the ERR α protein from proteasome degradation^[38]. The ERR α -LSD1 complex regulates a subset of genes involved in migration and invasiveness in breast cancer. The LSD1-ERR α complex binds the TSSs of common target genes and this interaction induces LSD1 to demethylate H3K9 leading to transcriptional activation^[39] [Figure 2B].

Among co-regulated genes LSD1-ERR α enhances the expression of the matrix metalloproteinase 1 (MMP1), a secreted protein involved in extracellular matrix degradation and cell invasion, and this can account for the capacities of LSD1-ERR α to induce tumor progression^[39].

Although the majority of work indicates that LSD1 is a key positive regulator of the EMT program, in cooperation with other proteins such as the NuRD complex, it could promote opposite effects. It has been reported that the LSD1/NuRD complex inhibits TGF- β signaling pathway, reducing breast cancer metastatic potential^[20] [Figure 2C].

LSD1 has been found to have a role also as epigenetic regulator of EMT-TFs transcription factors expression [SNAIL, zinc finger E-box-binding homeobox 1 (ZEB1) and ZEB2]^[34]. It has been reported that in breast cancer stem cells LSD1 interacts with the Ubiquitously transcribed tetratricopeptide repeat, X chromosome

Figure 2. Lysine specific demethylase 1 (LSD1) regulates cell motility and epithelial to mesenchymal transition (EMT). A: Snail is stabilized through the formation of a ternary Snail-LSD1-CoREST complex. SNAG domain of Snail binds LSD1 and recruits it together with CoREST to E-boxes of Snail target gene promoters. LSD1 binds the histones H3 tail and removes the activation marks on H3K4. HDAC1 and 2 deacetylate histones 3 and 4 (H3/H4), subsequently PRC2 directs the trimethylation of H3K27; B: H3K9 demethylation activity by LSD1 in complex with ERRα leads to transcriptional activation of pro-invasive genes; C: LSD1 inhibits EMT process through binding to NuRD impairing TGF-β signaling genes expression. D LSD1 with UTX functions as epigenetic silencer of EMT TFs

(UTX)^[14]. UTX functions as lysine-specific demethylase on H3K27me2/H3K27me3. Choi *et al.*^[14] demonstrated that the role of UTX in epigenetic silencing of EMT-TF is not due to its H3K27 demethylation activity but to the ability to disrupt c-Myc and MLL4 recruitment on the E-boxes of their promoters. LSD1 recruited by UTX on the E-boxes form a transcriptional repressive complex with histone deacetylase 1 (HDAC1) and DNA methyltransferase 1 (DNMT1) [Figure 2D]. LSD1 together with UTX in this case of human breast cancers functions directly as epigenetic silencer of EMT TFs and consequently acts as tumor suppressor^[14].

LSD1 POST-TRANSLATIONAL TARGETING IN EMT MODULATION

Several studies established that LSD1 activity and stability is altered by post-translational modifications^[40,41]. LSD1 is acetylated in epithelial, but not in mesenchymal cells. In particular, the acetyltransferase MOF (or KAT8, lysine acetyltransferase 8) is critically involved in LSD1-induced EMT, acting on LSD1 acetylation^[21]. MOF-mediated acetylation of LSD1 on lysines 432, 433 and 436 alters the association between LSD1 and target chromatin loci, increasing H3K4me2 levels and expression of epithelial markers. Moreover, while LSD1 is ubiquitously expressed, MOF is enriched in epithelial cells, but down-regulated in mesenchymal cells^[21]. Thus, MOF-mediated acetylation of LSD1 may represent a crucial regulatory switch that, modulating LSD1 control of the EMT process. Accordingly, in epithelial breast cancer cells, MOF blocks LSD1 association with epithelial gene promoters, increases H3K4me2 levels at these loci and activates E-cadherin expression^[21] [Figure 3A].

In addition, recent evidences highlight that phosphorylation of LSD1 on Serine-111 (analogous to murine serine-112) is crucial for its activity in the EMT programs. It has been reported that PKCα (Protein kinase

Figure 3. Lysine specific demethylase 1 (LSD1) is differently modified at post-translation level in epithelial and mesenchymal cells. A: In epithelial cells, MOF acetylates LSD1, and this modification induces the dissociation of LSD1/SNA1 complex. Then, LSD1 cannot block CDH1 transcription; B: in mesenchymal cells, PKC α phosphorylates LSD1. LSD1 phosphorylated interacts with SNA1 in order to silence CDH1 gene

C alpha), that phosphorylate LSD1 at Serine-111, is required for LSD1 association with the E-cadherin promoter^[42]. Specifically, LSD1-mediated demethylation at E-cadherin promoter is PKC α dependent and knockdown of PKC α impairs EMT induced by LSD1 overexpression in breast cancer cells [Figure 3B]. Another study reports that, upon induction of EMT, LSD1 is transiently induced and regulates epigenetic changes that result in transcriptional activation of several EMT-related genes in breast cancer cells. Phosphorylation of LSD1 at Serine-111 by a different PKC isoform, the PKC- θ (Protein kinase C theta), regulates its pro-EMT function^[22]. Indeed, PKC- θ co-localizes with LSD1 in mesenchymal-like, but not in epithelial breast cancer cells and co-binding with LSD1 occurs predominantly at promoter regions of genes activated during EMT. Moreover, LSD1 phosphorylated at Ser-111 is enriched in chemo-resistant breast cancer cells with mesenchymal phenotype after therapy. *In vivo* studies also demonstrate that targeting LSD1 in combination with chemotherapy significantly reduces tumor growth by inhibiting the mesenchymal properties generated by chemotherapy alone^[22].

Thus, targeting specific LSD1 post-translational modifications may be instrumental to modulate LSD1 functions and poses the basis to develop selective therapeutic tools.

LSD1/HIF-1 α AXIS IN BREAST CANCERS

Several studies demonstrate that LSD1 acts also on several non-histone substrates, such as lysine 370 on p53, which allows the binding of 53BP1^[28,43]. Furthermore, LSD1 regulates the protein stability of the DNMT1^[29], E2F1 (E2F transcription factor 1)^[30], MYPT1 (myosin phosphatase)^[31], STAT3 (signal transducer and activator of transcription 3)^[32] and HIF-1 α (hypoxia inducible factor 1 subunit alpha)^[33,44] through its non-histone demethylase activity. LSD1 demethylation of non-histone substrates confirms its versatility to regulate different processes. One of the most important LSD1 non-histone substrate is HIF-1 α , the master transcriptional regulator of developmental response to hypoxia^[45]. High levels of HIF-1 α have been strongly implicated in cancer biology, as well as a number of other pathophysiologicals, vascularization and angiogenesis, metabolism, cell survival, and tumor invasion. HIF-1 α protein accumulates under a hypoxic microenvironment, and it appears increased in various cancers. HIF-1 α plays a crucial role in adaptive responses of the hypoxic tumor cells and it functions as a transcriptional activator of genes that regulate biological processes required for tumor survival and progression. Furthermore, high levels of HIF-1 α induce up-regulation of different EMT-associated transcription factors, which in turn activate or repress EMT-associated signaling pathways and modulate EMT-associated inflammatory cytokines^[46]. In breast cancer cells, EMT is prompted by ZEB1-MYB-E-cadherin signaling under hypoxic stress, which induces higher expression of ZEB1 and lower expression of MYB^[47]. In particular, HIF-1 α promotes EMT through the regulation of E-cadherin, SNAIL, ZEB1, TWIST (twist family bHLH transcription factor 1), and

transcription factor 3 (TCF3, also known as E47)^[47-49]. In this contest, LSD1 has a pivotal role in HIF-1 α post-translation regulation. LSD1 demethylates lysine 32 (K32) of HIF-1 α , while the same site can be methylated by SET9 inducing HIF-1 α protein degradation^[50] [Figure 4A].

Moreover, in breast cancer, it has been reported that LSD1 regulates indirectly HIF-1 α at post-translation level influencing its stability and avoiding its degradation. In particular, LSD1 upregulates HIF-1 α demethylating the RACK1 (receptor for activated C kinase 1) protein (a component of the HIF-1 α ubiquitination machinery) on lysine 271 (K271). After that, the degradation of HIF-1 α is suppressed. These results indicate that in breast cancer the levels of FAD in the cells and the FAD-dependent LSD1 activity on RACK1-K271me2 could be the main determinants of HIF-1 α stability during prolonged hypoxia^[51] [Figure 4B]. Accordingly, it has been shown that LSD1 inhibitors also impair the accumulation of HIF-1 α , which is implicated in the activation of EMT in breast cancer. Therefore, even if at the moment there is a lack of evidences for an *in vivo* link between LSD1/HIF-1 α /EMT, this pathway needs to be further explored since FAD modulation could represent a potential therapeutic strategy to regulate LSD1 and HIF-1 α pathway.

CONCLUSION

Oncogenic roles of LSD1 in the pathogenesis of different epithelial cancers, such prostate, bladder, liver, non-small cell lung cancer and neuroblastomas, have been widely reported.

In breast cancer, LSD1 expression increases with cancer progression and its overexpression is positively correlated with the estrogen receptor negative status; high levels of LSD1 are a considerate molecular marker for predictive aggressive biology in ER-negative^[17,24] and basal-like^[17] breast cancer. Moreover, the depletion of LSD1 reduces proliferation and invasiveness of breast cancer cells *in vitro*.

In breast cancer, the oncogenic role of LSD1 depends on its versatility to interact with different partners. Current clinical trials utilizing epigenetic drugs for combination therapy have been shown to be promising in treating metastatic cancers. Vasilatos *et al.*^[52] suggest that the combination therapy of LSD1 and HDAC inhibitors leads to expression activation of genes such as E-cadherin in Triple-negative breast cancer (TNBC)^[52-54]. More recently, Yang *et al.*^[55] proposed that LSD1 interacts with SIN3A/HDAC complex, which plays a role in EMT-induced cancer stemness inhibiting a series of genes, such as TERT (Telomerase reverse transcriptase), CUL4A (Cullin4A), TGFB2 (Transforming growth factor beta 2), MDM2 (Mouse double minute 2 homolog), RHOA (Ras homolog family member A) and HIF-1 α ^[55].

Progresses have been made in drug targeting for breast cancer over the years. Current clinical treatments typically involve surgery if disease is promptly diagnosed. Moreover, depending on molecular characteristics of injury, breast cancer surgery may be followed by radiation, chemotherapy, hormone therapy and targeted therapy. Nevertheless, the major limitation of targeted anticancer therapies is the intrinsic or acquired resistance^[56].

Epigenetic therapies are prime candidates for adjuvant treatments to improve cancer therapy efficacy. Thus, establishing how exactly LSD1 regulates cell proliferation and invasive capacity will potentially facilitate the development of epigenetic therapies to attenuate tumor progression and metastasis in human breast cancer.

Recent studies identify LSD1 as a potent inhibitor of anti-tumor immunity and responsiveness to immunotherapy. LSD1 inhibition leads to double-stranded RNA stress and activation of type 1 interferon, which stimulates anti-tumor T cell response and represses tumor growth^[57].

Qin *et al.*^[58] have recently shown that the inhibition of LSD1 reactivates key immune checkpoint regulator and cytotoxic T cell-attracting chemokines in TNBC to immune checkpoint blocking antibodies. *In vivo*,

Figure 4. Non-histone lysine specific demethylase 1 (LSD1) substrate: hypoxia inducible factor-1 alpha (HIF-1α) protein stability is modulated by LSD1. A: Methylation-demethylation by SET7/9 and LSD1 respectively regulates HIF-1α degradation; B: LSD1-mediated regulation of HIF-1α protein stability during hypoxia: In early stage of hypoxia, the LSD1 (FAD-dependent) demethylase activity protects HIF-1α from RACK1-mediated degradation and HIF-1α activates transcription of its target genes. In prolonged hypoxia, the absence of FAD impairs FAD-dependent LSD1 activity on HIF-1α with consequent RACK1-dependent HIF-1α protein degradation

the inhibition of chemokine receptors, by combined treatment with PD-1 antibody and LSD1 inhibitors, suppresses tumor growth and metastasis^[58].

In conclusion, LSD1 inhibitors represent a promising epigenetic approach to treat breast Cancer. Furthermore, for a possible therapeutic goal, developing new drugs that target LSD1 and its partners or immune modulators would carry high innovation and translational potential.

DECLARATIONS

Authors' contributions

All authors participated in drafting the article and to its critical revision and approved the final version to be published.

Abstract

The epithelial-mesenchymal transition (EMT), in which cells undergo a switch from a polarized, epithelial phenotype to a highly motile fibroblastic or mesenchymal phenotype is fundamental during embryonic development and can be reactivated in a variety of diseases including cancer. Spatio-temporally-regulated mechanisms are constantly orchestrated to allow cells to adapt to their constantly changing environments when disseminating to distant organs. Although numerous transcriptional regulatory factors are currently well-characterized, the post-transcriptional control of EMT requires continued investigation. The hnRNP E1 protein displays a major role in the control of tumor cell plasticity by regulating the translational control through multiple non-redundant mechanisms, and this role is exemplified when E1 is absent. hnRNP E1 binding to RNA molecules leads to direct or indirect translational regulation of specific sets of proteins: (1) hnRNP E1 binding to specific targets has a direct role in translation by preventing elongation of translation; (2) hnRNP E1-dependent alternative splicing can prevent the generation of a competing long non-coding RNA that acts as a decoy for microRNAs (miRNAs) involved in translational inhibition of EMT master regulators; (3) hnRNP E1 binding to the 3' untranslated region of transcripts can also positively regulate the stability of certain mRNAs to improve their translation. Globally, hnRNP E1 appears to control proteome reprogramming during cell plasticity, either by direct or indirect regulation of protein translation.

INTRODUCTION

Epithelial-mesenchymal transition in tumor progression and metastasis

Metastasis represents a critical step in tumor progression and accounts for more than 90% of cancer-induced mortality^[1]. Despite the tremendous efforts made by the scientific community over recent decades, the cellular and molecular events that control tumor cell plasticity remain incompletely elucidated.

It has been shown that the epithelial-mesenchymal transition (EMT) is essential in embryonic development and in tumor metastasis and is among the mechanisms deemed critical in tumor cell plasticity. EMT consists of a fine-tuned phenotypic switch, characterized by the loss of apical-basal polarity and cellular adhesion in epithelial cells^[2,3]. Cells undergoing transition gradually express mesenchymal features, such as enhanced cytoskeletal rearrangement and extracellular matrix (ECM) degradation, both essential for cell motility [Figure 1].

EMT is not a unidirectional mechanism. The transition is a fine-tuned, reversible mechanism that allows cells to switch between epithelial and mesenchymal phenotypes while manifesting all intermediate phenotypic shades^[2,4]. The reverse mechanism, known as mesenchymal-epithelial transition (MET), allows reversion to the differentiated phenotype. Reversion is important for the potential formation of metastases that can occur as tumor cells attempt to relocate to distant organs to develop secondary tumors. Due to its transience, its presence in multiple-states, and its reversible nature, EMT is technically challenging to observe throughout tumor progression *in vivo*^[4]. Nevertheless, it is clearly demonstrated that transitioned cells harbor higher invasive capacities^[5-7]. In the early steps of metastasis, epithelial cancer cells must acquire the ability to separate from the primary tumor^[4,8]. Such departure may occur as single cells or as clusters of cells, and always requires the loss or the alteration of cell-to-cell and cell-to-matrix interactions^[9].

In the current model, EMT-positive tumor cells displaying newly-acquired mesenchymal features invade their surrounding environment and intravasate into the circulatory system. Cancer dissemination in this model results from ECM degradation and increased motility^[10,11]. It was also proposed that the survival of circulating tumor cells (CTCs) in the blood stream was enhanced by the phenotypic plasticity observed during EMT^[12-15]. Following dissemination into the circulation, CTCs extravasate and colonize distant organs to ultimately form secondary tumors. The ultimate metastatic colonization occurs through the re-epithelialization of cells by MET and is followed either by a proliferative cycle with subsequent drug resistant secondary tumor growth, or by a dormant cycle with latency of tumor relapse. Although there are countless reports demonstrating that genetic mutations are recurrently arising in many types of primary tumors, the attempts to identify genes that are recurrently mutated in the genomes of metastasized cells have consistently failed until now. Such observations are advocating for the prime role of cell plasticity in tumor cells dissemination. However, the experimental evidences of the casual function of EMT in metastasis formation remain to be clearly demonstrated. The explicit role of EMT in tumor progression remains actively debated but its implication in the increased resistance seen in both conventional and targeted antitumor therapies is currently well-accepted by the scientific community^[12,14,16-21]. It seems now clear that the controversy around the role of EMT in tumor dissemination might be attributed to its non-linear and multi-modal nature and that these many intermediate stages of EMT may occupy different regions on such a multi-dimensional landscape^[22]. Many groups are still investigating the role of EMT in tumor cells dissemination, and at this point, multiple hypotheses are still emerging to underline the mechanisms involved in the successful dissemination of tumor cells beyond the current EMT/MET view^[23].

Heterogeneous nuclear ribonucleoprotein E1

Heterogeneous nuclear ribonucleoproteins (hnRNPs) encompass a large family of RNA-binding proteins (RBPs) that contribute to multiple aspects of nucleic acid metabolism. These aspects include alternative splicing, mRNA stabilization, transcriptional control, and translation regulation. The coding sequences

Figure 1. Epithelial-mesenchymal transition relies upon a gradually orchestrated switch from a polarized, epithelial phenotype to a highly motile fibroblastic or mesenchymal phenotype. Epithelial cells are polarized with strong cell-cell cohesions and are organized by multiple cell junction proteins such as E-Cadherin, Occludin, Zonula Occludens, β-catenin and other epithelial markers. During EMT, tumor cells lose their epithelial features and acquire a mesenchymal phenotype, which promotes their motility and invasive capacity. The switch is acquired through a deep reprogramming of the transcriptional landscape and involves activation of EMT transcription factors such as ZEBs, reorganization of cytoskeletal components by regulation of proteins such as Vimentin, and modulation of expression/secretion of invasion-mediating proteases such as matrix metalloproteinases

of hnRNPs reveal a modular structure consisting of one or more RNA-binding motifs, and at least one auxiliary domain that regulates protein-protein interactions and subcellular localization^[24]. Indeed, all hnRNPs contain RNA binding domains that may include RNA recognition motifs (RRM), the quasi-RRM, glycine-rich domains and KH domains. Contrary to RNA-binding domains, auxiliary domains are divergent in protein sequence and are unstructured but are highly involved in regulating subcellular localization and other biological features. Most of the hnRNP proteins contain nuclear localization signals and are therefore mainly located in the nucleus during steady state. However, they can translocate into the cytosol via signaling pathway activation or by recruitment by other proteins. Importantly, for most of the hnRNPs, cellular functions are tightly regulated through post-transcriptional modifications including but not limited to methylation, phosphorylation, ubiquitination and sumoylation.

Poly(rC)-binding protein 1 (PCBP1 also called hnRNP E1) belongs to a hnRNP family that is composed of hnRNP K/J and the alpha-complex proteins (PCBP1-4α or CP1-4). Proteins in this family contain three hnRNP K homology (KH) domains for RNA-binding. The human PCBP1 gene encodes the hnRNP E1 protein, and was initially defined as clone sub2.3, with poly(C)-binding activity and observed similarity to hnRNP E2^[25]. hnRNP E1 harbors three highly conserved KH domains, KH1 to KH3. KH1 and KH3 domains were initially predicted to bind to RNA and *in vitro* studies later showed that the KH2 domain of hnRNP E1 also binds to RNA to regulate protein translation^[26-28]. The hnRNP E1 and hnRNP E2 proteins share 82% amino acid identity, with an even higher level of conservation (93%) for their KH domains^[24].

The subcellular localization of hnRNP E1 is predominantly nuclear, and demonstrates accumulation within nuclear speckles, with precise sites of accumulation observed with splicing factors prior to nascent transcript loading^[29]. The nuclear localization of hnRNP E1 is abolished by Actinomycin D^[30]. Since splicing factors undergo continuous and rapid nucleo-cytoplasmic shuttling^[31], and because splicing is coupled to

transcription, RNA polymerase inhibition results in the cytoplasmic accumulation of many splicing factors. Such observations support the primordial nuclear role of hnRNP E1 in pre-RNA splicing^[32]. The subcellular localization of hnRNP E1 is also governed by cell signaling stimuli. It was demonstrated that SMAD3 and hnRNP E1 were induced to govern alternative splicing, mediated by their colocalization in SC35 (also known as SRSF2)-positive nuclear speckles, downstream of EGF and TGF β , respectively^[33]. Even if it is to a lesser extent, hnRNP E1 is also clearly observed in the cytoplasm, and its presence potentially correlates to its function as a translational regulator^[29,34,35].

REGULATION OF TRANSCRIPTION

HnRNP E1 functions as a regulator of gene expression at the transcriptional level, although this does not appear to be its primary role. Recombinant cloning of the four members (PCBP1 to PCBP4) of the poly(C) binding protein family (PCBP) demonstrated that transcriptional activity of the mouse μ -opioid receptor (MOR) gene increased due to interaction between PCBPs and the 26-bp polypyrimidine stretch in the MOR proximal promoter^[36]. PCBPs can bind either to single-stranded or to double-stranded DNA^[27]. hnRNP E1 also exhibits a mild but consistent activation of the promoter of the BRCA1 gene^[37]. Finally, hnRNP E1 was found to regulate eIF4E transcription^[38]. Recruitment of hnRNP E1 to the eIF4E basal element (4EBE) in the eIF4E promoter region occurs downstream of serum or EGF-mediated cellular stimulation, and this mechanism requires Pak1-dependent phosphorylation of hnRNP E1 protein^[38]. These findings suggest that both hnRNP E1 and its phosphorylation downstream of growth factor-induced signaling play a regulatory role in eIF4E transcription in mitogen-stimulated cells.

TRANSLATION REGULATION

The hnRNP E1 protein regulates translation through either direct or indirect mechanisms. Examples of the most common mechanisms include regulation of mRNA stability, direct control of the ribosomal machinery, or the generation of RNA species that prevent miRNA-mediated translational repression of specific mRNAs.

Control of mRNA stability

The role of hnRNP E1 in RNA stability is exemplified by a broad spectrum of mRNA interactions. Mainly, hnRNP E1 regulates gene expression via binding to specific AU-rich elements (AREs) or U-rich elements located in the 3' untranslated regions (UTR) of target mRNAs. For instance, the binding of hnRNP E1 to p27^{kip1} 3' UTR via its KH1 domain stabilizes p27^{kip1} mRNA, fueling p27^{kip1} protein expression by enhancing its translation prior to degradation. The upregulated p27^{kip1} protein consequently inhibits cell proliferation, cell cycle progression, and tumorigenesis, and can concurrently promote cell apoptosis under paclitaxel treatment^[39]. Interestingly, other cyclin-dependent kinase inhibitors such as p21^{Waf1} are also regulated through hnRNP E1 mediated mRNA stability. Co-immunoprecipitation of p21^{Waf1} mRNA from MDA-MB-468 breast cancer cells using hnRNP E1 antibody suggests that hnRNP E1 protein binds to one or more motifs distributed throughout the p21^{Waf1} 3' UTR to stabilize the mRNA^[30].

The eNOS mRNA 3' UTR contains multiple evolutionarily conserved pyrimidine (C and CU)-rich sequence elements that are both necessary and sufficient for mRNA stabilization. The hnRNP E1 protein binds to these 3' UTR elements. Hence, hnRNP E1 is recruited to a stabilizing RNP complex that protects eNOS mRNA from the inhibitory effects of its antisense transcript sONE, and from 3' UTR-targeting small interfering RNAs (siRNAs) and miRNAs^[40]. HnRNP E1 regulates the stability of p63 mRNA via binding to a CU-rich element (CUE) within the p63 3' UTR^[41]. The p63 protein contribution to EMT could vary according to the biological context. It has been shown that p63 directly modulates the tumor cell plasticity by either attenuating EMT in human prostate cancer cells or promoting tumor cell invasion during human and mouse breast tumor cells dissemination^[42,43]. Phosphorylation of hnRNP E1 also contributes to stabilization

of mu opioid receptor (MOR) mRNA via interaction with ARE RNA-binding protein 1 (AUF1) and poly A binding protein (PABP)^[44].

Alternative polyadenylation

The addition of the poly-(A) to the messenger RNA 3' UTR is a co-transcriptional process occurring in the nucleus. As 3' UTRs contain cis elements that are involved in various aspects of mRNA metabolism, 3' UTR alternative polyadenylation (APA) can affect post-transcriptional gene regulation considerably in various ways, including modulation of stability, translation, nuclear export and cellular localization of mRNA. 3' UTR-APA can also affect the localization of the encoded protein^[45]. Polyadenylation of mRNA is a two-step process consisting of endonucleolytic cleavage and addition of an untemplated poly(A) tail.

The role for hnRNP E1 in the regulation of alternative polyadenylation has been established in an *in vitro*-transcribed and polyadenylated alpha-globin 3' UTR assay^[46]. Furthermore, a screening study for alternative polyadenylation utilizing RNA interference (RNAi) identified hnRNP E1 as the second highest factor in the control of polyadenylation signal usage. The mechanism by which hnRNP E1 modulates polyadenylation has yet to be characterized^[47].

Direct control of translation machinery through BAT elements

As we and others have previously demonstrated, the regulation of gene expression at the post-transcriptional level plays an indispensable role in TGF β -induced EMT and metastasis^[30,34,48-52]. We identified a transcript-selective translational regulatory pathway in which a ribonucleoprotein (mRNP) complex binds to a 33-nucleotide TGF β -activated translation (BAT) element in the mRNA 3' UTR and silences the translation of a cohort of mesenchymal protein-encoding mRNAs. hnRNP E1 is a critical component of the BAT-binding mRNP complex^[53]. Silenced mRNAs include Disabled2 (Dab2) and Interleukin-like EMT-inducer (ILEI), which are involved in mediating EMT^[34,51,54,55]. Furthermore, TGF β activates a kinase cascade terminating in the phosphorylation of hnRNP E1 protein at Serine 43. This phosphorylation occurs by isoform-2 specific activation of Akt and induces the release of the mRNP complex from the BAT element. This results in the reversal of translational silencing of mesenchymal protein-encoding transcripts that are required for EMT. By using a genome-wide combinatorial approach involving expression, polysome profiling and RIP-Chip analysis, we have identified the members of the cohort of translationally regulated mRNAs that are induced during TGF β -mediated EMT^[53].

At the molecular level, the eukaryotic elongation factor-1 A1 (eEF1A1) is an important additional functional component of the mRNP complex. We have previously demonstrated that the BAT element, hnRNP E1 and eEF1A1 form a ternary complex that mediates translational silencing at the translational elongation step^[35]. In non-stimulated cells exhibiting epithelial characteristics, hnRNP E1 binds to eEF1A1 and blocks progression of the 80S ribosome by preventing the release of eEF1A1 from the ribosomal A-site following GTP hydrolysis. EMT induced by either TGF β or hnRNP E1 knockdown disrupts the mRNP complex, allowing eEF1A1-mediated translational elongation of mesenchymal transcripts to proceed^[34,35] [Figure 2].

This mode of translational regulation represents an unusual case of dependency upon either agonists or stimuli to upregulate translation through 3'-UTR elements. Thus, the elucidation of this post-transcriptional regulatory pathway identified an "EMT gene signature" and provided mechanistic information as to how cell plasticity could be tightly regulated. Taken together, this work underscores the contribution of the non-phosphorylated hnRNP E1 protein to maintenance of epithelial cell integrity under normal conditions. During tumor-related epithelial plasticity, hnRNP E1 also acts as the trigger for the reversal of translational silencing, resulting in a fine-tuned, spatio-temporally controlled increase in mesenchymal protein expression.

Figure 2. Molecular mechanism of hnRNP E1-mediated translational silencing. The eukaryotic elongation factor-1A1 (eEF1A1) forms a complex with hnRNP E1 and the BAT element, and silences specific protein expression by stalling the elongation of their translation by ribosomes. Given the necessity for cognate-codon interaction with the ribosomal A site, it is likely that the formation of the BAT mRNP complex occurs post-delivery of the aminoacyl-tRNA to the ribosome. The ability of the BAT mRNP complex to inhibit eEF1A1-dependent elongation suggests that the 3'-UTR is interacting with the 5'-UTR in a circularized model to facilitate its proximity to the 80S ribosome^[35]. It has been suggested that translatable mRNAs are likely to be found in circular forms due to interaction between PABP, eIF4G, and the cap-binding protein eIF4E^[56]

Indirect control of translation through alternative splicing

Alternative splicing regulates over 90% of multi-exon protein-coding genes in humans^[57]. Abnormal regulation of alternative splicing often produces disease-specific protein isoforms^[58,59]. Additionally, genome-wide analysis has identified tens of thousands of “splice variant” mRNAs that are enriched in a wide range of human diseases^[60,61]. The hnRNP E1 protein is well documented for its repressive role in alternative splicing mechanisms as they apply to human health and disease. For instance, hnRNP E1 represses tumor cell invasion by inhibiting the alternative splicing of CD44^[62]. It was therefore demonstrated that enforced hnRNP E1 expression inhibited CD44 variants expression in HepG2 human liver cancer cells while knockdown of endogenous hnRNP E1 induced these variants splicing^[62]. Interestingly, another study based on *in vitro* and *in vivo* models of breast cancer progression demonstrated the switch of CD44 expression occurring from variant isoforms to the standard isoform during EMT. This isoform switch to CD44s was essential for cells to undergo EMT and was required for the formation of breast tumors that display EMT characteristics in mice^[63]. hnRNP E1 also binds to the growth hormone receptor pseud exon and prevents its usage to allow the expression of a functional protein^[64]. Disruption of hnRNP E1 binding and subsequent activation of an alternative splicing event responsible for Laron syndrome was demonstrated either by hnRNP E1 knockdown or by alterations to the genomic pseudosite. We also recently reported the binding of hnRNP E1 to a pre-RNA pseudosite in the serine/threonine-protein phosphatase 1 regulatory subunit 10 (*PNUTS*) transcript^[30]. The hnRNP E1 protein binds to a conserved BAT element that is similar in structure to those observed in the 3'-UTRs of the mesenchymal encoding mRNAs discussed above. The loss of hnRNP E1 binding to the alternative splicing site of *PNUTS* following hnRNP E1 knockdown, phosphorylation, and/or cytoplasmic translocation activates usage of the pseudosite and generates an alternatively spliced isoform of *PNUTS*. This alternative *PNUTS* isoform does not encode a functional protein, but rather a non-coding isoform of the gene. Functionally, the lncRNA-*PNUTS* acts as a decoy for miRNA-205 and binds to the miRNA causing a decrease in miRNA-205 bioavailability. This abolishes translational inhibition of mesenchymal factors such as ZEB mRNAs that would otherwise be suppressed in epithelial cells^[30]. Since alternative splicing and generation of lncRNA-*PNUTS* is an early event in TGFβ-mediated EMT, the lncRNA-*PNUTS* likely operates as a transient inhibitor of the miRNA-205 to allow for the temporal upregulation of ZEBs and subsequent regulation of downstream EMT events. Indeed ZEBs proteins are reciprocally linked in a feedback loop with the miR-200 family, each strictly controlling the expression of the other^[18,65]. In this way, a transient, but nevertheless, strong decrease in miR-205 bioavailability, sufficient to activate the ZEB proteins, would allow for transcriptional repression of the miR-200 family or other miRNAs

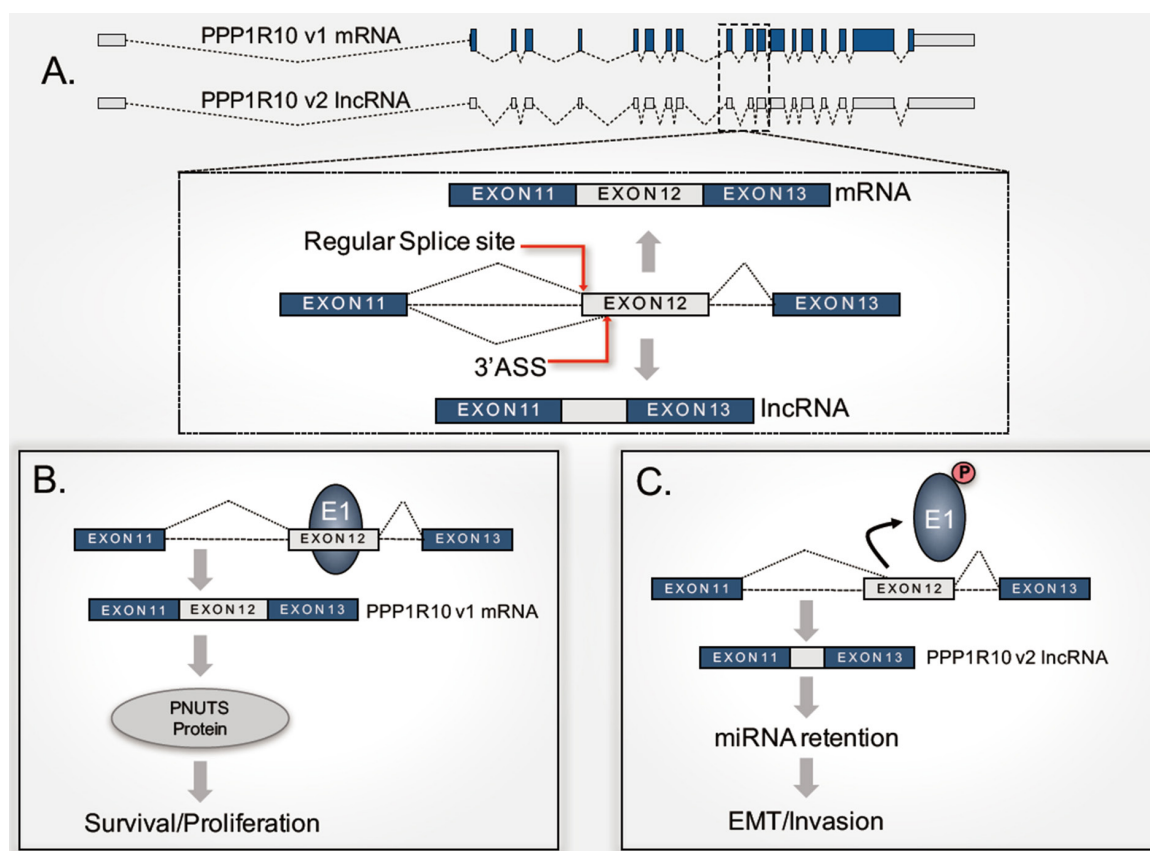

Figure 3. Molecular mechanism of hnRNP E1-mediated alternative splicing of *PNUTS*. A: The PPP1R10 (*PNUTS*) gene locus can encode either a protein coding mRNA or a non-coding RNA isoform. The *PNUTS* gene locus is highly conserved between human and mouse and expresses both coding and non-coding transcripts. The lncRNA-PNUTS is generated by the usage of the 3' alternative splice site (3'ASS) located at the 5' end of exon 12. This usage leads to the change of the open reading frame and the generation of a premature stop codon; B: the binding of hnRNP E1 to a BAT consensus element located in the alternative splicing site results on its masking and prevents its usage to generate the *PPP1R10* mRNA translated into the PNUTS protein; C: loss of hnRNP E1 binding to the alternative splice site uncovers it and allows its usage by the spliceosome machinery. The lncRNA-*PNUTS* acts as a decoy for miRNA-205 and thus allows the de-repression of ZEB protein translation. Reactivated expression of ZEB proteins induces the shutdown of epithelial markers such as E-Cadherin, allowing EMT to proceed

such as miR-183 or miR-203 thereby further stabilizing ZEB proteins and reinforcing the EMT process^[30]. Moreover, it has been suggested that the feedback loop of miR-200/ZEB also generates hybrid phenotypes of the cells during EMT-mediated tumor cell plasticity^[66] [Figure 3].

CONCLUSION

For many years, characterization of the role of RBPs in tumor biology and cell plasticity resulted in substantial progress, and the investigation of hnRNP E1 provided understanding of many facets of its molecular function in cells. The function of the PCBP1 gene encoding the hnRNP E1 protein was first demonstrated through characterization of its role as a negative regulator of alternative splicing. Since then, many additional roles have also been discovered, and most of them appear to have critical participation in the maintenance of cell phenotype integrity^[34,39,67]. At the molecular level, the ability of hnRNP E1 to specifically bind to mRNA species often leads to a direct or indirect regulation of their translation. This occurs either by controlling processivity of ribosomal machinery, stabilizing mRNA, or locking/unlocking dormant translational controls. Since it is well established that hnRNP E1 controls cell plasticity in health and disease through multiple fine-tuned regulatory mechanisms, it will be essential to develop investigations involving novel therapeutic strategies. Moreover, targeting the KH domain of hnRNP E1 may be relevant.

However, because hnRNP-E1 is pleiotropic and ubiquitous, confining therapeutic strategies to tumor cells may be challenging.

The phenotypic changes observed during cell plasticity and tumor progression demand radical proteomic reprogramming of cells concomitant with a modulation of the codon usage by the translational machinery. Accumulation of evidence advocates for acknowledgement of a primary role for hnRNP E1 in cell plasticity, and this is reinforced by identification of mechanisms involving hnRNP E1 that directly or indirectly converge upon the translational control of plasticity-associated proteins. We therefore propose that hnRNP E1, together with its associated proteins, acts as a hub that orchestrates the demands of proteome reprogramming during health and disease-associated cell plasticity.

DECLARATIONS

Abstract

Aim: To investigate whether AF1q, overexpressed in metastatic cells compared with the primary tumor cells, plays a pivotal role in breast cancer metastasis.

Methods: To investigate whether AF1q has a responsibility in the acquisition of a metastatic phenotype, we performed RNA-sequencing (RNA-Seq) to identify the gene signature and applied the Metacore direct interactions network building algorithm with the top 40 amplicons of RNA-Seq.

Results: Most genes were directly linked with intercellular adhesion molecule-1 (ICAM-1). Likewise, we identified that ICAM-1 expression is attenuated in metastatic cells compared to primary tumor cells. Moreover, overexpression of AF1q attenuated ICAM-1 expression, whereas suppression of AF1q elicited the opposite effect. AF1q had an effect on ICAM-1 promoter region and regulated its transcription. Decreased ICAM-1 expression

affected the attachment of T cells to a breast cancer cell monolayer. We confirmed the finding by performing the analysis on Burkitt's lymphoma.

Conclusion: Attenuation of ICAM-1 by AF1q on tumor cells disadvantages host anti-tumor defenses through the trafficking of lymphocytes, which affects tumor progression and metastasis.

INTRODUCTION

While primary lesion breast tumors are not fatal to the patient, the metastatic breast tumors are. For this reason, breast patients are often given other treatments after surgery to try to eliminate metastatic tumor cells that might have spread to other organs. Although the prognosis for breast cancer has improved during the last decade, we still lack specific treatments that target metastases. The discovery of such treatment will be of great benefit to patients.

The *AF1q* gene, located in chromosome 1, band 21, is an MLL fusion partner that was identified in acute myeloid leukemia patients with t (1; 11) (q21; q23) chromosomal abnormality^[1]. The function of AF1q is not yet fully known; however, elevated AF1q expression is associated with poor clinical outcomes in various malignancies. We have demonstrated that the enhanced AF1q expression promotes cell proliferation, migration, sphere formation, and chemo-resistance *in vitro* and *in vivo* breast cancer models^[2]. During the course of our study, we made an exciting discovery that AF1q physically interacts with TCF7, a key factor in the Wnt signaling pathway that enhances its activation^[2]. The Wnt signaling pathway plays a leading role in various processes that are important for cancer progression, including cancer initiation, growth, cell death, differentiation, and metastasis^[3]. Strikingly, we observed that AF1q-positive cancer cells are significantly more prevalent at metastatic sites than in primary breast tumors, when comparing paired samples from breast cancer patients^[2]. Moreover, the Wnt signaling pathway was activated by AF1q crosstalk to the STAT3 pathway via the PDGF/PDGFR cascade^[4]. The PDGF-B/PDGFR signaling cascade was activated upon enforced AF1q expression and this caused an increase in STAT3 DNA binding activity through *Src* kinase action in cancer cells^[4]. Moreover, AF1q is one of the genes that are differentially expressed between highly metastatic breast cancer cells and their parent cells^[2]. Importantly, when breast tumor cells were treated with doxorubicin or etoposide, endogenous AF1q expression was further activated, implying that current chemotherapeutics may increase the risk of metastasis of breast cancer. Taken together, characterization of AF1q-induced breast cancer and new treatment strategies for hyperactive AF1q expression patients are urgently needed.

Intercellular adhesion molecule-1 (ICAM-1) plays a key role in inflammatory conditions, nervous system development, and immune response through antigen recognition and lymphocyte surveillances^[5,6]. There is still controversy regarding the contribution of ICAM-1 expression to tumor progression. Expression of ICAM-1 on tumor cells negatively correlates with tumor progression and development, including tumor size and lymph node metastasis^[7]. A better prognosis was also reported for patients with ICAM-1 positive tumors compared with ICAM-1 negative tumors^[8,9]. However, *in vitro* studies demonstrated that ICAM-1 overexpression can positively affect tumorigenicity^[10]. Despite the controversy, it is clear that ICAM-1 plays a pivotal role in immune response. ICAM-1 levels on tumor cells stimulate T-cell receptor-mediated cellular immune response^[11]. Recent studies revealed that ICAM-1 expression plays an important role in interactions between lymphokine-activated killer cells and cancer cells^[12,13]. These results suggest that a decrease of ICAM-1 may be one of the mechanisms by which tumor cells escape cell-mediated cytotoxicity and lysis by the host cellular immune system.

Metastatic cancer cell, MDA-MB-231LN, is subtype of MDA-MB231 breast cancer cells and it has shown enhanced tumor growth and widespread metastasis than parents cell line in xenograft models^[14]. We observed AF1q, a metastasis enhancer, is highly expressed in metastatic cancer cells (MDA-MB-231LN) than in the primary tumor cells (MDA-MB-231). In this study, we investigated whether AF1q is responsible in the acquisition of metastatic phenotype using RNA-sequencing (RNA-Seq) and applied the Metacore direct interactions network building algorithm. Intriguingly, most genes were directly linked with ICAM-1. Likewise, we identified that ICAM-1 expression is attenuated in metastatic cancer cells compared to primary cancer cells.

In addition to AF1q oncogenic functions, we demonstrated that intensity of AF1q expression in metastatic sites is higher than in primary sites^[2]. Thus, similarly to that reported for certain oncogenes (i.e., Myc and Ras), AF1q has been shown to be endowed with a dual function in malignancy, being a protein apparently involved in both initiation and promotion of cancer progression through regulation of ICAM-1 expression. Our results suggest that targeting AF1q is valuable in developing treatments for breast cancer metastasis.

METHODS

Cell lines and cell culture conditions

MDA-MB-231 was purchased from American Type Culture Collection (ATCC). MDA-MB-231-luc-D3H2LN (MDA-MB-231LN) was purchased from Caliper Life Science. The cells were maintained as a monolayer culture in DMEM, supplemented with Glutamax and penicillin-streptomycin (Invitrogen). Fetal bovine serum (FBS) (Thermo Fisher Scientific) was added to the media. Burkitt's lymphoma cell lines, Ramos, Akata, Mutu, Raji, Jiyoye, BL-5, BL-7, and BL-8, were maintained in RPMI-1640, supplemented with Glutamax, penicillin-streptomycin, and 10% FBS (Thermo Fisher Scientific).

Whole blood was collected from healthy volunteers at James Graham Brown Cancer Center, University of Louisville with donors' written consent. The CD4-positive and CD8-positive human T cells were purified from buffy coats via positive selection using a 1:1 mixture of CD4- and CD8- MicroBeads (Miltenyi Biotec) according to the manufacturer's protocol. Isolated T cells were maintained in RPMI-1640, supplemented with 300 IU/mL IL-2 (R&D) and 10% FBS (Thermo Fisher Scientific). All cells were maintained at 37 °C under a humidified atmosphere of 5% CO₂.

RNA-Seq

Total RNA were isolated from MDA-MB-231 and MDA-MB-231LN cells with the use of the Purelink RNA min Kit (Thermo Fisher Scientific) in triplicates. Of total RNA, 1 µg was depleted of cytoplasmic and mitochondrial ribosomal RNA using the Illumina Ribo-Zero Gold rRNA Removal Kit (Human/Mouse/Rat) (Illumina). The rRNA-depleted RNA was ligated with Illumina adapters and further processed for sequencing following the Illumina TruSeq Stranded Total RNA library preparation kit (Illumina). All samples were pooled and a 75-cycle single-end sequence run was performed using the Illumina High Output Kit v2 on the Illumina NextSeq 500 platform.

RNA-Seq data analysis

RNA-Seq data were mapped using UCSC human genome, hg38, with STAR (version 2.5.2b). The read count and reads per kilobase of transcript per million mapped reads (RPKM) were calculated on the basis of the human GRCh38 Ensembl Release 91 gene annotation. To search differentially expressed genes, Cuffdiff (version 2.2.1) was used. For further analysis, 1485 significantly differentially expressed genes were selected as following criteria, when the value of averaged RPKM from three replicates is greater than or equal to 1 in at least one of the two samples, when the absolute value of log₂ (fold-change) is greater than or equal to 1, and when false discovery rate is less than or equal to 0.01.

Tumor data selection

We selected data from The Cancer Genome Atlas (TCGA) project to represent the breast invasive carcinoma (BRCA). We downloaded publicly available 1,222 RNA-Seq data of 1,092 breast cancer cases from TCGA database. Using FPKM values from all 1,222 samples, the expression level of AF1q was compared to that of ICAM-1.

RT and real-time PCR analysis

Total RNA was subjected to reverse transcription (RT) with a High capacity RNA-to-cDNA kit (Thermo Fisher Scientific), and the resulting cDNA was subjected to real-time polymerase chain reaction (RT-qPCR) analysis with BrightGreen qPCR master mix (ABM) and a StepOne real time PCR system (Thermo Fisher Scientific). The amplification protocol comprised 40 cycles of incubations at 95 °C for 30 s and at 60 °C for 60 s. PCR primer sequences (forward and reverse) were as follows: 5'-TGAGTACAGCACCTTCAACTTC-3' and 5'-GGGAAAGGAGTGGAAGGAAG-3' for AF1q; 5'-CAATGTGCTATTCAAAGTCCCC-3' and 5'-CAGCGTAGGGTAAGGTTCTTG-3' for ICAM-1; 5'-CAGAGGGCTACAATGTGATGGC-3' and 5'-GCTGAGGATTTGGAAGGGTG-3' for HPRT1.

Plasmid construction

Full-length AF1q cDNA was inserted into pLUTdNB, which is a pTRIPZ base modified doxycycline-inducible vector by cloning the HindIII and XhoI fragments as previously described. Short hairpin RNA (shRNA) of AF1q was purchased from Open Biosystems. Empty pLUTdNB, and pTRIPZ-scramble were used as controls for pLUTdNB-AF1q, and pTRIPZ-AF1q shRNA, respectively.

Viral production and infection

Lentivirus was produced by co-transfection of HEK 293T cells (ATCC) with the lentiviral constructs pVSV-G and psPAX2 (Addgene). Transfections were carried out using Lipofectamine 2000 (Invitrogen). For enforced AF1q expression or shRNA targeting, cells underwent lentiviral transduction and were selected using 1 µg/mL puromycin (Thermo Fisher Scientific) as previously described^[15]. After antibiotic selection, cells were cultured in complete medium including 1 µg/mL doxycycline (Thermo Fisher Scientific) for AF1q or shRNA induction.

Western blot

For blots of whole-cell lysates, cells were lysed directly in GLB buffer (2% SDS, 10% glycerol and 50 mmol/L Tris, pH 6.8), boiled, and separated by electrophoresis on a 4%-12% SDS-PAGE gradient gel. Proteins were transferred to PVDF membrane (Millipore) and blocked in 5% skim milk (Bio-Rad) in 0.05% PBST. Rabbit monoclonal anti-AF1q, ICAM-1, and β-actin antibodies were purchased from Abcam. After the appropriate antibody incubations, an enhanced chemiluminescence (Denville) system was used for developing blots.

Reporter gene construct, transfection, and Luciferase assay

Dual-Luciferase reporter assays were performed using an ICAM-1 reporter plasmid. To construct reporter plasmids, 850 bases of an ICAM-1 promoter fragment were cloned to between the XhoI and HindIII sites of the pGL4-Luciferase reporter plasmid (Promega). Briefly, 1×10^4 cells were plated in each well of a 96-well plate. The next day, the reporter plasmid (100 ng) and *Renilla* plasmid (10 ng, Promega) were co-transfected into the cells with lipofectamine 2000 (Thermo Fisher Scientific). After 48 h, cells were washed with PBS and assayed with the Dual-Luciferase reporter assay system (Promega) according to the manufacturer's instructions. Luciferase activity was determined using Synergy H1 Multi-Mode reader (Biotek). Quantitation of luminescent signal from reporter plasmid was normalized by quantitation of the luminescent signal from *Renilla*.

Surface and intracellular staining

Cells were harvested using non-enzymatic dissociation solution (Corning) and washed once with PBS. For staining of ICAM-1, cells were incubated in Human Fc Block (BD) for 10 min. Thereafter, cells were stained

with FITC-conjugated antibody to ICAM-1 in the presence of Fc Block for 30 min at 4 °C. Cells were then washed 3× with PBS and analyzed by FACS Caliber (BD). Data analysis was performed using Flowjo V10 software (Ashland).

Monocyte adhesion assay

Isolated T cells were incubated with Cell Tracker (Thermo Fisher Scientific) for 30 min at 37 °C and then 10⁵ cells per well were incubated on MDA-MB-231LN monolayers in HBSS supplemented with 2 mmol/L calcium and magnesium for 1 h. After removing nonadherent cells, the number of Cell Tracker-labeled cells bound to the MDA-MB-231LN cells was quantified under fluorescent microscopy.

Immunohistochemistry

Tissue samples were fixed in 4% paraformaldehyde, embedded in paraffin, and then 4-μm sections were prepared. Sections were de-waxed and a steamer pre-treatment in Tris/EDTA buffer (DAKO) was performed. Endogenous peroxidase activity was quenched by incubation in 3% hydrogen peroxide in PBS. For blocking steps, avidin (Sigma-Aldrich), biotin (Sigma-Aldrich) in PBS, and a super block (IDlabs Biotechnology) were used. Rabbit monoclonal AF1q antibody and mouse monoclonal ICAM-1 antibody in a 1:200 dilution were incubated at 4 °C overnight. IHC detection was performed with the IDetect Super Stain System HRP (IDlabs Biotechnology). Specific signals were amplified using 3-amino-9-ethylcarbazole (IDlabs Biotechnology) under visual control, followed by counterstaining with hematoxylin.

Statistical analysis

Quantitative data are presented as means ± SD and were subjected to analysis of variance followed by a *t* test with the use of Prism V.7 software (GraphPad Software). A *P* value of < 0.05 was considered statistically significant.

RESULTS

Next-generation sequencing and transcriptome data analysis

We observed AF1q, a metastasis enhancer, was highly expressed in metastatic cells, MDA-MB-231LN (invasive subline from MDA-MB-231), than in the primary tumor cells (MDA-MB-231) [Figure 1A]. To validate the results of RNA-seq, we performed RT-qPCR analysis using randomly selected genes [Figure 1B]. Both MDA-MB-231 and MDA-MB-231LN cell lines were subjected to RNA-Seq analysis with three biological replicates for each cell line. The 75 bp-long single-end sequencing reads were mapped to the human genomic reference using STAR aligner. More than 27.7 million sequencing reads were mapped to genome on each replicate (averaging 35.3 million mapped reads) [Supplementary Table 1]. Out of the 58,289 annotated genes, 18,042 (31.0%) by Ensemble were expressed with more than 10 read counts on at least one of our replicates [Supplementary Table 2]. Only uniquely mapped reads were used further for searching differentially expressed genes using Cuffdiff. Total 1,485 genes were selected as significantly differentially expressed with the criteria explained above. Among those, 762 genes showed increased value of RPKM in MDA-MB-231LN cell line compared to MDA-MB-231 and 723 genes showed the opposite. Row-scaled RPKM value of each replicate represents that the differential expression of genes is consistent throughout replicates of each cell line [Figure 1C].

With those differentially expressed genes, pathway analysis was performed using Metacore. By selecting top 40 network objects resulted from the pathway analysis [Table 1], direct interaction network building algorithm was applied. Interestingly, pathway process showed that most genes were directly linked with ICAM-1 [Figure 2A]. In addition, we found out that ICAM-1 transcript level was significantly decreased in MDA-MB-231LN cell line compared to MDA-MB-231 confirming that ICAM-1 expression is attenuated in metastatic cell line [Figure 2B].

To explore the relationship of AF1q with ICAM-1 in breast cancer, we used 1,222 RNA-seq data of 1,092 breast cancer cases from TCGA database. Using FPKM values from all 1,222 samples, the expression level of

Table 1. Top 40 network objects ranked by occurrence in top 50 pathway maps

Ranking	Network objects	Number of maps containing network object	Ranking	Network objects	Number of maps containing network object
1	IL-6	24	10	TGF- β receptor type II	8

Network object ranking reflects the popularity of each network object in pathway map. Smaller rank value means that network object occurs in greater number of maps. ICAM-1: intercellular adhesion molecule-1

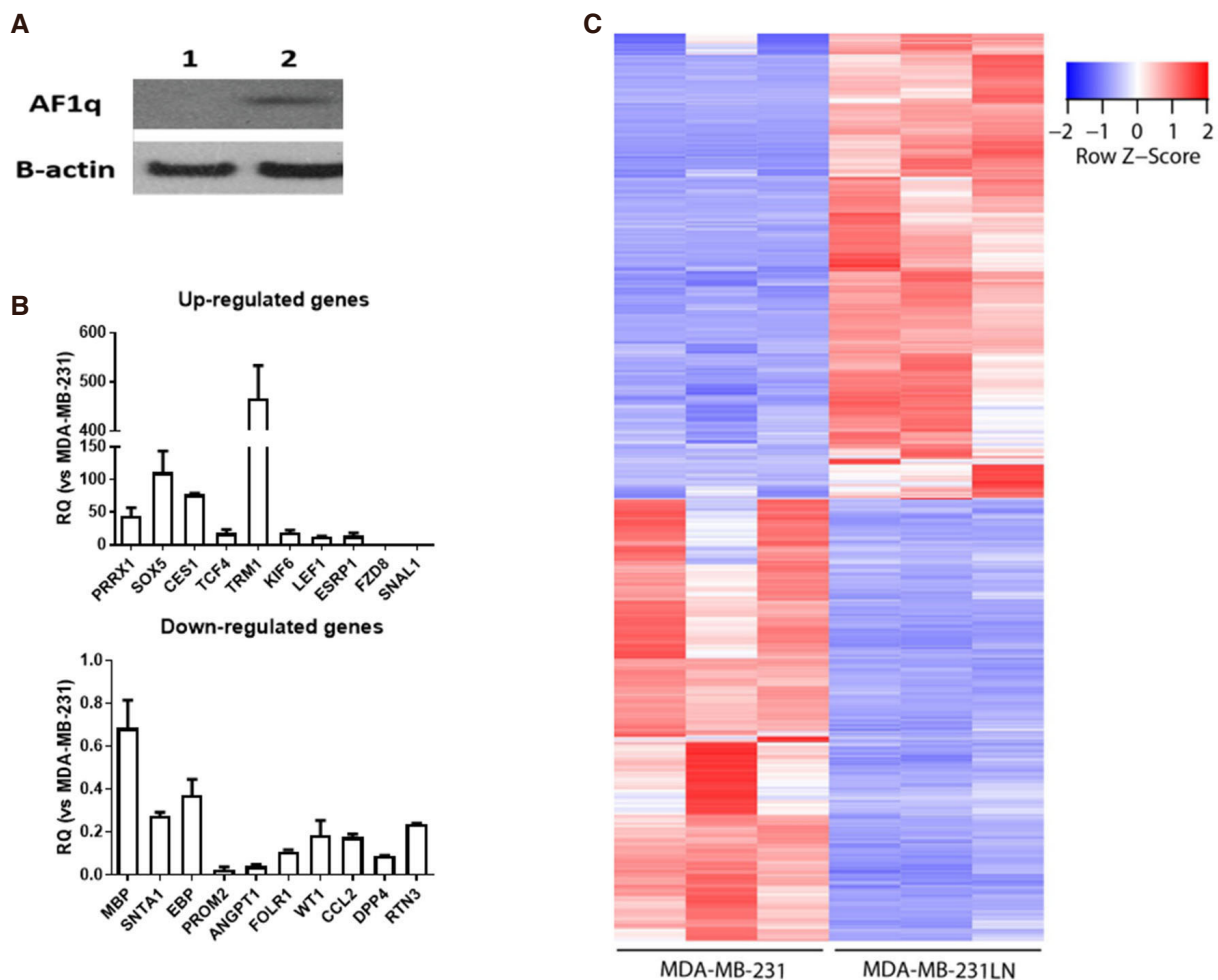

Figure 1. A: AF1q expression status in breast cancer cell lines (1: MDA-MB-231, 2: MDA-MB-231-luc2-LN); B: validation of relative expression of gene obtained from RNA-seq by qPCR. qPCR analyses were performed as described in the method section using randomly selected 20 genes (upregulated genes 10 and downregulated genes 10). Relative expression values are presented as an average \pm SD of three biological replicates; C: significantly expressed genes. 1,485 genes are significantly expressed in both cell lines with three biological replicates, respectively. Among those, transcripts of 762 genes increased in MDA-MB-231LN cell line and those of 723 genes decreased

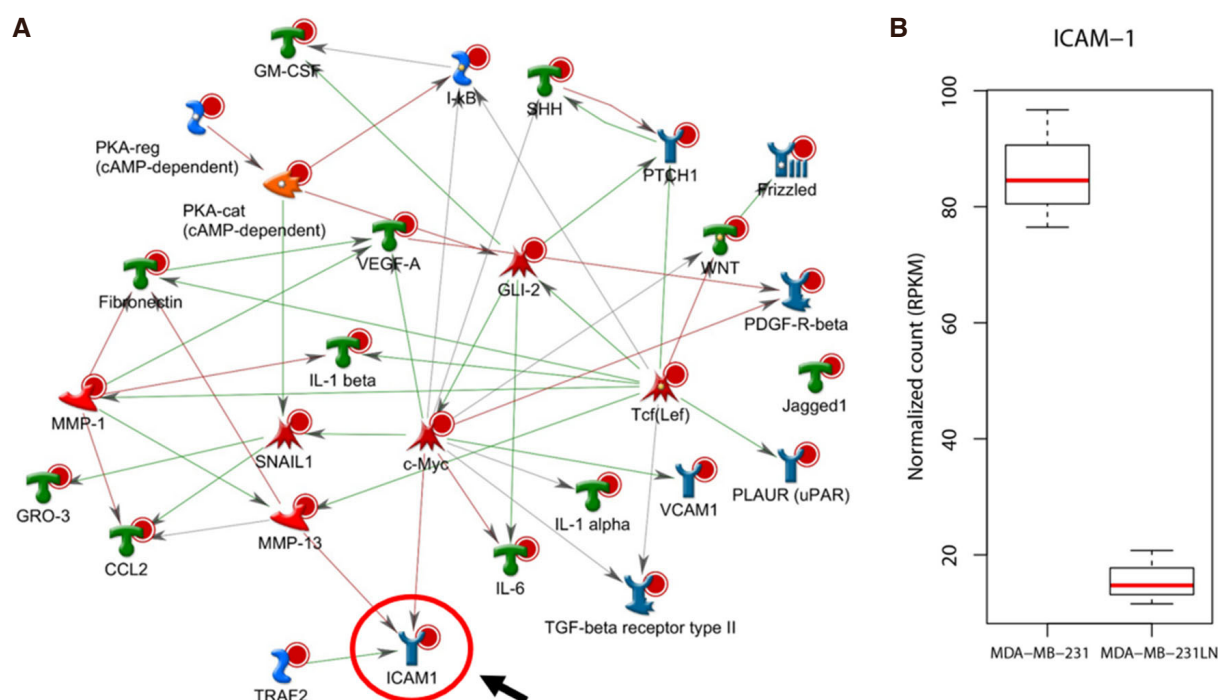

Figure 2. Functional interaction network analysis. A: 1,485 significantly selected genes were further analyzed for pathway process using Metacore. Top 40 network objects were, then, used for building direct interactions. ICAM-1 is directly linked with most genes and positioned at the end of the pathways. Red line represents suppression, blue line represents activation; B: RNA-seq shows that expression level of ICAM-1 is drastically decreased in MDA-MB-231LN cell line compared to MDA-MB-231

AF1q was compared to that of ICAM-1. Vast majority of the samples did not show clear correlation between the expression levels of AF1q and ICAM-1 [Supplementary Figure 1]. Interestingly, however, all those with high FPKM values of AF1q showed low expression level of ICAM-1 supporting our observation that overexpression of AF1q attenuated ICAM-1 expression. Although majority of samples did not show clear correlation, this finding is consistent with our previous report that the role of AF1q is a co-factor rather than a transcription factor^[2].

ICAM-1 is transcriptionally regulated by AF1q

To demonstrate that the AF1q expression was involved in ICAM-1 gene expression in breast cancer, we first experimentally overexpressed or suppressed AF1q expression in MDA-MB-231LN. We used a lentiviral transduction system to overexpress and suppress AF1q with endogenous AF1q expression. As shown in Figure 3A and B, overexpressed AF1q (AF1q) remarkably decreased ICAM-1 mRNA and protein expression, compared to that of control (Ctrl). The ICAM-1 expression, however, was increased by the suppression of AF1q with shRNA (shAF1q) than control (shCtrl). These results indicate that AF1q regulates ICAM-1 expression in transcription. FACS analysis comparing ICAM-1 surface expression on cells show that the attenuation of ICAM-1 on the surface of MDA-MB-231LN in response to AF1q was also confirmed [Figure 3C].

We assessed whether AF1q influences ICAM-1 promoter activity by performing a Luciferase reporter assay. We first experimentally overexpressed or suppressed AF1q expression in HEK293, then, HEK293 cells with a construct containing 850 bases of an ICAM-1 promoter fragment. Overexpressed AF1q displayed 0.7 fold lower luminescence. However, the luminescence was 1.4 fold higher when AF1q expression was suppressed by shAF1q [Figure 3D].

ICAM-1 plays an important role in T cell adhesion and cytotoxicity

Because ICAM-1 is associated with the recognition of T cells, we wanted to determine whether ICAM-1 dysregulation by AF1q is essential for the T cell attachment to breast cancer cells. To demonstrate that

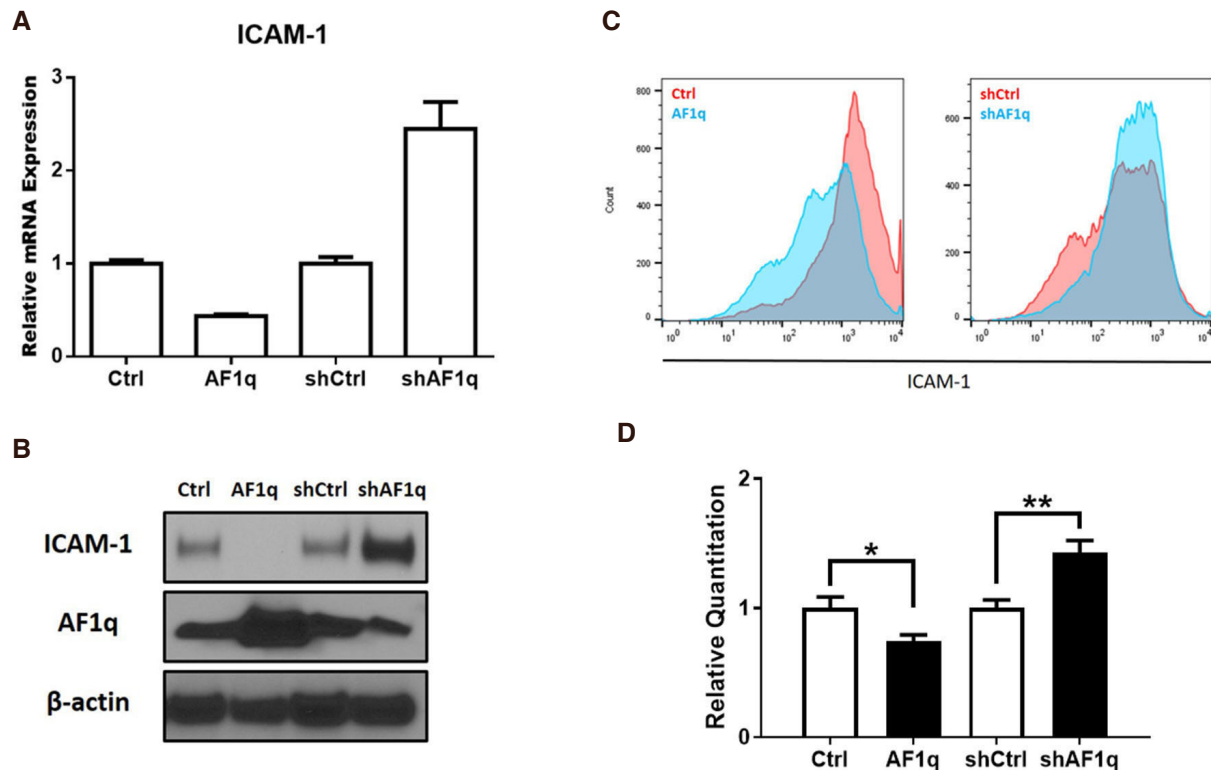

Figure 3. Transcriptional regulation of ICAM-1 expression by AF1q in breast cancer. A: ICAM-1 mRNA expression was quantified using qPCR in MDA-MB-231LN cells engineered to overexpress or suppress AF1q; B: the blot shows ICAM-1 protein expression; C: MDA-MB-231LN cells were stained with ICAM-1 mAb and flow cytometry analysis were performed using FACS Calibur. On left panel, Red is profile of the MDA-MB-231LN/Ctrl and Blue is MDA-MB-231LN/AF1q. On the right panel, Red is MDA-MB-231LN/shCtrl and Blue is shAF1q cells. Representative data of three similar experiments are shown; D: Luciferase activity in HEK293T cells transfected with reporter constructs of the proximal promoter of ICAM-1. Renilla Luciferase activity was used to normalize the promoter activity

ICAM-1 plays a critical role in the adhesion of T cells, we performed an *in vitro* adhesion assay. The attachment between breast cancer cell monolayer and T cells was significantly reduced by AF1q-induced ICAM-1 attenuation, while enhanced ICAM-1 expression by AF1q suppression increased the attachment [Figure 4A]. The attachment between T cells and breast cancer cell monolayer was significantly reduced by pretreatment with a blocking antibody to ICAM-1 [Figure 4B].

Cell cytotoxicity assays are shown in Figure 4C where the corresponding MDA-MB-231LN sublines were used as the target cell. Assays were carried out using *ex vivo* expanded T cells derived from healthy donors. These data indicate that ICAM-1 can function as an important determinant of a tumor cell's sensitivity to T cell-mediated killing.

AF1q reciprocally regulate expression of ICAM-1

We extended our finding to Burkitt's lymphoma. It is well known that downregulation of ICAM-1 in Burkitt's lymphoma enhances the probability of escape of tumor cells from T cell surveillance^[16]. RT-qPCR and Western blot analysis showed that the AF1q expression at both the mRNA and protein levels reciprocally regulated the expression of ICAM-1 in Burkitt's lymphoma cell lines [Figure 5A and B]. We validated our finding in Burkitt's lymphoma patient samples. To investigate the expression levels of AF1q and ICAM-1 in Burkitt's lymphoma patient samples, immunohistochemical staining of patient tissues was performed. We have observed identical results from the IHC study [Figure 5C]. These findings are consistent with observation in breast cancer cells.

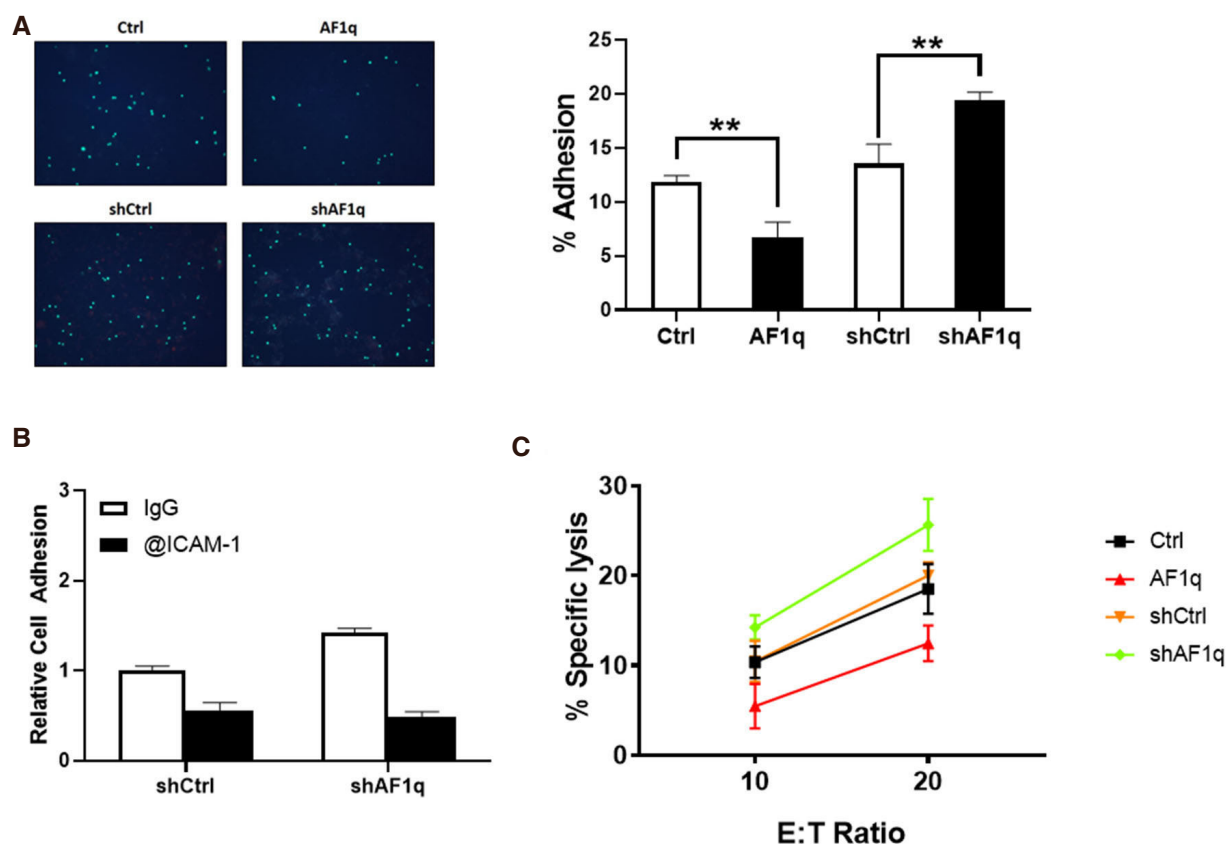

Figure 4. ICAM-1 is important for attachment and cytotoxicity of T cells to breast cancer. A: Labelled T cells attached to MDA-MB-231LN cells monolayer. AF1q significantly reduced the number of attached T cells to the monolayer. When AF1q expression was suppressed, the number of attached T cells was increased. The Bar graph represents the % adhesion cells of total cells; B: ICAM-1 blocking antibody significantly reduced the number of attached T cells to the monolayer; C: a 72 h cytotoxicity assay was performed in 24 well plates where co-cultured at 10:1 or 20:1 E:T ratio with MDA-MB-231LN cells

DISCUSSION

We have here identified ICAM-1 which reciprocally regulated by AF1q was associated with metastasis of cancer cells. Although elevated AF1q expression is associated with poor clinical outcomes in various malignancies^[4-6], the function of AF1q is not yet fully understood. Our findings further explain why high AF1q expression is associated with poor clinical outcomes. However, greater mechanistic understanding of how AF1q is involved in promoting cancer metastasis is necessary before these laboratory investigations can be translated into clinical interventions. Thus, it is very important to continue to investigate the underlying biological functions of AF1q and its association with breast cancer metastasis.

We observed that nuclear factor-kappa B (NF- κ B) activity was attenuated in response to AF1q expression in breast cancer cells (data not shown). NF- κ B translocated to the nucleus binds to the proximal NF- κ B consensus sequence of the ICAM-1 promoter and binding of NF- κ B to the proximal binding site of the ICAM-1 promoter induces transcriptional activity^[17]. Published reports show that Wnt/ β -catenin negatively regulates NF- κ B activity through a β -catenin-NF- κ B interaction in colon and breast cancer cells^[18,19]. β -catenin can physically complex with NF- κ B, resulting in a reduction of NF- κ B DNA binding, transactivation activity, and target gene expression^[20]. Activated β -catenin is associated with repressed NF- κ B activity in human cancer cells^[20]. Interestingly, the interaction between them is only indirect, as these two proteins do not bind to each other without a helper protein. Structurally, AF1q has highly acidic peptide regions highly conserved between species that fulfill the criteria for an acidic blob, a typical feature for cofactors. We also noted an internal peptide repeat within the sequence of 90 amino acids of human AF1q, which is located at both ends of the peptide, indicative of similar binding interfaces^[2]. Previously,

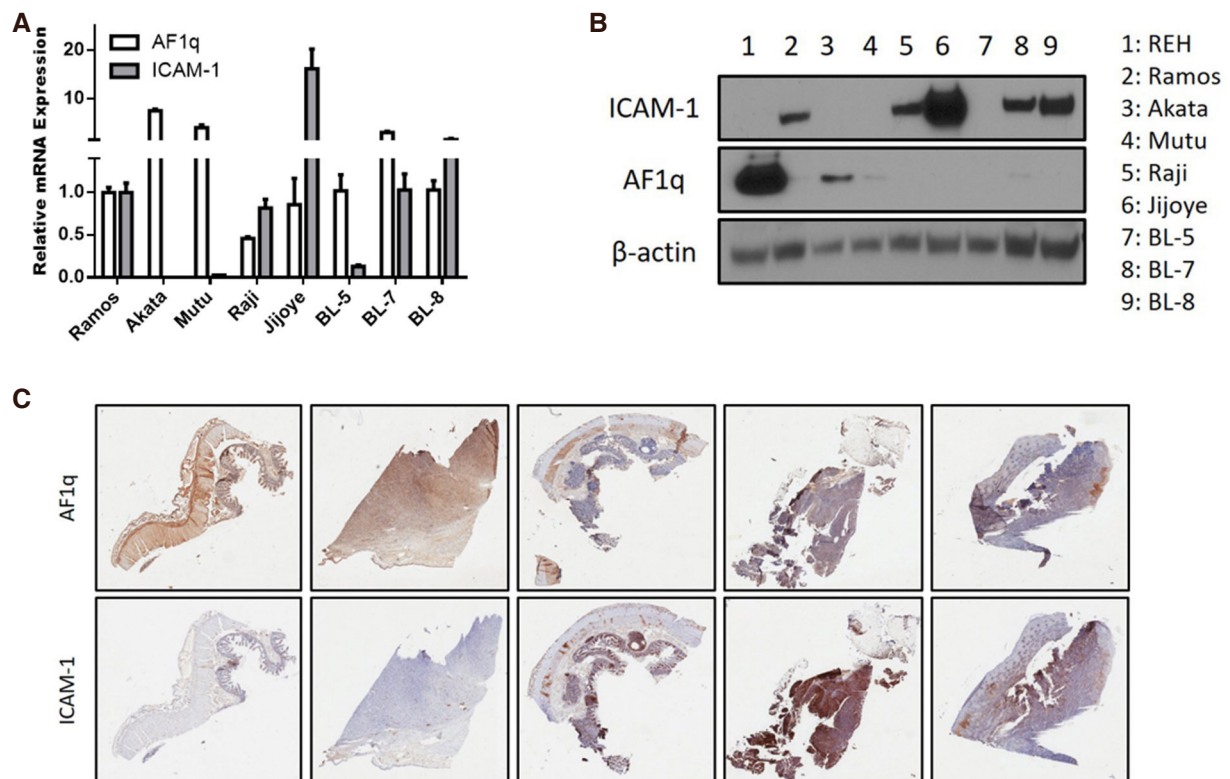

Figure 5. AF1q reciprocally regulates the expression of ICAM-1 in Burkitt's lymphoma. A: ICAM-1 mRNA expression was quantified using qPCR in MDA-MB-231LN cells engineered to overexpress or suppress AF1q; B: Western blot analysis of ICAM-1 and AF1q in Burkitt's lymphoma cell lines; C: representative images of AF1q and ICAM-1 staining in human Burkitt's lymphoma tumor metastasis tissues. High IHC staining of AF1q in tissue samples show low ICAM-1 expression

we reported that AF1q enhances the TCF7/LEF/β-catenin complex binding affinity as a cofactor. When we performed immunoprecipitation with NF-κB antibody in cancer cells overexpressing AF1q, we observed that β-catenin and AF1q were pulled down together (data not shown). However, it is not clear yet whether AF1q promotes protein interaction between β-catenin and NF-κB. These results suggest that activated β-catenin by AF1q would archive higher affinity to bind with NF-κB.

Cancer cells utilize multiple mechanisms to prevent host immune cells from exercising their antitumor activities. Many of these mechanisms are now known on a cellular and molecular level. These mechanisms, which enable the tumor to escape from the host immune system and to progress, are being intensively investigated in hope of finding therapeutically safe and effective inhibitors able to counteract tumor-induced immunosuppression. Tumor escape has been a major problem in cancer immunotherapy, and it has been held responsible for the failure of many immune interventions in cancer. For this reason, it is important to study and understand the various suppressive pathways human tumors utilize.

Tumors use blood vessels to supply themselves with oxygen and nutrients as well as for waste removal^[21]. Lymphocytes also use blood vessels as the gateway where integrin interactions with endothelial cell adhesion molecules are required to infiltrate into the tumor^[22,23]. The downregulation of ICAM-1 by several inhibitory mechanisms limiting T cell transendothelial migration have been described^[24-26]. Also, other componets of the tumor stroma and cancer-associated fibroblasts, can suppress T cell infiltration, which can influence cancer progression and metastasis^[27].

The interaction between tumor and lymphocytes through ICAM-1 plays an important role in leukocyte adhesion, transduction, and cytotoxicity^[28-30]. For example, tumor clones from melanoma metastasis split

into 2 groups with high and low susceptibility to killing by IL-2 activated lymphocytes. The subset with low lysability expressed ICAM-1 at levels 10 fold lower than those of tumor clones with high lysability^[31]. These results suggest that a constitutively high expression of ICAM-1 on tumors would be the parameter contributing to the high lysability of these tumor cells by any effector.

This study investigated the role of AF1q-attenuated ICAM-1 in progression and metastasis of breast cancer. Based on published reports, ICAM-1 strongly stimulates metastasis but also regulates lymphocyte infiltration via interactions between immune cells and malignant cells. This suggests that ICAM-1 needs an on-off switch for cancer progression and metastasis. It needs “off” to escape from host immune surveillances system in the initial phase of cancer, but “on” to invade and grow afterwards. Our results suggest that AF1q is a switch for ICAM-1 expression. Therefore, AF1q is a promising target for developing treatment for breast cancer metastasis.

Abstract

Head and neck squamous cell carcinoma (HNSCC) has a large global burden of disease and poor survival outcomes. Recent targeted therapies and immunotherapies have been explored in HNSCC, but there has been limited translation to clinical practice outside of recurrent or metastatic cases. Window of opportunity settings, where novel agents are administered between cancer diagnosis and planned definitive therapy, have begun to be employed in HNSCC. Tumor tissue biopsies are obtained at diagnosis and after the investigation treatment, along with other biospecimens and radiographic exams. Thus, this study design can characterize the safety profiles, pharmacodynamics, and initial tumor responses to novel therapies in a treatment-naïve subject. Early window studies have also identified potential biomarkers to predict sensitivity or resistance to treatments. However, these early investigations have revealed multiple challenges associated with this trial design. In this review, we discuss recent window of opportunity trials in HNSCC and how they inform design considerations for future studies.

INTRODUCTION

Head and neck squamous cell carcinoma (HNSCC) imparts significant morbidity and mortality as the sixth most common cancer in the world^[1]. In the United States alone, over 10,000 deaths and 51,000 new cases were estimated to occur in 2018^[1]. Nonspecific symptoms often lead to advanced stages at clinical presentation and thus poor survival outcomes, with an average 5-year survival in the United States of 65%^[2]. Surgical extirpation is a widely employed curative approach for advanced HNSCC, but there is often a time lapse of several weeks for preoperative workup and planning. Window of opportunity or “window trials” [Figure 1] leverage this time, where normally no treatment is rendered, in order to trial novel agents without delaying standard of care therapy^[3] in the context of a tumor microenvironment and human pathophysiology that cannot be replicated in preclinical models. Tissue is widely available for study, given the necessity of a biopsy for initial pathologic confirmation of the diagnosis and the subsequent curative therapy. Recent genomic studies have highlighted a number of potential molecular alterations in HNSCC, which can provide valuable targets which can be studied through window trials. Additionally, immunotherapies that have shown promise in recurrent or metastatic cases can be studied in treatment-naïve subjects through this approach. Of note, neoadjuvant trials typically do not qualify as window trials, as neoadjuvant therapies are given preoperatively typically with the goal of a measurable pathologic or clinical response. Some recent neoadjuvant trials in HNSCC, however, have followed window trial methodology, in that a tumor response to therapy did not preclude or delay surgery. These trials have shed light on the safety, possible efficacy, and potential patient selection biomarkers for the therapies employed. Thus, in this article, we review select neoadjuvant and window trials in HNSCC and discuss potential future directions.

RECENT WINDOW TRIALS OF TARGETED THERAPIES

Genomic methodologies have characterized numerous molecular alterations in HNSCC, many critical in tumor cell survival and proliferation pathways, that could form the basis for targeted therapies^[4-6]. However, translation of these findings into clinical practice has been slow.

ANTI-EPIDERMAL GROWTH FACTOR RECEPTOR BASED WINDOW TRIALS

Currently, the only molecularly targeted drug approved for HNSCC is cetuximab, a monoclonal antibody that targets the EGFR, an antiapoptotic transmembrane protein which is amplified or overexpressed in the vast majority of HNSCC and is correlated with reduced survival^[7]. In a phase III trial, cetuximab has been shown to improve overall survival in HNSCC when combined with radiotherapy, although only a fraction of patients receive benefit^[8]. Thus, identifying biomarkers that predict response to cetuximab is an ongoing area of study that potentially can be explored in a window of opportunity setting.

Schmitz *et al.*^[9] administered cetuximab to 33 subjects planned for curative surgery and compared radiologic tumor response via 18-fluorodeoxyglucose positron emission tomography (¹⁸FDG-PET) and tumor cellularity to 5 control subjects who did not receive any drug preoperatively [Table 1]. No treatment-limiting adverse events were noted, and there was a high rate of tumor response by ¹⁸FDG-PET (90% in cetuximab group vs. 0% in the control group). Tumor cellularity was correlated with ¹⁸FDG-PET standardized uptake values. As expected, cetuximab administration decreased pEGFR and phosphorylated extracellular signal regulated kinase expression, but neither of the biomarkers correlated with ¹⁸FDG-PET avidity. Cetuximab was also studied in a window of opportunity setting by Ferris *et al.*^[10], who noted an objective response in tumor size by computed tomography (CT) in a third of evaluable patients. Larger numbers of circulating EGFR-specific T cells^[10] as well as HLA class I upregulation^[11] were correlated with response to cetuximab.

Erlotinib is another EGFR inhibitor that has been approved in other cancers such as non-small cell lung cancer and pancreatic cancer. An uncontrolled neoadjuvant trial conducted by Thomas *et al* administered erlotinib in 35 subjects with advanced nonmetastatic HNSCC who were awaiting surgery^[12]. Four subjects

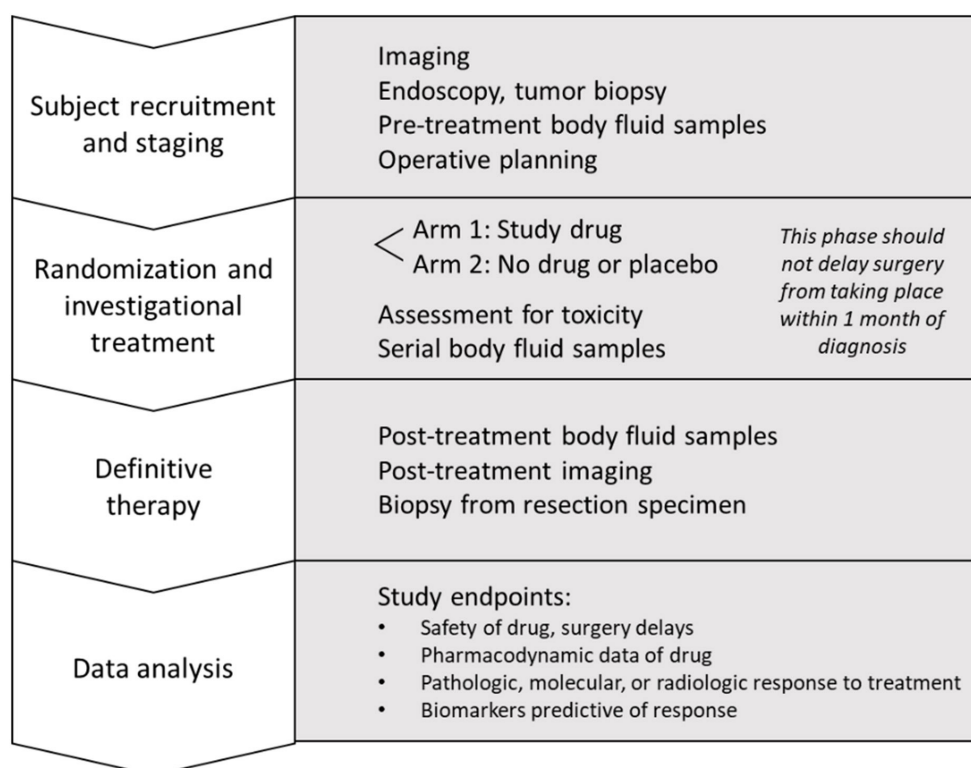

Figure 1. The typical format of a window of opportunity study

withdrew consent, and three subjects stopped treatment entirely due to grade 2-3 toxicities. Notably, length of treatment varied between enrolled subjects, with three subjects restarting treatment at a lower dose after grade 2-3 toxicities from the starting dose of erlotinib. Of 31 evaluable patients, decreased tumor size was seen in 9 subjects. Of multiple biomarkers studied, only the pre-erlotinib immune response score for p21^{waf}, or cyclin-dependent kinase inhibitor 1, was significantly correlated with response to treatment.

Cyclooxygenase-2 (COX2) pathways are also upregulated in HNSCC, and concurrent targeting of EGFR and COX pathways has shown synergistic effects in preclinical models^[13]. Thus, in a randomized double-blind window trial by Gross *et al.*^[13], 47 subjects received either erlotinib, erlotinib plus sulindac (a non-selective COX inhibitor), or placebo. One subject discontinued treatment for grade 2 anxiety, and another had their erlotinib dosage decreased for grade 2 mucositis. The primary endpoint of the Ki67 proliferation index, a cellular marker of proliferation, was only evaluable in 27 subjects. There was an ordered significant reduction of Ki67 between the erlotinib-sulindac combination *vs.* erlotinib alone, with no change in Ki67 attributable to the placebo group. No biomarkers tested appeared to mediate the decrease in Ki67, although higher pSrc expression was correlated with smaller decreases in Ki67. No clinical outcomes were evaluated.

Building from these results, Bauman *et al.*^[14] randomized subjects to a placebo arm or erlotinib with or without dasatinib, a small molecule inhibitor of Src family kinases. No significant treatment-altering toxicities were seen in any arm of the study. Erlotinib with or without dasatinib was correlated with a significant reduction in tumor size by response evaluation criteria in solid tumors (RECIST) measurement techniques using baseline and preoperative CT scans. Dasatinib did not appear to provide synergistic effects. No significant changes in expression levels of potential biomarker proteins was observed. Pretreatment mitogen-activated protein kinases (MAPK) and signal transducer and activator of transcription 3 expression were correlated with erlotinib sensitivity and dasatinib resistance respectively. Interestingly, the Ki67 proliferation index did not correlate with change in tumor size.

Table 1. Window trials of targeted therapies in head and neck squamous cell carcinoma

Ref.	Agent(s)	n*	Inclusion criteria	Duration	Outcome(s)	Biomarkers	Toxicity/surgery delays
Day <i>et al.</i> ^[17]	Rapamycin	16 (21 [‡])	Stage II-IV OC/OP	21 days	Tumor size (clinically, CT/RECIST)	NS	
Machiels <i>et al.</i> ^[15]	1. Afatinib 2. No drug	25 5 (30)	Stage II-IV OC/OP	14 days	¹⁸ FDG-PET response (EORTC, RECIST); DCE-MRI; DW-MRI	TP53 genotype, hypoxia screen	G3 diarrhea, renal failure (<i>n</i> = 1), surgery delay (<i>n</i> = 3)
Bauman <i>et al.</i> ^[14]	1. Erlotinib 2. Desatinib 3. Combination 4. Placebo	14 15 14 15 (56)	Stage I-IV OC/OP/L	2-21 days	Tumor size (CT)	pMAPK, pSTAT3	None
Uppaluri <i>et al.</i> ^[16]	Trametinib	20 (20)	Stage II-IV OC	7-16 days	Tumor size, SUV (PET/CT; WHO); tumor stage	NR	G4 duodenal perforation (<i>n</i> = 1), G2 nausea (<i>n</i> = 1); 3 patients stopped treatment
Ferris <i>et al.</i> ^[10]	Cetuximab	40 (40)	Stage III-IV OC/OP/L/HP	21-28 days	Tumor size (CT); progression free survival	EGFR-specific T cell counts	NR
Gross <i>et al.</i> ^[13]	1. Erlotinib 2. Erlotinib + Sulindac 3. Placebo	19 16 12 (39 [†])	Stage II-IVA OC/OP/L/HP	7-14 days	Ki67 proliferation index	pSrc	G2 anxiety (<i>n</i> = 1 stopped treatment), G2 mucositis (<i>n</i> = 1 decreased dosage)
Schmitz <i>et al.</i> ^[9]	1. Cetuximab 2. No drug	33 5	T1-T4 OC/OP/L/HP	21 days	¹⁸ FDG-PET response (SUV); tumor size (CT/MRI); tumor cellularity	NS	None
Thomas <i>et al.</i> ^[12]	Erlotinib	35	T2-T4 OC/OP/L/HP	18-29 days	Tumor size (CT)	p21 ^{waf}	G3 pruritis and G2 rash (<i>n</i> = 6; <i>n</i> = 3 stopped treatment)

Studies listed by date published. ‡*n* = 21 and *n* = 37 listed as accrual number and actual enrollment on ClinicalTrials.gov, with *n* = 16 included in the published manuscript; †accrual number modified based on discontinuation of parent study; *sample sizes listed include actual number of subjects, with the amount necessary for full accrual in parentheses if published. Biomarkers listed in the table include biologic characteristics statistically associated with sensitivity or resistance to the tested therapy. Toxicities only include those attributed to or possibly attributed to the drug being studied that are grade (G) 3 or higher or caused treatment dosage reduction or discontinuation. Ref.: reference; HNSCC: head and neck squamous cell carcinoma; OC: oral cavity; OP: oropharynx; P: pharynx; HP: hypopharynx; L: larynx; CT: computed tomography; ¹⁸FDG-PET: 18-fluorodeoxyglucose-positron emission tomography; SUV: standardized uptake value; DCE-MRI: dynamic contrast enhanced magnetic resonance imaging; DW-MRI: diffusion-weighted MRI; RECIST: response evaluation criteria in solid tumors; EORTC: European Organization for Research and Treatment of Cancer; WHO: World Health Organization; NS: not significant; NR: not reported

In another recent multicenter window study, Machiels *et al.*^[15] randomized 30 subjects to afatinib (an irreversible second generation inhibitor of the EGFR-family of receptor tyrosine kinases) or no drug prior to surgery. There were several afatinib-related adverse events, leading to discontinuation of the drug in one patient and a delay of surgery by 24 days in one subject, as well as delayed surgery with continuation of afatinib in two additional subjects. Radiologic response was seen in 16 of 23 evaluable subjects in the afatinib arm by ¹⁸FDG-PET and in 5 of 23 subjects by RECIST criteria. Tumor protein p53 (*TP53*) wild type allele and a hypoxia expression screen were associated with ¹⁸FDG-PET results but not responses by RECIST criteria.

OTHER TARGETED WINDOW TRIALS

Uppaluri *et al.*^[16] hypothesized that MAPK/extracellular-signal-regulated kinase (ERK) pathway could be targeted in oral cavity HNSCC. They performed a window trial^[16] of trametinib, an inhibitor of MAPK/ERK kinase, that resulted in decreased tumor size by FDG avidity by PET/CT and tumor downstaging in approximately half of the 17 evaluable subjects. There were, however, 3 subjects who discontinued the study, including one who suffered a grade 4 duodenal perforation. While there was biochemical evidence of a suppressed MAPK/ERK pathway in a third of evaluable patients, no clear correlation between biochemical results and responsiveness to trametinib was drawn.

Recently, Day *et al.*^[17] undertook a single-armed window trial of rapamycin, an inhibitor of the mammalian target of rapamycin pathway that is dysregulated in the majority of HNSCC. Their inclusion criteria differed

Table 2. Window trials of immunotherapies in head and neck squamous cell carcinoma

Ref.	Agent(s)	n*	Inclusion criteria	Duration	Outcome(s)	Biomarkers	Toxicity/ surgery delays
Bell <i>et al.</i> ^[27]	Anti-OX40 (MEDI6469)	17 (55 [‡])	Stage III-IV	5-6 days	TIL counts and expression profiles	MHC I genes	None

Timar <i>et al.</i> ^[21]	1. IL-2 2. Historical pathologic controls	19 20	T2-3 OC	21 days	Pathologic analysis, Tumor dimensions (MRI)	CD4:CD8 ratio	None

Studies listed by date published. ‡Active study on ClinicalTrials.gov; *sample sizes listed include actual number of subjects, with the amount necessary for full accrual in parentheses if published. Biomarkers listed in the table include biologic characteristics statistically associated with sensitivity or resistance to the tested therapy. Toxicities only include those attributed to or possibly attributed to the drug being studied that are grade (G) 3 or higher or caused treatment dosage reduction or discontinuation. Ref.: reference; HNSCC: head and neck squamous cell carcinoma; OC: oral cavity; OP: oropharynx; P: pharynx; HP: hypopharynx; L: larynx; TIL: tumor infiltrating leukocyte; CT: computed tomography; PET: positron emission tomography; MRI: magnetic resonance imaging; RECIST: response evaluation criteria in solid tumors; NR: not reported

from the previously discussed window trials in that subjects were either planned for curative surgery ($n = 15$) or chemoradiation ($n = 1$). There was one grade 3 hypokalemia reported but no resultant delays in surgery. Decreased tumor size was seen in 14 of 16 subjects clinically and 4 of 16 patients by RECIST criteria. Ki67 was significantly decreased in all patients.

Ongoing targeted therapy window trials in HNSCC without published results include use of olaparib, a poly-ADP ribose polymerase inhibitor, and AZD6738, a serine/threonine-specific protein kinase inhibitor (NCT03022409).

RECENT WINDOW TRIALS OF IMMUNOTHERAPIES

Studies have shown impairment of the innate and adaptive immune systems in HNSCC patients^[18]. Immunotherapies are designed to sensitize the body's immune system to the tumor and to counteract various strategies that tumors use to evade immunologic detection. With the recent FDA approval of nivolumab^[19] and pembrolizumab^[20] for patients with recurrent/metastatic HNSCC, there has been expansion of phase II window of opportunity trials utilizing immunomodulating drugs [Table 2]. In 2005, Timar *et al.*^[21] administered an interleukin-2 (IL-2) treatment to subjects with oral cavity cancer prior to surgery. Treatment consisted of peritumoral and perilymphatic injections 5 times per week over 3 weeks, along with a preceding intravenous cyclophosphamide administration and oral indomethacin and zinc sulfate medications. Matched historical pathologic specimens were used as controls. No treatment related adverse events were reported. Partial or complete response as judged by histopathologic examination or tumor dimensions on magnetic resonance imaging (MRI) were observed in 8 of 19 subjects treated with IL-2. Additionally, increased CD4+:CD8+ ratios were observed in treated subjects, although a statistically significant ratio increase between responders and non-responders was observed only in the tumor stroma.

In a later study, Wolf *et al.*^[22] utilized subcutaneous injections of IRX-2, a biologic composed of a mixture of purified cytokines, along with cyclophosphamide, indomethacin, and zinc in a cohort of 27 patients with HNSCC. There were no significant adverse events related to treatment noted. Of 23 evaluable subjects, 4 had an objective decrease in tumor size, although this did not constitute a true partial response by RECIST criteria. Increased lymphocytic infiltration into tumors was associated with increased response and overall survival^[22,23].

More recently, Uppaluri *et al.*^[24] presented preliminary results from an ongoing single-armed trial of advanced HPV negative HNSCC subjects who received neoadjuvant pembrolizumab (an anti-PD-1 antibody) that was continued post-operatively. No serious drug-related adverse events were reported. Significantly decreased high-risk pathologic features, pathologic treatment response, and clinical-to-pathologic downstaging was observed among the 21 subjects. Baseline high tumor expression of the programmed cell death protein ligand (PD-L1) was correlated with pathologic treatment effect. Ferris *et al.*^[25] presented interim results of a window trial of nivolumab (another anti-PD-1 antibody) for HNSCC. In half of the 23 evaluable subjects, tumor dimensions were reduced after treatment. As part of another ongoing neoadjuvant trial, Colevas *et al.*^[26] are administering anti-PD-1 antibody prior to planned curative surgery or radiation in HNSCC. They presented results from a single subject where their novel nuclear medicine imaging test correlated with tissue markers of immunologic activity.

A novel antibody MEDI6469, an OX40 (CD134) agonist, was also studied in a window of opportunity setting by Bell *et al.*^[27]. No significant adverse events were reported, and immunologic response was detected in 4 of 17 subjects. There was a significant difference between responders and non-responders in genes associated with major histocompatibility complex (MHC I)-mediated antigen processing.

Shayan *et al.*^[28] combined motolimod, a small molecule agonist of the toll-like receptor 8, along with cetuximab in 14 patients planned for curative surgery. One subject withdrew from the study due to an unspecified cetuximab toxicity. Study results showed that the expected increase in suppressive co-signaling molecule expression induced by cetuximab monotherapy was counteracted by the addition of motolimod, resulting in increased circulating EGFR-specific T cells and greater tumor infiltration of leukocytes.

OTHER WINDOW TRIALS

While not a classic targeted therapy or immunotherapy, metformin, an anti-hyperglycemic, has been shown to be associated with improved outcomes in HNSCC^[29]. It is postulated that metformin's metabolic effects through inhibition of mitochondrial oxidative phosphorylation may be proapoptotic in HNSCC. Curry *et al.*^[30] executed a single-armed window trial of metformin among 39 subjects with HNSCC of the oral cavity or larynx, each who took between 9-24 days of the drug without significant side effects. Markers of increased apoptosis and altered stromal metabolism were identified in the 33 evaluable subjects.

The results of several additional targeted therapy and immunotherapy trials have yet to be published. Those listed in ClinicalTrials.gov are briefly reviewed in [Table 3](#).

CONSIDERATIONS IN DESIGNING FUTURE WINDOW TRIALS

Window trials offer the opportunity to study the safety, mechanism, and efficacy of novel agents in treatment-naïve HNSCC. The studies outlined here have demonstrated the overall safety of each agent studied, with limited numbers of treatment-related adverse events and no clear post-operative complications attributable to the investigational drug. They have also confirmed the intended knockdown of upregulated pathways in HNSCC with targeted therapies and have shed light on the immunomodulatory mechanisms behind newer immunotherapies. Promising preliminary data reveal clinical, radiologic, and pathologic responses in some treated subjects along with possible biomarkers predictive of sensitivity or resistance to

the studied agents, although work remains to duplicate and understand these results.

By definition, window trials occur in a short timeframe, which requires careful coordination to obtain the desired imaging studies, tumor tissue, and serial biologic samples. As the authors of a recent study discuss^[15,31], this can be difficult in a patient population that often has socioeconomic and adherence challenges with an already complicated diagnosis and treatment strategy to discuss. For this reason and because patients may be hesitant to take an investigational drug that should not be marketed to improve clinical outcomes in the research setting, accrual can take longer than expected. Accrual goals were not uniformly available for the studies included in this review, and many unpublished planned window trials may have failed due to poor accrual. Narrowing subject selection to specific tumor sites (i.e., oral cavity, oropharynx, larynx, or hypopharynx) or immunogenomic profiles may further elongate recruitment timelines.

Pre- and post-treatment tissue is readily available by nature of the window of opportunity design, but the timing, selection, processing, and analysis protocols for tumor tissue and other desired body fluid samples must be considered. Tumor heterogeneity is a well-known phenomenon, and immunogenomic profiles can vary across both space and time. Pharmacokinetics of the drug under study should also be factored into the timing of obtaining biologic samples. Unlike in breast cancer where Ki67 is commonly employed, HNSCC studies have not coalesced on particular biomarkers, nor do standardized protocols for obtaining biomarker data or evaluating their clinical impact exist as of yet^[14,15]. Several window trials discussed here were not randomized or did not use data from control subjects, which has been known to complicate

pharmacodynamic and predictive biomarker assessment^[13]. Studies presented herein have also collected serum samples, but analytes from other body fluid samples that could serve as future “liquid biopsies^[32]” have yet to be characterized in window trials.

Given that there may be physical reduction in tumor size from the drug under study, it is important to confirm with subjects that surgery is still required as part of the study even if the tumor shrinks or disappears radiographically, and surgical margins should be based on pre-treatment tumor dimensions^[31]. Similar to biologic samples, the type, timing, protocols, and quality thresholds for radiologic tests must be carefully planned, particularly if imaging from multiple institutions are used. The window trials presented here used a variety of exams, including CT, MRI with different protocols, ¹⁸FDG-PET, and investigational PET technologies. Additionally, criteria for assessing radiologic response included those from RECIST, modified RECIST^[14], EORTC (European Organization for Research and Treatment of Cancer)^[15], the World Health Organization^[16], and others. Researchers should also be aware that pseudoprogression during immunotherapy, or an initial tumor flare due to inflammatory processes provoked by the drug, may complicate image interpretation during the short timeframe of a window study^[33,34]. This should not be confused with hyperprogression, a phenomenon of tumor growth during immunotherapy treatment experienced by a small minority of patients, which may delay curative surgery^[34,35]. Limited data are available on the optimal timing of surgery, but it is suggested that HNSCC resection should take place within a month of diagnosis^[36,37]. Treatment-related adverse events beyond hyperprogression may delay curative surgery, so investigational drugs selected for window trials should have well-characterized safety data and a tolerable safety margin. Trial stopping points based on safety events should be well-defined and monitored by an independent committee.

Finally, it is important to note that window trials cannot assess the long-term response, acquired resistance mechanisms, or safety profile for the studied treatment. Complementary study designs should be utilized to contextualize window trial results. For instance, a single window trial may provide compelling preliminary data for a full confirmatory neoadjuvant trial. The I-SPY2 TRIAL (Investigation of Serial Studies to Predict Your Therapeutic Response with Imaging and Molecular Analysis)^[38] utilizes this approach in breast cancer, with the added benefit of conducting studies on multiple agents in parallel. This technique could be applied in HNSCC, although the window trial approach is likely most effective for treatment-naïve and healthier patient populations. Biomolecular insights gained from window trials, on the other hand, could inform pathophysiology in multiple patient populations, as well as subject/agent selection for all types of clinical trial designs.

CONCLUSION

Window of opportunity studies are challenging to design and execute. Despite this, early window trials have explored the safety, pharmacodynamics, short-term efficacy, and predictive biomarkers for novel targeted therapies and immunotherapies. Window trials are a promising study design complementary to traditional clinical trials to advance understanding and treatment of HNSCC.

DECLARATIONS

Authors' contributions

All authors made substantial contributions to the conception and writing of the article.

Abstract

Aim: The convergence of tumorigenic and embryonic signaling pathways drives us to exploit the embryonic stem cell (ESC) microenvironment to restrict metastatic potential of cancer cells. We have previously demonstrated that bioengineered ESC microenvironments could restrict growth and metastatic potential of highly aggressive breast cancer cell (BCC). This study aims to further understand the regulation of convergent EGFR and canonical Wnt/ β -catenin signaling pathway function in triple negative metastatic BCCs using the 3D in vitro ESC microenvironment created by encapsulating ESCs in alginate hydrogel microstrands.

Methods: Co-culture with ESC-microstrands increased sensitivity to two chemotherapeutic drugs in metastatic BCCs. To test whether these changes were due to restored signaling pathway regulation in BCCs, we probed for changes in gene expression of key molecules related to the EGFR and canonical Wnt/ β -catenin signaling pathways using quantitative reverse transcription polymerase chain reaction and Western blot analysis.

Results: ESC-microstrands are able to alter the gene expression of highly aggressive BCCs at both mRNA and protein levels. These changes are indicative of a reversal of EGFR and canonical Wnt/ β -catenin signaling pathway hyperactivation following co-culture. Increased NKD2 mRNA and protein expression coinciding with dual signaling pathway inhibition within co-cultured BCCs suggests that this reversal may be attributable to restored regulation of NKD2 within these pathways.

Conclusion: ESC-microstrands are able to reverse oncogenic signaling pathway hyperactivation and restore signaling pathway regulation in metastatic BCCs. Further studies could provide insight into what role NKD2 up-regulation plays

in BCC inhibition, leading to the development of a new targeted therapy for metastatic breast cancer.

Keywords: Metastasis, cancer cell, signaling, 3D culture, stem cells, EGFR, Wnt/ β -catenin, NKD2

INTRODUCTION

Human breast cancer is currently the highest diagnosed form of cancer and the second leading cause of cancer-related deaths in American women. Triple negative breast cancer is of the basal subtype and displays poor prognosis owing to its highly metastatic properties. Current treatments focused on eradicating breast tumors in lieu of or following local therapy include chemotherapy, hormonal therapy, and targeted therapy. Hormonal therapy is not an option for triple negative breast cancer as it does not contain hormone receptors, and there are currently no approved biological targeted therapies. Chemotherapy has proven unsuccessful because triple negative breast cancer is highly drug resistant and is associated with high toxicity^[1]. It remains a huge challenge to fully understand the mechanisms of cell migration and invasion of cancer cells, such as triple negative breast cancer cells, and to eliminate these cancer cells to prevent disease recurrence and metastasis.

Metastatic breast cancer cells have been linked to embryonic stem cells (ESCs) due to their sharing of certain similar gene signatures and convergence of tumorigenic and embryonic pathways (e.g., EGFR, Wnt/ β -catenin, and TGF- β)^[2-4]. ESC microenvironments have been exploited to restrict metastatic potential of cancer cells^[5-7]. In particular, our previous studies have shown that bioengineered 3D ESC microenvironments using alginate hydrogels have great potential to supply critical signaling molecules and reprogram highly aggressive breast cancer cells to a non-invasive phenotype^[4,8-10], including decreased cell proliferation, increased apoptosis, reduced cell migration, invasion and metastatic marker expression, reversed epithelial-mesenchymal transition (EMT), and altered cell metabolism of metastatic breast cancer cells. The engineering of unique ESC microenvironments *in vitro* which can restrict the metastatic potential of triple negative breast cancer cells (BCCs) may permit advanced study of cancer metastasis. Consequently, this could provide greater insight into the decision-making processes regarding the growth, migration, and invasion of cancer cells and its subsequent prevention.

The EGFR and canonical Wnt/ β -catenin signaling pathways control many cell properties that contribute to the metastatic phenotype. The EGFR (also known as the ErbB1/HER1) belongs to the ErbB family of tyrosine kinase receptors. Binding of ligands (e.g., EGF, TGF- α) to the EGFR initiates dimerization of the EGFR with one of the other three receptors within the same family. Dimerization activates the intracellular tyrosine kinase domain, which undergoes autophosphorylation. This causes a conformational change which exposes the activation loop and allows for protein binding and phosphorylation of downstream signaling targets^[11,12]. Phosphorylation initiates signaling cascades, such as Ras/Raf/mitogen-activated protein kinase/ERK, phosphoinositol 3 (PI3)-Akt-mechanistic target of rapamycin (mTOR), PLC- γ , JAK/signal transducers and activators of transcription (STAT), and Src kinase pathways^[11-13]. These signaling pathways affect cell growth and proliferation, differentiation, invasion, migration, apoptosis, angiogenesis, cell cycle progression, and immune function^[11,14,15]. The canonical Wnt/ β -catenin signaling pathway is initiated when one of its ligands binds to the receptor complex. This causes phosphorylation and activation of the protein dvl-1, which inhibits a destruction complex normally responsible for recruitment, phosphorylation, ubiquitylation, and proteasomal degradation of β -catenin. Signal activation and sequestration of the destruction complex to the plasma membrane prevents the phosphorylation of β -catenin, which subsequently accumulates in the cytoplasm, translocates to the nucleus, and activates transcription of target genes^[16-19]. In human breast cancer, β -catenin transactivates vimentin, a known EMT marker^[20]. β -catenin also forms a complex that binds to the cytoplasmic tail of E-cadherin, connecting it to the actin cytoskeleton^[21-24].

Cross-talk between the canonical Wnt/ β -catenin and EGFR signaling pathways is evidenced in cancer cells. For example, the EGFR signaling pathway activates the transcription of canonical Wnt/ β -catenin target genes such as cyclinD1, c-myc, and survivin. In oral and non-small cell lung cancers, there is a link between EGFR mutations and accumulation of β -catenin within the nucleus^[25,26]. The EGFR signaling pathway is turned on by Wnt ligands through the Fzd receptor, leading to cleavage of EGF-like ligands^[27,28]. EGFR signaling is transactivated in breast cancer patients after knockdown of the Wnt negative regulator SFRP1. Increased expression of Wnt1 and decreased expression of APC activates EGFR signaling in breast cancer^[28,29]. Down-regulation of β -catenin decreases levels of EGFR, STAT3 and Akt mRNA^[30]. E-cadherin regulates EGFR localization and activation^[31]. NKD2 is a negative regulator of Dvl-1, which promotes β -catenin translocation to the nucleus^[32,33]. The N-terminal region of NKD2 also contains a moiety capable of binding to precursor TGF- α (36 kDa), a ligand for the EGFR signaling pathway. This interaction facilitates the escort of precursor TGF- α to the plasma membrane, whereby it is cleaved into mature TGF- α (17 kDa), cleaved into a soluble form (6 kDa), and secreted^[29,34].

These previous studies establish a relationship between the EGFR and canonical Wnt/ β -catenin signaling pathways. They also illustrate the complexity involved in this signaling pathway cross-talk. Hyperactivation of both signaling pathways is a signature of aggressive human breast cancer. NKD2 is involved in a positive feedback loop in the EGFR signaling pathway and is a known inhibitor of the canonical Wnt/ β -catenin signaling pathway. It is likely that NKD2 acts as a “molecular switch” between these pathways in breast cancer development and/or progression. The exact mechanism for this communication remains elusive. We have established a 3D *in vitro* ESC-microstrand tumor model by encapsulating ESCs in small-diameter alginate microstrands and co-culturing with metastatic human BCCs. The creation of a 3D *in vitro* ESC-microstrand tumor model to probe signaling pathway-related molecules following restoration of signaling pathway function will provide insight into this complex process^[8,10]. This model restricts metastatic BCC proliferation, survival, metabolism, invasion, migration, and oncogene expression, as summarized in Table 1^[10]. To further understand the underlying mechanism for ESCs’ inhibitory effect on BCCs, we hypothesized that ESC-microstrands will inhibit the EGFR and canonical Wnt/ β -catenin signaling pathways in highly aggressive cancer due to restored signaling pathway regulation. To test this hypothesis, co-cultured BCCs were treated with EGFR and canonical Wnt/ β -catenin signaling pathway inhibitors. Next, co-cultured BCCs were probed at the molecular level for expression of key molecules related to the EGFR and canonical Wnt/ β -catenin signaling pathways using quantitative reverse transcription polymerase chain reaction (qRT-PCR) and Western blot analysis. Changes in gene expression would reflect the ability of pluripotent signals from ESC-microstrands to reverse oncogenic signaling pathway hyperactivation and restore signaling pathway regulation in metastatic BCCs.

METHODS

Cell culture

Mouse CCE ESCs were purchased from StemCell Technologies (Vancouver, Canada) and cultured in 0.1% gelatin-coated flasks. The growth medium consisting of DMEM with 4.5 g/L D-glucose supplemented with 15% (v/v) FBS, 100 U/mL penicillin, 100 μ g/mL streptomycin, 0.1 mmol/L MEM non-essential amino acids, 10 ng/mL murine recombinant LIF (StemCell Technologies, Vancouver, Canada), 0.1 mmol/L monothioglycerol, 2 mmol/L L-glutamine, and 1 mmol/L sodium pyruvate. Cell media was changed every day and cells were passaged every 2 to 3 days. Human MDA-MB-231 and MCF7 BCCs were purchased from ATCC (Manassas, VA). Cells were cultured in growth medium consisting of DMEM supplemented with 15% (v/v) FBS, 100 U/mL penicillin, 100 μ g/mL streptomycin and 2 mmol/L L-glutamine. Human 3T3 fibroblasts were obtained from the NIH and cultured in growth medium containing DMEM supplemented with 15% (v/v) FBS, 100 U/mL penicillin, and 100 μ g/mL streptomycin. All cell lines were maintained at 37 °C in a humidified atmosphere containing 5% CO₂.

Microfluidic synthesis of 3D ESC-microstrands by encapsulating ESCs in alginate hydrogels

A sodium alginate solution (1.5% w/v alginate dissolved in 0.9% w/v sodium chloride) containing ESCs suspended at a density of 1×10^6 cells/mL was loaded into a 3 mL syringe, which was placed in a New Era NE-1000 syringe pump (New Era, Farmingdale, NY). A 50 mmol/L CaCl_2 solution was placed in one well of a 24-well plate at a volume of 2 mL. The sodium alginate-ESC mixture in the syringe was pumped into the CaCl_2 solution at a constant rate of 0.1 mL/min. Exposing the divalent cation, Ca^{2+} , to sodium alginate cross-linked the polymer chains. This set-up consistently formed microstrands with an approximate 200 μm diameter [Figure 1A]. After microstrand formation, the CaCl_2 was carefully removed using 200 μL micropipette tips, without disturbing the microstrands, and replaced with ESC maintenance media.

Co-culture of 3D ESC-microstrands with breast cancer cells

As shown in Figure 1B, ESC-microstrands were co-cultured with 2D BCCs or fibroblasts by cutting them to a specific length, and gently adding them to the well with tweezers. On the same day that ESC-microstrands were formed, MDA-MB-231 BCCs, MCF7 BCCs, and/or 3T3 fibroblasts were seeded at a cell density of 2×10^4 cells/mL in their media. After 24 h., BCC or 3T3 media was replaced with ESC maintenance media. ESC-microstrands were then measured and cut to an appropriate length based on BCC or 3T3 cell density (35.0 mm for approximate 2×10^4 cells) and added to the wells with BCCs or 3T3 cells in ESC maintenance media. After 24, 48, or 72 h, BCCs were analyzed using various biological assays. Controls included non-co-cultured BCCs and empty alginate hydrogel microstrands. The non-co-cultured control consisted of BCCs in ESC maintenance media and the empty microstrand control included BCCs in ESC maintenance media co-cultured with empty microstrands.

Cell proliferation assay

Cell proliferation of MDA-MB-231 BCCs was measured using a Premixed WST-1 Cell Proliferation Reagent (Clontech, Mountain View, CA), per manufacturer's instruction.

Treatment with EGFR and canonical Wnt/ β -catenin signaling pathway inhibitors

MDA-MB-231 BCCs were co-cultured with ESC-microstrands for 48 h. and subsequently treated with 5, 10, or 20 $\mu\text{mol/L}$ of either the EGFR inhibitor Erlotinib, the canonical Wnt/ β -catenin inhibitor PNU74654, or both to determine how sensitive these cells were to both chemotherapeutic inhibitors. Controls included non-co-cultured BCCs and non-drug-treated BCCs. After 48 h, the sensitivity of the BCCs to drug treatment was assessed using a WST-1 cell proliferation assay per manufacturer's instructions. For the drug resistance experiments, cells were treated with chemotherapeutic drugs up to four times for 24 h each and allowed to recover for either 24 or 48 h prior to analysis.

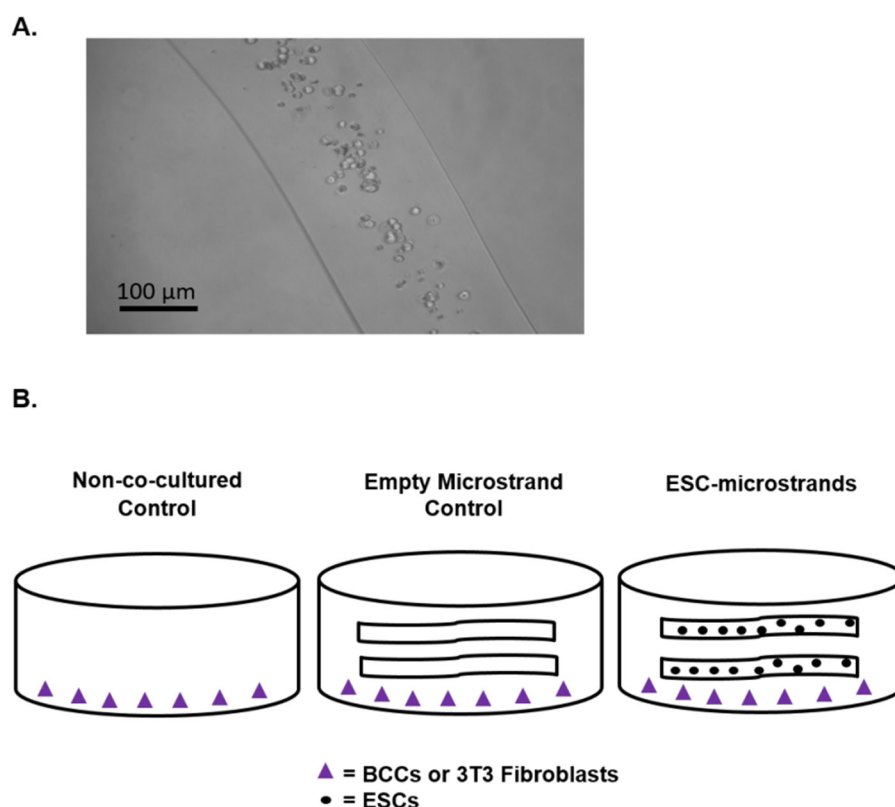

Figure 1. Schematic for co-culture of 3D embryonic stem cell (ESC)-microstrands with human breast cancer cells (BCCs). A: Optical image of mouse ESCs encapsulated in alginate hydrogel microstrands; B: experimental set-up of BCC alone (left), cultured with empty microstrands (middle), and co-cultured with 3D ESC-microstrands (right). No microstrands, empty microstrands, and 3T3 fibroblasts instead of BCCs served as experimental controls

qRT-PCR analysis

Cells were washed once with 0.5 mL of ice cold PBS. Total RNA of MDA-MB-231 BCCs was isolated using an RNeasy Mini Kit (Qiagen, Valencia, CA), per manufacturer's instruction. The RNA was of high purity with 260/280 values close to 2.0. Starting with 125 ng/mL of total RNA, cDNA was synthesized using an Omniscript first-strand cDNA synthesis kit (Invitrogen, Grand Island, NY). qRT-PCR was executed using a StepOnePlus™ Real Time PCR System (Applied Biosystem, Foster City, CA). The Mastermix contained 1.25 μL of the forward and reverse primers [Table 2], 12.5 μL of SYBR® Green PCR Master Mix (Life Technologies, Carlsbad, CA), and 5 μL of Molecular Biology Grade water (Corning, Inc., Corning, NY). Each sample was performed in triplicate and a negative control containing Molecular Biology Grade water instead of cDNA was included in every trial. The $\Delta\Delta C_t$ method was applied for quantification using β -actin as an internal control.

Western blot analysis

BCCs were washed with ice cold PBS and lysed through exposure to 0.2 mL of ice cold RIPA buffer (Sigma Aldrich) for 20 min while pipetting up and down. Cell lysates were centrifuged at 12,000 rpm for 20 min at 4 °C. The cell pellet was discarded, and the concentration of total protein was assessed using a BCA assay, per manufacturer's instructions. The protein samples were boiled for 10 min and loaded into the wells (15 μg) of a NuPage® Novex® 4%-12% Bis-Tris Protein Gel (Thermo Fisher Scientific, Waltham, MA) for separation through electrophoresis (100V for 2 h). The running buffer, 1 × NuPAGE® MOPS SDS (Thermo Fisher Scientific, Waltham, MA), contained 50 mmol/L MOPS, 50 mmol/L Tris Base, 0.1% SDS, and 1 mmol/L EDTA. Prior to loading, cell lysates were mixed with LDS sample buffer (4:1) (Pierce™ Chemical, Rockford, IL) containing 0.5 mol/L dithiothreitol (DTT) (10:1) (Invitrogen, Grand Island, NY).

RIPA buffer was added to give a final volume of 20 µL per well. β-actin was utilized as a loading control and 10 µL of Precision Plus Protein™ WesternC™ Standards (BioRad, Hercules, CA) was added to a well as a molecular weight reference. The proteins were wet-transferred onto a nitrocellulose membrane for 1 h at 100V. The transfer buffer consisted of 1 × Tris-glycine buffer with 20% (v/v) methanol. Prior to transfer, the nitrocellulose membrane was incubated for 10 min in 100% methanol for activation. Following wet transfer, the nitrocellulose membrane was washed three times in Tris-buffered saline and Tween 20 (TBST) in 15-min intervals and incubated for 1 h at RT in 5% (w/v) BSA diluted in TBST. The nitrocellulose membrane was incubated overnight at 4 °C in a primary antibody [Table 3], which was diluted in TBST. Three 15-min washes in TBST were performed, followed by one-hour incubation at RT in a secondary antibody diluted in TBST. Three washes were performed again in TBST and the nitrocellulose membrane was placed in Supersignal™ West Femto Maximum Sensitivity Substrate (Thermo Fisher Scientific, Waltham, MA) according to manufacturer's instructions. Signal detection was accomplished using a FluorChem E system (Protein Simple, San Jose, CA).

Statistical analysis

Data analyses were performed using a one-way ANOVA with multiple comparisons. Data were expressed as the mean ± standard deviation. A value of $P < 0.05$ was considered statistically significant. Experiments were repeated 2-3 times.

RESULTS

ESC-microstrands increase MDA-MB-231 BCC sensitivity to chemotherapeutic drugs

Highly aggressive MDA-MB-231 BCCs were treated with the chemotherapeutic drugs Erlotinib and PNU 74654, which inhibit the EGFR and canonical Wnt/β-catenin signaling pathways, respectively. For both drugs, there was a reduction in BCC viability when treated at a dose of 20 µmol/L with a 24-h recovery period [Figure 2A].

PNU 74654 decreased metastatic BCC viability more than Erlotinib, with a reduction exceeding 30%. Combining both drugs further diminished cell viability compared to individual treatment. To examine the

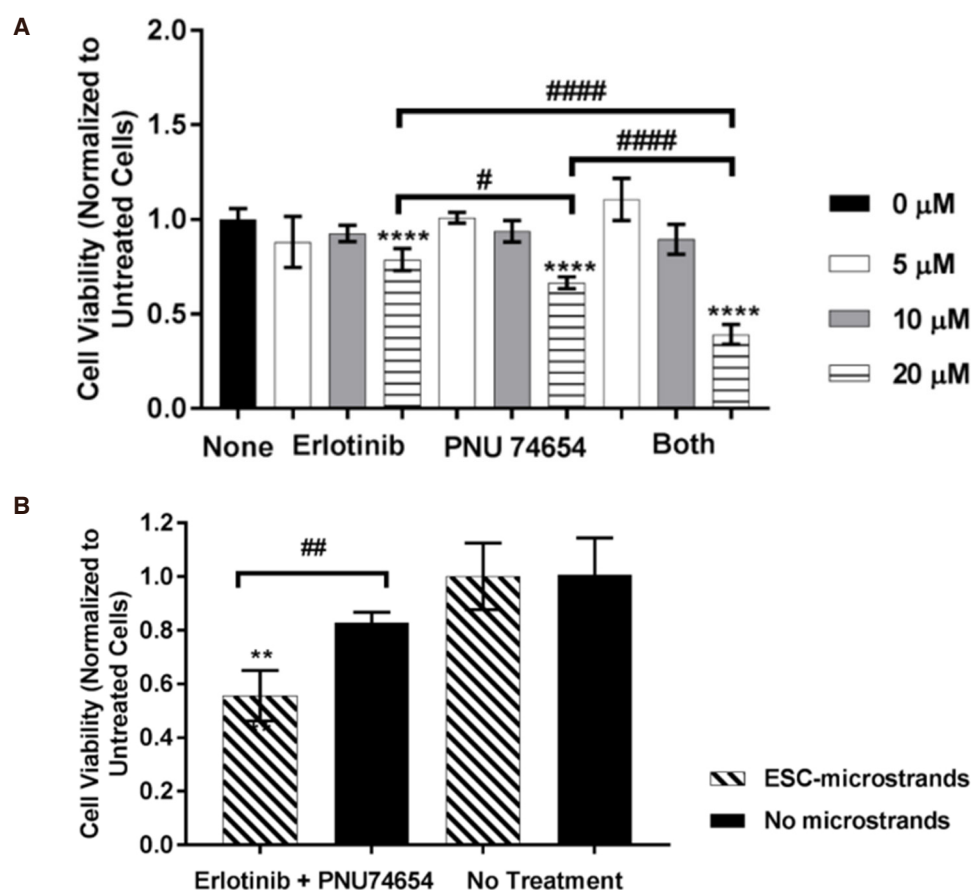

Figure 2. Exposure to embryonic stem cell (ESC)-microstrands overcomes chemotherapeutic drug resistance and reduces metastatic MDA-MB-231 cancer cell survival after drug treatment. A: MDA-MB-231 breast cancer cells (BCCs) were sensitive to the chemotherapeutic drugs Erlotinib and PNU 74654 when treated with 20 $\mu\text{mol/L}$ for 30 min, followed by a 24-h recovery period. Simultaneous treatment with Erlotinib and PNU 74654 resulted in the largest decrease in cell viability suggesting that both pathways play a role in the metastatic phenotype; B: after being co-cultured with ESC-microstrands, MDA-MB-231 BCCs exhibited significant reduction in cell viability after three cycles of treatment and recovery with both drugs at 20 $\mu\text{mol/L}$ compared to non-co-cultured BCC control. *Statistical significance compared to untreated control (* $P < 0.05$, **/ $P < 0.01$, and ****/#### $P < 0.0001$)

effect of ESC-microstrands on chemotherapeutic drug resistance, cells were treated three times with both chemotherapeutic drugs at a dose of 20 $\mu\text{mol/L}$, and viability was compared to the non-co-cultured BCCs. Three 24-h treatment and 24-h recovery cycles were performed to simulate the drug resistant state caused by multiple chemotherapeutic treatments *in vivo*. At the end of the treatments, the co-cultured BCCs were more sensitive to the chemotherapeutic drugs compared to the non-co-cultured BCCs [Figure 2B].

Co-culture with ESC-microstrands reverses oncogenic gene expression of MDA-MB-231 BCCs

To understand the inhibitory effect of exposure to ESC-microstrands on metastatic BCCs, relative mRNA expression levels of EGFR and canonical Wnt/ β -catenin signaling pathway-related molecules of MDA-MB-231 BCCs following co-culture with ESC-microstrands were examined using qRT-PCR. We have previously shown that co-culture with ESC-microstrands increases NKD2 and decreases TGF- α mRNA expression after 48 h^[10]. NKD2 is a negative regulator of the canonical Wnt/ β -catenin signaling pathway and TGF- α is a ligand that activates the EGFR signaling pathway. Similar changes in NKD2 and TGF- α gene expression following co-culture with ESC-microstrands were also observed after 72 h [Figure 3A].

The differences between BCCs co-cultured with ESC-microstrands and both the empty microstrand and non-co-cultured controls were statistically significant. For both 48 h (data not shown) and 72 h, there was a

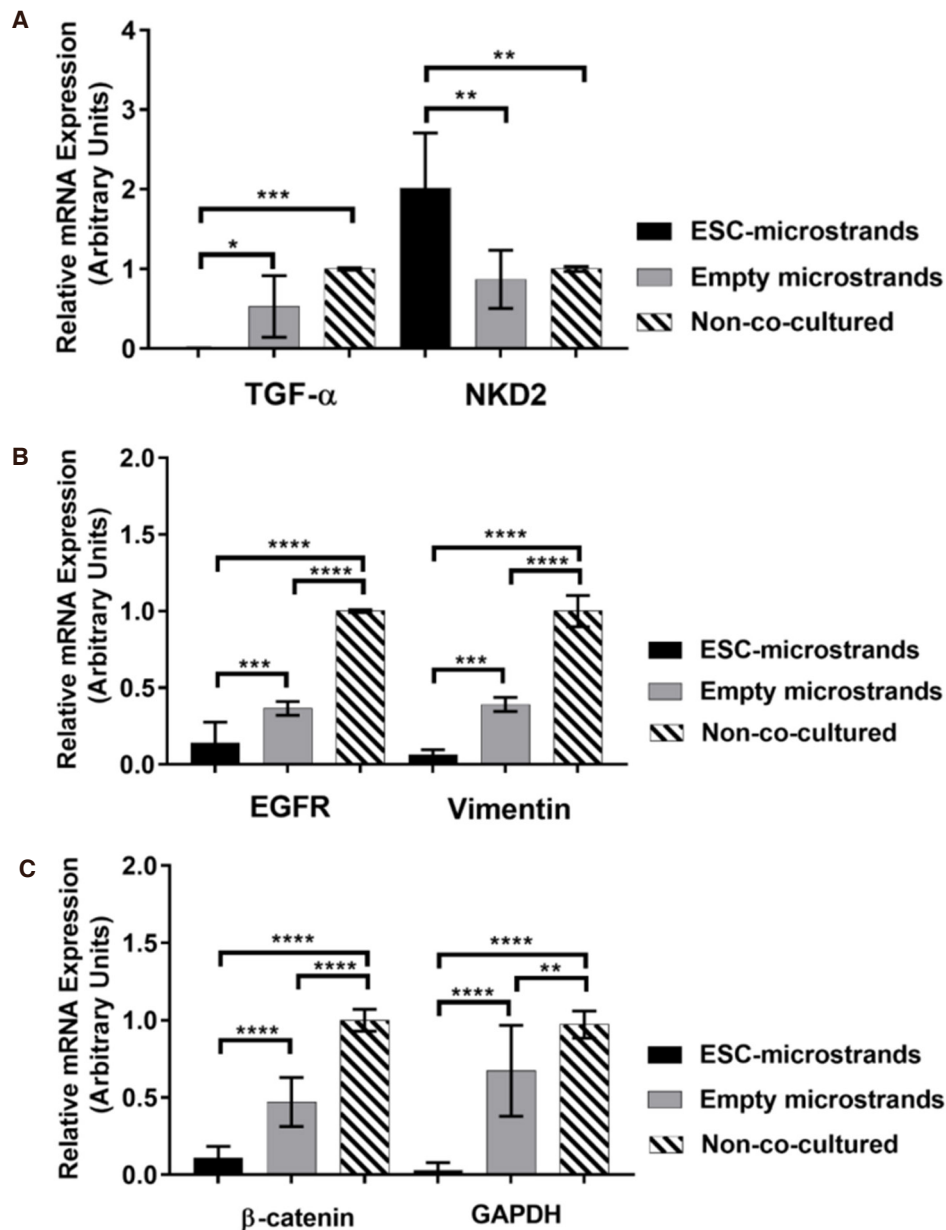

Figure 3. Reversal of gene expression of metastatic MDA-MB-231 breast cancer cells (BCCs) after exposure to embryonic stem cell (ESC)-microstrands at the transcriptional level as revealed by qRT-PCR analysis. A: After 72 h, significantly decreased TGF- α and increased NKD2 gene expression in BCCs co-cultured with ESC-microstrands compared to both empty microstrand and non-co-cultured controls; B: after 72 h, EGFR and vimentin gene expression decreased significantly compared to both controls; C: after 48 h, β -catenin and GAPDH gene expression declined in BCCs co-cultured with ESC-microstrands compared to the both controls (**** $P < 0.0001$; *** $P < 0.001$; ** $P < 0.01$; * $P < 0.05$)

decline in both EGFR and vimentin mRNA levels in the BCCs co-cultured with ESC-microstrands [Figure 3B]. There was also a decline in expression in the empty microstrand group for both EGFR and vimentin, but it is not as extreme as for the ESC-microstrand group. Finally, both β -catenin and GAPDH mRNA levels decreased in the BCCs after co-culture with ESC-microstrands for 48 h [Figure 3C]. This decrease persisted for β -catenin, but not for GAPDH, after 72 h (data not shown).

ESC-microstrands reverse EGFR and β -catenin protein expression in metastatic BCCs

We further examined expression of EGFR, β -catenin, NKD2, and TGF- α in metastatic MDA-MB-231 BCCs at protein level after 48 h of co-culture with ESC-microstrands, in comparison with non-invasive

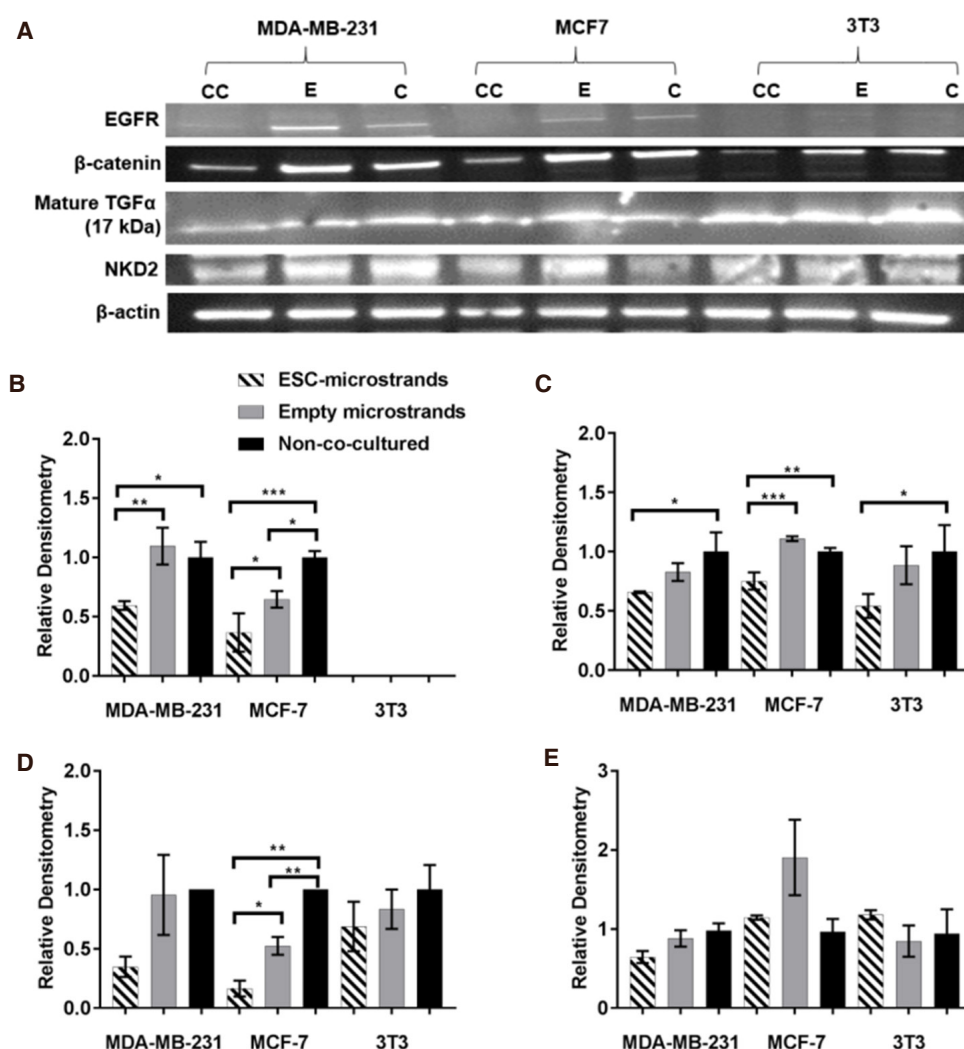

Figure 4. Protein expression of key signaling pathway molecules in metastatic MDA-MB-231 breast cancer cells (BCCs) after co-culture with embryonic stem cell (ESC)-microstrands for 48 h in comparison to non-aggressive MCF7 BCCs and 3T3 fibroblasts. Western blots show reduced EGFR, β -catenin, and mature TGF- α protein expression in the co-cultured MDA-MB-231 BCCs (CC: co-cultured with ESC-microstrands; E: co-cultured with empty microstrands; C: non-co-cultured control) (A); densitometry of protein expression of EGFR (B); β -catenin (C); mature TGF- α (D); NKD2 (E) (*** P < 0.001; ** P < 0.01; and * P < 0.05)

MCF7 BCCs and 3T3 fibroblasts [Figure 4A]. Western blot analysis of MDA-MB-231 BCCs after 48 h of co-culture with ESC-microstrands revealed a decline in EGFR protein expression compared to both empty microstrands and non-co-cultured controls [Figure 4B]. A similar trend was observed in the MCF7 BCCs, however, the reduction following co-culture with ESC-microstrands was also significantly different than the non-co-cultured control. The 3T3 fibroblasts did not express EGFR. There was also a reduction in β -catenin expression following co-culture with ESC-microstrands for all three cell types that was statistically different than the non-co-cultured control [Figure 4C]. However, only the MCF7 BCCs showed statistical significance when comparing the ESC-microstrands to the empty microstrands. TGF- α expression was decreased for both BCC types following co-culture with ESC-microstrands, but only the MCF7 BCCs showed statistical significance when compared to both controls [Figure 4D]. Finally, after 48 h, NKD2 protein expression did not significantly change following co-culture with ESC-microstrands or empty microstrands for any cell type [Figure 4E].

ESC-microstrands restore EGFR and canonical Wnt/ β -catenin signaling pathway function

Since co-culture with ESC-microstrands decreased EGFR and β -catenin expression in MCF7 and MDA-MB-231 BCCs following 48 h of co-culture, ESC-microstrands and media were removed and replaced with

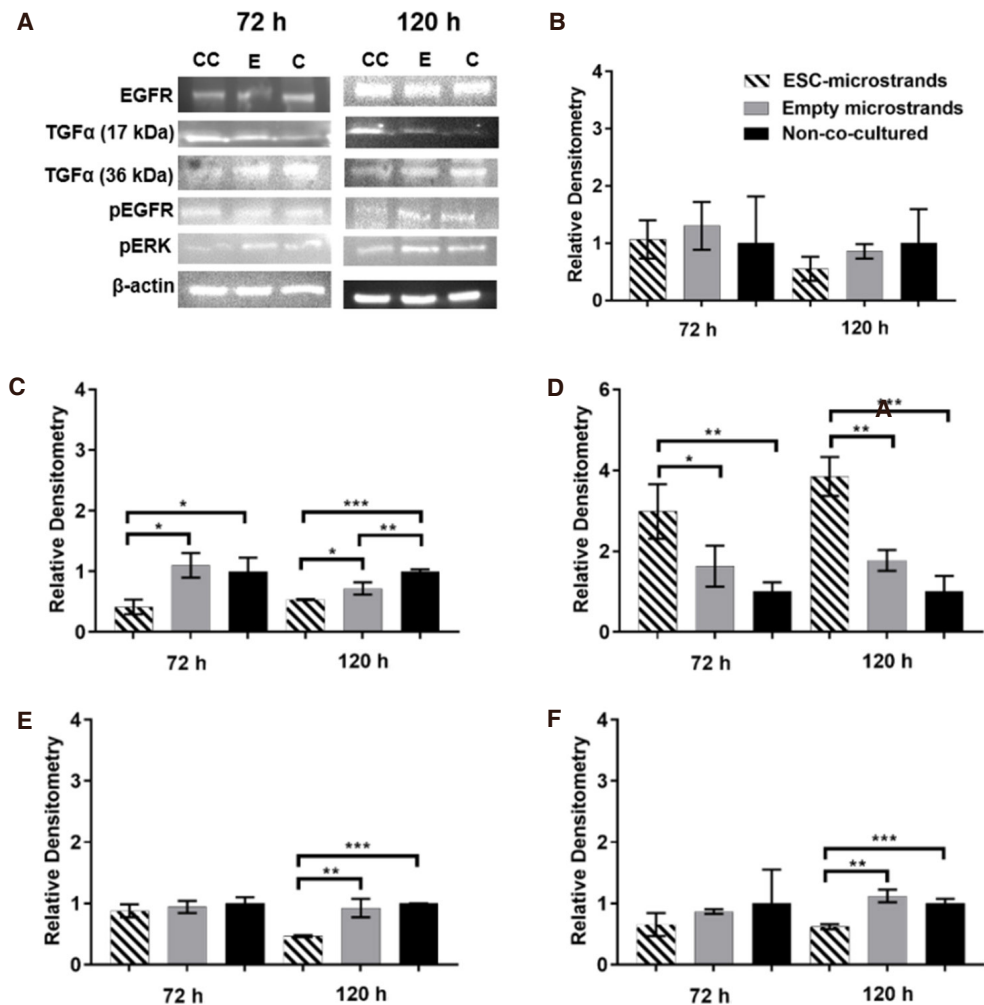

Figure 5. Western blot analysis of long-term protein expression of key EGFR signaling pathway molecules. Metastatic MDA-MB-231 breast cancer cells (BCCs) were co-cultured with embryonic stem cell (ESC)-microstrands for 48 h, followed by removing ESC-microstrands, replacing BCC media, and analyzing protein expression at 72 h and 120 h. Western blots for protein expression in metastatic MDA-MB-231 BCCs (CC: co-cultured with ESC-microstrands; E: co-cultured with empty microstrands; C: non-co-cultured control) (A); densitometry of expression of EGFR (B), precursor TGF- α (C), mature TGF- α (D), pEGFR (E), and pERK (F) (*** $P < 0.001$; ** $P < 0.01$; * $P < 0.05$)

BCC media to see if there are other long-term signaling pathway-related changes in protein expression in MDA-MB-231 BCCs. The BCCs recovered for either one day or three days, which are denoted as 72 h and 120 h, respectively. Figure 5A shows the immunoblots for proteins associated with the EGFR signaling pathway. Contrasting to results for 48 h of co-culture, after 72 h, there was no change in EGFR expression in the MDA-MB-231 BCCs following co-culture with ESC-microstrands [Figure 5B]. Precursor TGF- α levels declined by 72 h [Figure 5C]. There was a statistically significant increase in mature TGF- α expression at the 72-h mark [Figure 5D], which was enhanced by 120 h. There was a decrease after 72 h in pEGFR expression [Figure 5E]. Finally, there was reduced pERK by 72-h and 120-h marks [Figure 5F].

Immunoblots for molecules related to the canonical Wnt/ β -catenin signaling pathway are provided in Figure 6A. Precursor E-cadherin was not present in any of the samples until 120 h, and for that reason, there is no band in the blot for the 72-h point. β -catenin expression was unchanged following co-culture with ESC-microstrands after 72 h, however, it was significantly reduced by 120 h compared to both controls [Figure 6B]. At 72 h and 120 h, there was an upsurge in NKD2 expression following co-culture with ESC-microstrands that was significant compared to both controls [Figure 6C]. By 120 h, there was precursor

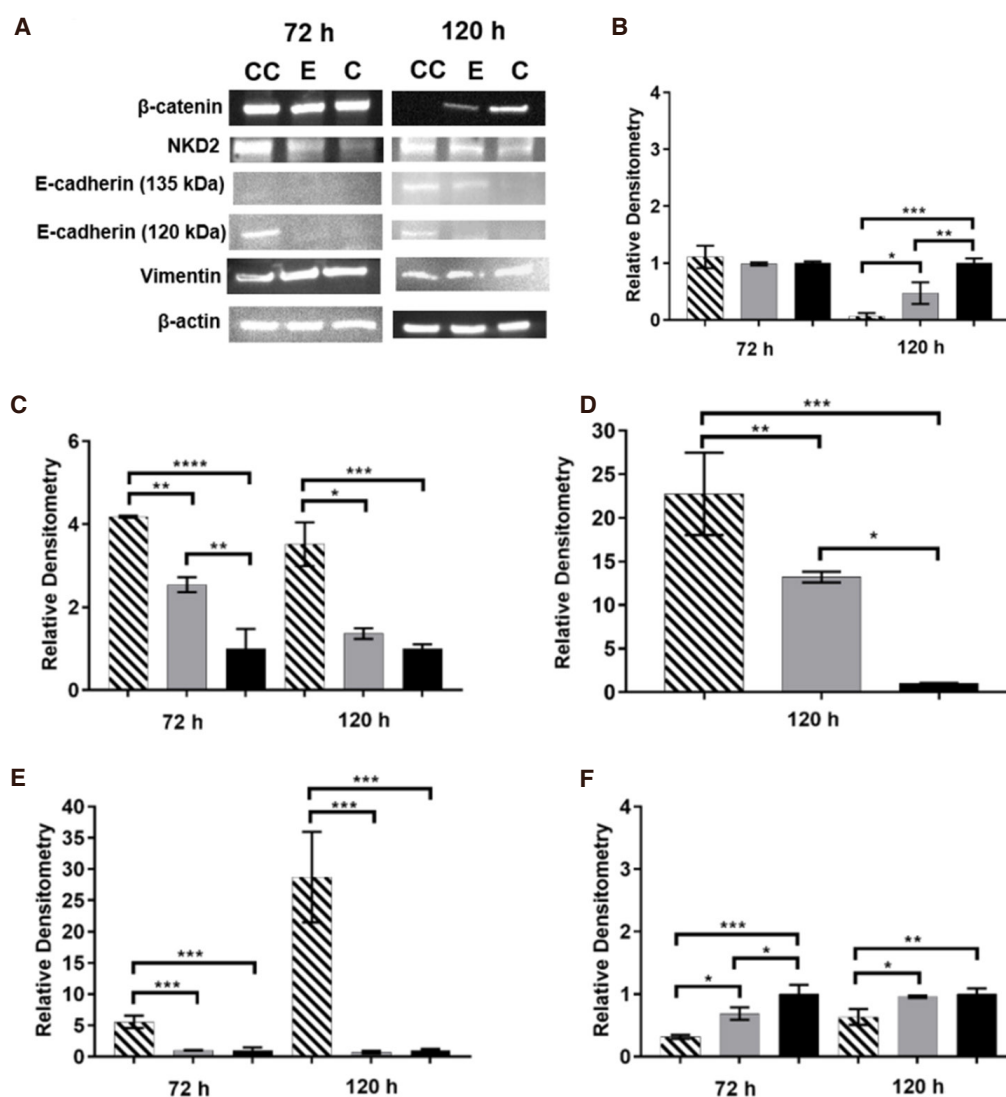

Figure 6. Western blot analysis of long-term protein expression of key canonical Wnt/β-catenin signaling pathway molecules. Metastatic MDA-MB-231 breast cancer cells (BCCs) were co-cultured with embryonic stem cell (ESC)-microstrands for 48 h, followed by removing ESC-microstrands, replacing BCC media, and analyzing protein expression at 72 h and 120 h. Western blots for protein expression in metastatic MDA-MB-231 BCCs (CC: co-cultured with ESC-microstrands; E: co-cultured with empty microstrands; C: non-co-cultured control) (A); densitometry of expression of β-catenin (B), NKD2 (C), precursor E-cadherin (D), mature E-cadherin (E), and vimentin (F) (** $P < 0.001$; * $P < 0.01$; $P < 0.05$)

E-cadherin present in the BCCs co-cultured with ESC-microstrands, and it was extremely elevated [Figure 6D]. Mature E-cadherin was expressed in the BCCs co-cultured with ESC-microstrands, but not in the non-co-cultured controls at 72 h. and 120 h [Figure 6E]. There was some expression in the empty microstrand control at 72 h, however, it was much less. Our previous work demonstrated that co-culture with ESC-microstrands decreases vimentin protein expression after 48 h^[10]. At 72 h and 120 h, vimentin protein expression was diminished in MDA-MB-231 BCCs co-cultured with ESC-microstrands [Figure 6F].

DISCUSSION

This work has demonstrated the utility of a bioengineered 3D ESC microenvironment (so-called ESC-microstrands) for the study of cross-talk of signaling pathways in cancer cells. It reveals that inhibitory effects of the ESC microenvironment on triple negative, metastatic MDA-MB-231 BCCs is attributable to restoration of EGFR and canonical Wnt/β-catenin signaling pathway regulation. Simultaneous treatment of

Figure 7. Schematic representation of the effects of co-culture with embryonic stem cell (ESC)-microstrands on expression of key signaling pathway molecules in MDA-MB-231 breast cancer cells (BCCs). Left Panel: BCC alone; Right Panel: co-cultured breast cancer cells with ESC-microstrands. Changes in protein and mRNA expression after co-culture with ESC-microstrands indicated inhibition of the canonical Wnt/ β -catenin (above the dash line) and EGFR (below the dash line) signaling pathways. Co-culture with ESC-microstrands causes NKD2 up-regulation at both the mRNA and protein levels, and this coincides with dual signaling pathway inhibition. It suggested restored ability of NKD2 to inhibit the canonical Wnt/ β -catenin signaling pathway and reduced ability to promote the EGFR signaling pathway following co-culture

metastatic BCCs with EGFR and canonical Wnt/ β -catenin signaling inhibitors suppresses growth more than individual treatment, suggesting that both pathways play a role in the restriction of metastatic phenotype.

The microenvironments of ESCs play a fundamental role in providing cells with appropriate signaling to induce cell proliferation, differentiation, or death. ESCs secrete soluble factors or exosomes that could reprogram malignant cancer cells to benign phenotype and suppress tumorigenesis^[35-39]. To recapitulate the native stem cell niche, researchers have exploited several bioengineering methods. Researchers have demonstrated that human ESC pluripotency is maintained when the ESCs are cultured in a 3D hyaluronic acid^[40], alginate^[41,42], or chitosan scaffold^[43]. Specifically, our lab has reported that mouse ESCs encapsulated inside aqueous alginate hydrogel microspheres remain pluripotent and restrict rat breast cancer cell proliferation and migration^[8]. Our previous work has also established that ESCs encapsulated in alginate microstrands exhibited biological effects on cell behavior of BCCs after co-culture with these ESC-microstrands, restricting highly aggressive human breast cancer proliferation, survival, invasion, migration, EMT, and metabolic activity^[10] as summarized in Table 1. This study aims to further probe whether this restriction is due to restored signaling pathway function, specifically related to the canonical Wnt/ β -catenin and EGFR signaling pathways, which are hyperactivated in human breast cancer.

Deregulation of canonical Wnt/ β -catenin and EGFR signaling is implicated in various forms of tumorigenesis causing colorectal, lung, breast, ovarian, prostate, liver, and brain cancers^[12,44]. For the canonical Wnt/ β -catenin signaling pathway, cancer also arises from overexpression of Wnt ligand genes, DNA hypermethylation of negative regulators such as p16 and E-cadherin, and overexpression of R-spondins that enhance Wnt ligand function^[23,44]. In BCC lines and primary tumors, Wnt ligands and Fzd receptors are expressed, and β -catenin is often localized within the nucleus^[44]. Inhibiting EGFR in cancer cells either directly or with cDNA transfections *in vitro* and *in vivo* causes a decrease in proliferation^[45]. Signaling pathways downstream of the EGFR are deregulated through EGFR mutations, constitutive activation, autocrine/paracrine signaling loops, enhanced ligand production, up- or down-regulation of signaling mediators, and prolonged interactions of EGFR with ErbB2 that either increase EGFR expression, activate EGFR, or prevent its deactivation^[14,46]. Activation of Rho GTPases downstream of EGFR signaling reduces E-cadherin expression and actin reorganization^[45]. Certain tumors contain mutations that delete the extracellular binding domain of the EGFR, which constitutively activates the receptor. In glioblastoma, there is frequently an in-frame deletion of exon 2-7 of the EGFR. Ligand-independent activation of the EGFR is caused by overexpression of urokinase-type plasminogen activator receptor and its association with the integrin $\alpha 5 \beta 1$ ^[11,29,47]. Prolonged interaction of ErbB2 with EGFR fosters breast CSC self-renewal through activation of the PI3K/Akt signaling cascade. Increased cellular stress and radiation have been shown to down-regulate phosphatases responsible for the EGFR signal abrogation^[48]. Downstream of the EGFR signaling pathway, the PI3K/Akt/mTOR pathway activates protein kinase B through loss of PTEN, a tumor suppressor and negative regulator of PI3K/Akt signaling. The result is stabilization of β -catenin through phosphorylation and inactivation of GSK3. As demonstrated by the previous examples, deregulated canonical Wnt/ β -catenin and EGFR signaling play an enormous role in many types of aggressive cancer, which highlights the importance of understanding their contribution to aggressive breast cancer progression. As such, our first aim was to examine whether exposure of aggressive MDA-MB-231 BCCs to ESC-microstrands increases sensitivity to chemotherapeutic drugs known to specifically target these two pathways.

Highly aggressive MDA-MB-231 BCCs were treated with the chemotherapeutic drugs Erlotinib and PNU74654. Erlotinib specifically targets the EGFR signaling pathway by binding to the ATP-binding site of the EGFR and preventing phosphorylation by its tyrosine kinase. PNU 74654 targets the canonical Wnt/ β -catenin signaling pathway by preventing the interaction of β -catenin with the transcription factor T-cell factor/lymphoid enhancer factor. The canonical Wnt/ β -catenin signaling pathway may play a larger role in MDA-MB-231 BCC aggressiveness as these cells were more sensitive to PNU74654. However, both signaling pathways are involved in the aggressive phenotype because combining both drugs significantly increases sensitivity. Co-culturing the MDA-MB-231 BCCs with ESC-microstrands prior to dual chemotherapeutic drug treatment coupled with the addition of multiple treatment and recovery periods, demonstrated that co-culture with ESC-microstrands increases BCC sensitivity to chemotherapeutic drugs.

Co-culture with ESC-microstrands reduced GAPDH mRNA expression. GAPDH is an enzyme responsible for catalyzing the sixth step of glycolysis. The original intention was to employ GAPDH as a housekeeping gene for this study, though recent works have confirmed GAPDH up-regulation in human breast cancer. A subsequent study by Maltseva *et al.*^[49] identified five reliable housekeeping genes in human breast cancer and β -actin, which was used in this study, was one of the top choices. In our model, GAPDH mRNA expression was decreased in the co-cultured MDA-MB-231 cells, which may explain their decreased glycolytic rate^[10]. The PI3K/Akt pathway lies downstream of the EGFR signaling pathway. GAPDH stabilizes activated Akt allowing oncogenic cells to circumvent caspase-independent cell death. Interestingly, Akt kinase is one of the main contributors to the Warburg effect and Akt also prevents the nuclear accumulation of GAPDH necessary for caspase-dependent cell death^[50].

In this work, inhibition of the EGFR signaling pathway following co-culture is demonstrated through reduced EGFR and TGF- α mRNA expression, increased mature TGF- α protein expression, and decreased

precursor TGF- α , pEGFR, and pERK protein expression. The reduction in EGFR protein levels in the co-culture after 48 h. is not sustained in the long-term experiment suggesting that EGFR signaling pathway inhibition in the co-culture is not entirely attributable to modulation of EGFR availability. Both soluble (6 kDa) and precursor (36 kDa) TGF- α protein levels are elevated in triple negative human breast cancer because cleavage of the precursor form is prevented and cleavage of the mature form is augmented^[51]. Possible explanations for the decrease in precursor TGF- α expression include (1) prevention of NKD2 from either interacting with precursor TGF- α and/or transporting it to the plasma membrane triggering its degradation; (2) increased cleavage of precursor TGF- α into mature TGF- α within the plasma membrane; and (3) decreased precursor TGF- α production caused by reduced TGF- α mRNA expression. The increase in NKD2 expression coinciding with decreased precursor TGF- α expression suggests that precursor TGF- α is being prevented from interacting with NKD2 and this is triggering its degradation. This would imply that decreased cleavage of mature TGF- α into its soluble form is the major contributor to the augmented mature TGF- α expression, as opposed to increased cleavage of precursor TGF- α . The EGFR signaling pathway utilizes phosphorylation cascades to activate downstream molecules that affect cell behavior. Suppression of pEGFR and pERK protein expression after 120 h indicates that EGFR signaling pathway activation is being suppressed in the co-cultured BCCs. Taken together, the changes in relative mRNA and protein expression in the co-cultured BCCs are extremely promising as they suggest that co-culture is altering the BCCs at both transcriptional and translational levels, indicating that this model can be applied to study the mechanism(s) for signaling pathway inhibition and highly aggressive BCC restriction.

The canonical Wnt/ β -catenin signaling pathway is hyperactivated in human breast cancer, and this leads to increased β -catenin expression. In this work, exposing MDA-MB-231 BCCs to ESC-microstrands decreases β -catenin mRNA and protein expression. The decline in β -catenin protein levels in western blot analysis signifies its increased ubiquitylation and degradation leading to decreased canonical Wnt/ β -catenin signaling pathway activation. Three other major signs of canonical Wnt/ β -catenin inhibition in BCCs co-cultured with ESC-microstrands are increased E-cadherin protein levels, augmented NKD2 mRNA and protein expression, and decreased vimentin mRNA and protein levels. E-cadherin is synthesized as a 135 kDa precursor that undergoes cleavage to its mature 120 kDa form^[52]. β -catenin is responsible for anchoring mature E-cadherin to the plasma membrane, and this interaction may contribute to the comparable β -catenin protein levels in the co-culture and controls after 72 h coinciding with the extreme up-regulation of mature E-cadherin in the co-cultured BCCs. Co-culture may directly prevent cytoplasmic β -catenin from translocating to the nucleus. The belief that β -catenin translocation to the nucleus involves more than its cytoplasmic concentration has gained steam, for example, Fang *et al.*^[53] assert that Akt, which is downstream of EGFR signaling pathway, promotes β -catenin nuclear translocation through phosphorylation. One possibility is that co-culture leads to decreased activated Akt, which is allowing β -catenin that has accumulated in the cytoplasm to be used for cell-cell adhesion. After 48 h, there are no detectable levels of mature or precursor E-cadherin in the MDA-MB-231 BCCs but there is mature E-cadherin expression in the MCF7 BCCs (data not shown). Interestingly, after restoring the BCC media to demonstrate the long-term effect of co-culture, there is mature and precursor E-cadherin present at the 72- and 120-h marks, respectively. NKD2 is a tumor suppressor that has a very short half-life of approximately sixty minutes and is hypermethylated in human breast cancer^[33]. The increase in NKD2 mRNA expression in the co-culture denotes a reversal of its methylation status and its increased protein expression suggests an active role in dvl-1 inhibition. Finally, the decreases in vimentin protein and mRNA expression levels in co-cultured BCCs are another sign of inhibition of this pathway because vimentin is transactivated by this pathway.

Our results showed that ESC-microstrands induced changes in gene expression of key regulators at both the mRNA and protein level in MDA-MB-231 BCCs that signified a reversal of the hyperactivated status of EGFR and canonical Wnt/ β -catenin signaling pathways and restored signaling pathway regulation present in normal non-tumorigenic cells. Specifically, decreased EGFR, pEGFR, pERK, and precursor TGF- α

coupled with augmented mature TGF- α expression indicated that the EGFR signaling pathway was being suppressed, whilst decreased vimentin and β -catenin expression coinciding with increased precursor and mature E-cadherin levels supported the notion of canonical Wnt/ β -catenin signaling pathway suppression. Importantly, these changes corresponded with an extreme up-regulation of NKD2 at both the mRNA and protein levels [Figure 7]. A possible explanation for this phenomenon is that co-culture with ESC-microstrands restores NKD2 expression in metastatic MDA-MB-231 BCCs, which enables it to inhibit the canonical Wnt/ β catenin signaling pathway, but that NKD2 is also prevented from transporting precursor TGF- α to the membrane for activation of the EGFR signaling pathway.

Altogether, we have demonstrated that exposure of triple negative BCCs to a bioengineered 3D ESC microenvironment restricts their tumorigenic, invasive, and metastatic features owing to restoration of EGFR and canonical Wnt/ β -catenin signaling pathway regulation. In particular, NKD2 could act as a “molecular switch” between these pathways in BCCs. Co-culture with ESC-microstrands has up-regulated NKD2 in triple negative, metastatic BCCs both at mRNA and protein levels. The exact role of NKD2 in this metastatic phenotype reversal will be the focus of subsequent studies. Exposure of MDA-MB-231 BCCs to ESC-microstrands may prevent NKD2 myristoylation allowing it to solely interact with Dvl-1 and thwarting precursor TGF- α transport to the plasma membrane causing its increased degradation. Future work will elucidate the mechanism leading to NKD2 preference for either EGFR or canonical Wnt/ β -catenin signaling pathway interaction allowing for the targeting of NKD2 to treat triple negative breast cancer. This work is important because it establishes that the bioengineered 3D ESC model can not only restrict triple negative breast cancer survival and metastatic potential, but can also be applied to determine the mechanism for this restriction and identify therapeutic targets to reverse metastatic disease. This is the first example of exploring the role of NKD2 in aggressive breast cancer as all other studies in literature were performed in colon cancer. In the future, we may test whether using ESC-microstrand-conditioned media could achieve the same level of restriction of cancer metastasis. Additionally, the use of a panel of triple negative metastasis breast cancer cells (e.g., MDA-MB-157, MDA-MB-468) will further validate our findings and confirm the utility of the 3D ESC model system for understanding cancer metastasis.

DECLARATIONS

Abstract

Aim: Metastasis to the brain has become a major limitation to the life expectancy and quality of life for many patients with breast cancer. Unfortunately, other than radiation and palliative treatments with trastuzumab, and pertuzumab, no effective therapy for brain metastases is currently available. This study seeks to identify novel gene targets and pharmaceutical Intervention against breast cancer brain metastasis.

Methods: The detailed methods applied to this study, including comparative RNA sequencing and bioinformatics analysis of sequence data, ingenuity pathway analysis, protein-protein interaction analysis, high throughput screening of clinical and pre-clinical drugs, cell viability and proliferation assay, toxicity and apoptosis assay using fluorescence-activated cell sorting, real-time PCR, western blotting, statistical analysis of data.

Results: The study reveals critical roles for SRC, ERBB2, PIK3CA, and GABA in the proliferation and survival of breast cancer brain metastatic (BBM) cells and showed that SRC- and ERBB2-mediated activation of PIK3-AKT/mTOR signaling regulates BBM cell survival. Selective inhibition of these candidate genes alone or in combination induces robust apoptosis in BBM cells

Conclusion: The findings of this study provide a rationale for further preclinical evaluation of SRC-targeting regimens in combination with ERBB2 inhibitors and/or GABA agonists to target breast cancer brain metastasis.

Keywords: Breast cancer, brain metastasis, human epidermal growth factor receptor 2, ERBB2, SRC, astrocytes, PI3KCA

INTRODUCTION

Brain metastases represent a significant clinical challenge for the treatment of patients with human epidermal growth factor receptor 2 (HER2)-positive breast cancer. Although modern multimodality therapies have improved the survival of patients with primary breast cancer and systemic metastases, the overall median survival of patients with brain metastases is dismally less than one year^[1,2]. Furthermore, as the brain represents a “sanctuary site” for HER2+ metastases, and has comprised a larger proportion of relapse sites over time^[3,4]. Despite this increasing incidence, there is no current consensus on therapy for those with intracranial progression^[5,6]. Current clinical options for HER2+ brain metastases patients are limited to trastuzumab (anti-HER2 monoclonal antibody) treatment in conjunction with whole-brain radiotherapy or stereotactic radiosurgery^[7], neither of which clinically effective in treating life-threatening brain metastases that often lead to severe cognitive complications.

The poor prognosis of breast cancer brain metastatic (BBM) patients with local therapies underscores the need for better systemic treatments. Over the last few years, preclinical and clinical progress in the treatment of BBM has led to novel hypotheses for improving therapeutic outcome. The limited efficacy of trastuzumab against BM is often attributed to an inadequate penetration through the BBB^[8]. Lapatinib, a small molecule kinase inhibitor of epidermal growth factor receptor (EGFR) and HER2, was evaluated in BCBM due to its ability to better penetrate the BBB than trastuzumab^[9,10]. The success of lapatinib and capecitabine in preventing brain metastasis led to its inclusion in patients with established brain metastases. New generation ErbB family inhibitors neratinib and afatinib are more potent and specific than lapatinib, showed significant responses in limited cases of BBM^[11]. The downstream HER2 signaling inhibitors including the PI3K inhibitor BKM120 and the mTOR inhibitor everolimus were evaluated to overcome de novo or acquired resistance to anti-HER2 therapy. Indeed, targeting the HER2 family member HER3, critical for HER2 downstream signaling, enhances the efficacy of HER2-targeted therapies in preclinical models of BBM^[12,13].

Recent clinical findings described the efficacy of antibody-based therapy in BBM. Upon treatment Bevacizumab and trastuzumab-DM1 adequately accumulate in brain metastatic lesions to exert positive effect^[14-17]. Antibody-chemotherapy conjugate such as ado-trastuzumab emtansine (T-DM1) was approved for the treatment of HER2-positive breast cancer due to its higher efficacy over lapatinib and capecitabine in patients with disease progression after trastuzumab^[18]. As T-DM1 targets acquired or microenvironment-mediated activation of Her2 independent signaling pathways, this agent would be expected to be effective in such patients.

Using RNA sequencing (RNA-seq) analysis of primary HER2+ breast cancer and HER2+ breast to brain metastatic tumor resections, along with normal breast and normal brain tissues, we demonstrated that SRC- and ERBB2-mediated regulation of PI3K-AKT/mTOR signaling plays a critical role in BBM cell proliferation^[19]. Inhibition of SRC, ERBB2, and downstream kinases induced robust apoptotic cell death. In parallel experiments, we conducted a high throughput screening of 1650 clinical and preclinical drug candidates and found that activation of GABA signaling using a GABA agonist induces apoptosis in the breast to brain metastatic cells.

Interestingly, it has been shown that the SRC family of non-receptor tyrosine kinases is critical for both HER2+ and triple-negative breast cancer^[20]. SRC activation maximizes the HER2: HER3 interaction and serves as a convergent point of multiple downstream signals, including the PI3K-AKT/mTOR pathway, thus regulating cell viability^[20,21]. Similarly, activation of GABA signaling negatively regulates not only neural stem cells but also embryonic and cancer stem cells^[22-24]. GABAergic breast to brain metastatic cells rely on GABA as an energy source, and activation of GABA signaling prevents cell proliferation directly or by blocking the supply of GABA to the invading cells. This collective evidence suggests that inhibiting HER2 and simultaneous targeting SRC and/or GABA is a promising strategy for the treatment of breast cancer brain metastasis.

METHODS

Patient consent and tissue processing

De-identified archival and fresh tumor tissue samples were collected from consented patients undergoing resection of primary breast or breast to brain metastases, in accordance with a City of Hope Institutional Review Board (IRB)-approved protocol (#05091).

RNA isolation and sequencing

The flash frozen patient tissue samples were subjected to total RNA preparation using an RNeasy Mini Kit (Qiagen), according to the manufacturer's instructions, eluted in 50 μ L of RNase/DNase-free water, and the initial concentration and purity assessed on a NanoDrop ND-1000 spectrophotometer (NanoDrop Technologies, Wilmington, DE). Prior to sequencing, RNA quality was assessed by microfluidic capillary electrophoresis using an Agilent 2100 Bioanalyzer and the RNA 6000 Nano Chip kit (Agilent Technologies, Santa Clara, CA). Sequencing libraries were prepared with the TruSeq RNA Sample Prep Kit V2 (Illumina, San Diego, CA), according to the manufacturer's protocol with minor modifications. Briefly, ribosomal RNA was removed from 500 ng of total RNA using a RiboZero kit (Illumina) and the resulting RNA was ethanol precipitated. Pellets were re-suspended in 17 μ L of Elute/Prime/Fragment Mix (Illumina) and first-strand cDNA synthesis performed using DNA polymerase I and RNase H. cDNA was end repaired, 3' end adenylated, and universal adapter ligated followed by 10 cycles of PCR using Illumina PCR Primer Cocktail and Phusion DNA polymerase (Illumina). Libraries were purified with Agencourt AMPure XP beads, validated with the Agilent 2100 Bioanalyzer, and quantified with Qubit (Life Technologies). Libraries were sequenced on an Illumina HiSeq 2500 with single-end 40-bp reads. Raw sequences were aligned to the human genome assembly (version 19, GRCh37.p13) using Tophat v2 and RefSeq gene expression levels were counted using HTseq-count. The genes expression counts were normalized using the trimmed mean of M-values method implemented in the Bioconductor package "edgeR." The differential expression analysis, clustering analysis, and pathway analysis were conducted using the DAVID online annotation tool and Ingenuity Pathway Analysis (IPA) to determine tissue-specific gene signatures and signaling pathways. The gene expression data of candidate genes was confirmed by real-time PCR.

Breast cancer brain metastasis cell cultures

HER2+ tumor samples were acquired from patients undergoing resection of the breast to brain metastases in accordance with a City of Hope IRB-approved protocol (IRB #05091). A portion of each specimen was cultured in DMEM-F12 (Life Technologies) supplemented with 10% fetal bovine serum, 1% glutamax, and 1% antibiotic-antimycotic (Life Technologies) in collagen-coated T75 flasks (Life Technologies) to derive low-passage primary cell lines COH-BBM1 (BBM1) and COH-BBM2 (BBM2).

High throughput screening of therapeutic candidates

The Lopac 1280 compound library (Sigma), DiscoveryProbe Neuronal Signaling Library (ApexBio), and clinical drugs targeting primary breast cancer and CNS tumors (Cayman Chemical) were obtained commercially. All the compounds of the two libraries are in preclinical or clinical candidates. Over 50% compounds of the library target neural disorders. The compounds were dissolved in DMSO at concentrations of 100 μ mol/L. For the initial screening, BBM1 cells were grown in 96-well plates (10000/well) and treated with the compounds at a final concentration of 1 μ mol/L ($n = 3$ per treatment). Control cells were treated with DMSO only. The viability of the cells was measured at 48 and 72 h post-treatment by using a CellTiter-Glo[®] Luminescent Cell Viability Assay kit (Promega). The compounds that suppressed BBM1 cell viability by at least 70% compared to the control were selected for secondary screening in both BBM1 and BBM2 cell lines. The compounds that showed consistent toxicity of both BBM1 and BBM2 cells over a period of 10 days were assessed for toxicity against BBM1 cells but not astrocytes.

To analyze cell type-specific toxicity, human astrocytes and BBM1 cells were grown overnight prior to treatment with 1 μ mol/L of the active compounds ($n = 6$). Control cells were treated with DMSO only. The

viability of the cells was measured at 48 and 72 h post-treatment using the CellTiter-Glo® Luminescent Cell Viability Assay kit. Compounds that showed at least two-fold greater toxicity against BBM1 cells compared to astrocytes cells were further analyzed for their concentration-dependent effects on BBM1 cells. For concentration-dependent toxicity, cells were treated with 0, 31.2, 62.5, 125, 250, 500, 1000 nmol/L final concentration of the compounds ($n = 8$). The viability was measured at 72 h post-treatment. The data normalization compared to control and IC_{50} determination was done using GraphPad Prism 7.

Real-time PCR and Western blot analysis

Total RNA from astrocytes and BBM1 and BBM2 cells was extracted using Trizol (Invitrogen) and treated with RNase-free DNase (Qiagen), according to the manufacturer's instructions. To analyze gene expression, cDNA was synthesized using an iScript reverse transcription kit (Bio-Rad). Real-time PCR quantification was conducted using gene-specific primers and SYBR Select Master Mix (Applied Biosystems) using a CFX real-time PCR system (Applied Biosystems). Control PCR reactions were conducted using glyceraldehyde-3-phosphate dehydrogenase (GAPDH) and/or actin-specific primers. PCR data was analyzed using the CFX manager (Bio-Rad).

For Western blot analysis, total cell lysates were prepared in protein lysis buffer (50 mmol/L Tris-HCl, pH 7.5; 100 mmol/L NaCl; 1% Triton X-100; 1 mmol/L EDTA; 1 mmol/L EGTA, 50 mmol/L β -glycerophosphoran, 1 mmol/L dithiothreitol, 1 mmol/L phenylmethanesulfonyl fluoride; 2 mmol/L sodium orthovanadate, 10 μ g/mL aprotinin; 10 μ g/mL leupeptin; and 10 μ g/mL pepstatin A) by incubating cells for 20 min at 4 °C, followed by centrifugation ($15000 \times g$, 15 min, 4 °C). Protein extracts were analyzed by using antibodies specific to ERBB2; phosphorylated ERBB2 (pERBB2); Protein kinase B (AKT); phosphorylated AKT (pAKT) were obtained from Millipore; Phosphatidylinositol-4,5-Bisphosphate 3-Kinase Catalytic Subunit, Alpha (PIK3CA), phosphorylated PIK3CA (pPIK3CA); SRC Proto-Oncogene (SRC); phosphorylated SRC (pSRC); MYC Proto-Oncogene (MYC); Mammalian Target of Rapamycin (mTOR); phosphorylated mTOR (pmTOR); procaspase3 and cleaved caspase 3 were obtained from Cell Signaling. Actin and α -tubulin antibodies were also obtained from Cell Signaling.

Apoptosis analysis

Apoptosis induction in treated and control cells was measured using Annexin V-FITC staining followed by FACS analysis. In brief, cells were treated with the compounds 24 to 48 h prior to fixing in 4% PFA. Control cells were treated with vehicle alone. The cells were immunostained with Annexin V-FITC (Invitrogen) followed by PI (Life Technology) and analyzed using BD FACS Aria Flow Cytometer (BD Biosciences). The experimental control cells were stained with IgG with or without PI.

Statistical analysis

Verification of RNA-seq data was done with real-time PCR in at least three biological replicates to confirm reproducibility and repeated at least twice. Results are expressed as the means \pm SEM. Unless otherwise stated, the two groups comparisons analyses were performed by using Mann-Whitney U tests in GraphPad Prism® 7.0 (GraphPad Software Inc., La Jolla, CA, USA). $P < 0.05$ was considered to be statistically significant.

RESULTS

Breast cancer brain metastases display a unique brain-like transcription profile

Primary HER2(ERBB2)+ breast cancer tissue (PT) and HER2+ breast to brain metastatic tissue (MT) collected from the consented patients, along with normal breast (nBreast) and normal brain (nBrain) tissues, were subjected to RNA-seq analysis. Hierarchical clustering of the normalized expression data of 20,257 transcripts revealed that, whereas PT shows transcriptome similarity with nBreast tissue, MT exhibits a brain-like transcription profile [Figure 1A and B]. IPA of the 367 MT-specific revealed ERBB2 signaling as a

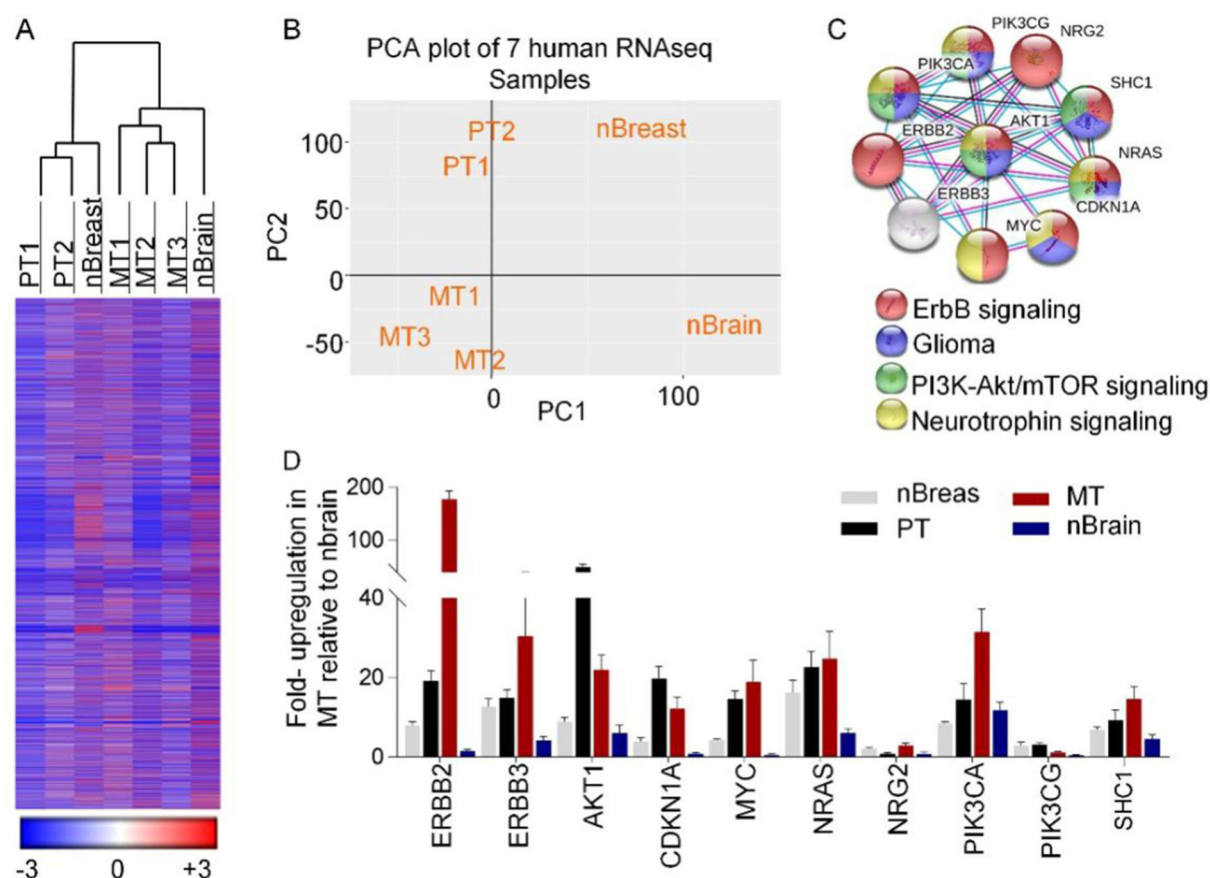

Figure 1. RNA-Seq analysis of two primary breast tumors (PT1-2), one normal breast tissue sample (nBreast), three breast to brain metastatic tumors (MT1-3), and one normal brain tissue sample (nBrain). Colors indicate relatively low (blue) or high (red) gene expression; B: the principal component analysis (PCA) of log₂-normalized FPKM values, showing similarities and differences between sample groups; C: protein-protein interactions of selected genes overexpressed in metastatic tissue (MT) samples compared to all other groups; D: real-time PCR quantification of genes overexpressed in different samples ($n = 3$, $P < 0.05$). Error bars indicate SEM

major canonical pathway overexpressed in MT [Supplementary Figures 1 and 2]. Protein-protein interaction analysis of the MT-specific genes revealed ERBB2/PI3K/AKT/mTOR as a potential major regulator of the breast to brain metastatic cell survival and proliferation [Figure 1C]. Similarly, KEGG pathway analysis projected ERBB2, PIK3-Akt/mTOR, and neurotrophin signaling as major pathways associated with MT-specific genes [Supplementary Figure 2].

Based on IPA, followed by protein-protein interaction and KEGG pathway analyses, we focused on a set of 10 genes that showed at least two-fold overexpression in MT tissue compared to all other groups and may be important for the proliferation of BBM cells.

To confirm the expression of these genes, we synthesized gene-specific primers and performed real-time PCR analysis of RNA extracted from MT (MT1-3), PT (PT1-2), and nBrain tissue [Figure 1D]. To further confirm the expression of these MT-specific genes, we cultured two BBM tissue-derived low-passage cell lines, BBM1 and BBM2, along with human reactive astrocytes. Both BBM cell lines showed distinct morphological differences compared to astrocytes [Figure 2A]. The real-time PCR analysis of extracted RNA showed significant ($P < 0.05$) upregulation of MT-specific genes, except for NRG2 and PIK3CG, in BBM cells compared to astrocytes [Figure 2B].

Figure 2. A: Bright field images of human Astrocytes and breast cancer brain metastasis 1 (BBM1) and 2 (BBM2) cells showing morphological differences between cell lines. Scale bars = 100 μm/L; B: real-time PCR analysis of genes enriched in Astrocytes and BBM (BBM1 and BBM2) cells ($n = 3$, $P < 0.05$). Error bars indicate SEM

Disruption of ERBB2 and the PIK3/AKT/mTOR signaling pathway induces apoptosis in BBM cells

Bioinformatics analysis of our sequence data, published data, and previous findings from our lab indicate MT-specific ERBB2-mediated activation of the PI3K-AKT/mTOR pathway [Figure 3A]. We found expression of ERBB2, PIK3CA, and MYC was 20, 8 and 4 fold, higher in HER2+ MT tissue compared to PT, indicating the potential function of the neural microenvironment in substantially increasing their expression. To confirm the function of ERBB2 on PI3K-AKT/mTOR signaling, we treated BBM1 cells with 50 nmol/L of the ERBB2 inhibitor Lapatinib or the PIK3CA inhibitor Idelalisib for 48 h. Western blot analysis of total protein extracts showed that Lapatinib and Idelalisib inhibited phosphorylation of ERBB2, PIK3CA, AKT, and mTOR [Figure 3B]. To confirm the effects of the inhibitors on cell viability, BBM1 cells were treated with various concentrations (0, 31.2, 62.5, 125, 250, 500, 1000 nmol/L) of Lapatinib and Idelalisib, as well as inhibitors of AKT (AZD5363) and mTOR phosphorylation (Rapamycin). Our analysis showed that treatment with each of the inhibitors suppressed cell viability [Figure 3C]. Lapatinib induced the highest inhibition of BBM1 cell proliferation with an IC_{50} value of 25.1 nmol/L at 72 h post-treatment.

Drug screen indicates that SRC, ERBB2, and GABA signaling pathways play critical roles in BBM1 cell proliferation

To identify novel clinical or preclinical drug candidates to target breast cancer brain metastasis, we performed a high throughput screening of 1,650 compounds. Preliminary screening was done by treating BBM1 cells with 1 μmol/L of each compound for 72 h. We identified 105 compounds that showed robust toxicity (at least 70% inhibition) against BBM1 cells [Figure 4A].

In a secondary screening, we analyzed the consistency and stability of the compounds against two HER2+ BBM cell lines (BBM1 and BBM2). Cells were treated with 50 nmol/L of each compound and analyzed over

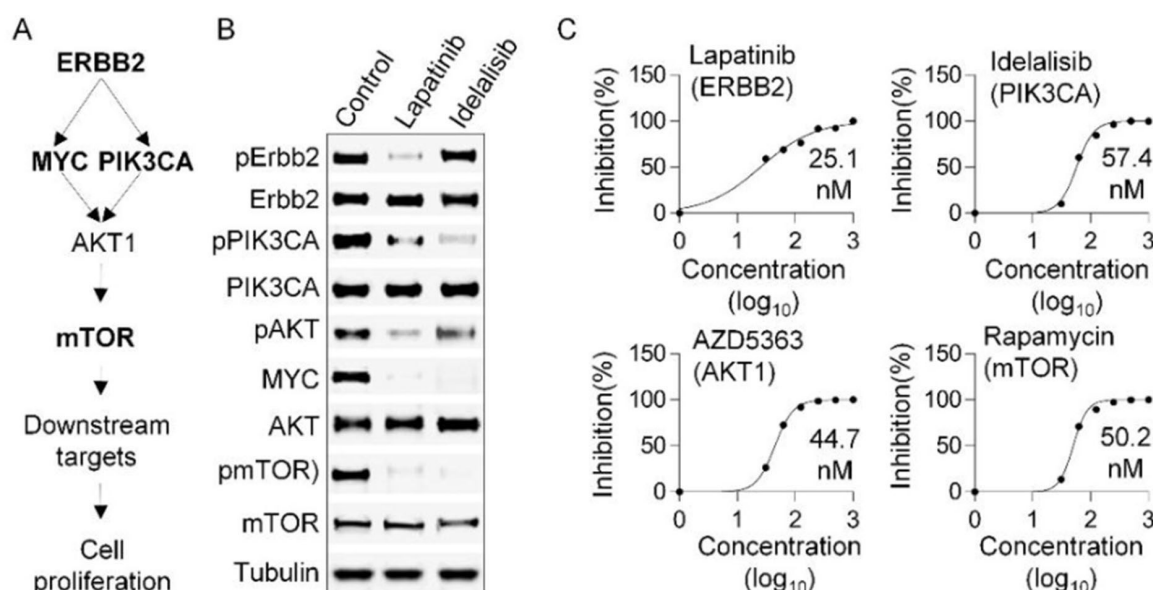

Figure 3. Disruption of ERBB2 and PI3K-AKT/mTOR signaling suppresses BBM cell survival. A: Schematic depicting the ERBB2/MYC/ AKT and PI3K-AKT/mTOR signaling pathways that affect BBM cell proliferation; B: cells were treated with ERBB2 (Lapatinib) and PI3K (Idelalisib) inhibitors at a final concentration of 100 nmol/L for 48 h. Total protein lysates from were analyzed using antibodies specific to ERBB2, pERBB2, PIK3CA, pPIK3CA, AKT, pAKT, MYC, mTOR, and pmTOR. Tubulin was used as a loading control; C: BBM1 cells were treated with pharmaceutical inhibitors of ERBB2 (Lapatinib), PI3K (Idelalisib), AKT (AZD5363), and mTOR (Rapamycin) at final concentrations 0, 31.2, 62.5, 125, 250, 500, 1000 nmol/L. Control cells were treated with DMSO only. The viability of the cells at 72 h post-treatment is shown. The IC₅₀ values of the compounds are in the bottom right of each plot

10 days. We identified 35 compounds that showed robust toxicity towards both BBM1 and BBM2 cell lines, throughout the study period [Supplementary Figure 3].

Further screening was done to identify compounds with BBM cell-specific toxicity using both BBM1 and human reactive astrocytes cells. We identified 12 compounds that were at least two-fold more toxic towards BBM1 cells than toward astrocytes [Figure 4B and C]. Finally, we analyzed concentration-dependent toxicity and identified 6 compounds that showed linear concentration-dependent suppression of BBM1 cell viability. IC₅₀ analysis revealed that Doxorubicin, a DNA-binding chemotherapeutic agent for multiple cancers, was the most toxic compound towards BBM1 cells. The SCR inhibitor (AC-93253; IC₅₀ = 85 nmol/L) and GABA receptor agonist (Isoguvacine; IC₅₀ = 99.2 nmol/L) showed greater toxicity than the Wnt agonist (CID11210285), sirtuin (SIRT) inhibitor (JDF00244), and leucine-rich repeat kinase-2 (LRRK2) inhibitor (GSK2578215A), which had IC₅₀ values ranging from 183 nmol/L to 304 nmol/L [Figure 4D]. Consistent with the drug screening data, our RNA-seq analysis indicated relatively higher expression of SRC in MT cells compared to nBrain and nBreast but not to PT [Supplementary Figure 4].

Combinatorial inhibition of ERBB2 with an SRC or PIK3CA inhibitor or a GABA agonist induces robust apoptosis in BBM1 cells

Bioinformatics analysis showed that SRC1 is an upstream regulator of ERBB2 and its targets, MYC and PIK3CA, and an activator of PI3K-AKT/mTOR signaling [Figure 5A], indicating that SRC1 potentially plays a critical role in BBM cell survival and proliferation. To confirm this function of SRC, we treated BBM1 cells with different inhibitors specific to SRC and its downstream targets for 48 h. Apoptosis analysis showed that these inhibitors induced robust apoptosis in BBM1 cells [Figure 5B]. Further confirmation of apoptosis was obtained via Western blot analysis of procaspase3 and cleaved caspase3 proteins in the treated cells [Figure 5C].

Consistent with the RNA-seq data, our compound screening results indicated that SRC-mediated activation of the PIK3-AKT/mTOR pathway plays a critical role in BBM cell survival and proliferation. To confirm the

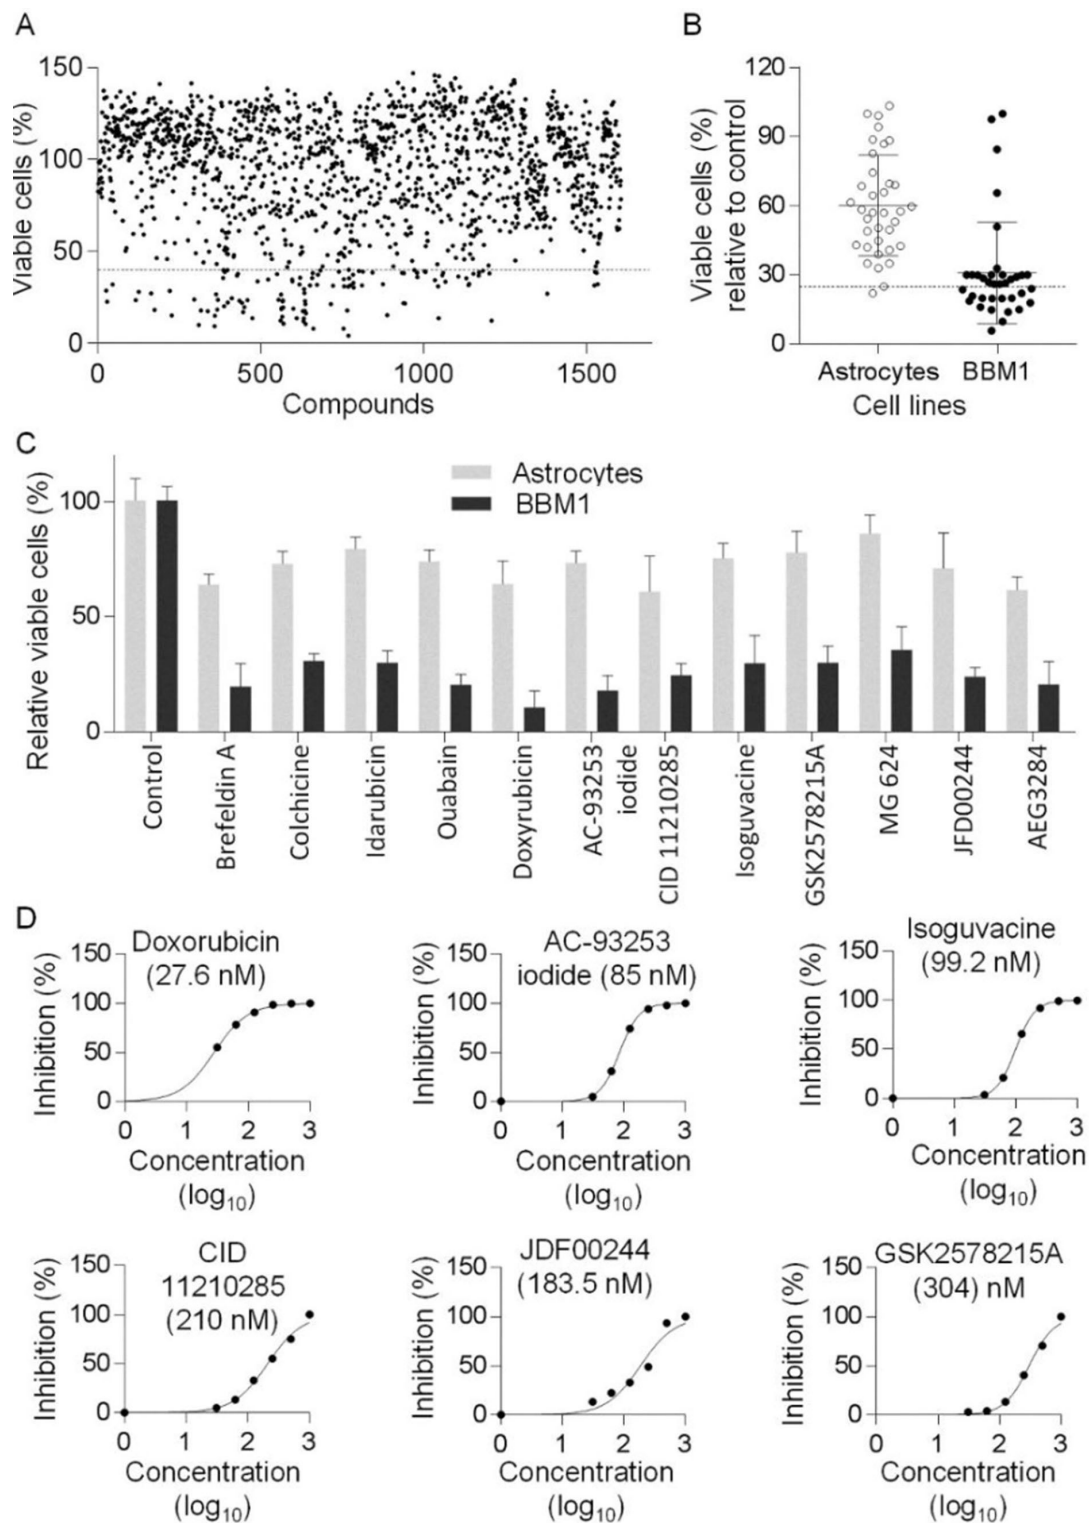

Figure 4. Screening of clinical and preclinical drugs to identify novel candidates targeting breast cancer brain metastases. A: Preliminary screening of 1,650 compounds for their efficacy against BBM1 cells. BBM1 cells were grown overnight prior to treatment with the compounds at a final concentration 1 $\mu\text{mol/L}$ for 48 or 72 h ($n = 2$). The percentages of viable cells in each treatment group relative to viable control cells treated with DMSO are shown for data collected after 72-h treatment. Compounds that suppressed viability below 70% compared to control (107 total, separated by a dashed line) were selected for secondary screening using both BBM1 and BBM2 cells lines; B, C: tertiary screening of the active compounds based on cell type-specific effects. Human astrocytes and BBM1 cells were grown overnight prior to treatment with the 35 active compounds identified in the secondary screening at a final concentration of 1 $\mu\text{mol/L}$ for 48 or 72 h ($n = 6$). The percentages of viable cells relative to viable control cells treated with DMSO are shown for data collected after 72-h treatment; C: relative viability of BBM1 cells treated with compounds (12) that reduced BBM1 cell viability by at least two-fold compared to that of astrocytes at a concentration of 1 $\mu\text{mol/L}$ for 72 h; D: concentration-dependent effects of six potent active compounds. BBM1 cells were grown overnight prior to treatment with the compounds at final concentrations ranging from 0, 31.2, 62.5, 125, 250, 500, 1000 nmol/L ($n = 8$). The viability of the cells at 72 h post-treatment is shown. The IC₅₀ values of the compounds are shown in parenthesis

SRC-mediated activation of PIK3/AKT/mTOR signaling, we treated BBM1 cells with 100 nmol/L of AC93253 for 48 h, followed by Western blot analysis of the total protein extract. Our analysis showed that inhibition of SRC leads to inhibition of PIK3CA and mTOR phosphorylation [Figure 5D]. As our analysis indicated that SRC is an upstream regulator of ERBB2 and the PIK3-AKT/mTOR pathway in BBM1 cells and that inhibition of both SRC and ERBB2 induces BBM1 cell death, we analyzed the combined effect of SRC and ERBB2 inhibitors on BBM1 cell viability. We treat the cells with 50 nmol/L of AC93253 and 50 nmol/L of Lapatinib, separately and in combination, for 48 h. Our analysis showed robust inhibition of BBM1 cells in the presence of either inhibitor alone, however, the effect was greatest in presence of both [Figure 5E]. Similar to combinatorial SRC/ERBB2 treatment, concurrent inhibition of ERBB2 and PIK3CA showed a significant additive inhibitory effect on BBM1 cell survival [Figure 5E].

We also evaluated the combinatorial treatment of ERBB2 and SRC inhibitors with a GABA agonist. BBM1 cells were treated with either 100 nmol/L of Isoguvacine alone or in combination with Lapatinib or AC93253 for 48 h. Cell viability and apoptosis analyses showed that the combination of Isoguvacine with both Lapatinib and AC93253 induced higher inhibition of cell viability compared to independent treatments [Figure 6A and B]. Our analysis showed that the expression of GABA receptors and subunits was significantly higher in nBrain compared to PT, MT, and nBreast [Figure 6C, Supplementary Figure 5].

DISCUSSION

Brain metastases are the most common and complicated central nervous system disease in adults. The incidence of brain metastases is increasing due to both improved diagnosis and increased cancer patient survival through advanced systemic treatments. Outcomes of patients remain disappointing and treatment options are limited, usually involving multimodality approaches of radiation and palliative chemotherapy. Brain metastases represent an unmet clinical challenge in caring for solid tumor, especially in breast cancer, where the incidence of brain metastases are frequent and that result in impaired quality of life.

BBMs are common in patients with the HER2-positive and TNBC breast cancer subtypes, and the natural course of BBM is strongly influenced by the biology of the primary tumor subtype. Although the biology of BBM according to tumor subtypes is still poorly understood, recent breakthroughs have been achieved in the identification of specific mediators of BBM and in the development of preclinical models for therapeutic studies. However, the use of established cell lines and comparative analysis of unrelated tissue samples often identify factors that eventually fail to represent as a key regulator in preclinical and clinical stage. To overcome this issue we obtained both primary and metastasis tissue from same individual patients (PT1/MT2 and PT2/MT2). Due to the inherent difficulty in the procurement of such tissue pairs we have used limited numbers of tissue samples. Our RNA-seq analysis revealed that ERBB2-mediated activation of PIK3CA and its downstream AKT/mTOR pathway plays a critical role in the survival and proliferation of breast to brain metastatic cells. Inhibition of ERBB2 or its downstream targets suppresses BBM cell viability to different degrees. The critical function of ERBB2 in HER2+ primary and metastatic breast cancer has been well established, and the ERBB2 inhibitor Lapatinib and trastuzumab have been used as chemotherapeutic agents targeting HER2+ breast cancer^[25-28]. In addition, our earlier studies revealed the contribution of neural factors, such as the astrocyte-secreted brain-derived neurotrophic factor, in the activation of HER2-TrkB signaling that leads to AKT1 activation and BBM1 cell proliferation^[25]. Several studies have also reported mutations and/or copy number changes in PIK3CA in hormone receptor-positive breast cancers^[29-31]. Indeed, targeting PIK3-AKT/mTOR signaling to inhibit breast cancer has been evaluated extensively, and there is phase I to III preclinical trial data demonstrating that inhibition of this pathway leads to regression of solid tumors and breast cancer^[32-37].

Recent gene expression analyses of BBM samples identified cyclooxygenase (COX)-2, EGFR ligands, and a sialyltransferase, as mediators of cancer cell passage through the BBB^[38]. In contrast to COX-2 and EGFR,

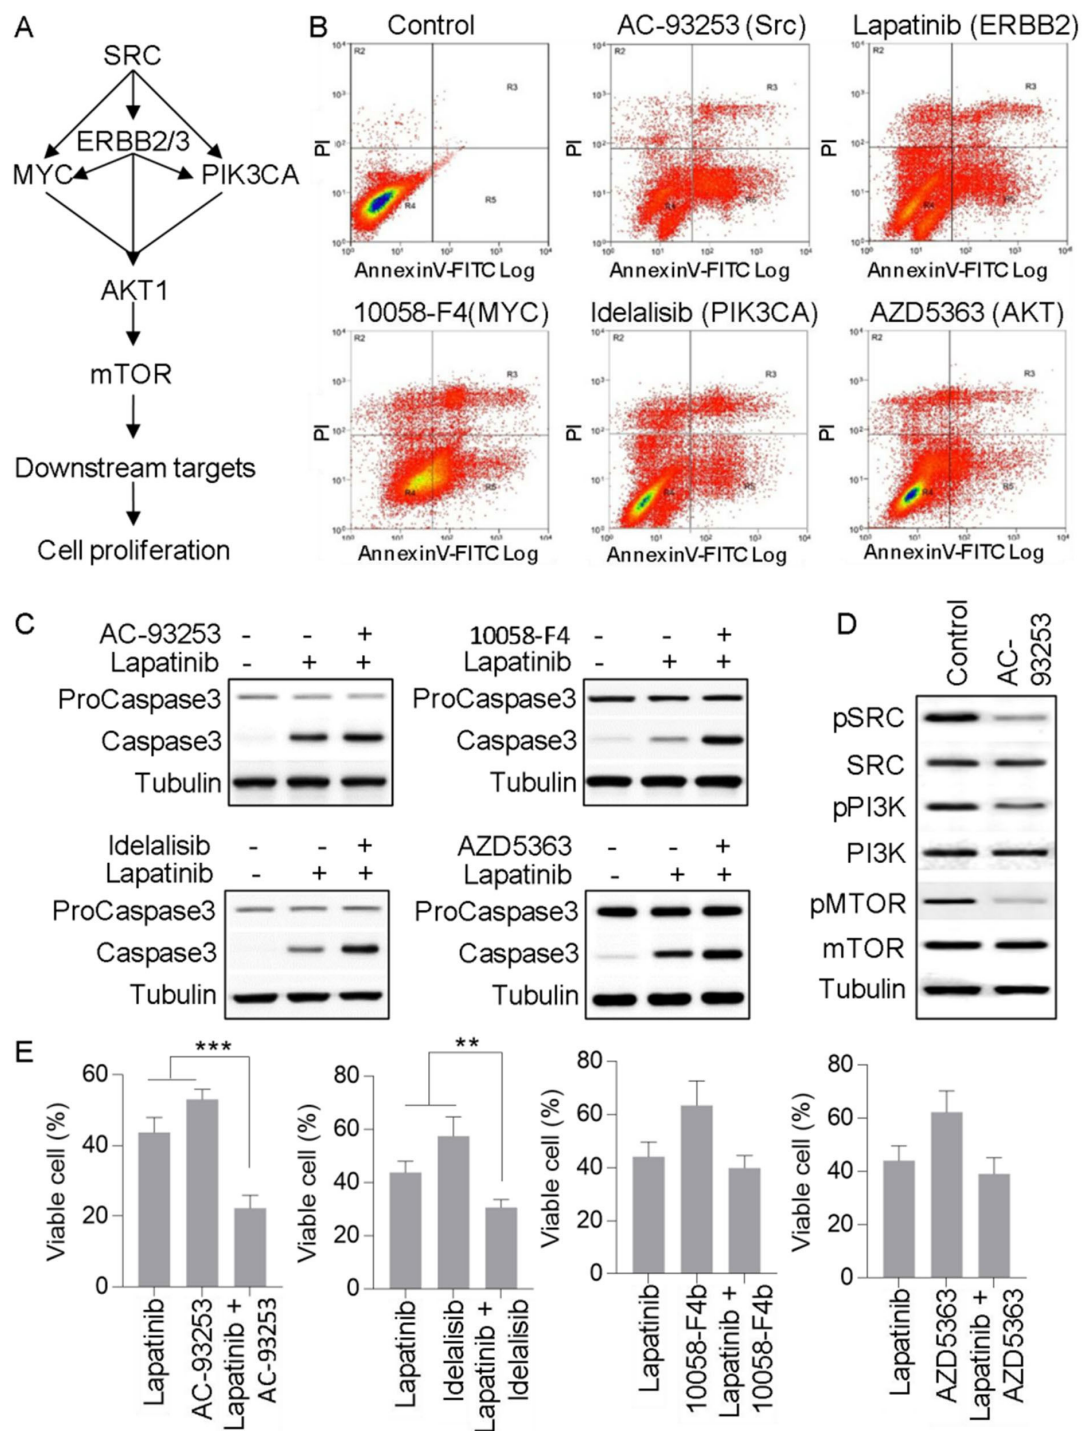

Figure 5. Inhibition of BBM1 cell proliferation by combinatorial treatment with the ERBB2 inhibitor Lapatinib and inhibitors of the PI3K-AKT/mTOR signaling pathway. **A:** Schematic depicting the functions of SRC, ERBB2, and PIK3CA in activating PI3K-AKT/mTOR signaling-mediated cell proliferation; **B:** effect of inhibition of SRC kinase, ERBB2, and PI3K-AKT/mTOR signaling on apoptosis induction in BBM1 cells. Cells were treated with inhibitors of SRC (AC-93253), ERBB2 (Lapatinib), MYC (10058-F4b), PIK3CA (Idelalisib), and AKT (AZD5363) at a final concentration of 100 nmol/L for 48 h. Control cells were treated with DMSO alone. Apoptosis induction was measured using Annexin V-FITC staining followed by FACS analysis; **C:** cells were treated with inhibitors (100 nmol/L) for 48 h, and total protein extracts were subjected to Western blot analysis using antibodies against ProCaspase3 (inactive) and cleaved Caspase3 (active). Tubulin was used as loading control; **D:** selective inhibition of the SRC kinase with AC-93253 disrupts PI3K-AKT/mTOR signaling. Cells were treated with AC-93253 (100 nmol/L) for 48 h, and total protein lysates from the cells were analyzed using antibodies specific to SRC, pSRC, PI3K, pPI3K, mTOR, and pmTOR. Tubulin was used as loading control; **E:** effect of the ERBB2 inhibitor Lapatinib alone and in combination with SRC, PIK3CA, MYC, and AKT inhibitors on BBM1 cell viability. Cells were treated with 50 nmol/L Lapatinib alone or in combination with AC-93253, Idelalisib, 10058-F4b, or AZD5363 at a final concentration of 50 nmol/L. The percentages of viable cells in each treatment group relative to viable control cells treated with DMSO are shown for data collected after 48 h. Error bars indicate SEM ($n = 3$, ** $P < 0.05$; *** $P < 0.01$)

Figure 6. Inhibition of BBM1 cell proliferation upon treatment with a GABA agonist alone and in combination with ERBB2 or SRC inhibitors. A: BBM1 cells were treated with GABA agonist Isoguvacine, AC-93253, and/or Lapatinib at final concentrations of 100 nmol/L. The percentages of viable cells in each treatment group relative to viable control cells treated with DMSO are shown for data collected after 48 h ($n = 3$, $P < 0.05$). Error bars indicate SEM; B: the induction of apoptosis was measured using Annexin V-FITC staining followed by FACS analysis. Control cells were treated with DMSO alone; C: hierarchical clustering based on the expression GABA receptors and subunits in primary breast cancer (PT1-2), breast to brain metastatic tumor tissue (MT1-3), normal breast tissue (nBreast), and normal brain tissue (nBrain). Low expression (blue), high expression (red)

which are also linked to other organ metastases, aberrant expression of ST6GALNAC5 specifically mediated BBM, potentially by enhancing adhesion circulating cells to the CNS endothelium. Similarly, using larger cohort of patient samples metastasis suppressor KISS1 a prognostic marker for increased risk of breast cancer progression was identified^[39]. These concurrent genomic analysis indicates that an effective molecular target for complete remission of BBM is yet to be identified.

Supporting the RNA-seq data, our parallel screening of clinical and preclinical drug candidates identified ERBB2, PIK3CA, and their downstream targets as critical regulators of BBM cell proliferation. We identified SRC as an upstream regulator of ERBB2, PIK3CA, and MYC. Inhibition of each of SRC and ERBB2 alone or in combination with a GABA agonist-induced robust apoptosis in BBM1 cells.

The previous study also demonstrated that SRC is hyperactivated in brain-seeking breast cancer cells and that SRC activation promotes tumor cell extravasation into the brain parenchyma via permeabilization of the blood-brain barrier^[21]. Indeed, the preclinical study showed that SRC and SRC family kinases mediate intracellular signaling pathways that control key biologic/oncogenic processes in glioblastoma^[21]. In addition to neurotransmission and regulation of secretion, GABA through GABAA receptors negatively regulates proliferation of neural stem cells^[23]. GABAergic signaling and its control over proliferation have also emerged as critical in brain tumors^[40-42].

Indeed, previous studies from our group showed that human breast cancer metastases to the brain display GABAergic properties in the neural niche and metabolize GABA as an energy source^[40]. Consistent with previous findings on the inhibitory effects of GABA signaling on neural and embryonic stem cells^[43,44], our findings indicate that the attenuation of GABA signaling is potentially associated with the rapid proliferation of tumor cells in the brain. The activation of GABA signaling potentially reverses the availability of GABA as

an energy source for GABAergic BBM cells, leading to suppression of viability and proliferation. Our results indicate that combinatorial treatment with a GABA agonist and SRC or ERBB2 inhibitors is a potentially effective therapeutic approach targeting BBM. Finally, consistent with the drug screening data, aberrant Wnt signaling is a hallmark of many cancers. Dysregulation of canonical and non-canonical Wnt signaling was reported in triple-negative breast cancer^[45-47]. No previous studies have shown any relationship of SIRT and LRRK2 with HER2+ breast cancer brain metastasis. In conclusion, we have identified both molecular targets and active clinical/preclinical inhibitors to target breast cancer brain metastasis. In our future studies, we will evaluate the efficacy of these inhibitors in animal models *in vivo*.

CONCLUSION

The study reveals critical roles for SRC, ERBB2, PIK3CA, and GABA in the proliferation and survival of BBM cells and showed that SRC- and ERBB2-mediated activation of PIK3-AKT/mTOR signaling regulates BBM cell survival. Selective inhibition of these candidate genes alone or in combination induces robust apoptosis in BBM cells. In addition, the finding revealed that agonist-mediated activation of GABA signaling in combination with inhibition of SRC/ERBB2 signaling acts as an effective strategy to inhibit BBM cell proliferation. In future studies, we will analyze BBM cell-specific toxicity of the lead candidates alone or in combinations using larger numbers of BBM, primary breast cancer and glial cell lines. We will identify the candidates or combination with significantly higher BBM cell selective toxicity for preclinical evaluation using animal models. In conclusion, the findings of this study provide a rationale for further preclinical evaluation of SRC-targeting regimens in combination with ERBB2 inhibitors and/or GABA agonists to target breast cancer brain metastasis.

DECLARATIONS

Acknowledgments

We tender our heartfelt gratitude to Kerin Higa for critically evaluating and proofreading the manuscript. We acknowledge Integrative Genomics Core's sequencing service.

Authors' contributions

Made substantial contributions to conception and design of the study and performed data analysis and interpretation: Ansari SR, Jandial Z, Wu X, Liu X, Ansari KI
Performed data acquisition, as well as providing administrative, technical, and material support: Ansari SR, Jandial Z, Chen MY, Ansari KI

Abstract

Alternative splicing is a major contributor to transcriptome and proteome diversity in eukaryotes. Comparing to normal samples, about 30% more alternative splicing events were recently identified in 32 cancer types included in The Cancer Genome Atlas database. Some alternative splicing isoforms and their encoded proteins contribute to specific cancer hallmarks. In this review, we will discuss recent progress regarding the contributions of alternative splicing to breast cancer metastasis. We plan to dissect the role of MTDH, CD44 and their interaction with other mRNA splicing factors. We believe an in-depth understanding of the mechanism underlying the contribution of splicing to breast cancer metastasis will provide novel strategies to the management of breast cancer.

Keywords: Breast cancer, metastasis, CD44, MTDH, splicing, epithelial-mesenchymal transition

INTRODUCTION

Breast cancer is the most common type of cancer among women. Despite emerging new treatments such as PARP inhibition and immune checkpoint blockade, it remains a major challenge^[1,2] and is the primary cause of cancer mortality in women. In the majority of cases, the death from breast cancer is not due to the primary tumor per se, but rather the result of metastasis to other organs in the body^[3]. Metastasis is a multi-step process involving stromal invasion, cell migration, intravasation, anoikis resistance, extravasation and

subsequent implantation and proliferation in sites other than the primary location^[4]. Although we have gained ample knowledge in this cellular process, an in-depth understanding at the molecular level remains to be deciphered.

Alternative splicing might be such a molecular mechanism that contributes to metastasis. It is a process whereby multiple functionally distinct transcripts are encoded from a single gene by the selective removal or retention of exons and/or introns from the maturing RNA. This process is highly regulated, involving trans-acting splicing factors and cis-acting regulatory motifs and so is susceptible to hereditary and somatic mutations. Alternative splicing is common in many eukaryote lineages. Using deep transcriptome sequencing of the human genome, over 95% of multi-exon genes were found capable of producing at least one alternatively spliced isoform^[5]. Many single-gene studies have also characterized the role of alternative splicing in various cellular processes. Disruption or dysregulation of alternative splicing has also been associated with pathological states^[6,7]. Maguire *et al.*^[8] demonstrated that spliceosomal mutations occur in a mutually exclusive manner in breast cancer and that distinct components of the spliceosome are targeted by somatic mutations in different types of breast cancer. The exact splicing pattern associated with a particular breast cancer type or stage still requires a broad characterization through molecular analysis of splicing isoforms in different patients. However, existing evidence strongly supports a pivotal role of alternative splicing in breast cancer biology and innovative tools are under development to use splicing events for diagnostic and therapeutic purposes^[9]. Shapiro *et al.*^[10] observed an epithelial-mesenchymal transition (EMT)-associated global change in alternative splicing of a number of genes that are involved in functions crucial for EMT progression, such as cell adhesion, cell motility, and cytoskeletal remodeling. Several of the splicing changes discovered *in vitro* were also found to occur in a panel of breast cancer cell lines and *in vivo* in primary human breast cancer samples. Dysregulation of alternative splicing has been increasingly recognized in cancer-related pathways. It is thus critical to investigate the functional significance of splicing regulation in the context of cancer. This review will discuss some recent progresses about the alternative splicing regulators such as CD44, heterogeneous nuclear ribonucleoprotein M (hnRNPM), SND1 and MTDH *etc.* in breast cancer metastasis.

SPlicing VARIANTS MAY ENHANCE EMT AND METASTASIS IN BREAST CANCER

Dorman *et al.*^[12] reported splicing defects in large-scale breast cancer sequencing studies. Nine hundred and eighty-eight splicing variants including exon skipping, leaky or cryptic splicing from 5,206 putative mutations were confirmed for splicing mutations in 442 Breast Cancer patients from The Cancer Genome Atlas dataset. These splicing variants were significantly increased in patients with lymph node metastasis, but not in lymph node-negative tumors. Silipo *et al.*^[13] reported that the expression profile changes of splicing factors including serine/arginine-rich splicing factor 1 (SRSF1), SRSF2, SRSF3, SRSF5, SRSF6 and SRSF10; the heterogeneous nuclear ribonucleoproteins (hnRNPs) including hnRNP A2/B1, hnRNPI, hnRNPA1 and hnRNP K; as well as eight RNA-binding proteins including HuR, Sam68, BRM5, FOX2, YB-1, PRMT6, SPF45 and PELP1 in breast cancer cells compared with normal cells, which are strongly associated with the alternative splicing pattern of many cancer-related genes despite the absence of mutations in genomic DNA. Inoue *et al.*^[14] reported aberrant splicing of CD44 gene in breast cancer, which promotes metastasis. The status of splicing factors and other splicing-related proteins in breast cancer are important to provide insights into the mechanisms that lead to breast cancer metastasis^[15]. The correlation analysis of somatic variants with alternative splicing events confirmed known trans- associations with variants in SF3B1 and U2AF1, and additional trans-acting variants (e.g., TADA1, PPP2R1A). Tumors have up to 30% more alternative splicing events than normal samples. Many tumors have thousands of alternative splicing events that are not detectable in normal samples. On average, 930 exon-exon junctions (“neojunctions”) were identified in tumors not typically found in normal tissue included in the Genotype-Tissue Expression (GTEx) project^[15]. CD44 is a cell surface protein with various isoforms that involves in motility, cell survival and proliferation

Figure 1. Mechanisms of alternative splicing of CD44 in epithelial-mesenchymal transition and breast cancer metastasis were summarized

and the formation of tumor microenvironment. Alternative splicing can produce various isoforms of CD44 with properties at different specific tissue^[16,17]. The RNA-binding protein hnRNPM was found to promote breast cancer metastasis by activating the switch of alternative splicing during EMT.

HNRNPM INCREASES CD44 ALTERNATIVE SPLICING TO ENHANCE BREAST CANCER METASTASIS

CD44 was identified as a key downstream target of hnRNPM by genome-wide deep sequencing analysis. hnRNPM is associated with increased standard form of CD44 (or CD44 standard, CD44s) in aggressive breast cancer patient specimens. Overexpressed hnRNPM competes with epithelial splicing regulatory protein 1 (ESRP1), and binds to the same cis-regulatory RNA elements of CD44 for the precisely control CD44s splice isoform switching during EMT^[18]. ESRP1 is a splicing regulator to promote an epithelial splicing program and hnRNPM is a mesenchymal splicing regulator. Harvey *et al.*^[19] reported that hnRNPM and ESRP1 co-regulate a set of cassette exon events in EMT genes associated with cell migration and cytoskeletal reorganization. Competitive binding to these cis-elements by hnRNPM and ESRP1 to antagonize alternative splicing was proposed. The expression of hnRNPM is closely correlated with invasion and metastasis of tumor cells. hnRNPM expression was upregulated in breast cancer tissues. HnRNPM and CD44s expression are positively correlated in breast cancer tissues. Cancer stem cells marker ALDH1+ was found positively associated with overexpression of CD44s and hnRNPM. High hnRNPM is associated with higher levels of CD44s, shorter overall survival and higher rates of lymph node metastases in breast cancer patients^[20].

MORC2-MUTANT M276I PROMOTES AN HNRNPM-MEDIATED CD44 ALTERNATIVE SPLICING TO ENHANCE BREAST CANCER METASTASIS

A cancer-associated Microorchidia family CW-type zinc finger 2 (MORC2) (M276I) mutant was reported to promote metastatic ability of TNBC cancer cells by enhancing interaction with hnRNPM and splicing switch of CD44 from the epithelial isoform (CD44v) to the mesenchymal isoform (CD44s) [Figure 1]. Expression of mutant MORC2 in TNBC cells increased cell migration, invasion, and lung metastasis. The M276I mutation enhanced binding of MORC2 to hnRNPM, a component of the spliceosome machinery. This interaction promoted an hnRNPM-mediated splicing switch of CD44 from CD44v to CD44s, ultimately driving EMT. Knockdown of hnRNPM reduced the binding of mutant MORC2 to CD44 pre-mRNA and reversed the mutant MORC2-induced CD44 splicing switch and EMT. As a consequence, the migratory, invasive, and lung metastatic potential of mutant MORC2-expressing cells was impaired^[21].

*MTDH interacting mRNAs identified in both High-throughput sequencing of RNA isolated by Cross-linking immunoprecipitation (HITS-CLIP) and Photoactivatable Ribonucleoside-Enhanced Cross-linking and Immunoprecipitation (PAR-CLIP)

TDP43, CPEB2A/B AND ESRP1/RBFOX2 IN BREAST CANCER METASTASIS

Ke *et al.*^[22] reported that the loss of TDP43 (TAR DNA-binding protein 43), an important splicing regulator involved in the SRSF3 regulated unique splicing of downstream gene PAR3, promotes metastasis in TNBC. Highly expressed TDP43 is correlated with poor prognosis in TNBC. Knockdown of TDP43 inhibits SRSF3 and PAR3 mediated metastasis. Two CPEB2 splicing isoforms with or without exon 4 was reported to mediate opposing effects on cancer-related phenotypes. The CPEB2A isoform, which is produced by exclusion of exon 4 from the mature CPEB2 mRNA, inhibited tumor growth. The CPEB2B splicing isoform with the inclusion of exon 4 into the mature CPEB2 mRNA was overexpressed in aggressive forms of human breast cancer and enhanced cancer metastasis was observed^[23]. CPEB2A/B promotes the translation of two critical downstream proteins TWIST1 and HIF1a in the hypoxia/EMT pathway^[23]. Splicing factor ratio might be an index of EMT and tumor aggressiveness in breast cancer. In fact, the association of low ESRP1/RBFOX2 ratio with high risk of metastasis in early breast cancer was speculated to be a new early prognostic marker of breast cancer metastasis^[24].

RNA BINDING PROTEIN RBM47 INHIBITS BREAST CANCER METASTASIS BY REGULATING SPLICING

RNA binding motif protein 47 (RBM47) was identified as a suppressor of breast cancer metastasis through analysis of clinical breast cancer gene expression datasets, cell line models, and mutation data. Transcriptome-wide HITS-CLIP analysis revealed widespread mRNAs associated with RBM47 by binding to their introns and 3'UTRs. The dickkopf WNT signaling pathway inhibitor 1 (DKK1) is one of downstream mRNAs of RBM47. RBM47 inhibits breast cancer metastasis by increasing stability of the Wnt antagonist DKK1^[25].

NON-CODING RNA REST-003 PROMOTES BREAST CANCER METASTASIS

Non-coding RNAs (ncRNAs) RE1-silencing transcription factor (REST)-003 was reported to promote breast cancer metastasis. REST-003 is cRNAs derived from the first exon of an alternatively spliced REST transcript processed by serine/arginine repeat-related protein SRRM3. REST is a transcription factor to regulate expression of genes important for neuronal development. Interestingly, SRRM3 expression is repressed by REST^[26].

MTDH PROMOTES BREAST CANCER METASTASIS PARTIALLY BY REGULATING ALTERNATIVE SPLICING

High metadherin gene expression was highly correlated with breast cancer metastasis^[27,28]. MTDH was identified to bind to the vasculature of the lung by phage display screening cDNAs from metastatic breast carcinoma^[27]. Experimental metastasis can be inhibited by metadherin specific antibody or siRNAs. Hu et al reported that MTDH drives breast cancer metastasis to the lungs by increasing adhesion to the walls of blood vessels^[28]. Amplification of a minimal 2.9 Mb piece of chromosome 8q22 was identified in poor-prognosis breast cancers by ACE (analysis of CNAs by expression data) and fluorescence in situ hybridization (FISH) analysis. Only the enforced expression of MTDH in this amplified 8q22 region was identified to increase lung seeding after tail vein injection of the mildly metastatic breast cancer cell line MDA-MB-231^[28]. Interaction of MTDH with Staphylococcal nuclease domain-containing 1 (SND1) was independently identified by mass spectrometry (MS) by three labs^[29-31]. Overexpression of MTDH and SND1 in primary tumors is strongly associated with reduced metastasis-free survival in multiple large-scale datasets of breast cancer patients^[32,33]. SND1 acts as a novel alternative splicing regulator by interacting with SAM68 to regulate exon v5 inclusion in the CD44 mRNA splicing that promotes cancer metastasis [Figure 1]^[34-36]. Several other splicing regulators including hnRNPA0, hnRNPA2B1, hnRNPF, hnRNPA3 isoform were also identified by MS in MTDH pull-down assay^[29]. High-throughput sequencing of RNA isolated by Cross-linking immunoprecipitation (HITS-CLIP) and Photoactivatable Ribonucleoside-Enhanced Cross-linking and Immunoprecipitation (PAR-CLIP) were recently developed methods to study RNA-protein interactions^[37,38]. As shown in Table 1, mRNAs encoding for mRNA splicing regulators were identified in MTDH RNA interactome for multiple times at different sites by MTDH antibody specific PAR-CLIP and 12 splicing factors were confirmed by MTDH HITS-CLIP^[39]. Therefore, MTDH may promote breast cancer metastasis by regulating mRNA splicing through interacting with mRNAs or proteins of splicing factors.

CONCLUSION

Increased expression of mRNAs alternative splicing isoforms derived from alteration of splicing factors and MTDH expression could promote EMT and breast cancer metastasis, which provides new targets for breast cancer therapy.

Abstract

Aim: The progression free survival of non-small cell lung cancer (NSCLC) patients has been doubled over the last years, but still single epidermal growth factor receptor (EGFR) tyrosine kinase inhibitors (TKIs) lead to incomplete responses. Compensatory signaling pathways are activated upon single EGFR TKIs. We have shown that compounds, which inhibit these pathways, are synergistic with EGFR TKIs. Proviral integration site for Moloney murine leukemia virus (PIM) has been connected to cancer therapy resistance, being involved in receptor tyrosine kinase, signal transducer and activator of transcription 3 (STAT3) and interleukin-6 signaling. We hypothesized that combined PIM and EGFR inhibition may improve the upfront therapy of EGFR-mutation positive NSCLC.

Methods: We reviewed the literature on PIM kinases, and performed cell viability assays, gene expression analyses, and immunoblotting experiments to reveal the mechanisms of action of the PIM inhibitor (AZD1208) alone and combined with osimertinib in five EGFR-mutation positive NSCLC cell lines.

Results: Osimertinib alone induced the activation of signal transducer and activator of transcription 3 (STAT3) as well as other signaling nodes. Combined osimertinib and AZD1208 yielded moderate synergistic effects in all

NSCLC cell lines investigated. Among the EGFR-mutation positive cell lines examined, the H1975 and PC9 cell lines had the highest PIM1 and STAT3 mRNA expression. The combination decreased the osimertinib-induced STAT3 phosphorylation.

Conclusion: This study provides a short review on PIM kinases, and shows our results of combined PIM and EGFR inhibition in EGFR-mutation positive NSCLC cell lines. The combination was moderately synergistic but decreased STAT3 phosphorylation, an important signaling node in therapy resistance.

Keywords: Non-small cell lung cancer, EGFR, PIM-1, AZD1208, tyrosine kinase inhibitors

INTRODUCTION

Activation of the epidermal growth factor receptor (EGFR) leads to downstream induction of signaling pathways, including phosphatidylinositol 3-kinase/AKT, Ras/mitogen-activated protein kinase and Janus kinase 2 (JAK2)/signal transducer and activator of transcription 3 (STAT3) [Figure 1]. Consequently, these pathways stimulate cell proliferation, cell motility, cell cycle progression and cell survival^[1,2]. EGFR mutations were discovered in 2004^[1]. This finding has radically changed the therapy of EGFR-mutation positive non-small cell lung cancer (NSCLC) patients, replacing standard chemotherapy with EGFR tyrosine kinase inhibitors (TKIs)^[1,3]. Treatment with first-, second-, and third-generation EGFR TKIs has significantly improved the progression free survival of NSCLC patients, harboring EGFR mutations^[4]. The third-generation EGFR TKI, osimertinib is now the standard first-line therapy of these patients^[5]. However, although initially effective, monotherapy with EGFR TKIs, including osimertinib, triggers intrinsic or acquired resistance pathways^[6-8], and the patients eventually succumb to their disease.

Signaling nodes, including signal transducer and activator of transcription 3 (STAT3) and Src/Yes-associated protein 1 (YAP1), are not abrogated or even activated upon EGFR blockade. Moreover, besides EGFR, other receptor tyrosine kinases (RTKs) are present and induce downstream signaling, independent of EGFR inhibition^[9-13]. We have demonstrated that simultaneous inhibition of EGFR, STAT3 and Src-YAP1 was highly synergistic *in vitro* and *in vivo*. Moreover, multiple RTKs and non-RTKs were up regulated at baseline or after treatment with EGFR TKIs, limiting their efficacy^[6-8]. Proviral integration site for Moloney murine leukemia virus-1 (PIM-1) is a serine/threonine kinase, involved in cell cycle progression, cell growth, cell survival and therapy resistance. PIM-1 is activated in various types of cancer, amongst which prostate^[14-16], colorectal^[15,17-19], triple negative breast cancer (TNBC)^[20,21], hematologic malignancies^[22-24], neuroblastoma^[25] and lung cancer^[26]. For this reason, PIM kinases could provide a common target for the treatment of diverse malignancies.

PIM activation is induced by changes in the tumor microenvironment, such as hypoxia, and causes resistance to antiangiogenic drugs^[15]. The combination of PIM inhibitors with antiangiogenic compounds, down regulates the expression of hypoxia inducible factor 1 (HIF1) and decreases tumor cell proliferation, the formation of tumor vasculature and the ability of the cells to metastasize^[15]. A second study has also shown the involvement of PIM kinases in therapy resistance through hypoxia. Although the authors in this study propose a HIF1-independent, nuclear factor-erythroid 2 p45-related factor 2 induced hypoxia, PIM kinase inhibitors are again the solution to prevent therapy resistance and induce cell death in different tumor types^[27].

PIM-1 is involved in RTKs, STAT3 and interleukin-6 (IL-6) signaling [Figure 1]. Specifically, STAT proteins bind to the promoter of the *PIM-1* gene, and increase PIM-1 expression. A feedback loop, in turn, regulates the expression of STAT proteins^[14,18,21,28,29]. Considering the fact that there are no approved STAT3 inhibitors, the combination of EGFR TKIs with a PIM-1 inhibitor could be of interest to block STAT3

Figure 1. We present our initial literature-based model of EGFR-mutation positive NSCLC tumor cells, treated with single TKIs, and the parallel compensatory pathways that are being activated. Upon TKI treatment the downstream PI3K/AKT and RAS/MAPK pathways - in light grey - are inhibited, limiting the ability of the cells for proliferation and survival. However, our previous work has shown that this inhibition is the direct cause of the activation of the JAK2/STAT3 and Src-YAP1 pathways, and cannot abrogate coexpressed RTKs (e.g., MET, CDCP1) on the cell membrane. This in turn causes increased cell proliferation and survival, and thus leads to therapy resistance. PIM is an important signaling node in this network, potentially activated through IL-6/STAT3 and/or hypoxia. PIM was shown to be activated in multiple tumor types, and may therefore provide a druggable target for various tumor types. EGFR: epidermal growth factor receptor; NSCLC: non-small cell lung cancer; TKI: tyrosine kinase inhibitor; PI3K: phosphatidylinositol 3-kinase; MAPK: mitogen-activated protein kinase; JAK2: Janus kinase 2; STAT3: signal transducer and activator of transcription 3; YAP1: Yes-associated protein 1; RTK: receptor tyrosine kinase; PIM: proviral integration site for Moloney murine leukemia virus; IL-6R: interleukin 6 receptor; CDCP1: CUB domain-containing protein 1; EphA2: EPH receptor A2; PXN: Paxillin

activation. In prostate and gastric cancer, the efficacy of AKT inhibitors is attenuated by PIM-1 signaling, which upregulates the expression of MET, ERBB2 and other RTKs. Combined AKT and PIM-1 inhibition is synergistic in preclinical models^[16,30]. Similarly, in the activated B cell-like (ABC) subtype of diffuse large B cell lymphoma (DLBCL), the efficacy of the Bruton's tyrosine kinase inhibitor ibrutinib, was attenuated in the presence of PIM-1 mutations. In addition, chronic exposure of an ABC-DLBCL cell line to ibrutinib increased PIM-1 expression, and the combination of ibrutinib with the pan-PIM inhibitor (AZD1208) showed synergistic effects^[24]. Finally, in MET amplified NSCLC and gastric cancer cell lines, PIM-1 was identified as a mechanism of resistance to MET inhibitors. Treatment of MET inhibitor-resistant cells with PIM inhibitors restored sensitivity to MET inhibition, both in culture and in xenograft models^[26].

Several PIM inhibitors have been developed, and can be categorized into first- and next generation inhibitors. AZD1208 falls in the latter category, and inhibits all isoforms of the PIM kinase (1, 2 and 3). AZD1208 has been shown to improve outcome to radiation therapy in castrate-resistant prostate cancer cells^[14]. Moreover, PIM-1 levels were correlated to MET expression in both cell lines and patient-derived tumor samples, driving migration and invasion of cancer cells. Patient-derived tissues from a phase 1 clinical trial (ClinicalTrials.gov Identifier: NCT01489722), exploring the safety, tolerability, pharmacokinetics and efficacy of AZD1208 in acute myeloid leukemia, confirmed the mechanism of action of PIM-1 through MET regulation^[31].

The ability of AZD1208 to induce cell cycle arrest and apoptosis by inhibition of all PIM kinase isoforms indicates its potential as an anticancer treatment. Previous publications have shown that PIM inhibition augments the efficacy of targeted therapies in diverse tumor types. Therefore, dual PIM-1 and EGFR inhibition might modulate cell survival pathways and block progression and growth of cancer cells, by preventing the EGFR TKI-induced STAT3 and RTKs activation in EGFR-mutation positive NSCLC cell lines^[6-8]. This research aims to evaluate whether the pan-PIM inhibitor AZD1208 improves the efficacy of osimertinib in EGFR-mutation positive cell lines.

METHODS

Chemicals and reagents

Human lung adenocarcinoma PC-9 cells, harboring EGFR exon 19 deletion and 11-18 cells, harboring EGFR exon 21 L858R mutation were provided by F. Hoffmann-La Roche Ltd. (Basel, Switzerland), and by Dr. Mayumi Ono, (Kyushu University, Fukuoka, Japan), respectively. EGFR exon 19 deletion positive HCC4006 and HCC827 cells were purchased from the American Type Culture Collection (ATCC). The H1975 cell line, harboring both EGFR exon 21 L858R and resistant T790M mutation as well as the TNBC MBA-MB-231 cell line were purchased from ATCC. All cell lines were maintained in RPMI (Roswell Park Memorial Institute medium) 1640 supplemented with 1% penicillin/streptomycin/glutamine (Gibco) and 10% fetal bovine serum (FBS; Gibco) in a 5% CO₂ 37 °C cell culture incubator and routinely evaluated for mycoplasma contamination.

The pan-PIM inhibitor, AZD1208, and osimertinib were bought from Selleck Chemicals (Houston, TX, USA). Drugs were prepared in dimethylsulfoxide (DMSO) at a concentration of 10-100 mmol/L stock solutions and stored at -20 °C. Further dilutions were made in culture medium to final concentration before use. All antibodies used in our study, including dilution and company catalog number can be found in [Supplementary Table 1](#). All primers used can be found in [Supplementary Table 2](#).

Cell viability assay

Cells were seeded in 96-well plates at the following densities: 1.5×10^3 (PC9), 2.0×10^3 (H1975) 3.0×10^3 (HCC4006, HCC827 and 11-18), and incubated for 24 h, as previously described^[6]. For the combined treatment cells were seeded in 96-well plates at the following densities: 1×10^3 (PC9 and H1975), 1.5×10^3 (HCC827, HCC4006 and 11-18), and incubated for 24 h. Cell viability was assessed using the 3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide (MTT) assay (Sigma Aldrich, St Louis, MO, USA). Cells were treated with serial dilutions of the drugs. For the half maximal inhibitory concentration (IC₅₀) determination, AZD1208 doses ranged from 0-200 µmol/L and treatment lasted 72 h. For the MTT viability assays with a combination of AZD1208 and osimertinib (IC₅₀s were previously obtained) drug doses were as follows: PC9, H1975, HCC4006, HCC827 cells were treated with osimertinib ranging from 0-100 nmol/L, and AZD1208 ranging from 0-100 µmol/L, or with the combination of both. The 11-18 cells were treated with osimertinib ranging from 0-200 nmol/L, and AZD1208 ranging from 0-100 µmol/L, or with the combination of both. The combined treatment lasted 96 h. After treatment incubation, 0.5 mg/mL of MTT reagent was added to the medium in the wells for 2 h at 37 °C and formazan crystals in viable cells were solubilized with 100 µL DMSO and spectrophotometrically quantified using a microplate reader (Varioskan Flash; Thermo Fisher Scientific, Waltham, MA, USA) at 565 nm of absorbance. Fractional survival was then calculated as percentage to control cells. Data of combined drug effects were subsequently analyzed by the Chou and Talalay method^[32,33]. Combination index (CI) values < 1, = 1 and > 1 indicated synergism, additive effect and antagonism, respectively.

Western blotting

For immunoblotting experiments, 1.5 million cells were seeded in T75 flasks (Starstedt, Newton, USA). The next day, PC9 and H1975 cells were treated with 24 nmol/L osimertinib, 5 µmol/L AZD1208 and

a combination of both. Untreated cells received an equivalent dose of vehicle (DMSO). After 24 h cells were washed with cold PBS and re-suspended in ice-cold radioimmunoprecipitation assay buffer (50 mmol/L Tris- hydrochloric acid in pH 7.4, 1% Nonidet P-40, 0.5% sodium deoxycholate, 0.1% sodium dodecyl sulfate (SDS), 150 mmol/L sodium chloride, 1 mmol/L ethylenediaminetetraacetic acid, 1 mmol/L sodium vanadate and 50 mmol/L sodium fluoride) containing protease inhibitor mixture (Roche Applied Science, Penzberg, Germany). Following cell lysis by sonication and centrifugation at $18620 \times g$ for 10 min at 4 °C, the resulting supernatant was collected as the total cell lysate. Briefly, the lysates containing 45 µg proteins were electrophoresed on 10% SDS-polyacrylamide gels (Life Technologies, Carlsbad, CA, USA) and transferred to polyvinylidene difluoride membranes (Bio-Rad laboratories Inc., Hercules, CA, USA). Membranes were blocked in Odyssey blocking buffer (Li-Cor Biosciences, Lincoln, NE, USA). All target proteins were immunoblotted with appropriate primary and horseradish peroxidase (HRP)-conjugated secondary antibodies. Chemiluminescent (HRP-conjugated) bands were detected in a ChemiDoc MP Imaging System (Bio-Rad laboratories Inc.). β -actin was used as an internal control to confirm equal gel loading.

Quantitative real time polymerase chain reaction

RNA was isolated from cell lines using phenol-chloroform-isoamyl alcohol, followed by precipitation with isopropanol in the presence of glycogen and sodium acetate. RNA was re-suspended in water and treated with DNase I to avoid DNA contamination. Complementary DNA (cDNA) was synthesized using moloney murine leukaemia virus reverse transcriptase enzyme. cDNA was added to Taqman Universal Master Mix (Applied Biosystems, Carlsbad, CA, USA) in a 12.5 µL reaction with specific primers and probe for each gene. The primer and probe sets were designed using Primer Express 3.0 Software (Applied Biosystems) according to their Ref Seq (<http://www.ncbi.nlm.nih.gov/LocusLink>). Gene-specific primers are provided in Chemicals and reagents. Quantification of gene expression was performed using the ABI Prism 7900HT Sequence Detection System (Applied Biosystems) and was calculated according to the comparative Ct method. Final results were determined as follows: $2^{-(\Delta C_t \text{ sample} - \Delta C_t \text{ calibrator})}$, where ΔC_t values of the calibrator and sample are determined by subtracting the Ct value of the target gene from the value of the endogenous gene (β -actin). Commercial RNA controls were used as calibrators (Liver and Lung; Stratagene, La Jolla, CA, USA). In all quantitative experiments, a sample was considered not evaluable when the standard deviation of the Ct values was > 0.30 in two independent analyses. As a result, the number of evaluable samples varied among the genes examined.

RESULTS

Baseline mRNA expression of EGFR-mutation positive cells and sensitivity to PIM inhibition

We first evaluated the baseline mRNA expression of *PIM*, *STAT3* and other relevant genes^[8], in our panel of five EGFR-mutation positive NSCLC cell lines. As can be seen in Figure 2A, both PC9 and H1975 cell lines had higher *PIM-1*, *STAT3* and *JAK2* mRNA expression compared to the average gene expression of all five cell lines. Hereafter, cell viability assays were performed and the IC_{50} s of single AZD1208 treatment were determined. The IC_{50} s of osimertinib have been previously calculated and reported^[6]. As expected, none of the cell lines was sensitive to single AZD1208 treatment, with IC_{50} s ranging from 17.1 to 23.0 µmol/L [Figure 2B, left panel], while all of them were sensitive to osimertinib^[6] [Figure 2B, right panel].

Combination of osimertinib plus a PIM inhibitor in EGFR-mutation positive cells

Taking into consideration our previous findings, that osimertinib alone induces the activation of resistant signaling nodes^[6], we then tried to evaluate if AZD1208 increases the effect of osimertinib on cell growth inhibition. Dual treatment revealed moderate synergistic effects, with a CoI between 0.79 and 0.85 [Figure 3A, left panel]. The lowest CoIs and therefore stronger synergism, were seen in the PC9 [CoI of 0.79; 95% confidence interval (CI): 0.66-0.92] and HCC827 (CoI of 0.79; 95%CI: 0.69-0.89) cell lines. A moderate synergism was seen in HCC4006 cells, with a CoI of 0.83 (95%CI: 0.79-0.87). The combination was less

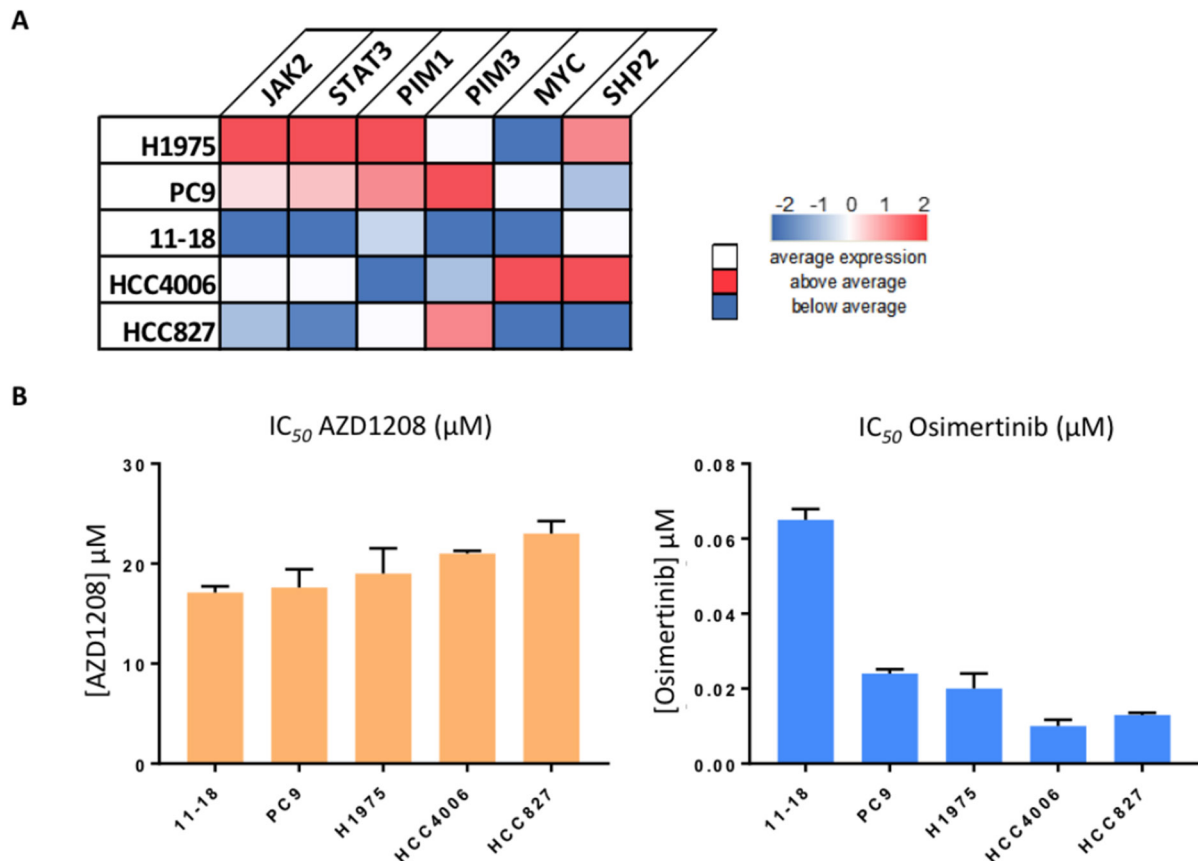

Figure 2. Baseline mRNA expression of EGFR-mutation positive cells and sensitivity to PIM inhibition. A: baseline mRNA expression of various genes in five EGFR-mutation-positive NSCLC cell lines (H1975, PC9, 11-18, HCC4006 and HCC827). Heatmap depicts gene mRNA expression (columns) in the different cell lines (rows) compared to the average mRNA expression of each gene in all cell lines. Experiments were performed in biological triplicates, and the average of these experiments are shown; B: cell viability assays were performed in all cell lines, to explore the effect of AZD1208 *in vitro*, and to determine the IC₅₀ in each cell line. Results of previously performed experiments with osimertinib in the same cell lines are also shown. Experiments were performed in biological triplicates, and the average and standard deviations are shown. EGFR: epidermal growth factor receptor; PIM: proviral integration site for Moloney murine leukemia virus; NSCLC: non-small cell lung cancer; IC₅₀: half maximal inhibitory concentration; JAK2: Janus kinase 2; STAT3: signal transducer and activator of transcription 3; SHP2 (PTPN11): tyrosine-protein phosphatase non-receptor type 11

effective, but still moderately synergistic, in the 11-18 (CoI of 0.85; 95%CI: 0.69-1.00) and H1975 (CoI of 0.85; 95%CI: 0.74-0.96) cell lines [Figure 3A, left panel].

We then tried to see the correlation between signaling nodes and cellular responses after combined treatment with osimertinib plus AZD1208. For this, we selected the PC9 and H1975 cell lines, which distinguished among the rest of the cell lines, having the highest *PIM-1*, *STAT3* and *JAK2* mRNA expression [Figure 2A]. Changes in the protein expression of RTKs, *STAT3* and other proteins after single osimertinib, AZD1208 or combined treatment were studied, using immunoblotting experiments [Figure 3B, right panel]. The results confirmed our previous findings^[6,8], as single osimertinib increased the phosphorylation of CUB-domain-containing protein 1 (CDCP1), YAP1, paxillin and *STAT3* in the PC9 and H1975 cell lines. Osimertinib abrogated or diminished EGFR and ERK phosphorylation, but it had no effect on Src phosphorylation [Figure 3B, right panel]. In contrast, single AZD1208 treatment was unable to inhibit activated EGFR and ERK, but in comparison with osimertinib, it induced at a much lower level the phosphorylation of CDCP1, YAP1, *STAT3* and paxillin. The combination of osimertinib plus AZD1208, abolished EGFR and ERK activation in both cell lines, but paradoxically, was unable to reverse - or even increased - the osimertinib-induced CDCP1 and YAP1 phosphorylation. To our positive surprise, the double

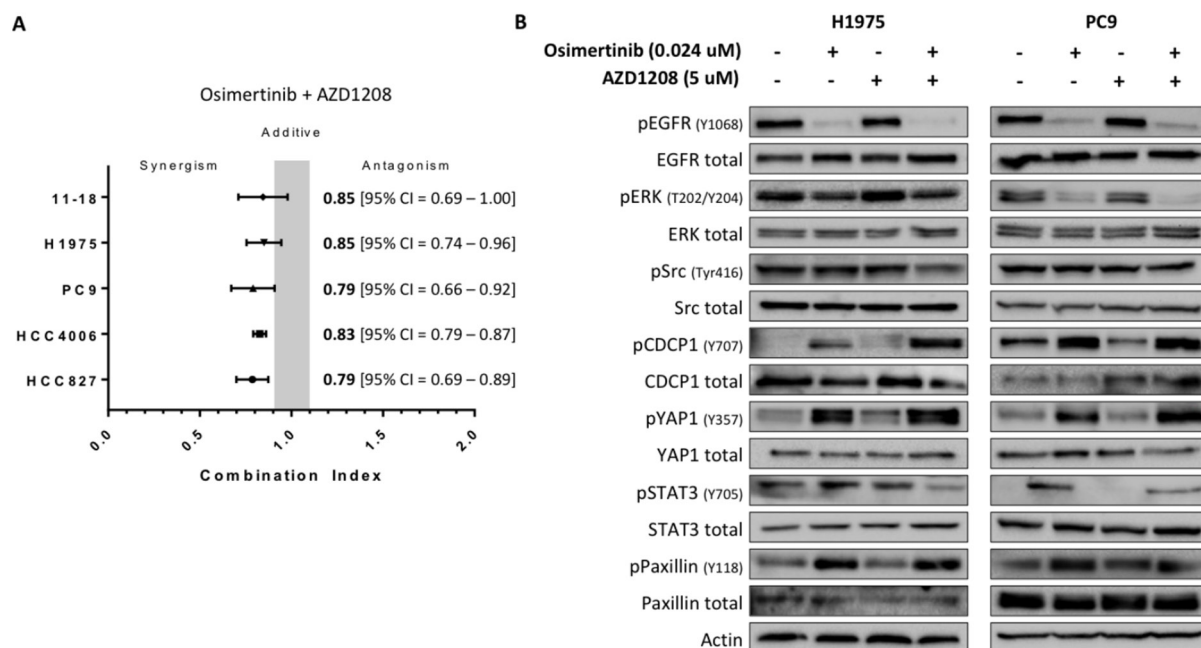

Figure 3. The effects of AZD1208 and osimertinib on RTKs and downstream components in EGFR-mutation positive NSCLC cells. A: in all cell lines, cell viability assays were performed to explore the effect of combined osimertinib and AZD1208 treatment. The obtained Col was calculated based on the Chou and Talalay method, and values < 1, = 1 and > 1 indicate synergism, additive effect and antagonism, respectively. Experiments were performed in biological triplicates, and the average and standard deviations plus 95% CIs are shown; B: two EGFR-mutation positive NSCLC cell lines (H1975 and PC9) were treated with single osimertinib (0.024 μmol/L), single AZD1208 (5 μmol/L) or with the combination. Untreated cells received an equivalent dose of vehicle (DMSO). Cell lysates were used for immunoblotting and changes in RTKs and non-RTKs upon the different treatments were investigated in the two cell lines. Experiments were performed in biological triplicates with similar results, and a representative blot is shown. RTK: receptor tyrosine kinase; EGFR: epidermal growth factor receptor; NSCLC: non-small cell lung cancer; Col: combination index; 95%CI: 95% confidence interval; DMSO: dimethylsulfoxide; CDCP1: CUB domain -containing protein 1; YAP1: yes-associated protein 1; STAT3: signal transducer and activator of transcription 3

combination reversed the osimertinib-induced STAT3 phosphorylation in both cell lines, and diminished paxillin and Src phosphorylation in PC9 and H1975 cells, respectively [Figure 3B, right panel]. Overall these data reconfirm our previous findings that, even in oncogene addicted EGFR-mutation positive cancer cells, single EGFR TKIs are insufficient^[6-8,34]. Concomitant PIM-1 inhibition may reverse some of the deleterious effects of osimertinib on the activation of oncogenic signaling pathways.

DISCUSSION

Herein, we have reviewed the available literature on PIM and we have found that this kinase is involved in multiple tumor types, including lung cancer^[26]. The survival of lung cancer patients has been improved in the last decade due to the availability of new and more effective targeted therapies. EGFR-mutation positive patients are treated with EGFR TKIs, and the last years we have seen the development and approval of three generations of these agents^[35]. However, ultimately resistance mechanisms take over and treatment options are not indefinite. Furthermore, about 20% of EGFR-mutation positive patients have intrinsic resistance to EGFR TKIs^[8,34], indicating that molecularly targeted therapy is not a one-size-fits-all approach. Therefore, defining biomarkers of resistance and designing a truly personalized therapy is of great relevance. We have previously seen, and we confirm in the present work, that EGFR TKIs, including osimertinib, induce STAT3 and Src-YAP1 activation^[6-8]. Rational double or triple combinations prevented this phenomenon and increased the efficacy of EGFR TKI monotherapy in EGFR-mutation positive models^[6-8]. Since PIM was shown to be a key player in IL-6/STAT3 signaling^[14,18,21,28,29], we hypothesized that by combining the PIM inhibitor, AZD1208 with osimertinib we may obtain similar results^[6-8].

Figure 4. Obtained model of EGFR-mutation positive NSCLC tumor cells, after dual EGFR- (osimertinib) and PIM- (AZD1208) inhibition. Upon osimertinib treatment, the downstream PI3K/AKT and RAS/MAPK pathways - in light grey - are inhibited, lowering cell proliferation and survival. However, AZD1208 treatment now blocks both the activation of PIM and the activation of the JAK/STAT3 pathway. This leads to moderate synergistic effects *in vitro*. However, the Src-YAP1 pathway is still activated (PC9) or only slightly inhibited (H1975), and can therefore compensate for the blockade induced by osimertinib and AZD1208. EGFR: epidermal growth factor receptor; NSCLC: non-small cell lung cancer; PIM: proviral integration site for Moloney murine leukemia virus; PI3K: phosphatidylinositol 3-kinase; MAPK: mitogen-activated protein kinase; JAK2: Janus kinase 2; STAT3: signal transducer and activator of transcription 3; YAP1: Yes-associated protein 1; CDCP1: CUB domain-containing protein 1; IL-6R: Interleukin 6 receptor; PXN: Paxillin

As expected, single AZD1208 was not effective, but the combination of AZD1208 and osimertinib augmented the effect of each drug alone on cell viability in a moderate synergistic manner, in five EGFR-mutation positive cell lines. This synergistic effect is probably due to the AZD1208-based inhibition of resistance pathways. Our model, in Figure 4, indicates that combined EGFR and PIM inhibition does not prevent the activation of all relevant resistance signaling nodes, but it is able to decrease STAT3 phosphorylation. Since currently there are no approved STAT3 inhibitors in clinical use, PIM inhibition merits further investigation in lung cancer as well as other tumor types. AZD1208 is not in clinical development any more^[22] and we plan to extend the current work using the pan-PIM inhibitor LGH447 (PIM447). LGH447 has single agent activity, and blocks resistance pathways when combined with standard of care treatments^[22,36-38]. The agent is currently being tested in a phase I/II clinical trial (ClinicalTrials.gov Identifier, NCT01456689) for relapsed/refractory multiple myeloma, and safety and efficacy results are awaited.

DECLARATIONS

Authors' contributions

Made substantial contributions to conception and design of the study and performed data analysis and interpretation: Bracht JWP, Karachaliou N, Rosell R

Performed data acquisition, as well as provided administrative, technical, and material support: Bracht JWP, Karachaliou N, Berenguer J, Fernandez-Bruno M, Filipiska M, Pedraz-Valdunciel C, Codony-Servat C, Codony-Servat J, Rosell R

Abstract

Cancer is a systemic disease. In order to fully understand it, we must take a holistic view on how cancer interacts with its host. The brain monitors and responds to natural and aberrant signals arriving from the periphery, particularly those of metabolic or immune origin. As has been well described, a hallmark of cancer is marked disruption of metabolic and inflammatory processes. Depending on the salience and timing of these inputs, the brain responds via neural and humoral routes to alter whole-body physiology. These responses have consequences for tumor growth and metastasis, directly influencing patient quality of life and subsequent mortality. Additionally, environmental inputs such as light, diet, and stress, can promote inappropriate neural activity that benefits cancer. Here, I discuss evidence for brain-tumor interactions, with special emphasis on subcortical neuromodulator neural populations, and potential ways of harnessing this cross-talk as a novel approach for cancer treatment.

Keywords: Breast cancer, hypothalamus, immunometabolism, sympathetic nervous system, neuromodulators

INTRODUCTION

Uncovering the relationships among cancer and the physiology of its host has cemented the notion that cancer is a systemic disease. Cancer patients frequently experience systemic symptoms like depression, sleep disruption, cognitive impairment, appetite and metabolic dysfunction, and weight loss. These phenomena span different cancer types and occur independently from treatment regimens. Clinical studies consistently report that such symptoms (such as weight loss, sleep disruption, and circadian misalignment) are predictors

Figure 1. A simplified schematic of reciprocal tumor-host interactions. Tumors promote aberrant physiology via alterations to the immune system and secretion of metabolic “waste” which contributes to further inflammation and altered function of distal organs, including the brain. Feedback from the brain (neural or humoral) can subsequently exacerbate tumor-associated immune and metabolic changes, ultimately facilitating tumor growth, angiogenesis, metastasis, or cancer-associated co-morbidities

of poor prognoses and reduced quality of life^[1-5]. Tumors are capable of altering local macronutrient contents that modulate infiltrating immune cell function resulting in aberrant inflammation. Additionally, they secrete metabolic “waste”, which can promote inflammation and alter the function of distal organs and tissues such as the liver and brain^[6-10]. As evidence accumulates, we are learning that many of these cancer-associated co-morbidities are (at least in part) due to deregulation of normal brain function by the cancer itself, cancer treatment(s), or other factors.

Reciprocally, the host system can influence tumor growth and metastasis via immune, endocrine, and neural pathways. For example, chronic stress, which results in dysregulation of glucocorticoid and adrenergic signaling, exacerbates tumor growth and angiogenesis^[11,12]. Additionally, chronic sleep fragmentation, resulting in top-down impairments to the immune system, further promotes tumor growth^[13]. The objective of this review is to provide an up-to-date overview of cancer as a systemic disease from a basic science perspective [Figure 1]. Special focus will be given to subcortical neural populations that are sensitive to signals arriving from peripheral tissues and the environment, as well as those that send long-range projections to modulate immune or metabolic function, ultimately facilitating cancer growth and/or metastasis. Through understanding these brain-tumor interactions, potential undescribed drug or lifestyle targets will be uncovered. Additionally, these studies would open up space for existing therapies to be repurposed for effective cancer treatment (as is the case with the anti-obesity drug Metformin^[14,15]).

NEURAL CIRCUITRY DEREGULATED IN CANCER

Sleep disruption

Disruption of sleep and/or circadian rhythms in physiology and behavior are frequently observed in cancer patients. Indeed, 35%-80% of cancer patients report poor sleep quality^[16,17], as compared to 29%-32% of the general population^[18] [Table 1]. These problems may stem from the cancer itself, the stress or stigma

Table 1. Non-exhaustive list of clinical observations of systemic co-morbidities potentially influencing brain function (sleep disturbance, circadian rhythm disruption, cognitive impairment, metabolic abnormalities, microbial dysbiosis, and systemic inflammation) in patients with cancer

Systemic problem	Patient population	Methods	Primary observation	Ref.
Sleep disturbance	823 patients with cancer receiving chemotherapy	Post-hoc analysis of data from a large randomized clinical trial; Hamilton Depression Inventory used to assess sleep disturbance	36.6% ($n = 301$) of the patients with cancer reported insomnia symptoms, and 43% ($n = 362$) met the diagnostic criteria for insomnia syndrome; breast cancer had the highest number of overall insomnia complaints	[120]
	85 women with Stages I-IIIa breast cancer	actigraphy for 72 consecutive hours and filled out questionnaires (PSQI, MFSI-SF, FOSQ, FACT-B, and CES-D) on sleep, fatigue, depression, and functional outcome	women slept for ~6 h a night and napped > 1 h during the day. Sleep was disturbed and fatigue levels were high; phase-delayed circadian rhythms	[121]
	97 women with advanced breast cancer (age = 54.6 ± 9.8 years)	72 h actigraphy; sleep efficiency was determined as the ratio of total sleep time to total sleep time plus wake after sleep onset	Sleep efficiency predicted reduction in overall mortality [hazard ratio (HR), 0.96; 95% confidence interval (CI), 0.94-0.98; $P < 0.001$] at median 6 y follow-up. Remained significant (HR, 0.94; 95%CI, 0.91-0.97; $P < 0.001$) after adjusting for age, estrogen receptor status, cancer treatment, metastatic spread, cortisol levels, and depression	[3]
	40 patients (50 years, SD = 11; 53% White, 28% Asian, 19% Other) with primary breast cancer (18% Stage I, 50% Stage II, 33% Stage III) undergoing chemotherapy	Neurocognitive battery of tests including PSQI, ISI, BFI, CAD, COWAT, HVLT; actigraphy for 7 consecutive days to track arousal/sleep	Better circadian function was associated with less sleep disruption (PSQI, $r = -0.44$, $P = 0.005$) and less insomnia (ISI, $r = -0.42$, $P = 0.008$). Both subjective sleep alteration and circadian disruption were associated with levels of fatigue (BFI, all P -values < 0.05) and sleep disruption measures were strongly associated with depression and anxiety (ISI: $r = 0.51$, $P = 0.001$; PSQI: $r = 0.43$, $P = 0.005$)	[122]
Circadian rhythm disruption	389 Caucasian cases and 432 Caucasian controls	Investigated the association between an exonic length variation in a circadian gene, Period3 (Per3), and breast cancer risk using blood samples collected from a recently completed breast cancer case-control study in Connecticut	<i>Per3</i> genotype (heterozygous + homozygous 5-repeat alleles) was associated with an increased risk of breast cancer among premenopausal women (odds ratio, 1.7; 95%CI, 1.0-3.0)	[123]
	57 presurgical breast cancer patients	Daily self-reports of cancer-specific distress and avoidant coping as well as actigraphic and salivary cortisol data	Distress and avoidant coping were related to rest/activity rhythm disruption (daytime sedentariness, inconsistent rhythms). Patients with disrupted rest/activity cycles had flattened diurnal cortisol rhythms	[124]
	104 patients with metastatic breast cancer	Salivary cortisol levels assessed at study entry at 800, 1200, 1700, and 2100 hours on each of 3 consecutive days; NK cells measured using flow cytometry, activity by chromium release assay	Cortisol slope predicted survival up to 7 years later. Earlier mortality occurred among patients with relatively "flat" rhythms, indicating a lack of normal diurnal variation (Cox proportional hazards, $P = 0.0036$); associated with low counts and suppressed activity of NK cells	[4]
	43 breast cancer patients	Actigraphy, cancer-specific distress (IES, POMS), saliva samples for assessment of diurnal cortisol rhythm, cortisol awakening response (CAR), and diurnal mean. Ten potential markers of tumor progression were quantified in serum and grouped by exploratory factor analysis	Poor circadian coordination as measured by rest-activity rhythms had higher factor 1 (MMP9, TGF-beta, VEGF) scores ($R^2 = 0.160$, $P = 0.038$). Patients with elevated CAR also had higher Factor 1 scores ($R^2 = 0.293$, $P = 0.020$). These relationships appeared to be driven largely by VEGF concentrations	[2]

Cognitive Impairment	321 patients admitted to the Edmonton General Palliative Care Unit over a period of 26 months	Mini-Mental State Examination (MMSE) was used as screening tool to assess cognitive functioning and was performed on all patients at the time of admission and once to twice weekly thereafter	142 pts (44%) had abnormal MMSE scores (MMSE < 0.8) on admission, whereas 176 patients (55%) had abnormal MMSE scores at the time of death or discharge; 157 (68%) had abnormal MMSE scores prior to death; Of 124 patients with normal final MMSE scores, 64 (52%) were discharged versus 16 of 116 patients (14%) who had abnormal MMSE final scores ($P < 0.0001$)	[125]
	Meta-analysis of 23 studies on cognitive impairment in cancer patients	Articles published 1980-2012, comparing subjective and objective cognition in cancer patients treated with chemotherapy. Of 818 potentially relevant articles, 23 studies met the inclusion criteria for the current review and one article was sourced from reference lists of included studies	8/24 included studies found a significant relationship between objective and subjective measures of cognitive performance. These studies were more likely to involve breast cancer patients and to assess the relationship between memory and perceived cognitive impairment	[126]
	22 breast cancer survivors who reported cognitive impairment and who were at least 1 year post-chemotherapy treatment	Qualitative interviews, recorded, transcribed verbatim, and analyzed using a content analysis approach	6 major domains identified: short-term memory, long-term memory, speed of processing, attention and concentration, language and executive functioning; All survivors found these impairments frustrating, and some also reported these changes as detrimental to their self-confidence and social relationships	[127]
	85 women with early stage breast cancer scheduled for chemotherapy, 43 women scheduled for endocrine therapy and/or radiotherapy and 49 healthy control subjects	3-year prospective study; neuropsychological performance assessed at baseline (T1), post-chemotherapy (or 6 months) (T2) and at 18 months (T3)	No significant interactions or main effect of group after controlling for age and intelligence; reliable decline on multiple tasks was seen in 20% of chemotherapy patients, 26% of nonchemotherapy patients and 18% of controls at T2 (18%, 14 and 11%, respectively, at T3). Those who experienced treatment-induced menopause were more likely to show decline on multiple measures at T2 (OR = 2.6, 95%CI 0.823-8.266 $P = 0.086$)	[128]
Metabolic Abnormalities	265 patients with advanced breast cancer receiving palliative chemotherapy	Retrospective study; mortality was compared for diabetic and nondiabetic patients as well as for patients that presented hyperglycemia during treatment	Overall survival was greater in diabetic patients with proper metabolic control than diabetic patients with hyperglycemia. The risk of death was higher in patients with mean glucose levels > 130 mg/dL during treatment	[129]
	Meta-analysis of 20 studies (5 case-control and 15 cohort studies) that reported relative risk (RR) estimates (odds ratio, rate ratio/hazard ratio, or standardized incidence ratio) with 95%CI for the relation between diabetes (largely Type II diabetes) and breast cancer incidence	RRs were calculated using a random-effects model	All 20 studies showed that women with (vs. without) diabetes had a statistically significant 20% increased risk of breast cancer (RR, 1.20; 95%CI, 1.12-1.28). The summary estimates were similar for case-control studies (RR, 1.18; 95%CI, 1.05-1.32) and cohort studies (RR, 1.20; 95%CI, 1.11-1.30)	[130]
	Pooled individual-level data from 758,592 premenopausal women from 19 prospective cohorts	Hazard ratios (HRs) of premenopausal breast cancer in association with BMI from ages 18 through 54 years using Cox proportional hazards regression analysis. Median follow-up; 9.3 years (interquartile range, 4.9-13.5 years) per participant, with 13,082 incident cases of breast cancer	Inverse linear associations of BMI with breast cancer risk were found that were stronger for BMI at ages 18 to 24 years (HR per 5 kg/m ² [5.0-U] difference, 0.77; 95%CI, 0.73-0.80) than for BMI at ages 45 to 54 years (HR per 5.0-U difference, 0.88; 95%CI, 0.86-0.91). 4.2-fold risk gradient between the highest and lowest BMI categories (BMI ≥ 35.0 vs. < 17.0) at ages 18 to 24 years (HR, 0.24; 95%CI, 0.14-0.40)	[131]
	10,786 women ages 35-69 were recruited in a prospective study in Italy; Four matched controls were chosen for each breast cancer case ($n = 144$)	Blood samples were collected after a 12-h fast between 7:30 and 9:00 a.m.	Adjusted relative risk (RR) for the highest quartile of serum glucose vs. the lowest was 2.8 (95%CI, 1.2-6.5), and P for trend was 0.02. Insulin showed a weaker association with breast cancer, the adjusted RR of the highest quartile vs. the lowest was 1.7 (95%CI, 0.7-4.1), and P for trend was 0.14, whereas the adjusted RR of the highest quartile of IGF-I was 3.1 (95%CI, 1.1-8.6), and P for trend was 0.01	[132]

Microbial Dysbiosis	Breast tumor tissue and paired normal adjacent tissue from the same patient	Qualitative survey of breast microbiota DNA	Bacterium <i>Methylobacterium radiotolerans</i> is relatively enriched in tumor tissue, while the bacterium <i>Sphingomonas yanoikuyae</i> is relatively enriched in paired normal tissue. The relative abundances of these two bacterial species were inversely correlated in paired normal breast tissue but not in tumor tissue, indicating that dysbiosis is associated with breast cancer	[133]
	48 postmenopausal breast cancer case patients, pretreatment, vs. 48 control patients	Microbiota profiles in fecal DNA were determined by Illumina sequencing and taxonomy of 16S rRNA genes. Estrogens were quantified in urine; linear and unconditional logistic regression of microbiota α -diversity (PD_ whole tree) and UniFrac analysis of β -diversity	Estrogens correlated with α -diversity in control patients (Spearman Rho = 0.37, P = 0.009) but not case patients (Spearman Rho = 0.04, P = 0.77). Compared with control patients, case patients had statistically significantly altered microbiota composition (β -diversity, P = 0.006) and lower α -diversity (P = 0.004). Adjusted for estrogens and other covariates, odds ratio of cancer was 0.50 (95%CI, 0.30-0.85) per α -diversity tertile	[134]
	31 patients with early-stage breast cancer	Bacterial DNA was extracted from the feces; qPCR amplified, targeting 16S rRNA sequences specific to bacterial groups, and then analyzed in relation to clinical characteristics	Absolute numbers of total bacteria and three bacterial groups (<i>Firmicutes</i> , <i>Faecalibacterium prausnitzii</i> , and <i>Blautia</i>) differed significantly according to the patient's body mass index. <i>C. coccoides</i> , <i>F. prausnitzii</i> , and <i>Blautia</i> , differed significantly according to the clinical stages and the histoprognostic grades	[135]
	Eighteen patients with breast cancer (BC), 18 with uterine leiomyoma (UL), and 30 healthy women	Feces were collected on 1st admission and processed immediately; qualitative and quantitative analysis of fecal flora	Premenopausal BC patients showed increased Enterobacteriaceae (<i>E. coli</i> , log 9.7 \pm 2.1, P < 0.001); aerobic streptococci (log 7.8 \pm 2.0) and lactobacilli (log 8.0 \pm 2.8). Anaerobic bacteria were increased (P < 0.001) for clostridia (log 9 \pm 1.7), bacteroides (log 7.2 \pm 3.1), and anaerobic lactobacilli (9.1 \pm 2.5). Similar changes in menopausal samples	[136]
Systemic Inflammation	Data from the Health, Eating, Activity, and Lifestyle (HEAL) Study (a multiethnic prospective cohort study of women diagnosed with stage 0 to IIIA breast cancer) (734 total survivors)	Concentrations of CRP and SAA were measured approximately 31 months after diagnosis and tested for associations with disease-free survival (approximately 4.1 years of follow-up) and overall survival (approximately 6.9 years of follow-up)	Elevated SAA and CRP were associated with reduced overall survival, regardless of adjustment for age, tumor stage, race, and body mass index (SAA P trend < 0.0001; CRP P trend = 0.002). The HRs for SAA and CRP tertiles suggested a threshold effect on survival, rather than a dose-response relationship (highest vs. lowest tertile: SAA HR = 3.15; 95%CI, 1.73-5.65; CRP HR = 2.27; 95%CI, 1.27-4.08)	[137]
	96 patients with metastatic breast cancer. During follow-up 51 patients died of their cancer	Evaluated the value of an inflammation-based score (Glasgow Prognostic Score, GPS) in patients with metastatic breast cancer (scored on 0-2 scale)	Multivariate analysis of the GPS and treatment received, only the GPS (HR 2.26, 95%CI 1.45-3.52, P < 0.001) remained significantly associated with cancer-specific survival	[138]
	Colorectal (n = 182), gastric (n = 87), breast (n = 99), or bronchogenic (n = 404) cancer patients, who had measurements of C-reactive protein and albumin	Median survival, univariate/multivariate analyses of correlations between inflammatory markers and survival	Association between duration of survival and both log ₁₀ C-reactive protein and albumin concentrations (P < 0.0002). log ₁₀ C-reactive protein was an independent predictor of survival (P < 0.0002). When all patients were analyzed (n = 772), the hazard ratio for a 10-fold increase in C-reactive protein concentration in cancer-specific survival was 2.21 (95%CI = 1.92-2.56, P < 0.0001)	[139]
	Cross-sectional and retrospective studies. CS included 100 women undergoing mastectomy for breast cancer risk reduction (n = 10) or treatment (n = 90). Retro study was 127 women who developed metastatic breast cancer	Metabolic syndrome-associated circulating factors were compared by CLS-B status. The association between CLS of the breast and the metabolic syndrome was validated; Distant recurrence-free survival (dRFS) was compared by CLS-B status	Pts with WAT inflammation had elevated insulin, glucose, leptin, triglycerides, C-reactive protein, and IL6 and lower high-density lipoprotein cholesterol and adiponectin (P < 0.05); Compared with patients without breast WAT inflammation, the adjusted HR for dRFS was 1.83 (95%CI, 1.07-3.13) for patients with inflammation	[140]

surrounding a cancer diagnosis, different treatment regimens (e.g., chemotherapy, immunotherapy and/or radiotherapy), or additional lifestyle factors^[19]. These problems are prevalent across a variety of cancer types, with lung and breast cancer patients making up the majority of the population experiencing these symptoms^[2,20-22]. A “chicken-or-the-egg” phenomenon has emerged: poor sleep associates with elevated cancer incidence and progression, and cancer and/or cancer treatments further promote sleep disturbance^[2,3,6,23]. Due to the heterogeneity among cancer types, patient populations, treatment regimens, and lifestyle factors, it has been challenging to pin down cause and effect. This lack of knowledge prevents targeted therapies from being developed and impairs quality of life and lifespan in cancer survivors. For example, sleep disruption is associated with increased mortality in breast cancer independent of other factors like estrogen receptor status, depression, anxiety, and socioeconomic status^[3].

The hypothalamus is a critical structure for maintaining homeostasis^[24,25]. Although beyond the scope of this review, a brief discussion of its relevant circuitry is warranted to put the rest of our discussion in context. Its functions include the regulation of sleep-wake cycles, circadian rhythms, body temperature, feeding/metabolism, the stress response, and reproduction, among others. Many of these are linked to either the promotion of cancer development or its progression (as I discuss in subsequent sections). The lateral hypothalamus (LH) is a highly heterogeneous structure that serves a primary role in arousal, metabolism, and motivated behavior^[24]. A neural population that has been intensely studied in this area are those that express the excitatory neuromodulators hypocretin-1 and hypocretin-2 (aka orexin-A and -B; HO)^[26,27]. Discovered by two groups at essentially the same time^[28,29], these neurons are critical for maintaining wakefulness, as their destruction results in the sleep disorder narcolepsy^[30-33].

HO neurons project throughout the brain to participate in functions ranging from arousal and motivation, to anxiety and reproductive behavior^[27]. Importantly, they also send long range projections that modulate sympathetic outflow from the brain^[34]. Indeed, disinhibition of HO neurons in the LH can directly influence hepatic gluconeogenesis, promoting *de novo* glucose production upon stimulation^[35]. Reciprocally, HO neurons are sensitive to metabolic signals arriving from the periphery. These include hormones and other messages important in cancer regulation, including leptin, ghrelin, glucose, dietary amino acids, and changes in extracellular pH and CO₂ concentrations^[27]. Stimulation of HO neurons further activates the hypothalamic-pituitary-adrenal (HPA) axis, resulting in rapid increases in circulating glucocorticoid concentrations^[36]. Aberrant glucocorticoid rhythms are highly prevalent in breast cancer patients^[4], and their actions on the immune system may influence patient prognosis (discussed below).

Leptin, an adipokine hormone that correlates with satiety and body fat accumulation, generally inhibits HO neurons through direct and indirect pathways^[36-38]. Specifically, intermingled neurons expressing the long-form leptin receptor (LepRb) provide direct inhibitory input to HO neurons. Overexpression of leptin or its cognate receptor (Ob-R) in mammary tumors and nearby normal epithelial cells is associated with progressive and metastatic breast cancer^[39,40]. In this way, leptin overexpression may be relevant to fatigue and sleep disruption in cancer patients, through its inhibitory actions on HO neurons. Ghrelin, an orexigenic hormone produced primarily in the stomach^[41-43] has an excitatory effect on HO neurons, and inhibition of HO neural activity can prevent ghrelin-induced feeding behavior^[44,45]. Ghrelin or the activity of its catalytic enzyme ghrelin-O-acyl-transferase is frequently deregulated in cancer^[46-48], where it associates with cancer-induced cachexia. The role these and other metabolic factors play in cancer and cancer-related co-morbidities is coming into focus as the research community begins to examine them in addition to long-standing candidates from the immune system such as cytokines [e.g., interleukin (IL)-1 β , IL-6, TNF- α] and chemokines (e.g., CCL2, CXCL12).

Indeed, brain-tumor-metabolic interactions were recently tested in a mouse model of non-metastatic breast cancer^[6]. Borniger, Walker and colleagues examined sleep and whole-body metabolic changes during the

Figure 2. Highlighted pathways linking the brain and periphery in the context of cancer. Environmental (e.g., light, stress) or endogenous signals reach the brain to alter the activity of neurons involved in sleep (LHA hypocretin/orexin), circadian rhythms (SCN-GABA), reward (VTA-Dopamine), metabolism, and energy balance (Parabrachial CGRP). Aberrant activity of these cells promotes signaling in the periphery that ultimately facilitates tumor growth, angiogenesis, and invasiveness. Systems highlighted are bolded in Table 2. LHA: lateral hypothalamic area; SCN: suprachiasmatic nucleus; GABA: gamma amino butyric acid; VTA: ventral tegmental area; PBN: parabrachial nucleus; CGRP: calcitonin gene related peptide; MDSCs: myeloid derived suppressor cells; SNS: sympathetic nervous system; AgRP: agouti related peptide

course of tumor progression. They observed marked peripheral inflammation driven by the cytokine IL-6. This was associated with a shift towards hepatic gluconeogenesis over glycolysis in tandem with disrupted sleep [Figure 2]. Additionally, tumor-bearing mice had reduced circulating leptin concentrations and were hypersensitive to the orexigenic hormone ghrelin. As HO neurons are sensitive to these peripheral metabolic signals, and they are powerful regulators of wakefulness, the authors examined whether their activity was modulated by tumor growth. They noted that tumors promoted aberrant activity within HO neurons, and inhibition of their signaling (via administration of a dual HO receptor antagonist) attenuated both metabolic and sleep problems. The authors reasoned that in order for HO neurons to influence peripheral glucose metabolism, a signal must reach the liver from the brain. A potential pathway through which this could occur is the sympathetic nervous system (SNS)^[35]. Ablating the SNS with administration of 6-hydroxydopamine (6-OHDA) rescued tumor-induced metabolic deficits, supporting the idea that HO neurons modulate peripheral glucose concentrations via downstream SNS activation^[6]. Significantly more research is required to unravel the complex signaling network linking tumors in the periphery to changes in the activity of this critical neural population. However, these findings suggest that repurposing drugs targeting this system [e.g., Suvorexant (Belsomra®)] may be a novel strategy for improving sleep and metabolic health in patients with cancer.

In two mouse models of lung cancer (LLC and TC1), Hakim *et al.*^[13] demonstrated that chronic sleep fragmentation promoted tumor growth, a phenotype that was abolished in mice lacking the endotoxin receptor TLR4. TLR4 is part of a family of pattern recognition receptors that powerfully engage the innate immune system upon ligand binding. Surprisingly, the effect of sleep fragmentation on tumor progression was maintained in mice lacking TLR4 effector molecules MyD88 or TRIF, although the effect was reduced. This was the first study to causally link disrupted sleep, tumor progression, and immune deregulation. Although this approach lacks cell-type specific investigations into neural populations influenced by the sleep fragmentation protocol, it suggests one or more neural populations sensitive to this manipulation may be responsible for top-down changes to the immune system that biases the host environment to one that favors tumor growth. Recently, McAlpine *et al.*^[49] demonstrated one such pathway, where sleep disruption decreased the number of HO-expressing neurons. This led to aberrant regulation of pre-neutrophils in the bone marrow, which were found to express HO receptor 1. This change in activity promoted egress of myeloid lineage cells, which then contributed to the development of atherosclerosis. I speculate that a similar phenomenon occurs in the context of cancer^[49]. The studies discussed in this section highlight the bidirectional pathway between

sleep and cancer, where disrupted arousal influences cancer growth and aberrant neoplasia reciprocally promotes changes in sleep.

Circadian deregulation

The paired suprachiasmatic nuclei (SCN) are the primary structures responsible for setting circadian rhythms in physiology and behavior that we observe across most of the phylogenetic tree^[50-53]. The SCN receive photic input from specialized retinal ganglion cells that serve a minimal role in vision. These cells express a photosensitive protein, melanopsin, allowing them to directly sense light, and are therefore named “intrinsically photosensitive retinal ganglion cells” (ipRGCs)^[54,55]. ipRGCs transduce photic input into a neurochemical one, with axons traversing the retino-hypothalamic tract and terminating in the suprachiasmatic nucleus. Here, glutamate-mediated synaptic transmission results in downstream cyclic adenosine monophosphate (cAMP) accumulation and cAMP response element binding (CREB) phosphorylation. Phosphorylation of CREB results in it binding the promoters of the core clock genes *per* and *cry*. In a transcription-translation loop, the protein products homo or heterodimerize (e.g., PER::CRY dimers), enter the nucleus, and suppress the transcription of the positive arms of the circadian clock, the genes *arntl1* (*bmal1*) and *clock*.

This process takes approximately 24 h to complete, where light-induced gene transcription has a phase-modulatory effect on the clock. This feedback loop operates in a cell-autonomous manner throughout the body, with peripheral clocks “set” via neural and humoral routes originating from the SCN^[56,57]. Behavioral and physiological outputs controlled by the clock include sleep-wake cycles, appetite and food intake, mating and reproductive behavior, rhythms in immune function and glucocorticoid secretion, and stress responses, among others.

Chronic circadian disruption (e.g., via aberrant light exposure, genetic manipulations, or phase shifting) is repeatedly associated with spontaneous cancer occurrence in humans and multiple rodent models spanning a variety of cancer types^[2,4,21,58,59]. For example, chronic circadian disruption via repeated inversions of the light-dark cycle promotes spontaneous tumor development in a mouse model of breast cancer mimicking Li-Fraumeni syndrome^[60]. This paradigm is known to cause significant disruption of the circadian clock as well as the sleep-wake cycle. Using a transgenic approach to specifically knockdown the tumor-suppressor p53 in mammary epithelial cells (*WAP-Cre::p53^{fl/fl}*), van Dyke and colleagues demonstrated that mice undergoing the inversion protocol developed mammary tumors ~8 weeks sooner (median; 17% sooner) than their control counterparts. This was accompanied by increased body mass gain in mice experiencing circadian disruption, as well as gross increases in sleep throughout the experiment. This was the first study to demonstrate a causal role for light-induced circadian disruption in the acceleration of spontaneous breast cancer development.

In a similar study, Papagiannakopoulos and colleagues investigated the effects of environmental and genetic circadian disruption on lung tumorigenesis^[61]. Using a cre-inducible model of lung cancer [*K-ras^{LSL-G12D/+};p53^{fllox/fllox}* (*KP*) mice], the authors subjected the mice to a jet-lag circadian disruption schedule and examined tumor growth, metabolism, and proliferative capacity. Chronic jet-lag accelerated tumor growth, severity, and mortality upon cre-mediated recombination. A similar phenotype was uncovered when manipulations consisted of knocking out core clock genes (*Per2* or *Bmal1* (*Arntl1*)) in animals that develop spontaneous cancer (*Kras^{LA2/+}* mice). Tumor cells deficient in *per2* were also more proliferative in culture, and mouse embryonic fibroblasts lacking *kras* and *per2* were more sensitive to cellular transformation than their *Per2*-intact counterparts. As energy balance is powerfully regulated by circadian rhythms, they investigated cellular metabolic pathways in *Per2* deficient cells. Indeed, cells lacking this core clock gene showed a marked increase in the excretion of core energy substrates lactate, glucose, and glutamine, indicating a systemic effect of circadian disruption. Using isotope labeled glucose (U-13Cglucose) and carbon 4 (M4) labeling they demonstrated that cells with disrupted circadian clocks increased the amount of glucose loaded into the tricarboxylic acid cycle, a finding that agreed with prior reports^[62]. Finally, they investigated whether clock

gene abnormalities were found in primary patient tumors and noted that all genes (except for *clock*) were down-regulated in lung cancer samples.

In a reciprocal set of experiments to those discussed above, Masri & colleagues investigated how tumors themselves disrupt host circadian rhythms, independent of the outside environment^[10]. In a mouse model of lung adenocarcinoma, they demonstrated that tumors dysregulated the circadian expression of genes controlling immunity and metabolism in a distal organ, the liver, without affecting core components of the circadian clock. This was subsequently confirmed in an additional model of non-metastatic breast cancer, as discussed above^[6]. These changes were hypothesized to be due (in part) to tumor-induced IL-6 signaling interfering with insulin-dependent glucose uptake via a SOCS3-regulated mechanism. Experiments like those discussed above highlight the bidirectional cross-talk among the circadian system (ultimately controlled by the brain), tumors, and the host. These findings suggest that novel approaches for cancer treatment lie in the normalization of circadian rhythms via light, nutrition, or clock phase or amplitude-modulating compounds. Indeed, a flavonoid found in citrus peel, nobiletin, is a powerful clock-enhancing molecule^[63] that shows promise in the treatment of a variety of cancers^[64-66].

Melatonin

Melatonin is an indoleamine hormone produced and secreted into circulation primarily by the pineal gland in mammals, where it acts as an endogenous signal of darkness^[56,67-70]. Through a poly-synaptic pathway, the suprachiasmatic nuclei control melatonin production and secretion, rendering the concentrations of this hormone sensitive to environmental light input^[71]. Because light activates the SCN to cause downstream inhibition of the pineal gland, darkness induced disinhibition permits melatonin secretion only during the night.

Melatonin is a pleiotropic immunomodulatory molecule. Broadly, melatonin is immune-enhancing, acting as a mild anti-inflammatory agent, buffering the immune system against glucocorticoids and reactive oxidative and nitrosative stress^[72-74]. Shift work and transmeridian travel, two behaviors that strongly alter melatonin rhythms, are associated with cancer incidence. In 2007, the International Agency for Research on Cancer classified shift work with circadian disruption or chronodisruption as a probable human carcinogen^[75]. Artificial light at night (e.g., street and house lights), which inhibits pineal melatonin, is associated with increased breast cancer prevalence^[22,76,77], although the findings are not universally consistent^[78]. The mechanisms behind these trends are becoming clearer thanks to basic research.

In a clever experimental design, Blask & colleagues investigated the role of melatonin on human breast cancer xenograft tumor progression in nude rats^[79]. Blood samples were collected from healthy female volunteers during the day, night, or after 90 min exposure to bright white light at night (to putatively knockdown circulating melatonin concentrations). Melatonin deficient- (daytime or light at night collected) or sufficient blood were then perfused into the tumor xenografts. Tumors perfused with daytime or light at night-exposed blood samples showed high proliferative activity and linoleic acid uptake/metabolism, while those perfused with melatonin-rich nocturnal blood had markedly reduced proliferative activity. Additionally, exposing tumor-bearing rats to increasing intensities of artificial light dose-dependently accelerated tumor growth in tandem with knockdown of circulating melatonin. These results were the first to suggest that light at night exerts its pro-tumorigenic effects via its actions on circulating melatonin concentrations^[79]. Since the publication of this study, melatonin has been intensely investigated as an anticancer molecule, particularly in the context of breast cancer^[80,81]. Potential mechanisms for its actions have been uncovered, including anti-estrogen, angiogenic, and oxidant pathways^[82]. As an ancient and pleiotropic hormone, melatonin is not the “cleanest” anti-cancer molecule, given its distributed effects on many tissues throughout the body. However, understanding the mechanisms by which it exerts its anti-cancer effects will likely lead to novel and targeted

treatments^[83]. Additionally, due to its low toxicity and high tolerability, it may be useful as a powerful and inexpensive adjunct therapy.

Midbrain reward system

The midbrain ventral tegmental area (VTA) and neighboring substantia nigra are the primary source of all dopamine (DA) within the brain. Known for its important role in reward and motivational processing (i.e., calculating reward-prediction errors), the VTA has recently become a target for modulating cancer. Elevated concentrations of dopamine are associated with blunted tumor growth, reduced angiogenesis, and lower metastatic capacity of cancer in rats^[84]. In general, dopamine seems to inhibit cancer growth, while serotonin facilitates it^[85]. The mechanisms underlying this phenomenon are unclear, although research has started to make headway in this area. In recent years, the VTA has been linked to the modulation of both innate and adaptive immunity^[86]. Using designer receptors exclusively activated by designer drugs (DREADDs), Rolls and colleagues demonstrated that activation of VTA-DA neurons promotes monocyte/macrophage expansion and innate immune responses to *E. coli* infection. Activation of these neurons further increased the number of circulating B-cells, subsequent IgM and IgG titers in response to *E. coli*, and interferon- γ production by T-cells, suggesting enhanced adaptive immunity.

After these initial studies, they applied their findings to a mouse model of lung cancer^[87]. After injecting viruses encoding Gq-coupled DREADDs into the VTA (as previously), mice were injected with subcutaneous tumor cells (LLC or B16 cancer cells), and then given daily injections of the DREADD ligand CNO, chronically activating the VTA. Mice that were “VTA-activated” developed smaller tumors than control mice that did not express the DREADD in the VTA [Figure 2]. To examine how this signal from the brain might reach the tumor, the authors ablated the sympathetic nervous system using the neurotoxin 6-hydroxydopamine (6-OHDA; as discussed earlier). Mice that were SNS-ablated (or received a beta-adrenergic receptor antagonist) failed to reduce their tumor burden upon VTA-DA activation. They further showed that VTA activation altered norepinephrine concentrations specifically in the bone marrow, a vital immune compartment. This strongly supports the hypothesis that VTA-DA neurons alter tumor growth via SNS innervation of the bone marrow. As myeloid derived suppressor cells (MDSCs) express beta-2 adrenergic receptors and regulate tumor growth via inhibition of anti-tumor immunity, the authors examined their phenotype in response to VTA activation. DREADD-induced VTA activation reduced the number of MDSCs, suggesting that the actions of central VTA stimulation on tumor growth may be through sympathetic suppression of MDSCs. To test the role these cells played in their model, they adoptively transferred MDSCs from VTA-activated mice to control mice not expressing the Gq-coupled DREADD in the VTA. This recapitulated the anti-tumor effect of VTA-activation. This suggests that modulation of the immune system via a discrete population of neurons within the brain acts (at least in part) to suppress tumor growth via the sympathetic nervous system.

Stress - glucocorticoids and catecholamines

Glucocorticoids (primarily cortisol in humans and corticosterone in mice) are powerfully regulated by circadian rhythms, stress, metabolic state, and immune status^[88]. Their production and regulation along the HPA-axis has been known for several decades. Their role in linking psychological stress to cancer, however, has only become a subject of intense research within the 21st century^[11]. First hinted at in the 70's and 80's, psychological stress has been suspected to influence tumor growth for several decades^[89,90]. Their role in cancer associated metabolic stress is more well defined. For example, upon metabolic stress induced by cancer-related inflammation (impairments in ketogenesis), glucocorticoids can act to suppress anti-cancer immunity^[91]. This is associated with disrupted rhythms in glucocorticoid secretion, a component controlled ultimately by a crosstalk between central clocks in the SCN and ancillary oscillators in the adrenal glands^[92]. Adrenergic signaling, largely driven by activation of the SNS in the context of stress, also has immunomodulatory properties (as discussed above).

Thaker, Sood & colleagues provided empirical evidence that psychological stress can facilitate tumor growth in multiple animal models via its promotion of glucocorticoid and adrenergic signaling^[12,93]. These studies demonstrated that multiple ovarian cancer tumor cell lines (e.g., EG, SKOV3, 222, HeyA8...) enhance invasiveness when exposed to norepinephrine and/or glucocorticoids (in part) via the upregulation of matrix metalloproteinases (MMPs), critical regulators of angiogenesis and tissue remodeling. Blockade of adrenergic signaling or inhibition of MMPs prevented elevations in cell invasiveness. *In vivo* experiments demonstrated that chronic behavioral stress (restraint) increased tissue catecholamines, tumor growth, vascularization, and invasiveness in an orthotopic mouse model of ovarian cancer. These effects were driven by adrenergic signaling (through the β_2 -adrenoceptor), resulting in downstream cAMP-protein kinase A (PKA) pathway activation. This subsequently promoted the transcription of vascular endothelial growth factor and the MMPs (-2 and -9). These findings highlight adrenergic-receptor signaling as a potential target for reducing tumor angiogenesis and growth. Indeed, perioperative cyclo-oxygenase 2 and beta-adrenergic blockade was shown to improve measures of metastasis in breast cancer patients, offering a safe and effective adjuvant treatment strategy^[94].

Energy balance and feeding

Disrupted energy balance resulting in enhanced capacity to sustain proliferative growth is a hallmark of cancer^[9]. Indeed, one of the first major breakthroughs in cancer research was the discovery that tumor cells are biased towards aerobic glycolysis rather than oxidative phosphorylation to produce energy (i.e., the Warburg effect^[95-97]). Therefore, a common finding in malignant cancers is a strong upregulation of lactate and catalytic enzymes required for lactate production from pyruvate (e.g., lactate dehydrogenase)^[98-101]. Lactate normally acts to aide in glucose sensing and food intake, where it is transported into the brain via monocarboxylate transporters present on endothelial cells lining the blood-brain barrier^[102]. After entering the brain, lactate is able to interact with neurons that normally promote food intake, such as those that produce agouti-related peptide (AgRP) within the arcuate nucleus. Lactate's mechanism of action on orexigenic cells is via its effects on the adenosine monophosphate kinase/methylmalonyl CoA signaling pathway within the hypothalamus^[103]. Lactate alone, however, does not seem to be responsible for cancer-associated anorexia (discussed below)^[104].

Anorexia is a common phenomenon in cancer patients with weight loss, and even when patients attempt to eat enough to compensate, they frequently cannot maintain a healthy weight. Although significant evidence suggests that inflammatory signaling secondary to tumor growth or cancer-treatment associates with anorexia, a specific neural population and mechanism governing this common problem is lacking^[99]. An attractive candidate neural population that may underlie these traits (in part) is the calcitonin-gene-related-peptide (CGRP) expressing population of cells in the parabrachial nucleus (PBN_{CGRP}). These cells powerfully suppress appetite and promote the termination of feeding behavior^[105,106]. CGRP neurons are activated by upstream circuits that respond to cancer-associated signals, and are inhibited by those that promote feeding, including hypothalamic AgRP/neuropeptide Y neurons^[107]. These neurons are also sensitive to peripheral noxious and painful stimuli, which are other aspects of cancer progression^[108].

In a mouse model of Lewis lung carcinoma, Schwartz and colleagues investigated how peripheral tumors modulate CGRP neural activity and their role in cancer-associated anorexia/cachexia^[109]. CGRP neurons were strongly activated in tumor-bearing mice compared with controls, a phenotype typically found after ingestion of a large meal. This suggests that tumors activate cells normally responsible for meal termination and cessation of feeding behavior. Using a cre-dependent tetanus toxin transgene, they demonstrated that inactivation of these cells prevented cancer-associated anorexia/cachexia. Additionally, this manipulation normalized the activity of neurons in circuits downstream from the PBN, namely the central amygdala (CeA) and oval subnucleus of the bed nucleus of the stria terminalis (ovBNST), which may play additional roles in cancer-associated behavioral phenotypes. To control the activity of PBN_{CGRP} neurons with better temporal precision, they used Gi-coupled DREADDs to transiently inhibit these neurons in anorexic/cachexic mice. This manipulation was able to recapitulate the effects seen with their previous approach using tetanus toxin.

Another research area that is rapidly growing in scope is that of brain-gut and gut-cancer interactions. Changes in systemic microbial diversity can influence brain function, alter immune phenotypes, and dictate subsequent cancer development or a tumor's response to immunotherapy^[110,111]. In a proof-of-principle experiment, Lakritz *et al.*^[112] demonstrated that *Helicobacter hepaticus*, a pathogenic gut microbe, promotes distal breast tumorigenesis in a neutrophil-dependent manner. Cancer-prone female mice (FVB-Tg(C3-1-TAg)cJeg/JegJ) were infected with *H. hepaticus* (via gastric gavage) at 3 months of age, and then assessed for subsequent mammary tumorigenesis. Mice infected with these bacteria developed significantly more tumors than their counterpart controls that were not infected. Additionally, mammary intraepithelial neoplasias were associated with strong neutrophil invasion (myeloperoxidase staining). Chronic depletion of neutrophils (via anti-Ly6-G antibodies) prevented *H. hepaticus*-induced cancer development. These data suggest that host-microbe interactions may drive cancer in distal tissues through an immune-mediated mechanism.

CONCLUSIONS AND IMPLICATIONS

Together, the studies discussed above aim to provide an understanding of the types of inputs the brain receives, the signals it propagates, and the effects of these messages on tumor growth and metastasis. Reciprocally, tumor-induced changes in physiology are relayed to the brain via endocrine, immune, or neural signals that ultimately change the activity of discrete neural populations important for maintaining homeostasis. Resolving the “conflict of interest” between cancer and the brain will undoubtedly lead to improvements in patient quality of life and unlock a novel means for cancer treatment. A summary of these findings from basic science are presented in [Table 2](#).

In this vein, treatments targeting the circadian system (i.e., chronotherapy) have gained significant traction in recent years^[113,114]. These approaches leverage natural circadian rhythms in metabolism and detoxification systems to schedule chemotherapy or radiotherapy to coincide with times of peak effectiveness with the lowest potential for side-effects. Animal models have further demonstrated that this approach can effectively limit hepatic toxicity and the inflammatory response to chemotherapeutics^[115,116]. Artificially boosting circadian rhythms (e.g., with nobiletin) adds an additional prospective anti-cancer strategy^[64].

Alternatively, targeted stimulation of specific brain areas deregulated in cancer may help overcome resistance to more traditional treatment strategies. As discussed above, stimulation of the dopaminergic ventral tegmental area promotes tumor suppression via the sympathetic nervous system^[87]. If findings such as these translate to humans, deep brain stimulation protocols could be adapted for adjuvant cancer treatment. For example, deep brain stimulation of the subthalamic nuclei for Parkinson's disease promotes sympathetic activation in a safe and reversible manner^[117,118], a procedure that could be repurposed in the context of advanced cancer. Alternatively, biobehavioral therapies can be designed to promote positive thinking and rewarding experiences (to activate the dopaminergic system) to aide in cancer suppression. Indeed, mindfulness meditation has been demonstrated to improve mood, reduce stress, and attenuate inflammation in patients with breast cancer^[119].

As cancer drastically alters energy balance, influencing the activity of specific brain nuclei regulating metabolism and food intake (e.g., hypocretin, AgRP, POMC, CGRP neurons) represents a strategy to not only improve quality of life, but limit energy availability to the cancer. Indeed, inhibition of aberrant hypocretin/orexin signaling promotes sleep and attenuates tumor-induced metabolic abnormalities in a mouse model of breast cancer^[6]. Repurposing drugs that modify food intake and energy balance (e.g., metformin) further provides additional avenues for adjuvant cancer therapy. However, significant more research is needed to understand both (1) how the brain influences cancer-associated immune populations and (2) how the tumor communicates with the brain to deregulate homeostasis and health. Only then can we begin to manipulate this cross-talk to facilitate cancer elimination.

Table 2. Non-exhaustive list of primary animal model evidence for brain-tumor interactions regulating cancer incidence, disease progression, morbidity and mortality (see Figure 2 for more details)

Cancer type/model	Main focus	Primary findings	Ref.
67NR/4T1/4T07 syngeneic breast cancer cells (female BalbC mice; subQ/orthotopic)	Effects of peripheral tumors on central regulation of sleep and metabolism	Tumors alter leptin/ghrelin signaling, disrupting central hypocretin/orexin activity to influence glucose metabolism and sleep via the sympathetic nervous system	[6]
LL2 Lewis Lung carcinoma/B6 (male C57bl6j mice; subQ)	Dopaminergic regulation of tumor growth	Activation of VTA-dopamine neurons blunts tumor growth via sympathetic modulation of bone-marrow myeloid derived suppressor cells	[87]
p53 ^{R270H/+} WAP-Cre mutant model of Li-Fraumeni syndrome (mouse; transgenic)	Circadian disruption-induced cancer development	Chronic phase shifting accelerated spontaneous tumor growth and altered tumor phenotype	[60]
<i>N</i> -nitroso- <i>N</i> -methylurea (NMU)-induced mammary tumors (rat; chemically induced)	Effects of tumors on affective behaviors	Tumor growth is associated with central cytokine concentrations, altered glucocorticoid responses, and the development of depressive-like behavior	[141]
Colon-26 adenocarcinoma cells (mouse; SubQ)	Effects of tumors on fatigue, muscle physiology, and affective behaviors	Tumors promoted central proinflammatory cytokine production and depressive-like behavior prior to defects in muscle function, behavior rescued by SSRI	[142,143]
HeyA8, SKOV3ip1, MB-231 orthotopic human ovarian carcinoma cells (nude mice; IP)	Effects of stress on tumor development and angiogenesis	Stress-induced adrenergic signaling (cAMP->PKA) promotes tumor growth and angiogenesis	[12]
Non-metastatic methylcholanthrene-induced sarcoma (F344/NTacFBR male rats; SubQ)	Effects of inflammation on central hypocretin/orexin neurons and fatigue	Tumors reduced hypocretin/orexin transcript expression and promoted fatigue	[144]
LL2 or TC-1 lung epithelial cells (male C57Bl6 mice; subQ)	Role of sleep fragmentation (SF) on tumor growth and progression	SF accelerates tumor growth, likely through a TLR4 dependent mechanism	[13]
LL2 Lewis Lung carcinoma cells/Apc/min+ mice (male and female C57Bl6; subQ/transgenic)	Role of calcitonin-gene related peptide (CGRP) neurons in cancer-associated cachexia	Inactivation of parabrachial CGRP neurons prevents and reverses cancer-induced anorexia, fatigue, and changes in affective behavior	[109]
MADB106 breast cancer cells (outbred "hyperreactive" Wistar rats; subQ)	Role of dopaminergic system in tumor growth/metastasis	Smaller tumors, fewer metastases, and reduced angiogenesis in rats with a hyperreactive dopaminergic system	[84]
K-ras ^{LSL-G12D/+} ;p53 ^{flox/flox} (KP) or K-ras ^{LSL-G12D/+} (K) lung cancer model 129SvJ x C57bl6 mice (cre-dependent p53 deletion)	Effects of circadian disruption (environmental and genetic) on lung tumor growth and progression	Both genetic and physiologic circadian disruption accelerate tumor growth and promote c-myc upregulation and metabolic reprogramming	[61]
diethylnitrosamine-induced hepatocarcinogenesis (male Sprague-Dawley rats)	Sympathetic nervous system effect on hepatocarcinogenesis	High density of SNS bundles associated with poor prognosis, SNS activation of Kupffer cells drives inflammation	[145]
Hepatocarcinoma Morris 7288CTC cells (male buffalo rats) or steroid receptor (SR)-1+ or SR-1- MCF-7 human breast cancer xenografts (female nude rats)	Role of light and melatonin in cancer progression	Melatonin depleted blood accelerates tumor growth and metabolism compared to melatonin-rich blood from healthy women; light accelerates tumor growth in dose-dependent manner	[79]
B16 melanoma cells (male nude mice/C57bl6 D ₂ receptor-KO)	Role of peripheral dopaminergic signaling in tumor growth/angiogenesis/metastasis	6-OHDA ablation of dopaminergic nerves enhanced tumor angiogenesis and growth, likely through D ₂ -mediated mechanism	[146]
GOS Glasgow osteosarcoma and pancreatic adenocarcinoma (P03) xenographs (male B6D2F ₁ mice; subQ into flank)	Effect of suprachiasmatic nucleus lesions on tumor growth	SCN lesions drastically increased tumor size in both cancer models examined	[147]
TC-1 mouse lung cancer cells and human lung adenocarcinoma cells (male C57bl6 mice and obstructive sleep apnea patients)	Effect of sleep fragmentation on plasma exosomes and tumor growth	Chronic sleep fragmentation alters the microRNA cargo of plasma exosomes to promote tumor cell proliferation	[148]
EG, SKOV3ip1, and 222 human ovarian cancer cells (nude male mice)	Effect of stress hormones on cancer invasiveness and growth	Adrenergic and glucocorticoid signaling promotes tumor invasiveness (in part) via upregulation of MMPs	[93]

VTA: ventral tegmental area; cAMP: cyclic adenosine monophosphate; PKA: protein kinase A; 6-OHDA: 6-hydroxydopamine; MMPs: matrix metalloproteinases

DECLARATIONS

Acknowledgments

I thank Drs. Luis de Lecea and Natalie Nevárez for providing critical critiques during the preparation of this manuscript. I thank Dr. Peter Dong for making the illustrations featured in this manuscript. This review was made possible thanks to a BRAIN Initiative NIMH F32MH115431. All efforts were made to include relevant research, failure to do so is the sole responsibility of the author.

Authors' contributions

Borniger JC contributed solely to this study.

Availability of data and materials

Not applicable.

Financial support and sponsorship

This study was supported by NIMH BRAIN Initiative (F32 MH115431).

Conflicts of interest

The author declared that there are no conflicts of interest.

Ethical approval and consent to participate

Not applicable.

Consent for publication

Not applicable.

Abstract

Obesity has the far reaching consequence on cancer pathogenesis and immune reactions. In particular, adiponectin (APN) produced by adipocytes played an important role in modulating obesity related malignancies. Via its interaction with corresponding receptors and their downstream signalling pathways, it regulates cells survival, apoptosis and cancer metastasis. Our review dissects the clinical evidence on how hypoadiponectinaemia associated with the increased risks of several cancers and the long-term prognosis and also addresses the controversies. APN also has its indirect effect on anti-cancer immune response which may influence the disease process. We also analyse the impact of APN on the immune system, the anti-tumour responses and the controversies surrounding this area. Targeting therapeutics on APN and its receptor axis represents a promising and novel anti-cancer treatment. Biological understanding of how APN and its interaction with its receptors may affect the immune reactivity. Careful strategizing the use of APN therapeutics in cancer treatment is important, as the APN receptor signalling on the immune cells can blunt anti-tumour response. Targeting APN or its receptors has an enormous implication for the treatment of cancers.

Keywords: Adiponectin, AdipoR1/R2, Cancer, signaling pathway, anti-tumor immunity, therapeutic targets

INTRODUCTION

Adipose tissue is no longer seen as only a passive energy store, but instead a complex metabolic and endocrine organ. Composed of adipocytes, nerve tissue, connective tissue matrix, stroma-vascular cells that

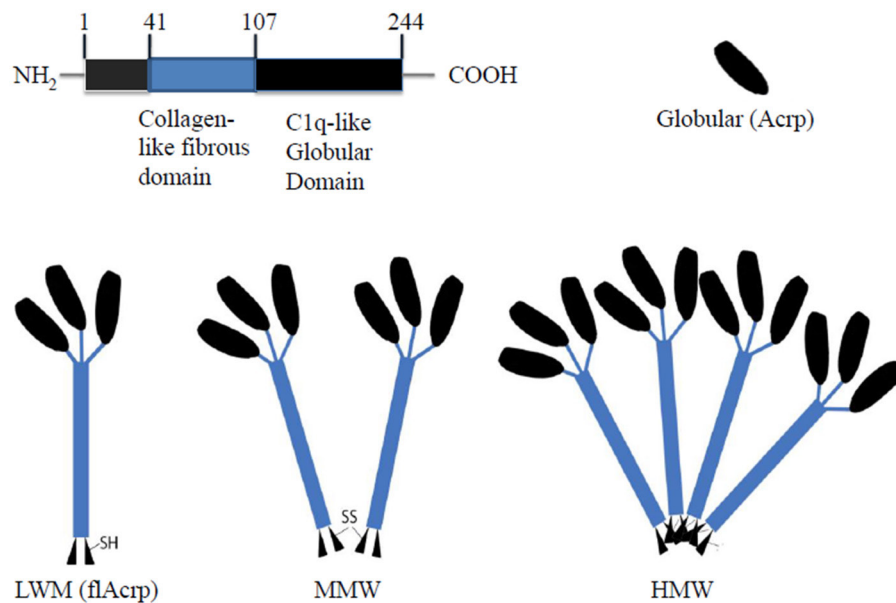

Figure 1. Structure of APN. Low molecular weight. MMW: middle molecular weight; HMW: heavy molecular weight; flAcrp: full length adiponectin; Acrp: globular adiponectin

can orchestrate the immune cells. It expresses, secretes, and responds to a number of key cellular modulators which may have a prominent role in the development and regulation of the disease process in the body^[1]. Adipocytes secrete cell signalling proteins, termed adipokines, of which adiponectin (APN) has been shown to have anti-inflammatory^[2], anti-atherogenic^[3], and anti-diabetic properties^[4,5].

With obesity being linked to approximately 20% of all cancers^[6], harnessing APN may be of great therapeutic benefit, especially with obesity-related cancer. For this to be successful, it is important to note that adipokines can have both anti-inflammatory and pro-inflammatory properties^[4]. When the homeostasis is disrupted, these molecules have the ability to cause harm, yet if we are able to counteract the imbalance, adipokines could pose an important anti-carcinogenic target for the future.

BACKGROUND OF APN AND ITS RECEPTORS

Discovery of APN and its structure

APN was first described in 1995 by Scherer *et al.*^[7] from a cDNA library containing adipocyte-specific genes. Monomeric APN is a 30-kDa glycoprotein encoded by the ADIPOQ gene on human chromosome 3q27. APNs full-length protein (flAcrp) structure was discovered three years later and structurally resembled complement protein C1q and proteins from the tumour necrosis factor (TNF) family^[8]. It consists of a N-terminal region, a hyper-variable sequence, a collagen-like fibrous domain linked to a C-terminal C1q-like globular domain [Figure 1]. Similarities between APN and C1q are seen in folding topology, intron positions, and the formation of trimers. Interactions between the collagen-like domains of three monomeric APNs form the low-molecular-weight (LMW) isoform. The LMW isoform then has the ability to form stable multimeric oligomers. Two LMW isoforms can connect via a disulphide bond to form a middle molecular weight (MMW) hexamer. With the help of post-translational modifications larger 12- or 18-mer high molecular weight (HMW) isoforms are generated^[9].

The majority of APN is produced by white adipose tissue, with lower quantities being produced from brown adipose tissue^[10]. That said, several studies have demonstrated APN being present much lower concentrations in other tissues: cerebrospinal fluid^[11], cardiomyocytes^[12], skeletal muscle^[13], liver^[14], and bone marrow^[15]. The different isoforms are found at varying concentrations throughout the body. The monomeric isoforms

are confined to adipocytes, the oligomeric isoforms are present in the circulation^[16], and the globular form (gAcrp) trimerise to form a stable complex in the circulation.

These different isoforms are thought to have varying biological effects with the HMW isoform being the most biologically active and having the highest plasma concentration. The normal plasma concentration levels of APN range from 2-30 g/mL^[17]. APN levels have been shown to be altered in many disease processes. Coronary heart disease^[18], atherosclerosis^[18], type 2 diabetes^[19], obesity^[20], insulin-resistance^[20], and many cancers are correlated with lower APN levels. Understanding how different isoforms exert effects upon various tissues may be central to understanding the pleiotropic actions of APN within the body.

APN receptors

Three receptors are known to bind with APN: AdipoR1^[19], AdipoR2^[19], and T-cadherin^[21]. AdipoR1 and AdipoR2 have an internal N-terminal region and an external C-terminal region with a central seven transmembrane domain. The topology of these receptors are extremely similar, sharing 67% of their protein sequences^[22]. However, compared to G-protein coupled receptors, their topology is completely opposite. AdipoR1 shows high-affinity binding to globular APN, and also binding to full-length APN and is highly expressed in skeletal muscle. While AdipoR2 shows intermediate-affinity binding to both forms and is predominantly expressed in the liver. More recently, T-cadherin was identified as an additional APN receptor^[21]. It is a glycosylphosphatidylinositol-anchored protein that is highly expressed in endothelial and smooth muscle cells, and has shown specific binding to MMW and HMW isoforms^[23].

APN AND CANCER

A number of cancers have been correlated with hypoadiponectinemia and altered levels of AdipoR1/R2 and T-cadherin. Therefore, APN may be a novel modifiable risk factor with uses as a prognostic or diagnostic biomarker.

Colorectal cancer

It has been long acknowledged that obesity, hyperinsulinaemia, and insulin-resistance are associated with colorectal cancer (CRC) pathogenesis. More recently it has been shown that APN levels are negatively correlated with a risk of developing CRC [Table 1]. This has been confirmed by three meta-analyses^[24-26] and multiple studies summarised in Table 1. Not only did CRC patients have lower levels of APN, but one study showed that men with high APN had a 60% reduced risk of CRC^[27]. A following study showed a similar reduced risk in CRC among men, however no link was seen in females^[28]. This highlights the point that the expression and response to APN can differ between sexes. APN also seems to have a role at the later stages of CRC and an influence on its clinicopathological characteristics. Two studies showed an inverse correlation between tumour stage/grade and APN^[29,30]. Furthermore, low pre-surgical APN levels were found in a higher proportion of relapsing patients, suggesting that APN may have potential to act an adjunctive tool to predict relapse. Mice knock-out models have suggested that interactions with AdipoR1, rather than AdipoR2, have a more protective role as only AdipoR1-KO mice demonstrated increased proliferative activity^[31].

To aid development of any therapy it is important to understand changes that occur to APN within CRC tumour cells. fAcrp can be post-translationally modified to Acrp within the tumour environment, such that the ratio between fAcrp:Acrp is higher than in the surrounding normal tissue^[32]. Local conversion to Acrp could help create a more beneficial tumour environment by functioning in an autocrine manner^[33]. Thus, not only do CRC patients often have lower circulating levels of APN, but also a different proportion of APN subtypes that benefit tumour progression.

Gastric cancer

APN levels have been shown to have an inverse correlation to gastric cancer (GC) [Table 1]. One study found that GC cells lacking AdipoR1 had higher peritoneal dissemination and lymphatic metastases than AdipoR1

Table 1. Epidemiological studies showing the relationship of serum APN and cancer

Study types	Study outcome	Ref.
Colorectal cancer - CRC		
RCC	$P < 0.001$; $P = 0.037$ 1. APN is significantly lower in CRC; 2. APN inversely correlates to tumor stage; 3. Lower APN is associated with CRC recurrence	[29]
	$P < 0.05$ 1. Lower APN; 2. No correlation visceral fat & APN in CRC or adenoma	[67]
	$P < 0.001$ - Lower APN in CRC	[68]
	1. OR = 0.0802 (0.321-1.003) for CRC risk 2. OR = 0.442 (0.189-0.946) for adenoma risk - APN is good marker for adenoma	[69]
	OR = 0.72 (0.53-0.99) for CRC risk, $P = 0.005$ - Lower APN correlates to CRC risk and APN inversely correlates to tumor grade	[30]
PCC	1. RR = 0.55 (0.35-0.86), $P = 0.02$ for men highest vs. lowest quartile 2. RR = 0.96 (0.67-1.39), $P = 0.74$ for women APN significant associated with reduced risk in men but not women RR = (0.23-0.78); P (trend) = 0.01 - Men with low APN had a higher risk of CRC	[28]
	1. RR = 0.71 (0.53-0.95), $P = 0.03$ for total APN when comparing highest vs. lowest quintile 2. RR = 0.45, (0.34-0.61), $P < 0.0001$ for non-HMW APN Total & non-HMW APN inversely correlates to CRC risk	[27]
	$P > 0.05$; OR = 0.8 (0.5-1.4) for highest vs. lowest APN quartile No significance correction between APN & CRC risk	[70]
	$P > 0.05$ - No significance association	[71]
Gastric cancer - GC		
RCC	$P = 0.0004$ - APN levels were significantly lower in Stage I cases than controls	[72]
	$P < 0.005$ - Negative correlation with pathologic findings such as tumor size, depth of invasion, tumor stage (only in undifferentiated GC)	[73]
RCC	$P > 0.005$ - No significant difference in tumor stage, localization, nodal status, lymphatic and vascular invasion	[74]
Esophageal cancer - OC		
RCC	$P < 0.05$; $P < 0.05$ - Significantly lower APN levels in ESCC & EA patients than controls EA patients had lowered APN than ESCC HR = 0.34 (0.14-0.82) - Nonlinear inverse association with risk of EA; the strongest associations were observed in 2nd tertile	[75]
	$P = 0.01$ - Serum APN was significantly lower in cases than controls	[76]
	$P = 0.802$ - APN levels were similar in various esophageal pathologies	[77]
Breast cancer - BC		
PCC	1. Adjusted OR = 0.2 (0.0-0.6); $P < 0.05$; 80% reduced risk in higher APN compared with stage I-III ^[41] 2. Adjusted OR = 0.04 (0.071-0.99) - Lower APN in early breast cancer vs. healthy controls ^[80] 3. $P = 0.04$ - 65% reduced risk in higher APN compared with stage I-III ^[40]	[40,41,80]
	1. $P < 0.005$ (for tumor size); $P < 0.05$ (for grade); > 2 cm tumor & Grade 2&3 BC cases were higher in lower tertile of serum APN ^[42] 2. $P = 0.036$ - Negative correlation with tumor size ^[43] P (trend) = 0.0270 - Inverse trend in ER/PR -ve BC (for not +ve)	[42,43]
	Adjusted HR = 0.39 (0.15-0.95) - Higher APN was associated longer BC (stage I-IIIa) survival	[44]
	Adjusted HR = 0.88 (0.81-0.96); $P = 0.03$; Lower APN was associated with a history of prior pT1mic/pT1a & higher risk of second BC in premenopausal and 12% reduction in risk of BC per unit increase of APN	[81]
	1. $P = 0.017$ ^[83] 2. OR = 0.805 (0.704-0.921); $P = 0.00$ ^[84] Lower APN was associated with nodal disease ^[83,84]	[82]
	Post-menopausal OR = 0.73 (0.55-0.98) but pre-menopausal OR = 1.30 (0.80-2.10) (all women OR = 0.89 (0.71-1.11)) Negative correlation in post-menopausal women $P = 0.43$ for linear trend - No association with risk	[83,84]
Endometrial cancer - EC		
PCC	OR = 0.56 (0.36-0.86) highest vs. lowest APN quartile Negative correlation independent of other obesity-related risk factors OR = 0.42 (0.19-0.94) comparing highest vs. lowest tertile Inverse association with risk of EC Stronger association in pre-menopausal than post-menopausal	[85]
RCC	OR = 0.52 (0.32-0.83); $P < 0.001$ - Significant negative correlation between APN level and EC risk $P < 0.001$; $P < 0.05$ - Significantly lower APN in EC patients than normal or polyps epithelium patients $P < 0.0001$ - Significantly reduced APN in cases than controls; Leptin:APN ratio correlated to post-menopausal EC risk	[86]
		[48]
		[87]
		[88]
		[89]

PCC	All Women: OR = 0.86 (0.53-1.39) and Post-menopausal: OR = 0.66 (0.29-1.50) Non-significant result (pre-diagnostic APN is not predictive of EC risk)	[50]
Pancreatic cancer - PC		
PCC	OR = 0.44 (0.23-0.82) - In never smoker, higher APN levels correlated to reduced risk of PC; OR = 1.59 (0.67-3.76) - No significance in smoker	[54]
	OR = 0.55 (0.31, 0.98); $P = 0.03$ for highest vs. lowest quintile - Higher APN were negatively correlated with PC risk	[52]
	Nonlinear association ($P < 0.01$) - Low pre-diagnostic levels of APN were associated with an elevated risk of PC	[89]
RCC	$P = 0.0035$ - Median APN levels significantly higher in PC group than controls/chronic pancreatitis group	[90]
	$P < 0.001$ - Greater APN:Leptin ration in PC patients	[91]
	OR = 2.81 (1.04-7.59) - Higher APN correlated with higher odds of PC and No association with PC stage	[53]
Renal cell carcinoma - RCC		
RCC	OR = 0.76 (0.57-1.00) $P = 0.05$ - Serum APN negatively correlated with RCC risk	[56]
	$P < 0.01$ (tumor size); $P = 0.029$ (non-metastatic vs. metastatic); $P = 0.044$ for total APN & $P = 0.041$ for HMW (non-metastatic vs. metastatic) - Strong inverse correlation was found between plasma APN levels and tumor size ^[57] , Lower APN in metastatic cases ^[57,58]	[57] [58]
	OR = 2.3 (1.1-4.6) - Higher APN was associated with RCC risk among African American males	[59]
Hepatic cancer - HC		
PCC	OR = 0.5 (0.22-1.15) for highest vs. lowest tertile for LMW APN - Higher % of LMW APN may be have a protective effect on HC	[92]
RCC	$P = 0.670$; $P = 0.752$ - No significance difference between cases and controls	[93]
Prostate cancer - PrC		
PCC	OR = 0.27 (0.07-0.87) for highest vs. lowest quintile for lethal PrC - Men with higher APN had reduced risk of HG or lethal PrC but overall no significant correlation between serum APN & PrC risk	[94]
NCC	OR = 0.86 (0.66-1.11), $P = 0.24$ for all men; OR = 0.62 (0.42-0.90), $P = 0.01$ for obese & overweight men APN levels negatively associated with PrC risk in obese & overweight men but not significant in all men	[60]
RCC	OR = 0.29 (0.10-0.89) for highest vs. lowest quartile - Reduced risk with higher APN independent of various confounders	[95]
	$P < 0.05$ - Significantly reduced APN in PrC patients	[96]
	$P < 0.001$ - APN levels in HG PrC were also significantly lower than LG or IG groups	[97]
PCC	OR = 0.87 (0.46-1.65) for highest vs. lowest tertile - No significance but the sensitivity of assays used was problematic	[98]
Lung cancer - LC		
RCC	$P < 0.0001$ - Leptin: APN ratio was significantly lower in the patients group compared to controls	[99]
	OR = 1.13 (0.80-4.97); OR = 0.25 (0.10-0.78) - Even though APN levels were not significantly different in cases than controls but they are significantly lower in advanced than limited disease stage	[64]
	$P > 0.05$ ^[100] ; OR = 2.00 (0.80-4.97), $P = 0.14$ ^[101] - No significance	[100,101]

A summary on the clinical data showing the association of serum APN with various cancers is shown. Many studies show that low levels of APN is associated with cancer risk and its progression of disease. CRC: Colorectal cancer; PCC: prospective case-control; RCC: Retrospective case-control; NCC: nested case control; OR: odd ratio; RR: relative risk; BC: breast cancer; EC: endometrial cancer; GC: gastric cancer; OC: oesophageal cancer; ESCC: esophageal squamous cell cancer; EA: esophageal adenocarcinoma; PC: pancreatic cancer; HC: liver cancer; RCC: renal cell cancer; PrC: prostate cancer; HG: high grade; LG: low grade; IG: intermediate grade

positive cells^[34]. Despite, the AdipoR1 positive group having longer survival rates, multivariate analysis indicated this was not an independent prognostic factor on GC survival. That said, it is thought AdipoR1 is the mediator of tumour growth suppression in GC and therefore could be a therapeutic target in tackling GC. One study demonstrated that rs266729, an ADIPOQ variant, may be an independent prognostic factor for non-drinking GC patients receiving surgical treatment^[35]. Similarly, APN levels have been shown to have a direct effect in GC postoperative outcomes. It was shown that the ratio of postoperative to preoperative levels of APN was the most useful predictor for postoperative infection^[36]. It is thought that reduced APN levels suggest a submaximal inflammatory response, thus predisposing to infection^[32]. Increasing APN in the weeks before surgery could be an additional method to improve surgical outcomes.

Oesophageal cancer

APN plays a significant role in the maintenance of the normal oesophageal mucosa^[32]. Lower levels of APN have been correlated with an increased risk of oesophageal cancer (OC) [Table 1]. Low tumour expression of AdipoR1 was suggested to be an independent predictor of improved overall OC survival^[37]. While, AdipoR2

expression was inversely correlated with tumour size. It was shown that low levels of LMW and high levels of HMW APN compared to the total APN ratio increased the risk of Barrett's oesophagus, which contributes to OC propagation^[38]. Looking at the dynamic changes between LMW and HMW APN levels during OC transformation could present an interesting predictive biomarker.

Breast cancer

A recent meta-analysis confirmed a link between hypoadiponectinaemia and an increased breast cancer (BC) risk^[39]. This increased risk was only found in post-menopausal women and not pre-menopausal women. Risk reduction in early BC patients with high APN levels has been reported to be from 65%-80%^[40,41]. A negative correlation has been demonstrated between APN levels and tumour size and grade^[42,43]. Interestingly, the correlation between APN and BC seems to be more prominent in oestrogen-negative and progesterone-negative BC^[44]. Therefore, it seems there may be a set group of BC patients that are most susceptible to the effects of APN and would benefit most from a potential treatment. That said, certain studies have shown no correlation between APN and BC risk^[45].

Endometrial cancer

A significant negative correlation has been found between levels of APN and endometrial cancer (EC)^[46] [Table 1]. A meta-analysis found that high levels of APN reduced the risk of EC by 53%^[47]. Whether APN levels effect pre- or post-menopausal women is unclear as studies have produced varying results^[47-49]. One proposed protective mechanism of action is that APN can reduce the number of EC cells by inhibiting proliferation and stimulating apoptosis^[49,50]. One study looked into the serum levels of the APNs isoforms and found that low levels of MMW isoform were the only independent risk factor for EC^[51]. It is unclear why this isoform in particular was most closely associated with EC, but highlights the pleiotropic effects APN exerts through its multiple isoforms.

Pancreatic cancer

The association between APN levels and pancreatic cancer (PC) is unclear from current studies [Table 1]. Some studies demonstrated a negative correlation between serum APN and PC^[52], while others showed high APN levels increasing the risk of PC^[53]. Of note, high APN levels were associated with a reduced PC risk in people that never smoked, but no significance found in smoker^[54]. PC has significant mortality associated with its diagnosis with a 5-year survival of only 9%^[55], therefore early detection using biomarkers could significantly alter treatment and prognosis. However, further prospective studies are needed to confirm APN as a PC marker.

Renal cancer

A negative correlation has been shown between serum APN and renal cancer (RCC), tumour stage, and metastasis^[56-58]. That said, one study showed how APN may exert different effects depending on ethnicity as a positive correlation was found between APN and RCC in African Americans but not Caucasians^[59].

Prostate cancer

A negative correlation between APN levels and prostate cancer (PrC) tumour grade and stage has been demonstrated in several studies [Table 1]. One study showed that the reduced risk was only found in obese and overweight men, but not all men^[60]. Furthermore, four ADIPOQ single nucleotide polymorphisms (SNP) (rs266729, rs182052, rs822391 and rs2082940) were shown to be significantly associated with PrC risk in Caucasians^[61]. Once again highlighting the differing effects of APN in different ethnicities.

Hepatic cancer

The relationship between hepatic cancer (HC) and APN levels is unclear [Table 1]. Certain studies showed that higher APN levels predicted a poorer survival with HC^[62]. APN expression pairs with tumour size but not several other parameters, therefore the rise in APN with tumour tissue may occur throughout the

process of carcinogenesis in an attempt to counteract the change and restore^[32]. Others studies suggested poor HC prognosis was associated with lower AdipoR1/R2 expression^[63]. AdipoR1 expression was correlated with the absence of vascular invasion and AdipoR2 was associated with a low stage and a lower histological grade. Although the role of APN in HC is unclear, APN may have a role pre-malignant hepatic conditions such as non-alcoholic steatohepatitis (NASH)^[32]. APN can suppress the hepatic damage caused by TNF- α in early NASH, thus highlighting an area where targeted APN treatment could help halt progression to cirrhosis and cancer.

Lung cancer

The majority of studies have not found a significant correlation between APN levels and lung cancer (LC) [Table 1]. Yet, one study demonstrated that there were lower levels of APN were present in patients with advanced disease compared to limited stage disease^[64]. AdipoR1 and AdipoR2 were only expressed in the cancerous tissue, with non-found in normal control tissue. Further studies are needed to determine a link between APN and LC.

Genetic polymorphisms

Multiple genetic polymorphisms have been associated with altered risk of malignancy in ADIPOQ, ADIPOR1, and ADIPOR2^[65]. These SNPs have been associated with a wide number of cancers and may enable screening and identification of high risk patients. This can allow for primary preventive measures, such as losing weight, diet, and exercise, as well as chemoprevention^[66]. Going forward we need to be take into consideration the interaction between various SNPs, ensure that a large and diverse group of the population are screened for more SNPs, and determine how SNPs can be applied to clinical decision making.

DIRECT EFFECT OF APN PATHWAY ON CANCER BIOLOGY

Insulin resistance and hypoadiponectinemia have been associated with multiple cancers. The binding of APN to AdipoR1/R2 triggers a number of downstream signalling cascades which have effects on cancer biology and anti-cancer immunity. Understanding these pathways can help give light to the multitude of APNs metabolic and immunological effects. These pathways are summarised in Figure 2.

Central to much of APNs actions is the AMP-activated protein kinase (AMPK) pathway^[102,103]. AMPK can act as a tumour suppressor by modulating inflammation, inducing cell-cycle arrest, and opposing metabolic changes during carcinogenesis^[104]. AMPK activation has been shown to have a beneficial effect on insulin sensitivity by increasing glucose uptake and fatty acid oxidation in muscles, and inhibiting gluconeogenesis in the liver. Interestingly, disruption of AdipoR1 reduced the AMPK activation, increased glucose production and impaired insulin resistance. While, AdipoR2 disruption enhanced insulin resistance and decreased PPAR α signalling^[20]. Downstream inhibition of the mTOR pathway contributes to AMPKs tumour suppressive qualities^[105,106]. This is due to mTORs central role as a regulator of cell growth, autophagy, and cell survival^[107]. AMPK activation has also been shown to be cytotoxic to cancer cell lines and cause apoptosis via p21 and p53 signalling^[108]. AMPK has the ability to monitor and respond to cellular energy requirements. In times of hypoxia, nutrient starvation, and redox imbalance, liver kinase B1 (LKB1) - its upstream kinase - activates AMPK. The importance of LKB1 can be seen in patients with Peutz-Jegher syndrome who are heterozygous for a *LKB1* gene mutation. Development of a second mutation in life then greatly increases the risk of multiple cancers. It is hypothesised that the loss of AMPK activation may contribute to this development of malignancy^[109]. LC and HC patients have shown evidence of LKB1 mutations and low LKB1 expression respectively^[104]. Therefore, APN mediated AMPK activation could help prognosis and disease progression in these specific cancers.

The PI3K/Akt pathway promotes cellular survival, growth, and proliferation^[110]. This signalling pathway is specifically known to be involved in gastrointestinal cancers (GI) whereby upstream mutations lead to

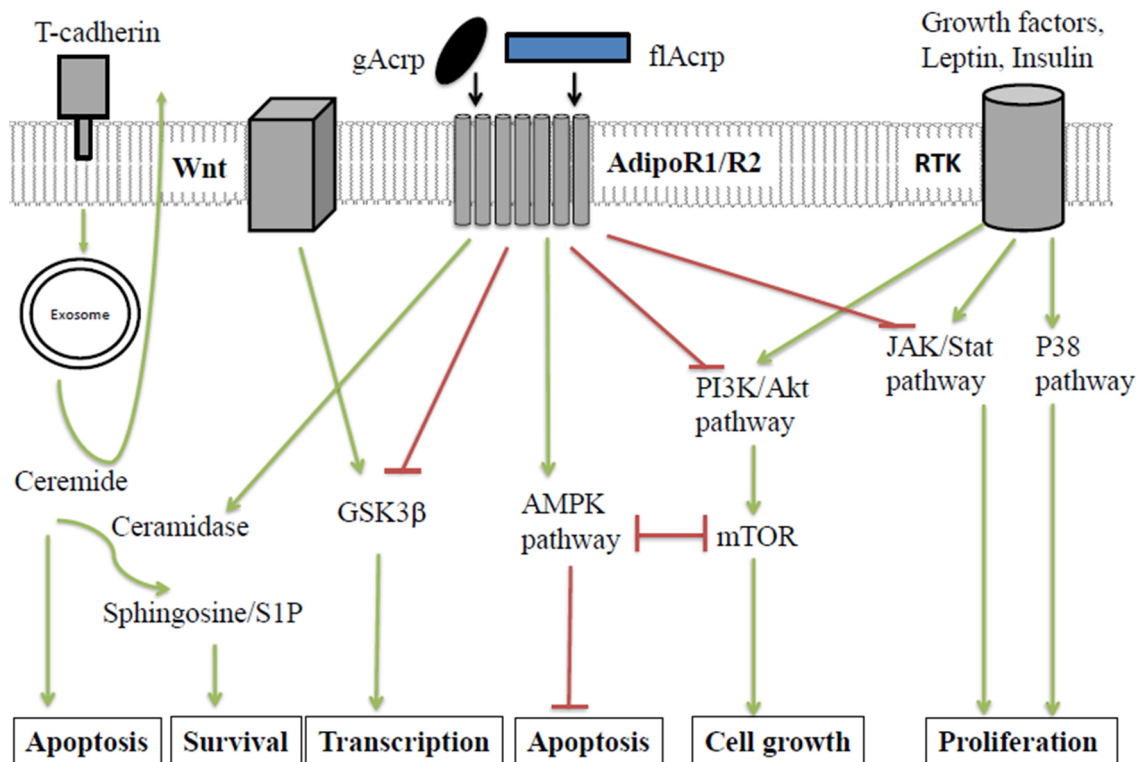

Figure 2. Direct effects of APN on epithelial cells and summary of APN's anti-cancer signaling pathways. In normal epithelial cells, APN is bound by T-cadherin and presented directly or indirectly to AdipoR1/R2 to inhibit signaling pathways activated in neoplasia. APN activates AMPK, and inhibits PI3K/AKT, mTOR, MAPK and JAK/Stat pathways, or directly affects GSK3β to suppress cancer promoting pathways. Cancer cells down-regulate T-cadherin while AdipoR1/R2 expression persists and cancer-promoting pathways prevail. One model is that ceramidase activity associated with AdipoR1/R2 weighs the balance in favor of cancer cell survival. T-cadherin expressed in the tumor vasculature promotes cancer as a pro-angiogenic factor in cooperation with APN (not shown). Green arrows represent activating pathways. Red lines represent inhibitory pathways. gAcrp: globular adiponectin; fAcrp: full length adiponectin; RTK: receptor tyrosine kinase; JAK: Janus kinases; Stat: signal transducer and activator of transcription proteins; PI3K: PI3-kinases; Akt: protein kinase B; mTOR: mammalian target of rapamycin; AMPK: 5' AMP activated protein kinase; GSK3β: glycogen synthase kinase-3 beta

its activation^[32]. Several factors related to obesity have been shown to induce this pathway and potentially result in carcinogenesis, thus making it a good target for obesity related GI cancer. APN can directly^[111] and indirectly^[112] inhibit the PI3K/Akt signalling pathway.

APN also interacts with several other pathways that are involved in carcinogenesis and the maintenance of tumour survival including: the Wnt/GSK3B/B-catenin-signalling pathway^[113], signal transducer and activator of transcription-3 (STAT-3), and mitogen activated protein kinase (MAPK). APN inhibits STAT-3 which has a role in cancer cell proliferation, invasion, and survival^[114]. STAT-3 promotes pro-oncogenic inflammatory pathways, including NF-κB and IL-6-Janus tyrosine kinase, and inhibits the STAT-1 and NF-κB mediated T helper 1 anti-tumour immune response^[114]. Both gAcrp and fAcrp have the ability to suppress STAT-3 and the associated JNK pathways in HC and PrC^[115]. APN also interacts with the MAPK which signals through cJNK, MAPKp38, and extracellular signal-regulated kinases (ERK)1/2^[40,116,117].

Multiple studies have found that AdipoR1/R2 are over-expressed in cancers. In the setting of hypoadiponectinemia it makes sense to have a compensatory upregulation of the receptors. However, this seems counter-intuitive as the cancer cells are over-expressing receptors that act to hinder their growth and proliferation. It is suggested that in a metabolically deprived tumour environment the cells metabolic needs take priority^[17]. That said, it has been shown that APN can also have proliferative effects on cancer cells^[118]. Further studies looking into how the expression of APN's receptors changes throughout tumorigenesis are important as the biological effects of APN depend on the tissue-specific expression of these receptor subtypes^[32].

One of the mechanisms by which APN prevents cancer growth is by promoting apoptosis via cytotoxic autophagy. A recent study using BC cells demonstrated that APN induces an accumulation and fusion of autophagosomes and lysosomes which leads to apoptosis. Central to this pathway is the AMPK mediated activation of the ULK1 (Unc-51 like autophagy activating kinase 1) axis which is regulated by upstream STK11/LKB1 (serine/threonine kinase 11/Liver kinase B1)^[119]. Autophagy can be cytoprotective, cytotoxic, cytostatic, or non-protective. Due to the cytoprotective role of autophagy many studies have looked to see whether inhibition of autophagy can be used in combination with chemotherapy to increase sensitivity to therapy^[120]. In contrast, this study has shown that by stimulating cytotoxic-autophagy it can enhance efficacy of chemotherapy. The dual role of autophagy in tumour suppression and promotion makes utilising this pathway therapeutically challenging and more studies are needed to determine how APN induced autophagy can be used in combination with other treatments.

The intracellular accumulation of ceramides have been associated with pathogenesis such as insulin resistance and endothelial dysfunction^[121,122]. Activation of ceramidase enhances ceramide catabolism to the anti-apoptotic sphingosine-1-phosphate^[123]. A recent study showed that APN signalling through T-cadherin, but not AdipoR1/R2, reduced cellular ceramide by enhancing exosome biogenesis and secretion^[124]. This is a novel mechanism by which APN can lower intracellular ceramide and prevent cellular damage. Unlike AdipoR1/R2, T-cadherin is usually downregulated in cancer cells and re-expression of the receptor has been associated with a better prognosis^[125]. Despite APNs anti-oncogenic pathways, dominance of the ceramidase pathway may enable over expression of AdipoR1/R2 to be pro- rather than anti-oncogenic. When assessing the overall effect of APN, it is important to consider the time at which AdipoR1/R2 are overexpressed in cancer, the concentration of serum APN, and which isoform is circulating.

INDIRECT EFFECT OF APN PATHWAY ON ANTI-CANCER IMMUNITY

Chronic inflammation in adipose tissue, mediated by adipokine signalling, and immune system dysfunction hold important roles in cancer initiation^[126]. APN has been shown to have anti-inflammatory properties through interaction with the innate and adaptive immune system [Table 2]. The majority of this is mediated by antigen-presenting cells (APC) of the innate immune system that produce anti-inflammatory cytokines and inhibit pro-inflammatory cytokines. That said, APN has also been shown to have pro-inflammatory effects [Table 2], suggesting that there may be situations where APNs effects shift from anti- to pro-inflammatory.

One of the central anti-inflammatory cytokines APN induces is IL-10 [Table 2]. The mechanism of IL-10 transcription from APN may be mediated through several pathways. One known pathway is that gAcrp exposure leads to AMPK and ERK1/2 mediated CREB transcription of IL-10^[129]. Multiple studies have demonstrated that gAcrp is the best inducer of IL-10. However, one study showed that activation of AdipoR1 by either gAcrp or fAcrp can upregulate IL-10 through the AMPK and MAPKp38 pathway [Figure 3]. IL-10 has a multitude of anti-inflammatory effects^[164], one of these may be exerted through activation of the STAT3/suppressor of cytokine signalling (SOC3) pathway. Activation of the IL-10 receptor activates this pathway which leads to downstream inhibition of NF-κB [Figure 3].

Although APN levels are generally negatively correlated with cancer risk, high expression of the APN receptors has equally been correlated with tumour progression. Activation of upregulated AdipoR1 and AdipoR2 on dendritic cells (DC) results in the arrest of DCs in an immature state and development of tolerance to tumour antigens^[117]. Each APN receptor has a separate pathway leading to inhibition of the NF-κB pathway thought to induce DC tolerance [Figure 3]. That said, suppression of the NF-κB pathway is a central anti-inflammatory mechanism that APN utilises [Table 3]. Activation of AdipoR1 results in a IL-10 dependent activation of the STAT3/SOC3 pathway and inhibition of the NF-κB pathway. A STAT3-knockout-DC study demonstrated that STAT3 is essential in developing the IL-10 dependent tolerance^[165].

Table 2. Effect of APN on the immune system

Anti-inflammatory effects	
Monocytes	Inducing anti-inflammatory cytokine; IL-10 ^[127] , IL-1RA ^[127]
Macrophages	<ol style="list-style-type: none"> 1. Inducing anti-inflammatory cytokines; IL-10^[127-138], IL-1RA^[127], IL-4^[130] 2. Suppressing pro-inflammatory cytokines; IL-1β^[128], IL-6^[131,132], TNF-α^[128,130,137-139] 3. Less cellular infiltration in disease models^[128,140] 4. Down-regulating chemokine; IP10/CXCL10^[141], I-TAC/CXCL11^[141], Mig/CXCL9^[141], CCL18 5. Inducing mannose receptors^[128] 6. Clearing early apoptotic cells via CRT pathway^[2] 7. Inhibiting MMP-12^[142] or inducing TIMP-1 due to IL-10 effect (independent of MMP-9 inhibition)^[135] 8. Inducing type 1 arginase^[128], HO-1^[130] 9. Suppressing scavenger receptors; MSR-AI^[132], class A^[139] 10. Inhibiting TF^[143] 11. Suppressing cellular maturation^[144]
Dendritic cells	<ol style="list-style-type: none"> 1. Inducing anti-inflammatory cytokine; IL-10^[127,145] & IL-1RA^[127] 2. Attenuating pro-inflammatory cytokine; IL-1β^[145], IL-8^[145], IL-12p40^[145,146], INF-γ^[145], TNF-α^[145] 3. Inhibiting positive co-stimulator (CD80^[145,146], CD86^[145,146], CD40^[145]) 4. Down-regulating HLA II^[145,146] 5. Up-regulating negative co-stimulator (PD1-PDL1^[146]) 6. Inhibiting ROS^[145] 7. Suppressing cellular maturation^[145,146]
Endothelial cells	<ol style="list-style-type: none"> 1. Inhibiting adhesion molecule, ICAM-1 (CD54)^[147], E-selectin^[148], sVEGFR1^[148] 2. Attenuating infiltration of immune cells into disease models^[141,149] 3. Inhibiting apoptosis^[18,150] 4. Suppressing pro-inflammatory cytokine; TNF-α^[18,151], IL-6^[148,152], IL-8^[153] 5. Promoting EPC function & localisation^[154]
Natural killer cells	Down-regulating TRAIL ^[155] & Fas Ligand ^[155]
T cells	<ol style="list-style-type: none"> 1. Inhibiting antigen-specific T cell proliferation^[145,146,156] 2. Inhibiting pro-inflammatory cytokine; IL-1β^[145], IL-2^[156], IL-8^[145], TNF-α^[156], INF-γ^[145,156] 3. Inducing T cell apoptosis^[156] 4. Less cellular infiltration in disease models^[141,149] 5. Promoting Th2 differentiation^[145]
Regulatory T cells	<ol style="list-style-type: none"> 1. Inducing expansion of Treg^[146] 2. Inducing T cell anergy^[145]
B cells	Inhibiting B lymphopoiesis ^[157]
Liver cells	<ol style="list-style-type: none"> 1. Inducing anti-inflammatory cytokine, IL-10^[130], IL-4^[130] 2. Inhibiting pro-inflammatory cytokines, TNF-α^[130,140], IL-1β^[140], IL-6^[140], CCL-2^[140], CXCL10^[140], ICAM-1^[140] 3. Alleviating apoptosis^[140]
Pro-inflammatory effects	
Macrophages	Only inducing transient TNF-α ^[132,133,138] , IL-6 ^[132] (subsequently suppressed by IL-10) or IL-6 (via IRS2 through unidentified APN receptor ^[158])
Dendritic cells	<ol style="list-style-type: none"> 1. Promoting positive co-stimulators; CD86^[159], CD40^[159] 2. Up-regulating HLA II^[159] 3. Inducing pro-inflammatory cytokines, IL-12^[159], IL-6^[159], IL-1β^[159], IL-23^[159] <p>*(APN suboptimal)</p>

Liver cells	Inducing pro-inflammatory chemokine, CXCL8 ^[161]
Fibroblasts	Inducing pro-inflammatory cytokines; IL-6 ^[162,163] **
	** (fIAcrp + suboptimal)

This table summarizes the controversies surrounding the role of APN on the immune system. On balance, majorities of work support the role of APN regulating the immune system negatively. However, the caveats associated with the ability of APN to stimulating the immune system are also demonstrated (as per discussed in the text). The body of evidence on this area tends pale into insignificance comparing to the large experimental data supporting the notion of APN as an immune modulator. IRS-2: insulin receptor substrate-2; ROS: radical oxygen species; C/EBPα: CCAAT/enhancer binding protein-α; MCP-1: monocyte chemoattractant protein-1; EPC: endothelial progenitor cell; eNOS: endothelial nitric oxide synthase; IP-10: interferon (IFN)-inducible protein-10; I-TAC: IFN-inducible T cell alpha chemoattractant; Mig: monokine induced by IFNγ, M1 markers (TNF-α, IL-6, MCP-1), CRT/CD91; CRT: calreticulin; HO-1: heme oxygenase-1; TF: tissue factor; Treg: regulatory T cells

Despite STAT3 being recognised as the dominant mediator for IL-10 functions, this pathway can mediate anti-inflammatory effects in an IL-10 independent manner^[166]. This includes downstream activation of ETS family transcriptional repressor, ETV3 and a helicase family corepressor, Strawberry notch homologue 2 (SBNO2) that can inhibit NF-κB activation^[167].

Figure 3. AdipoR1 and AdipoR2 mediated tolerance of dendritic cells. APN generates dendritic cell tolerance via two distinct pathways that converge upon NF- κ B inhibition. Green arrows represent activating pathways. Red lines represent inhibitory pathways. gAcrp: globular adiponectin; fAcrp: full length adiponectin; AMPK: 5' AMP activated protein kinase; Cox2: cyclooxygenase-2; PPAR- γ : peroxisome proliferator-activated receptor gamma; NF- κ B: nuclear factor kappa-light-chain-enhancer of activated B cells; STAT3: signal transducer and activator of transcription 3; SOC3: suppressor of cytokine signalling 3

The second distinct tolerogenic pathway is activated through AdipoR2 [Figure 3]. In AdipoR1-depleted DCs, use of IL-10 receptor antibodies had no effect on the DCs ability to induce T-cell tolerance - suggesting this is a IL-10 independent tolerance process. Instead, the COX-2 pathway upregulates peroxisome proliferator-activated receptors- γ (PPAR γ), inhibiting the NF- κ B pathway, and promoting anergic phenotypes on engaging T cells^[177]. After DCs interact with allogenic T cells the PPAR γ pathway drives Th2-cytokine production. Treating DCs with PPAR γ agonists produced similar responses^[176]. DCs with a more dominant AdipoR2 signalling produced significantly more Th2-skewing cytokine production than AdipoR1-dominant DCs^[177]. It is thought that the SOCS3 pathway may cause the smaller AdipoR1-dependent Th2-cytokine production^[177]. The role of PPAR γ is further confirmed through a PPAR γ -knockout model that prevented tolerance developing^[177]. It was thought that downstream NF- κ B effectors may contribute towards T-cell tolerance. However, inhibiting anti-NF- κ B effectors was unable to prevent DC promotion of T-cell anergy^[177]. These studies demonstrate AdipoR1/R2 pathways that enable DC-tolerance and allow cancer evade the immune system.

The role of T-cadherin and APN on the immune system is less known. One proposed mechanism is immune modulation through the enhancement of exosome biogenesis and secretion^[124]. When exomes are released from a cell, this may protect cells by modulating the immune function of recipient cells^[178], or stimulating repair of neighbouring cells^[179].

One study showed that T-cadherin is upregulated on chronic cold exposure, enabling APN to be recruited to M2 macrophage cell surface, and promote macrophage proliferation^[180]. Activation of browning and thermogenesis via this pathway may be a further mechanism that APN uses to protect from metabolic stress. Interestingly, in an AdipoR1 and AdipoR2 depleted system, APN-induced T-cell anergy was reversed, suggesting that T-cadherin mediated APN signalling is unlikely to contribute to this process^[177].

Table 3. Molecular signalling of APN on the immune system and its implication

Anti-inflammatory mechanisms	
Cells	Intracellular signalling mechanisms
Macrophages	<ol style="list-style-type: none"> 1. Suppression NF-κB pathway via inhibition of ERK1/2 & MAPK p38^[131], c-JNK & MAPKp38^[168], STAT3^[168] pathways 2. Fibroblasts	Activating NF- κ B via AMPK ^{[162,163]**} , MAPK p38 ^{[162,163]**} (via AdipoR1) ^{[162]**} + ER1/2 ^{[163]**} pathways **(with flAcrp & suboptimal dose)

Summary for the molecular mechanism associated with the effect on APN in the immune system is presented here. Current evidence support many molecular pathways are triggered by the APN and its receptors to regulate various arms of the immune system. APN can negatively affect both innate and adaptive immunities. Again, some mechanism on how it can stimulate the immune system is also demonstrated. M2 markers (IL-10, arginase-1, macrophage galactose N-acetyl-galactosamine specific lectin-1). Cav-1: caveolin-1; SDF-1: stromal cell derived factor-1; MIP-1 α : macrophage-inflammatory protein-1 α ; MCP-1: monocyte chemoattractant protein-1

APN has the ability to polarise macrophages towards a M2 anti-inflammatory rather than a M1 pro-inflammatory phenotype [Figure 4]. The administration of APN stimulated expression of M2 markers and reduced expression of M1 markers in human macrophages and adipose tissue^[169]. APN mediated macrophage polarisation is thought to occur in a IL-10 dependent manner^[127,129,131,135,138,169,181,182]. The gAcrp and flAcrp polarise macrophages by using separate signalling pathways. The gAcrp stimulates CREB that results in an IL-10 mediated M2 polarisation^[129]. Whereas, flAcrp utilizes a IL-4/STAT6-dependent mechanism^[182]. One study demonstrated that flAcrp, through AdipoR2, greatly polarised macrophages to an M2 phenotype. Whereas, gAcrp signalling via the AdipoR2, was much less effective at polarising to the M2 phenotype^[182].

There is significant evidence showing that APN can suppress pro-inflammatory cytokines including TNF- α , IL-1B, IL-6 [Table 2]. Multiple studies have linked APNs anti-inflammatory effects to TNF- α suppression.

Figure 4. APN-mediated polarisation of macrophages to anti-inflammatory M2 phenotype. Through AdipoR1 and undefined receptors APN causes NF- κ B inhibition and promotion of M2 phenotype. Green arrows represent activating pathways. Red lines represent inhibitory pathways. gAcrp: globular adiponectin; fAcrp: full length adiponectin; STAT6: signal transducer and activator of transcription 6; CREB: cAMP response element-binding protein; JNK: c-Jun N-terminal kinase; SOCS3: suppressor of cytokine signalling 3; Bcl3: B-cell lymphoma 3-encoded protein; TRAF1: TNF receptor-associated factor 1; TNIP3: TNFAIP3-interacting protein 3; NF- κ B: nuclear factor kappa-light-chain-enhancer of activated B cells

APN-knockout mice showed high levels of TNF- α in both plasma and adipose tissue^[5]. APN also inhibits a TNF- α induced adhesion molecule^[183] which was found to be in high expression in APN-knockout mice^[184]. Using a reperfusion model, administration of APN reduced apoptosis and TNF- α expression via AMPK and COX-2 respectively^[18]. However, certain studies have shown that APN causes a rise in TNF- α ^[181,185]. The initial increase in TNF- α is mediated by the ERK1/2 pathway which activates early-growth response protein-1 and via a NF- κ B-dependent pathway. Despite an initial rise in TNF- α , it leads to an increased expression of IL-10, eventually shifting the system from a pro- to anti-inflammatory state^[185].

Other studies have identified further pro-inflammatory effects of APN [Table 2]. One study demonstrated that through an unidentified APN receptor, APN increased IL-6 production through NF- κ B activation^[158]. APN was again shown to activate the NF- κ B pathway via phospholipase C (PLC)- γ and the c-Jun N-terminal Kinase (JNK) pathway^[186]. This lead to DC activation and enhanced Th1 and Th17 responses. In adult rat cardiac fibroblasts, gAcrp activation of AdipoR1 induced IL-6 synthesis and release through AMPK, p38MAPK, and ERK1/2 pathways^[163]. However, through AdipoR1 signalling, A20 (zinc finger protein) and B-cell lymphoma 3-encoded protein (Bcl3) upregulation can counter-inhibit IL-6 signalling induced by APN^[117,168]. This complicates the overall picture of APN as an anti-inflammatory cytokine, but likely reflects the complex homeostatic mechanisms that are occurring. Although some evidence suggests APNs pro-inflammatory nature, the overwhelming evidence across a number of cell lines suggest to the contrary [Table 2].

An important consideration in whether APN exerts pro- or anti-inflammatory properties is the concentration that is used in studies. The physiological level of APN in a non-obese, non-diabetic patient is ~ 10 μ g/mL^[187]. When conditioning immune cells, we must take into consideration the concentration of APN used. In certain systems, when the conditioning of immune cells was done at physiological levels, the

opposite effect occurred^[188]. Therefore, the concentration of APN used for conditioning may greatly change the outcome of a study.

Many of the studies showing APN having pro-inflammatory effects used concentrations of ~10 µg/mL^[160,186]. A recent study demonstrated that approximately a plasma APN concentration of 40 µg/mL was needed to induce IL-10 production and an anti-inflammatory response^[117]. Furthermore, physical exercise can increase APN by 260% off baseline^[189]. Therefore, it may be unlikely that using a physiological level of APN would result in the desired anti-inflammatory effects due to sub-optimal signalling.

Interpreting APNs role on immune cells is further complicated as the kinetics of AdipoR1/R2 differ depending on the specific immune cell and stage of differentiation. Expression of AdipoR1/R2 occurs in 80%-90% of CD14⁺, compared to 10% of T-cells^[156]. As monocytes differentiate into macrophages AdipoR1 expression decreases, whereas AdipoR2 expression is constant^[190]. Likewise, the presence of various APN oligomers and the multitude of signalling differences make it hard to pinpoint APNs exact role. For example, differences are observed between HMW APN and gAcrp inhibition of the NF-κB pathway^[191]. HMW APN required shorter incubation period to inhibit NF-κB compared with gAcrp. While gAcrp produces a transient activation and requires a longer incubation period to inhibit the pathway^[191].

In the adaptive immune system APN has been shown to act as a negative regulator for T-cells^[156] and affect the migration of T-cells towards diseased tissue^[141,149]. Although only 10% of T-cells express AdipoR1/R2 on their surface, the majority of T-cells store these receptors within intracellular clathrin-coated vesicles. After stimulation, T-cells upregulate these receptors on the surface and APN interaction subsequently enhances apoptosis and inhibits proliferation. In APN-deficient mice, infection lead to a significantly higher number of CD137⁺ T cells^[156]. Furthermore, culturing APN-DCs with allogenic T-cells decreased T-cell proliferation and pro-inflammatory cytokine production^[146]. A rise in regulatory T-cells was also identified, providing an alternative mechanism that APN can regulate the immune system^[146]. With regard to migration, APN can inhibit expression of chemokines that act as T-cell chemoattractants in atherogenesis^[141]. Therefore, when APN levels are low in cancer, this could favour T-cell recruitment, and contribute towards adaptive immune response. Lastly, one study suggested that rather than affecting proliferation, APN directly activates CD4⁺ T-cells and increases secretion of interferon-γ and IL-6^[160]. It is thought that this inflammatory activation likely desensitises the cells to further pro-inflammatory stimuli. That said, this study uses a low concentration of APN which may influence our interpretation of the results.

FUTURE IMPLICATIONS OF INTERFERING WITH THE APN PATHWAY ON CANCER

TREATMENT

It is clear that APN has the ability to alter cancer outcomes, biology, and anti-cancer immunity. Therefore, APN has been identified as a therapeutic and preventive target for cancer therapy. The pleiotropic nature of various APN isoforms has caused trouble initially engineering an APN analogue, consequently groups decided to screen for endogenous agonists or enhancing existing APN levels.

The first APN receptor agonist screened for and produced was ADP355^[192]. ADP355 binds both AdipoR1/R2, with a greater affinity to AdipoR1^[192]. *In vivo*, this agonist inhibited orthotopic human BC xenograft growth by 31%, with an acceptable safety profile. Similar to gAcrp, ADP355 regulated signalling pathways AMPK, STAT3, PIK3/Akt, and ERK1/2. The group was able to improve agonistic activity by 5-10 fold by substituting Gly4 and Tyr7 residues with Pro and Hyp respectively^[193]. High-throughput screening identified several endogenous adiponectin ligands: AdipoR1 agonists included matairesinol, arctiin, (-)-arctigenin and gramine, while AdipoR2 agonists included parthenolide, taxifolol, deoxyschizandrin, and syringing^[194]. Further studies identified AdipoRon as a strong AdipoR1/R2 agonist at low micromolar concentrations, signalling through AMPK and PPAR-α pathways^[195].

An alternative proposed method is to augment endogenous APN levels using PPAR γ ligands^[196]. Using synthetic PPAR γ ligands, one group demonstrated that expression and secretion of APN increased in a dose and time dependent manner^[197]. Efatutazone, a selective PPAR γ agonist, showed promise on a phase I trial in metastatic solid tumours^[198], metastatic colorectal cancer^[199], and thyroid cancer patients^[200]. However, trials were terminated after phase 2 due to insufficient efficacy^[201,202].

Another PPAR γ agonist Troglitazone has gained much attention in recent years. Troglitazone has been shown to inhibit migration and invasion in human prostate cancer cells^[203], inhibit matrix metalloproteinase-9 expression and invasion of breast cancer cells^[204], and have anti-tumour effects without marked adverse effects^[205]. One study showed that Troglitazone mediated PPAR γ activation enhances human lung cell cancer cells to TRIAL-induced apoptosis^[206]. Suggesting that if used in combination with TRIAL protein it could be useful against TRIAL-resistant cancer cells. That said, phase II studies in refractory breast cancer^[207] and metastatic colorectal cancer^[208] have had disappointing results. A synthetic derivative of Troglitazone, $\Delta 2$ -Troglitazone was shown to be more potent in reducing cancer cell proliferation, however no clinical value has been found^[209].

Rosiglitazone, a PPAR γ agonist, has been shown to have beneficial effects on atherosclerosis, insulin resistance, and type 2 diabetes^[210,211]. However, a phase II trial using Rosiglitazone in liposarcoma patients concluded that this agonist was not an effective anti-tumour drug^[212]. It is important to highlight the side-effect profile of these trial drugs. Rosiglitazone has been shown to increase risk of cardiovascular disease^[213] and Troglitazone presents concerns regarding hepatotoxicity^[207]. Additional cautions should be taken with chronically elevated APN levels which can be linked to infertility and reduced bone density^[214]. Furthermore, interfering with the AdipoR1/R2 pathways can have adverse effects for anti-tumour immune response^[145], consequently a fine balance must be achieved to ensure the anti-cancer pathways are promoted.

With there being limited success with current therapeutic agents one current use for APN is as prognostic markers for cancer^[215]. Both serum APN levels, the expression of AdipoR1/R2, and SNPs could all provide avenues for prognostic and predictive molecular tests in cancer. A number of SNPs in ADIPOQ or APNs receptors have been found associated with BC, CRC, EC, GC, PC, HC, RCC, PrC, and LC^[65]. The question arises whether there would be any change in clinical decision making through screening these SNPs or whether they would give any benefit above currently used biomarkers. That said, if well targeted, these tests could help early diagnosis, aid post-operative recovery, and initiate APN modulatory therapy

It has been shown that a Mediterranean-type diet, reduction in body weight, and exercise can increase circulating APN levels^[189,216]. Furthermore, aerobic exercise was shown to increase expression of AdipoR1 and AdipoR2 in young men^[217]. Therefore, using programmes that promote weight loss and a healthy diet in parallel with new APN promoting agents may enable more favourable outcome. Similarly, new APN therapeutic agents may show more promise when being used in combination with traditional treatment by sensitising cancer cells.

A number of cancers are strongly associated with chronic inflammatory processes, for example the association between inflammatory bowel disease and CRC, or *Helicobacter pylori* infection and GC^[218]. These type of cancers could greatly benefit from the anti-inflammatory properties of APN. In cancer there is often defective inflammatory responses, the goal is to restore the normal overall host response, without undesirable side effects. However, one needs to acknowledge that by altering these metabolic pathways there is a chance of detrimental changes to anti-tumour immunity. Moreover, as carcinogenesis progresses, there are changes to the way the tumour environment harnesses the immune system, therefore the timing of treatment may greatly alter the efficacy.

When considering APN as a therapeutic agent it is important to highlight several points. Firstly, many factors influence the levels of circulating APN. Sex, age, ethnicity, and intra-abdominal fat all have

independent roles in determining APN levels^[219]. This is important to consider as a therapeutic agent may have greatly differing effects across individuals. Secondly, the pleomorphic nature of APNs isoforms mean it will be hard to replicate each isoforms action. One option would be to use recombinant APN, however this has been difficult to produce and would be expensive over the long term. The solution has been to attempt to increase endogenous APN, but we must consider whether it may be beneficial to selectively increase one isoform. Thirdly, the dosage APN used can affect the inflammatory response in a varied manner. In creating a novel agent, the dose regime must be carefully designed to ensure the desired response is seen.

CONCLUSION

Obesity related-cancers are now a recognised phenomenon. APN is the key adipokine produced by the fat cells and its role in cancer pathogenesis and disease prognosis is now slowly revealed. Hypoadiponectinaemia is often found to be associated with cancers and also affects their prognosis. Therefore, various efforts have been made to harness its therapeutic effects. It can be applied either therapeutically or prophylactically to treat various cancers. For example, identification of ADIPOQ, AdipoR1 and AdipoR2 SNPs that may confer altered risks of cancer development may enable early screening and APN level augmentation via therapeutic interventions.

Overall this field holds a huge promise, however many challenges will need to be addressed prior to its routine use. Cellular and molecular function of APN in cancer either its pathogenesis phase or advanced forms of cancer will need to be fully researched. APN may have different effect on various stages of cancers either directly or indirectly via immune system. The role of each isoform in distinct tissues and under specific conditions needs be clarified. More importantly, the molecular conditions under which APN acts as cancer suppressing or promoting and anti-inflammatory or pro-inflammatory still needs to be fully evaluated. The exact roles of APN interacting which receptors (some identified but some remained to be defined) and their downstream pathways in different cancer have largely remained elusive. Exploring an effective APN-based therapeutic and when to applied this therapeutic may be the crucial step. Understanding the complexity of APN on anti-tumour response may need to be considered when using it as a therapeutic agent.

Abstract

Cancer remains a worldwide health problem, being the disease with the highest impact on global health. Even with all the recent technological improvements, recurrence and metastasis still are the main cause of death. Since photodynamic therapy (PDT) does not compromise other treatment options and presents reduced long-term morbidity when compared with chemotherapy or radiotherapy, it appears as a promising alternative treatment for controlling malignant diseases. In this review, we set out to perform a broad up-date on PDT in cancer research and treatment, discussing how this approach has been applied and what it could add to breast cancer therapy. We covered topics going from the photochemical mechanisms involved, the different cell death mechanisms being triggered by a myriad of photosensitizers up to the more recent-on-going clinical trials.

Keywords: Photodynamic therapy, breast cancer, photosensitizers, cell death

INTRODUCTION

Cancer remains a worldwide health problem. In particular, breast cancer is the disease with the highest impact on global health. Even with all the recent technological improvements, recurrence and metastasis still are the main causes of death. In fact, the high mortality as a consequence of distant metastasis in patients remains a bottleneck for an effective treatment in clinic^[1,2]. Metastasis are characterized by a sequential and complex process during which cancer cells invade specific organs including lung, liver, brain, and bone^[3].

Metastatic lesions are usually multiple and resistant to conventional therapies, jeopardizing successful surgical resection, chemo and radiation treatment^[4].

Light has been known to provide a therapeutic potential for several thousands of years. Over 3000 years ago, since the Ancient, Indian and Chinese civilizations it has been used for the treatment of various diseases^[5] mainly in combination with reactive chemicals, for example to treat conditions like vitiligo, psoriasis and skin cancer^[6]. After 1895 with the discovery of the phototherapy, which rendered Niels Ryberg Finsen the Nobel prize in Physiology/Medicine in 1903 in recognition of his work on the treatment of diseases, and in particular on the treatment of lupus vulgaris by means of concentrated light rays, many studies with the use of light and chemicals emerged^[7].

Photodynamic therapy (PDT) is currently being used as an alternative treatment for the control of malignant diseases^[8-10]. It is based in the uptake of a photosensitizer (PS) molecule which, upon being excited by light in a determined wavelength, reacts with oxygen and generates oxidant species (radicals, singlet oxygen, triplet species) in target tissues, leading to cell death^[11,12]. PDT cytotoxic properties have been established to be due to the oxidation of a large range of biomolecules in cells, including nucleic acids, lipids, and proteins, leading to severe alteration in cell signaling cascades or in gene expression regulation^[13,14]. Like all the newly proposed treatments, there is still place for improvements and lots of resources have been invested in this field recently. In this review, we set out to perform a broad up-date on PDT and its implication in cancer research and treatment. We have covered topics going from the photochemical mechanisms involved, the different cell death mechanisms being triggered by a myriad of photosensitizers up to the more recent reported preclinical studies and on-going clinical trials.

PHOTOCHEMICAL PRINCIPLES AND COMPONENTS OF PDT

As previously stated, PDT involves the photosensitized oxidation of biomolecules which can be separated in two mechanisms. In Type I, light energy passes from excited molecules to biomolecules through electron/hydrogen transfer (radical mechanism) in direct-contact reactions [Figure 1] and culminates in specific damage to biomolecules and in the initiation of radical chain reactions. On the other hand, in the Type II mechanism, the excitation energy is transferred to molecular oxygen ($^3\text{O}_2$), resulting in the formation of singlet oxygen ($^1\text{O}_2$), which is extremely electrophilic, being capable of causing damage to membranes, proteins and DNA [Figure 1]. Direct contact reactions usually cause more severe damage in biomolecules, but also cause photodegradation of the PS, while diffusive species are important to replenish the PS. By either mechanism, the formation of triplet excited species is the key step in terms of performance of the PS. Both tricyclic phenothiazinium salts and macrocyclic poly-pyrroles (porphyrins and derivatives) compounds generate reasonable amounts of triplets upon electronic excitation, being therefore PSs commonly used for PDT^[15]. There is no doubt that the outcome of PDT critically depends on the intrinsic efficiency of the PS. Even when the search for new PS remains mostly focused in the synthesis of compounds that produce singlet oxygen with greater efficiency, there are many factors needed to be considered including aggregation and photodegradation^[15].

Damages to proteins and membranes are of particular importance for PDT in order to optimize the cytotoxic efficiency to the process. Indeed, PSs displaying a higher degree of accumulation in cell and/or organelles membranes are usually more cytotoxic^[16,17]. The mechanism by which photosensitized oxidations on lipids cause membranes to leak out, has been recently described^[18]. In generic terms, changes in phospholipids occur due to lipid peroxidation, which are reactions that are initiated as a consequence of the formation of free radicals and singlet oxygen. After this starting point, the process becomes autocatalytic, leading to the formation of hydroperoxides and other byproducts. Figure 2 summarizes the main steps in photo-induced membrane damage. The first one usually involves the “ene” reaction between the lipid (LH)

Figure 1. Mechanisms of photosensitization. The photosensitizer (PS), is a molecule capable to absorb energy from light in a specific wavelength. Once excited, the PS transits from its ground state $PS(S_0)$, to its singlet excited $PS(S_1)$ and triplet excited $PS(T_1)$ states. At this point $PS(T_1)$ can react directly with biomolecules, like proteins or lipids (targets), via Type I photochemical reaction, resulting in formation of radicals, like PS^\bullet , capable to initiate radical chain reactions. Otherwise, $PS(T_1)$ can react with molecular oxygen 3O_2 , via the Type II photochemical reaction. Both generates diffusive oxidant species like radical superoxide, $O_2^{\bullet-}$, and singlet oxygen, 1O_2 , via type I and II respectively, capable to extend the damage

Figure 2. Mechanisms of photo-induced membrane damage. This graphical sketch represents how Type I and Type II photochemical reactions contribute to membrane leakage through lipid damage. Type I reactions lead to changes in membrane fluidity which occur as a result of direct-contact reactions between the PS triplet [$PS(T_1)$] and either the lipid double bond of LH or the LOOH. Type II reactions [$PS(T_1)$ and molecular oxygen (3O_2)] generates singlet oxygen (1O_2) which leads to the formation of hydroperoxide (LOOH) as primary product. Modified from [18]. R•: generic radical species; LH: non-oxidized lipid; L•, LOO•, LO•: lipid carbon-centered, peroxy and alkoxy radicals; LOOH, LOH, LO, LO•: lipid hydroperoxide, alcohol, ketone and excited state ketone

and singlet oxygen (formed via type II photochemical reaction between PS triplet $PS(T_1)$ and molecular oxygen) leading to the formation of hydroperoxide (LOOH). The other steps comprise direct reactions with the $PS(T_1)$ via Type I photochemical mechanism. Irreversible damage occurs with the abstraction of a hydrogen atom from an unsaturated fatty acid (LH), leading to the formation of a lipid radical (L•). This one suffers the addition of an oxygen molecule forming the peroxy radical (LOO•) which is, in turn, able to react with another LH fatty acid, initiating a new oxidation round leading to the formation of lipid hydroperoxide

(LOOH) and another L•. The propagation phase comprises the initiation of a new oxidation chain by the peroxy radical (LOO•) and the decomposition of the lipid hydroperoxides into other intermediate radicals. In light-induced reactions, formation of alkoxides is catalyzed by direct contact reactions between the triplet photosensitizer, the lipid double bond and the lipid hydroperoxide, leading to chain breakage by β -scission. This process leads to the formation of lipid truncated aldehydes and further products, which are molecules responsible for starting of the leakage process. This explains successful results as well as opens possibilities for cellular targeting strategies that will be discussed below.

RESEARCH IN PDT

Photosensitizers and photocytotoxicity mechanisms

The PS is one of the three crucial elements of PDT, apart from light and oxygen. Due to their photochemistry properties and uptake efficiency currently only a few PSs have official approval worldwide and are being used clinically. Related to cancer treatment, PS approved or in clinical trial are listed on [Table 1](#). In particular, Porphimer sodium (Photofrin), mTHPC (Foscan), NPe6 (Laserphyrin), SnEt2 (Purlytin), Visudyne (Veteporfin) and Motexafin lutetium (LuTex) are clinically or preclinically applied for breast cancer^[19-21]. These photosensitizers have shown selectivity towards tumor cells and are ideal for cellular and vascular-targeted PDT. Moreover their interference with cytoprotective molecular responses constitutes an area of growing interest^[22,23]. Other compounds such as porphyrin precursors [e.g., aminolevulinic acid (ALA)]^[24], phenothiazines (e.g., methylene blue)^[25,26], cyanines (e.g., merocyanine, indocyanine green)^[27], hypericin^[28], and xanthenes (e.g., Rose Bengal)^[29] have been considered as good candidates as PS used for PDT.

Several studies have been performed over the last decades in order to better characterize PS efficacy and selectivity. Some of them have focused on the development of agents with higher absorption wavelengths, allowing deeper penetration of illuminating sources and thus the depths at which tumor cells can be targeted, the so-called second-generation PSs. Third-generation PSs have recently emerged aiming mainly at targeting strategies, such as antibody-directed PS and PS-loaded nanocarriers. These approaches were developed in order to increase the power and efficiency of PDT and have allowed the broadening of the types of diseased tissues that could be treated^[36].

Besides the PSs photoactive capacity, which enables it as a therapeutic agent upon light activation, their autofluorescence is also an important characteristic. Indeed, PS's fluorescence confers them imaging properties to be used for detection of pre-cancer lesions and early malignancies, as well as tumor margins. Furthermore, this property can be used for the identification of remaining dysplastic tissue upon surgical tumor resections, and to monitor the progress of the PDT treatment. Thus the combination of imaging, detection and therapeutic properties confers them the characteristics of theranostic agents^[36,37]. PS 5-ALA, which is a prodrug enzymatically converted during heme synthesis to the active PS agent protoporphyrin IX, displays theranostic properties and has brought important knowledge in PDT research and treatment field. Additionally, in clinical trials 5-ALA has already shown clinical benefit in different types of tumors^[24].

PDT is considered to be involved in at least three main mechanisms of tissue destruction. The first one is the ability to directly kill cells through the action of damaging reactive chemical species generated by PS excitation. Direct phototoxic effect of PDT involves irreversible photodamage to specific targets, such as membranes and organelles^[38] as discussed in the previous section. The extent of the damage as well as the cell death mechanisms involved are dependent on the PS type, concentration, subcellular localization, energy applied and also on the intrinsic resistance characteristics of each tumor type. When perturbations of the intracellular and/or extracellular microenvironment are too intense, cells can die following a complete breakdown of the plasma membrane (necrosis morphology) or elicit specific cell death mechanisms^[39]. Additionally, PDT tumor destruction can also involve the damage of the tumor vasculature, thereby

Table 1. Photosensitizers investigated in clinical trial for cancer treatment^[15,21,23,30-35]

Photosensitizer	Chemical family	Treatment Wavelength (nm)	Cancer type	Characteristics
Porfimer sodium, HPD: hematoporphyrin derivative (Photofrin)	Porphyrin	630	Lung, esophagus, bile duct, bladder, brain, ovarian, breast skin metastases	1st generation PS Most probable intracellular localization: plasma membrane and mitochondria. Intravenous administration
5-ALA: 5-aminolevulinic acid (Levulan)	Porphyrin precursor	630	Skin, bladder, brain, esophagus	2nd generation PS Most probable intracellular localization: mitochondria Topical, oral or intravenous administration
MAL: methyl-aminolevulinate (Metvix)	Porphyrin precursor	630	Skin	2nd generation PS Most probable intracellular localization: mitochondria and ER Topical administration
h-ALA: hexylaminolevulinate (Hexvix)	Porphyrin precursor	White light	Basal cell	2nd generation PS Intracellular localization: TBD Topical administration
Veteporfin, BDP: benzoporphyrin derivative (Visudyne)	Porphyrin	690	Pancreas, breast	2nd generation PS Most probable intracellular localization: mitochondria Intravenous administration
Palladium bacteriopheophorbide, padeliporfin, WST-11 (Tookad)	Porphyrin	762	Esophagus, prostate	2nd generation PS Intracellular localization: TBD. Intravenous administration
Temoporfin, mTHPC: meso-tetrahydroxyphenylchlorine (Foscan)	Chlorin	652	Head and neck, lung, brain, bile duct, pancreas skin, breast	2nd generation PS Most probable intracellular localization: mitochondria, golgi apparatus and ER Intravenous administration
Talaporfin, mono-L-aspartyl chlorin e6, NPe6, LS11 (Laserphyrin)	Chlorin	660	Liver, colon, brain, lung, breast skin metastases	2nd generation PS Most probable intracellular localization: lysosomes Intravenous administration
HPPH: 2-(1-hexyloxyethyl)-2-devinyl pyropheophorbide-a (Photochlor)	Chlorin	665	Head and neck, esophagus, lung	2nd generation PS Most probable intracellular localization: mitochondria and/or lysosomes Intravenous administration
Rostaporfin, SnEt2: tin ethyl etiopurpurin I, or (Purlytin)	Chlorin	660	Skin, breast	2nd generation PS Most probable intracellular localization: lysosomes Intravenous administration
Fimaporfin, disulfonated tetraphenyl chlorin, TPCS2a (Amphinex)	Chlorin	633	Superficial cancers, Cholon	2nd generation PS Most probable intracellular localization: endo-lysosomal compartments Intravenous administration
Motexafin lutetium (Lutex)	Texaphyrin	732	Breast	2nd generation PS Broad intracellular localization Intravenous administration

TBD: to be determined

compromising the supply of oxygen and essential nutrients, as well as activation of the immune system, by inducing an inflammatory and an immune response against tumor cells^[23,35,40].

Cell death subroutines are strongly connected with successful therapy outcome. Even when a detailed explanation of cell death mechanisms is not the scope of this review (updated and deeper information can be assessed in^[39]), here we point some of their important features, since describing one or ones of them involved in cell toxicity constitutes a very important topic of research in the field of PDT.

At the cellular level, PDT has been shown to induce multiple cell death subroutines, that can be accidental or not [Figure 3]. Accidental cell death is an uncontrollable form of death corresponding to the physical disassembly of the plasma membrane caused by extreme physical, chemical, or mechanical cues. On the other hand, regulated cell death (RCD) results from the activation of one or more signal transduction modules, and hence can be pharmacologically or genetically modulated, at least to some extent^[39]. The RCD subroutines already related with PDT include apoptosis and different mechanisms of regulated necrosis

Figure 3. Overview of cell death subroutines that can be elicited by Photodynamic therapy. The most described locations of different photosensitizers (PS) are the plasma membrane (PM), endoplasmic reticulum (ER), mitochondria (M) or the lysosome (L). Depending on its localization, after activation by light (red lightningbolt) it can directly damage the PM causing unregulated necrosis or culminate in one or more regulated cell death (RCD) mechanisms. UPR: unfolded protein response; LMP: lysosome membrane permeabilization; Fe: iron; ROS: reactive oxygen species; -P: phosphate group presented in the active forms of RIPK3 and MLKL on necroptosis pathway; LDCD: lysosomal dependent cell death

(such as necroptosis and lysosome-dependent cell death)^[15,41]. Briefly, apoptosis^[42] is a type of RCD initiated by perturbations of the extracellular or intracellular microenvironment, being respectively classified as extrinsic (when signals are detected by plasma membrane receptors, and propagated by caspase-8 and precipitated by executioner caspases, mainly caspase-3) or intrinsic (demarcated by mitochondrial membrane permeabilization (MOMP), unbalance of pro and anti-apoptotic factors related with members of BCL2 family of proteins, and precipitated by the executioner caspases)^[39,43-48]. Necroptosis is a modality of RCD triggered by perturbations of extracellular or intracellular homeostasis that critically depends on phosphorylation, oligomerization and migration of MLKL (mixed lineage kinase domain-like protein) to plasma membrane, the kinase activities of RIPK3 and (at least in some settings) of RIPK1 (receptor interacting protein kinases-1 and -3, respectively)^[49]. Finally, lysosome-dependent cell death (LDCD) is a consequence of lysosomal membrane permeabilization^[50,51] and releasing of cathepsins, with optional involvement of MOMP and caspases. Indeed, one of the advantages of PDT is that this therapeutic approach has demonstrated to be able to cope with the very well described ability to bypass the several resistance mechanisms displayed by malignant cells^[26].

PS localization within or on the cell surface is critical to determining the mode of cell death induction and thus the cellular response to photodamage^[38,52,53]. Therefore, precise understanding of the preferential subcellular site of PS accumulation is important in order to determine its cytotoxic potential when used in PDT^[38,54]. PS uptake by the tumorigenic cells as well as its preferential intracellular site depends on chemical characteristics of each compound. Hydrophobic molecules can rapidly diffuse into plasmatic membranes while more polar drugs tend to be internalized via endocytosis or assisted transport by serum lipids and

proteins. After internalization, most of the PSs are localized in organelle membranes due to their common chemical core. In general, PS's cellular localization can be highly specific or quite broad, and have been reported to include the endoplasmic reticulum (ER), mitochondria, Golgi complex, lysosomes and the plasma membrane^[40,55]. To limit DNA damage and avoid the development of genetically resistant cells, PS should not accumulate in the cell nuclei^[30]. Accidental necrosis is more often observed when the PS site of action is in the plasma membrane and/or when it is activated with high energy doses^[40]. In order to suppress undesired damage to normal tissues, this effect should in general be avoided^[56]. In an organelle-specific photodamage scenario, the mechanism of autophagy is activated as a coordinated intracellular response aiming at reestablishing homeostasis. When impaired or insufficient autophagy is triggered, induction of cell death is the most common result observed^[26,38,57,58]. The best documented organelle specific cytotoxic effects of PDT are related with the photodamage of mitochondria, lysosomes and ER.

Porphyrins can present a variable localization pattern, mostly associated with plasma membranes and mitochondria. PSs that are located in the mitochondria can cause mitochondrial inner membrane permeabilization and selectively damage antiapoptotic proteins of the BCL-2 family, localized at the outer mitochondrial membrane while the proapoptotic proteins are left intact, resulting in an unbalance of pro- and anti-apoptotic players that results in caspase activation^[35]. On the other hand, some mitochondria-associated porphyrins can also activate necroptosis, as already shown in 5-ALA-PDT^[59]. A lysosome localization pattern was observed using negatively-charged porphyrins, NPe6 and the phenothiazinium methylene blue^[26,38,53]. A potential advantage of lysosome target PDT is that lysosomal damage might easily circumvent autophagic protection that can be activated in parallel of cell damage. Lysosome damaging PDT leads to LDCD^[39,51,60]. Release of cathepsins after PDT can result in cleavage of the pro-apoptotic protein Bid to a truncated form termed tBid. This product can in turn interact with mitochondria, leading to the release of cytochrome c, followed by the consequent activation of intrinsic apoptosis as already shown in NPe6-PDT^[41]. However, not only apoptosis can be activated by lysosome damage and although it has not been demonstrated as a PDT-induced mechanism yet, several parameters of regulated necrosis have been also associated with LDCD. Indeed, the degradation of caspase-8 and recruitment of necroptosis machinery^[61] or even the involvement of iron homeostasis modulation leading to an increased susceptibility to undergo ferroptosis^[62] have already been associated with lysosomal damage. Other porphyrins such as mTHPC and Hypericin, have been reported to target ER or both ER and mitochondria. Under massive photodamage in ER membranes, PDT can elicit pro-death signaling via the unfolded protein response cascade. The resulted ER stress, activates the pro-apoptotic transcription factor CHOP, which in turn mediates mitochondrial apoptosis^[63]. The induction of multiple cell death pathways is usually considered as an useful characteristic of PDT, since it increases photokilling in tumor cells harboring a particular cell death pathway resistance^[64].

PDT and immune response as a tool to deal with metastasis

The major challenge in the fight against cancer includes treatment toxicity and drug-resistance associated with incompletely tumor removal by surgical resection. In order to extend patient survival, systemic chemotherapy has become an essential part of treatment after surgery. However, therapies effective in both reducing the high mortality rate associated with the disease as well as improving patient quality of life still need to be developed^[22,35]. In an attempt to circumvent the appearance of a secondary disease, immunotherapy has been applied and developed as a tool to control cancer recurrence and metastases. There are few effective treatments for metastases, thus there is an increased interest in therapies that eliminate primary tumors and systemically activate antitumor immune responses. In this sense, PDT emerges as a potential therapy to be used alone or in combination with other approved or experimental approaches^[65] because of the recent findings indicating that PDT can also trigger systemic effects, including the reinstallation of immunosurveillance^[29,66].

Examples of immunotherapy include the use of monoclonal antibodies to block immune checkpoint activity of cancer cells, enabling anti-cancer T cell responses, or adoptive cellular therapy to prime patient's own

lymphocytes to attack cancer cells. The goal of immunotherapy is to generate a robust immune response, stimulating the endogenous cytotoxic lymphocytes to eradicate tumor cells and ultimately achieve long-term anticancer immunity^[67]. Therefore, the ideal cancer treatment should involve the direct cytotoxic action on tumor cells with potential to stimulate the immune system based on the immune-recognition of danger signals emitted by dying cells^[68]. In a typical immune response, antigens are captured by dendritic cells (DCs), which then mature and present antigenic peptides to T cells in lymph nodes, generating effector T cells that migrate towards sites of infection, inflammation or injury. IFN- γ and GM-CSF are central to the process of DC maturation and macrophage activation. DCs in turn release cytokines, like IL-1 β , IL-6, IL-12 or TNF, that shape the Natural Killer cell (NK) and T cell responses. T cells CD4+ and CD8+, together with NK cells, can receive survival signals and stimulation from IL-2, leading to full effector activities, and produce additional IFN- γ . Normal immune regulation involves cytokines like IL-10 and TGF- β to limit the activity of T cells and macrophages and reduce inflammation, terminating immune responses and protecting the host from immune-mediated damage^[67]. Some tumors appear to have somehow managed to avoid detection by the various arms of the immune system or have been able to limit the extent of immunological killing, thereby evading their eradication^[69].

The best way to reestablish an immune system response against tumors is by eliciting, therapeutically, a cancer cell death pathway that is accompanied by high immunogenicity and is possibly able to inhibit or reduce the influence of the pro-tumorigenic cytokine signaling. Over the last years, several studies demonstrated that few selected anti-cancer therapeutic approaches are able to induce a promising kind of cancer cell demise called immunogenic cell death (ICD)^[70]. The concept of ICD has been introduced to describe a cell death modality that stimulates an immune response against antigens coming from dead cells. After exposure to certain cytotoxic ICD-agents, changes in the composition of the cell surface promote the exposure or release of mediators, the so-called damage associated molecular patterns (DAMPs)^[71]. These signals are thus further recognized by DCs to stimulate the presentation of tumor antigens to T cells^[72]. It has emerged that initiating a tumor cell death modality associated with the activation of signaling pathways that release DAMPs markedly increases the immunogenicity of dying cancer cells^[73]. Up to now, the main DAMPs involved in ICD include surface-exposed calreticulin (CRT), surface-exposed heat shock protein (HSP) 70 and 90, secreted adenosine triphosphate and passively released high-mobility group box 1 (HMGB1)^[71,74]. Many conventional anticancer treatments, that include chemotherapies, radiotherapies and target therapies have had their immunogenic potential evaluated, but only a few of them have been characterized as ICD-inducers^[72]. This exclusive inducer-induction relationship exists because ICD requires, as a pre-requisite, induction of reactive oxygen species (ROS)-based ER stress, where ROS may or may not be mainly ER-directed^[75]. As a ROS-inducer therapy, the potential of PDT in stimulating ICD seems to be quite probable, and has been tested.

Preclinical studies have shown that in contrast to the effects of traditional therapies, low-dose PDT regimens can induce anti-tumor immunity, and these can be combined with high-dose PDT to achieve local tumor control with the immune suppression of distant disease^[76]. The potential mechanisms of PDT immune stimulation involve the acute inflammatory response following PDT, which might increase the presentation of tumor antigens to activate DC, and their homing in to regional and peripheral lymph nodes, thus ultimately stimulating CD8+ cytotoxic T cells and NK cells, accompanied by immune memory and the suppression of any subsequent tumor growth upon a second challenge. The degree of acute inflammation induced by PDT has been reported to be regimen dependent and to correlate with the extent of the induced vascular damage. PDT regimens that result in rapid cell death (within 1 h of treatment) and maximal tissue damage were demonstrated to cause minimal acute inflammation, presumably because of vascular shutdown, which would prevent neutrophil infiltration and systemic release of cytokines. In contrast, regimens that cause diffuse tumor damage should allow neutrophil infiltration followed by induction of expression and release of inflammatory mediators critical for enhancement of anti-tumor immunity^[77]. Ongoing studies are focused

on finding optimal PDT conditions to induce systemic immunity. Recent reports have shown that PDT can be an effective adjuvant therapy to surgery that increases the probability of long-term local disease control^[30]. Recently results from a preclinical study have also identified an anti-tumor combined PDT treatment regimen that controls primary and metastatic tumor growth and enhances anti-tumor immunity of both colon and mammary carcinomas^[76]. Recently, PDT utilizing the photosensitizer hypericin (Hyp-PDT), became the first PDT modality characterized as capable of inducing ICD^[28]. Although the immunogenic potential has not been tested for all PS yet, these recent findings with hypericin constitute an important achievement because they have allowed PDT to be classified as a therapy capable of inducing ICD. Accordingly, a recent study have shown that glycoconjugated chlorin-PDT suppressed colon rectal tumor cells (CT26) growth more efficiently in immunocompetent mice compared with immuno-deficient mice. Additionally, the exposure of the mice to PDT-treated CT26 cells was capable of protecting them against a subsequent challenge with CT26 cells and this immunogenic effect was dependent on CRT exposure in the plasma membrane and HMGB1 release, two known features of ICD^[65]. Moreover, the increased interest in PDT has actually helped in a deeper understanding of technical as well as conceptual aspects of ICD and the danger signals involved in this type of cell death. Further clinical research may perhaps point PDT as a method of vaccination against tumors^[78,79]. This clearly would be of great advantage since PDT in patients treated for primary breast cancer could also result in increasing acquired immunity against the cancer at distant sites.

Overall, accumulating evidence indicates that the therapeutic efficacy of several antineoplastic agents, including PDT, relies on their capacity to influence the tumor-host interaction, tipping the balance toward the activation of an immune response specific for malignant cells, especially for metastasize cancer.

Instrumentation, drawbacks and side effects

PDT has been shown to be effective in treating different types of cancers, especially the ones with superficial localizations, as this intervention provides a significant improvement in both the patient's quality of life^[80] and its cost-effectiveness compared to palliative surgery or palliative chemotherapy treatments^[81]. However, as happens with other therapies as well, the predominant unfavorable anatomical and microenvironment conditions have been reported to limit its efficacy and to contribute for the relatively slow transition from preclinical to clinical practice of PDT for treating these tumors^[82,83]. Adjustment of PDT parameters such as type and local concentration of the PS, light delivery and source or dosimetry in a context where there is no homogeneity is considered as one of the bigger obstacles of this therapeutic approach^[84].

The most common concern about the clinical use of PDT constitutes the limited penetration of light. However, nowadays this old idea that PDT is as a surface treatment because the application of external light may only treat superficial lesions is no longer believed. This problem is actually in the way of being solved because of the possibility of using fibers which can be placed in determined locations within the tumor site. Due to advances in fiber optics and microendoscopic technology, PDT can be used in the clinic with interstitial, endoscopic, intraoperative or laparoscopic light delivery systems. In this scenario, the laser light can be adapted into thin optical fibers for delivery of light into deeper and more difficult to access treatment sites^[85]. These fibers besides being used to deliver light, can also simultaneously act as diagnostic sensors that can gauge important PDT parameters which critically impact the therapeutic response, such as the fluence rate, PS concentration, PS photobleaching and the tissue oxygenation status^[86,87]. It is important to take into account that the vascular collapse promoted by PDT can decrease the tumor oxygenation. Since the success of the treatment relies on the preexisting ground state oxygen to produce singlet oxygen via type II photochemical reaction [Figure 1], tissue oxygenation state significantly affects the efficiency of PDT. Moreover during the treatment itself, the formation of ROS using high light fluence rates can deplete the oxygen levels in tumorigenic tissue too fast, aggravating the tumor hypoxia and hampering the treatment outcome^[40,88,89]. Thus, improvement the oxygen concentration is an important issue for PDT. In fact, adjusting the light and PS dosimetry, lowering light fluence rates or using light fractionated strategies

can prevent oxygen depletion and allow sufficient time for the replenishment of oxygen in the target tissue. However, it has already been reported that different PS affect the oxygen consumption rates differently^[90] and thus PDT outcome may vary. Altogether, these results point to the need of more studies addressing how to maintain PDT performance. An interesting study employing a combination of the fractionated PDT with a PS that could produce singlet oxygen during the dark periods^[91] has recently addressed this issue. Moreover, the presence of pre-existing hypoxic areas in tumors can be circumvented by a variety of strategies such as improving tissue oxygenation prior to PDT as well as by efficiently producing radical species via type I photochemical reactions^[88].

Regarding light source technology, researchers have been developing light delivery systems with uniform illumination, which is essential to improving light penetration and reproducibility. An example of this is the use of bulb-shaped isotropic emitters along with light detectors which have been used in hollow organs. Light dosimetry can also help to optimize the positioning of light diffusers. Furthermore, increasing the selectivity of PDT could be achieved by customizing the diffusers such as balloons and cylindrical applicators according to the form and dimensions of the target tissue^[92,93].

Additionally, recent advances in LED and diode lasers have allowed to merge their ability of output potency, enhanced portability and precision optical fiber coupling. These, non-collimated and less expensive light sources will certainly ease the translation of PDT to clinical procedures. They are usually employed due to their robustness, short bandwidth, relatively low maintenance cost and ability to be configured to the wavelength required by the PS. Lamps such as Tungsten filament lamps, metal halide lamps, powerful Xenon arc lamps and pulsed lasers are also commonly used in the PDT field^[92].

Besides the light source itself, defining the strategy of light application is of fundamental importance since different irradiation protocols using the same source can lead to different outcomes in PDT. Another drawback to be dealt with in PDT prescriptions is light dose regimens because they might also influence the host anti-tumor reactions and optimal strategies are likely case dependent^[35,85]. Therefore, a full understanding of light dosimetry is an important part of PDT. The issue of light in PDT is under careful investigation and improvements and new technologies in this field will certainly lead to optimized overall PDT efficacy and protocols^[94]. For example, one strategy to induce deep tissue phototoxicity is to perform repeated PDT or metronomic PDT (slow infusion of PS and low dose light)^[95]. Recent studies have shown that fractionated PDT might induce a high degree of necrosis deeper than PDT alone^[35,84,94]. The fact that this strategy may allow for continuous accumulation of PSs at the treatment site contributed to providing a better treatment response profile and increased the feasibility of reaching deeper tissues^[84].

In terms of adverse events associated with PDT, the most common is skin photosensitivity, especially when PSs of the first generation were systemically administered. In these cases, patients have to avoid sunlight and strong artificial light for weeks^[21]. Another side effect often reported is pain^[35]. The main mechanism behind PDT-induced pain has not yet been elucidated, but several studies have found it to be associated with the size of the treated area, PS type, lesion type, gender, age and light protocol. There are evidences suggesting that continuous activation of low levels of PS with methods using lower irradiance and possibly shorter incubation times are associated with decreased pain without loss of PDT efficacy^[96]. Additionally, the occurrence of inflammation, fever and nausea are typical but often successfully managed with medication. Tumor recurrence is often reported in clinical trials, probably due to inadequate tumor eradication. It can be a result not only to insufficient light or PS penetration, but also the presence of PDT resistant tumors. Although the causes for recurrence often lie beyond the scope of clinical trials, there is a strategy to overcome incomplete tumor elimination by PDT that is to combine two or more PSs. The idea behind this is to choose PSs that target different cellular compartments of the tumors allowing for a better overall

therapeutic outcome^[64,95,97]. Another strategy could be to associate PDT with other existing compounds used for chemotherapy. In a recent study the combined use of ferroptosis inducers and Gencitabine has shown to be able to significantly overcome the resistance to the chemotherapeutic agent displayed quite frequently in pancreatic adenocarcinomas^[98].

PDT in preclinical models of invasive cancer: an up-dated report

Most people diagnosed with cancer will require surgery as the main strategy for tumor removal with or without radiotherapy and systemic therapy. Tumor cells generally migrate from a primary tumor through the blood stream and lymphatic system and may be detected in one or more sentinel lymph nodes before spreading further to a secondary site. In the case of non-metastatic cancer, identifying cancer cells in the lymph nodes is one of the most important prognostic factors for determining the need for adjuvant radiation therapy and/or chemotherapy. Once cancer has spread to distant sites, the removal of tumor has not consistently shown a survival benefit. In these cases, surgery may help with palliative control of an ulcerated tumor on the chest wall and only unspecific broad-spectrum therapies are the currently treatment option available^[99]. Thus, effective and safe therapies for this stage of the disease are still needed.

Several *in vitro* studies have shown a synergism between PDT and ionizing radiation in killing cells^[100,101]. The combined application of low dose of radiotherapy (4Gy) and indocyanine green, with light proved to be very effective and resulted in a nearly complete reduction of survival^[101]. In a preclinical animal model, PDT following radiotherapy showed evidences of improved trabecular structure. Quantitative histological examination suggested that PDT induced increases in the bone-to-marrow ratio, due mainly to the increased formation of newly formed woven bone and an increase in osteoid formation in comparison with the situation in rats treated with radiotherapy alone^[102]. A subsequent study demonstrated that PDT appeared to improve vertebral integrity in combination with bisphosphonates or radiotherapy^[103], suggesting its potential use in adjuvant treatment of spinal metastases. These reports suggest that treatment of tumors with a combination of PS-mediated PDT and ionizing radiation could be superior to their individual use. The interaction of PDT and ionizing radiation could enhance the systemic therapeutic effect, thus reducing the radiation dose and potential side effects.

The effect of PDT combined with traditional chemotherapy for the treatment of breast cancer has also been studied and there are many examples. The treatment with appropriately combined low doses of cisplatin and indocyanine green- based PDT *in vitro* was proven to be more effective than each therapy alone^[104]. This synergistic effect is of extreme importance to be considered since cisplatin is one of the chemotherapeutics which is likely to cause severe side effects. Also the combination of mTHPC mediated PDT and 5-fluoro-2-deoxyuridine resulted in lower cell survival than the corresponding single mode treatment^[105]. Additionally, the enhanced antitumor effects between PDT and doxorubicin has already been demonstrated both *in vitro*^[106] and *in vivo*^[107] in a preclinical study on breast cancer. Although little is known about the mechanisms involving the interactions between chemotherapeutic drugs and PSs, or how they can be combined to increase cell killing and reducing side effects, all the cooperative effects between PDT and traditional chemotherapeutics cannot be neglected. Hence, PDT in combination with chemotherapy is among many strategies which have been proposed to potentiate the therapeutic outcome of low-dose chemotherapy and thus minimize side effects and acquisition of drug resistance^[35]. A great advantage of PDT is that it can be used either before or after chemotherapy, radiotherapy or surgery, without compromising these therapeutic modalities. Moreover, the adverse effects of chemotherapy or radiation do not affect sensitivity to PDT^[35]. These findings support the use of PDT, at least as an adjuvant therapy, for enhancement of anti-tumor immunity which may be capable of controlling cancer secondary disease.

Further research and more effort are required in order to allow PDT to be accepted as a suitable treatment for breast cancer. Even though, there is lot of evidence pointing that this therapeutic approach should

be considered as an antitumor treatment, the actual challenge for PDT is to translate the advances in understanding the effects in the cell-line-based and animal models studies into the clinical practice.

Clinical applications of PDT; Combination with other therapies; On-going trials

Despite the increasing number of studies with a growing number of chemical compounds and their generally increased number of favorable aspects as compared to more standard treatments, only a few PS have already been approved for clinical use and only for the treatment of a few diseases.

While the majority of PDT uses involve different types of cancer, ALA use with distinct formulations is already approved for several clinical applications, ranging from mild and moderate actinic keratosis to non-hyperkeratotic actinic keratosis. Some are also used to treat the Bowen's disease and basal cell carcinoma^[40]. Moreover, for serious ocular diseases such as age-related macular degeneration and myopic choroidal neovascularization there is a clinically approved PS called Verteporfin in current use^[108,109]. In 1993, Photofrin sodium (Photofrin) was the first PS approved for clinical use of PDT by the Canadian Health Agency for bladder cancer treatment. Later on, it was approved by the Food and Drug Administration (FDA) and also in several other countries for the treatment of various types of cancer, such as lung, esophageal, gastric, and cervical cancers as well as for cervical dysplasia^[110]. This photosensitizer is still widely used in PDT for treatment of various conditions^[111,112]. However, being a complex mixture of molecules with poor tissue selectivity and low light absorption, high concentrations of photofrin sodium are needed, which make it to persist over 2 months after the administration^[113], rendering patients photosensitive^[114]. A second-generation of PS has been then developed, with improved purity, longer wavelength absorptions and higher photosensitivity and tissue selectivity. Temoporfin was the second PS to receive approval and extensively used for treatment of advanced head and neck squamous cell carcinomas^[115,116]. Temoporfin was also tried for the treatment of breast, pancreatic and prostatic cancer^[117-121], with mixed results. For breast cancer there was response in all patients with minimal-invasive and few side effects^[119]. Similarly, for prostate cancer it appeared a safe procedure and after 8 of 10 PDT sessions, the prostate specific antigen fell by up to 67% and biopsies of treated areas revealed necrosis and fibrosis at 1-2 months^[120]. However, in patients with malignant biliary obstruction, endoscopically delivered Temoporfin-PDT caused efficient tumor necrosis and recanalization of blocked metal stents, but it showed a significant risk of complication with one leading to a fatal liver abscess and two patients developing haemobilia within 4 weeks of treatment, one of whom died with a gall bladder empyema^[118]. A mono-L-aspartyl chlorin, Talaporfin, was approved in Japan as a PDT for lung cancer but was also employed for early head and neck cancer patients and is going through the phase II trial for the treatment of colorectal neoplasms and liver metastasis^[122]. There are also other drugs approved as orphan drugs by the FDA for PDT treatment for Cutaneous T-cell lymphoma (SGX301) and for biliary tract cancer (LUZ11)^[40].

Since PDT has the potential to present a local effect, it lacks systemic adverse effects seen in other therapies. Additionally, because of its mechanism, PDT can be used in the clinic in combination with other procedures, such as radiotherapy, chemotherapy or surgery. At the present time there are a number of on-going trials using PDT with distinct PS for different types of cancer. Among all the on-going trials registered at clinicaltrials.gov (not concluded), about 50% of them use PDT alone or in combination with other therapies for at least one condition [Table 2]. So far PDT using distinct photosensitizers appears to be effective in decreasing tumor size and increasing patient survival in several of the trials, which target different kinds of tumors [Table 3]. Interestingly, the clear majority of current on-going trials for cancer are using photosensitizers that have already been approved for clinical use, mainly with Photofrin and ALA but also with Verteporfin and other still unapproved compounds.

The majority of approved PDT protocols are related to the treatment of superficial lesions of skin and luminal organs. However, due the enhancement of PS efficiency and light delivery, interstitial and intra-

Table 2. Number of on-going trials registered in clinicaltrials.gov using Photodynamic therapy for major conditions

Others (only 1 trial each)	6

operative approaches have been investigated for the ablation of a broad range of solid tumors^[22]. The first clinical application of PDT for breast cancer treatment was to treat skin metastases recurrence in the chest wall. The protocol tested was using Photofrin, and showed benefits in fifty percentage of the patients^[100]. Later studies with Photofrin^[123], m-THPC^[119] and Npe6^[124] supported PDT as an effective palliation treatment for chest wall recurrence in breast cancer patients. Further applications for PDT as treatment for breast cancer solid tumor and its sequelae, specifically its role in combination with adjuvant radiotherapy and chemotherapy, are being explored. Regarding the metastatic problem in breast cancer, although this systemic complication represents the most complex challenge in PDT-treatment for this type of tumor, a study conducted with fourteen patients with more than 500 truncal metastases showed that all patients presented tumor necrosis and nine of them demonstrated complete responses^[123]. Last but not least, a clinical trial of late-stage breast cancer patients treated by a local intervention using an 805 nm laser for non-invasive irradiation, indocyanine green and an immunoadjuvant (glycated chitosan) for immunological stimulation has shown that the combine therapeutic approach was safer and more efficient for treatment of metastatic breast cancer than each individual strategy^[125]. This study demonstrated that adjuvant treatment with immunotherapy following PDT may improve its effectiveness and represents a viable future treatment of tumors at distant sites, as discussed before, but still need more clinical studies.

PERSPECTIVES

There are several other new approaches being tested in “*in vitro*” and or in pre-clinical models aiming at improving the performance, the homing and delivery of PSs or including mixed formulations of chemotherapeutics in combination with PSs which appeared to show promising results up to now^[126,127]. The fast development of the field of nanostructured materials is in part responsible for the great increase of different innovative alternatives and approaches being studied. Of note is the notion that these approaches could also be used as detection and treatment alternatives at the same time supporting the idea that a better outcome could be reached by using these new multitasks tools in a near future. For example, a recent report has described the results of a pH, glutathione (GSH) and hyaluronidase (HAase) triple-responsive nanoplatform for HER2 and CD44 dual-targeted and fluorescence imaging-guided PDT/photothermal therapy (PTT) dual-therapy against HER2-overexpressed breast cancer. The nanoplatform was fabricated by functionalizing gold nanorods (GNRs) with hyaluronic acid (HA) pendant hydrazide and thiolgroups via Au-S bonds, and subsequently chemically conjugating 5-ALA, Cy7.5 and anti-HER2 antibody onto HA moiety for PDT. The final Nano platform bears fluorescent imaging and active targeting capacities, respectively. In this study the authors not only demonstrated that HER2 and CD44 receptors-mediated dual-targeting strategy significantly enhanced the cellular uptake of GNR-HA-ALA/Cy7.5-HER2 but also that the combined PDT/PTT treatment had significantly superior antitumor effect than PDT or PTT alone both in the MCF-7 cells model as well as in pre-clinical studies^[128]. Additionally, studies performed in human breast derived cell lines have shown that supersaturated hypericin (HYP) encapsulated on Pluronic® P123 (HYP/P123) micelles presented high stability and high rates of binding to cells, which resulted in their selective internalization in MCF-7, indicating their potential to permeate the membrane of these cells. Moreover, HYP/P123 micelles accumulated in mitochondria and endoplasmic reticulum organelles inducing

Table 3. Details of on-going clinical trials with the usage of PDT for handling neoplastic diseases

Indication	Photosensitizer	Study type	Estimated study completion date	Estimated enrollment (participants)	ClinicalTrials.gov Identifier
Anal Cancer	Aminolevulinic acid	Interventional	Apr/21	12	NCT02698293
Basal Cell Carcinoma	Aminolevulinic acid	Interventional	Nov/21	50	NCT03467789
Basal Cell Carcinoma	Aminolevulinic acid	Interventional	01/May/23	50	NCT03483441
Basal Cell Carcinoma	Aminolevulinic acid	Interventional	Sep/20	281	NCT02144077
	Methyl aminolevulinate				
Basal Cell Carcinoma	Methyl aminolevulinate	Interventional	01/Jun/20	20	NCT03167762
Basal Cell Carcinoma	Aminolevulinic acid	Interventional	Dec/22	117	NCT02367547
Basal Cell Neoplasms	Methyl aminolevulinate				
	Hexylaminolevulinate				
Basal Cell Carcinoma, Superficial	Aminolevulinic acid	Interventional	Aug/24	186	NCT03573401
Brain Tumor, Recurrent	Porfimer sodium	Interventional	Jun/31	30	NCT01966809
Brain Tumor, Recurrent	Porfimer sodium	Interventional	Apr/24	24	NCT01682746
Breast Cancer, Metastatic	Verteporfin	Interventional	Dec/19	15	NCT02939274
Cervical Intraepithelial Neoplasia	Aminolevulinic acid	Interventional	Nov/18	60	NCT02631863
Cholangiocarcinoma	Porfimer sodium	Interventional	22/Mar/18	55	NCT01755013
Cholangiocarcinoma	Porfimer sodium	Interventional	Jul/18	39	NCT02585856
Cholangiocarcinoma	Temoporfin	Interventional	Aug/19	20	NCT03003065
Cholangiocarcinoma	Fimaporfin	Interventional	Aug/19	55	NCT01900158
Cholangiocarcinoma, Hilar	Deuteporfin	Interventional	May/19	50	NCT02955771
Desmoid Tumors	Aminolevulinic acid	Interventional	Dec/26	140	NCT01898416
Esophageal Adenocarcinoma, Stages I, II, III	Porfimer sodium	Interventional	Dec/19	40	NCT02628665
Esophageal Squamous Cell Carcinoma, Stages I, II, III					
Esophagogastric Cancer	Palladium bacteriopheophorbide	Interventional	Apr/19	36	NCT03133650
Glioblastoma	Aminolevulinic acid	Interventional	Dec/19	10	NCT03048240
Head and Neck Carcinoma, Recurrent	Porfimer sodium	Interventional	01/Nov/22	82	NCT03727061
Head and Neck Carcinoma, Locally Advanced					
Lung Cancer	Porfimer sodium	Interventional	15/Sep/17	10	NCT03211078
Lung Cancer	Porfimer sodium	Interventional	Mar/19	10	NCT03344861
Lung Cancer, Metastatic					
Lung Cancer, Non Small Cell	Porfimer sodium	Interventional	Sep/21	66	NCT03564054
Lung Cancer, Non Small Cell	Porfimer sodium	Interventional	May/19	5	NCT02916745
Lung Metastasis					
Lung Cancer, Non-Small Cell	Porfimer sodium	Interventional	01/Aug/21	12	NCT03678350
Mesothelioma, Malignant					
Lung Cancer, Squamous Cell	Chlorin e6-PVP	Interventional	Oct/24	111	NCT03346304
Mesothelioma, Epithelioid Malignant Pleural	Porfimer sodium	Interventional	May/18	102	NCT02153229
Neurofibromatosis	Aminolevulinic acid	Interventional	Nov/18	30	NCT01682811
Neurofibromatosis	Aminolevulinic acid	Interventional	Aug/23	30	NCT02728388
Oral cancer	Aminolevulinic acid	Interventional	31/May/19	30	NCT03638622
Oral Cavity Squamous Cell Carcinoma, Stage I	HPPH*	Interventional	02/Nov/21	114	NCT03090412
Oral Cavity Squamous Cell Carcinoma, Stage II					
Pancreatic Cancer, Non-Resectable	Verteporfin	Interventional	Jan/22	15	NCT03033225
Pancreatic Cancer, Stage III	Porfimer sodium	Interventional	31/Jan/20	12	NCT01770132
Pancreas, Acinar Cell Adenocarcinoma of the					
Pancreas, Duct Cell Adenocarcinoma of the					
Peritoneal Carcinomatosis	<i>Hypericum perforatum</i> extract	Interventional	Jul/20	50	NCT02840331
Prostate Cancer, Localized	Palladium bacteriopheophorbide	Interventional	01/Mar/24	50	NCT03315754
Prostate Cancer, Recurrent	Verteporfin	Interventional	31/Dec/20	36	NCT03067051
Skin Cancer, Non-melanoma	Aminolevulinic acid	Interventional	Mar/21	20	NCT02751151
Skin Cancer, Non-melanoma	Aminolevulinic acid	Interventional	Dec/22	40	NCT02867722
Skin Cancer, Non-melanoma	Aminolevulinic acid	Interventional	30/Apr/21	20	NCT03110159
Squamous Cell Carcinoma	Aminolevulinic acid	Interventional	Jan/20	40	NCT03025724
Urothelial Carcinoma, Upper Tract	Palladium bacteriopheophorbide	Interventional	Aug/20	18	NCT03617003

Cholangiocarcinoma	Porfimer sodium	Observational	30/Dec/18	200	NCT01524146
Esophageal Adenocarcinoma, Early	any	Observational	Jan/22	400	NCT00587314
Lung Cancer	Porfimer sodium	Observational	30/Dec/24	1000	NCT01842555
Lung Cancer	any	Observational	15/Dec/23	1000	NCT03589456
Neoplastic Disease	any	Observational	Jul/21	400	NCT02159742
Prostate Cancer	any	Observational	01/Mar/20	200	NCT03492424

*HPPH stands for 2-1[Hexyloxyethyl]-2-Devinylypyropheophorbide-a

photodynamic cell death by necrosis and selective time- and dose dependent phototoxic effects on MCF-7 cells but little damage to non-tumorigenic cells. The micelles inhibited the generation of cellular colonies as well as migration of tumor cells indicating possible capacity to prevent the recurrence of breast cancer and to minimize the chances of cell spreading and thus the formation of metastases^[129].

Although PDT is based on the preferential accumulation in the tumor tissue, this selectivity is not absolute and some damage can occur to the surrounding tissue. Thus, a deeper understanding of the molecular mechanisms involved in drug delivery and specific targeting of tumors should contribute to the development of more specific technologies to deliver light and/or drugs to the tumor site and also to minimize resistance to PDT. Accordingly, the development of new PS targeting specific tumor sites have led to the modality of targeted-PDT^[130]. Another approach consists the photochemical delivery of drugs through photochemical internalization (PCI), a modified form of PDT. PCI is actually a light-controlled drug-delivery alternative in which light activation enables spatiotemporal specificity and control of the intracellular drug release^[131-133]. Moreover the potential of PCI to circumvent the resistance and increase the efficacy of a variety of anticancer agents, have been demonstrated in several tumor models including approaches to overcome PDT-resistance in breast cancer cells^[133,134]. Since identifying cellular resistance mechanisms by understanding the differences in cell response at the molecular level is of fundamental importance to improving the protocol and to increase the success of the therapy^[135], we have recently shown that breast cancer cells are differently affected by methylene blue (MB) concentrations at the same light dose in MB-PDT and that non-malignant human breast cells are significantly more resistant to the therapy compared to the malignant ones^[126]. One more example of how the use of a targeting agent would ideally improve the selectivity of PDT for the tumor tissue has been shown in a recent study. By using polyethylene glycol-coated, folate conjugated, benzoporphyrin derivative-loaded liposomes for PDT treatment of breast cancer cells, the researchers have reported that these liposomes are targeted for are greater uptake into TNBC cancer cells^[136]. Therefore, focusing on the molecular differences of cell death mechanisms induced by PDT, starting with an optimized PS choice and conditions of its delivery and activation, will certainly provide valuable clues for the development of new therapeutic strategies aiming at improving the efficacy of PDT against cancer cells^[7,15].

CONCLUSION

The challenges in fighting the disease rely on intrinsic tumor resistance properties, molecular heterogeneity, and metastasis. Considering all the information provided one can conclude that there are almost no doubts that one relevant advantage of PDT over other cancer treatments is the possibility of generating less side effects to the patients.

In summary, in this review we have explored and presented a broad up-date on the use of PDT as a therapeutic approach in the treatment of primary cancer as well as metastasis. We have covered several topics ranging from the photochemical mechanisms involved, the different cell death mechanisms being triggered by several photosensitizers up to the more recent-on-going clinical trials. Additionally, we have presented a significant amount of information underscoring the relevance of PDT as an alternative therapeutic approach capable of inducing several mechanisms of cell death, some of them simultaneously.

This capacity could be an interesting way of overcoming the problem of death resistance displayed by many tumors since one of the characteristics that is important for an alternative therapy for cancer treatment is to broaden the spectrum of cell death mechanisms being gathered in order to by-pass the different resistance mechanisms displayed by malignant cells.

Finally, even if more research is still needed in the field including the development and optimization of PS synthesis in order to increase the efficiency on specific tumor cell damage, light sources and irradiation protocols, it is evident that in the majority of the cases, PDT represents a suitable therapeutic alternative presenting several advantages over the traditional clinical approaches for cancer treatments. It is clear that PDT deserves more opportunities and investment in clinical trials. By doing so, it could be expected that the increase in the number of clinical studies with metastatic or non-metastatic cancer, in the near future, could allow the scientific and clinical community to make more robust conclusions about PDT's real translational potential to become a standard first-line therapy, either alone or in combination with other treatments, for a wide variety of tumors.

DECLARATIONS

Authors' contributions

Responsible for the paper: Baptista MS, Labriola L

Concept, design, definition of intellectual content: dos Santos AF, Baptista MS, Labriola L

Literature search, manuscript preparation and revision: dos Santos AF, de Almeida DRQ, Terra LF, Baptista MS, Labriola L

Manuscript editing: dos Santos AF, Labriola L

Abstract

Metabolism is defined as the collection of complex biochemical processes that living cells use to generate energy and maintain their growth and survival. Metabolism encompasses the synthesis and breakdown of glucose, fatty acids, and amino acids; the generation of energy (ATP); and oxidative phosphorylation. In cancer cells, metabolism can be commandeered to promote tumor growth and cellular proliferation. These alterations in metabolism have emerged as an additional hallmark of various cancers. In this review we focus on metabolic alterations in multiple myeloma (MM) - a malignancy of plasma cells - including derangements in glycolysis, gluconeogenesis, the tricarboxylic acid cycle, oxidative phosphorylation, and fatty acid/amino acid synthesis and degradation. Particular focus is given to metabolic alterations that contribute to myeloma cell growth, proliferation and drug resistance. Finally, novel approaches that target metabolic pathways for the treatment of MM are discussed.

Keywords: Metabolism, alterations, multiple myeloma, treatment

MULTIPLE MYELOMA

Multiple myeloma (MM) is a malignancy of terminally differentiated plasma cells typically characterized by clonal proliferation of these plasma cells in the bone marrow. MM represents 1% of all malignancies and 18% of hematologic malignancies in the United States; accounting for an estimated 30,770 new diagnoses and 12,770 deaths in 2018 alone^[1]. Classically, MM results in the secretion of a non-functional monoclonal immunoglobulin

(Ig) produced by the transformed plasma cells. Production of this aberrant Ig results in several of the complications associated with MM such as renal dysfunction, neuropathy, and hyperviscosity syndrome^[2,3]. However, in approximately 15%-20% of patients the abnormal plasma cells secrete only monoclonal free light chains, and in approximately 2%-3% of cases these cells secrete no monoclonal protein at all resulting in the so-called non-secretory myeloma^[4,5]. Myeloma cell growth in the bone marrow and the resultant cytokines produced by these transformed cells and/or other cells in the bone marrow microenvironment lead to the classic symptoms of active MM: osteolytic bone lesions, hypercalcemia, and anemia^[6].

The underlying epidemiology of MM remains largely undefined. Previously, exposure to ionizing radiation was thought to be a risk factor, but this was subsequently refuted in a large cohort of atomic bomb survivors in Japan^[7]. More recent data suggest a 2-3 fold increased risk for development of MM among African Americans which is thought to be related to increased rates of MGUS among this population^[8,9]. Interestingly, in contrast to most other malignancies, African Americans with MM tend to have a better prognosis compared to age-matched Caucasians with the disorder^[10]. Several meta-analyses have suggested obesity is associated with increased risk of myeloma with a relative risk ranging from 1.11-1.82^[11-14], and it has been shown that obesity significantly increases the risk of myeloma associated mortality^[15,16].

MM is primarily a disease of the elderly, with the median age at diagnosis being 69 in the United States^[1]. This population often suffers from significant co-morbidities making management of myeloma more challenging. Specifically, approximately 40% of this population meets criteria for obesity (BMI ≥ 30)^[17], and the rates of several obesity associated metabolic disorders such as diabetes and hyperlipidemia already approach 25% and 50% respectively, and continue to rise^[18,19]. Given these associations it is reasonable to wonder if these metabolic changes are significantly participating in MM pathogenesis. As this area has largely been uncharacterized, in this review we aim to highlight the metabolic changes that occur in myeloma patients, summarize how these changes are affected by myeloma directed therapy, and suggest possible interventions to enhance anti-myeloma based therapies by taking advantage of metabolic pathways which are often dysregulated in MM patients.

OVERVIEW OF METABOLISM

Glycolysis

Glycolysis is the primary process by which cells break down glucose releasing stored energy in the process which can be used to generate ATP^[20]. This process begins when membrane bound insulin receptors bind insulin resulting in autophosphorylation of the tyrosine residues. Subsequent phosphorylation of insulin receptor substrates, and activation of the PI3K and MAPK pathways promote cellular uptake of glucose^[21]. Insulin also regulates fructose 2,6-bisphosphate, a key regulator of glycolysis. In glycolysis, a single glucose molecule is phosphorylated by hexokinase (HK) to yield glucose-6-phosphate (a reaction which requires ATP), which then undergoes isomeric change by the enzyme glucose 6-phosphate isomerase to become fructose 6-phosphate. Fructose 6-phosphate is then irreversibly phosphorylated by phosphofructokinase (PFK) in a reaction that requires ATP to yield fructose 1,6-bisphosphate; this reaction is the rate-limiting and committed step of glycolysis. Fructose 1,6-bisphosphate is then cleaved by aldolase into two triose phosphates: glyceraldehyde-3-phosphate and dihydroxyacetone phosphate. Glyceraldehyde 3-phosphate is oxidized by glyceraldehyde 3-phosphate dehydrogenase using NAD⁺ as an electron donor to yield 1,3-bisphosphoglycerate (1,3-BPG). 1,3-BPG is then dephosphorylated at carbon-1 by phosphoglycerate kinase to yield 3-phosphoglycerate, and then reversibly converted to 2-phosphoglycerate by phosphoglycerate mutase. 2-phosphoglycerate undergoes a dehydration reaction catalyzed by enolase to form phosphoenolpyruvate (PEP) which is then irreversibly converted to pyruvate by pyruvate kinase (PK) in a reaction that also generates ATP^[22,23].

In eukaryotic cells, pyruvate can be reduced to produce ATP through two different pathways depending on the presence of mitochondria and appropriate blood and oxygen supply in the tissue of need: aerobic

respiration and anaerobic respiration. In aerobic respiration, pyruvate is transported into the mitochondria through a specific transporter and then decarboxylated by pyruvate dehydrogenase to produce acetyl-CoA which serves as the initial substrate for the tricarboxylic acid (TCA) cycle (see section 2 below). In anaerobic respiration, which in eukaryotes is typically limited to cells without mitochondria or poorly vascularized tissue (either endogenous or induced by states of physiologic stress), pyruvate accepts a hydrogen from NADH to produce lactate and NAD⁺. The NAD⁺ produced can then be used for glycolysis reactions or even react with TCA intermediates. Energy yield from anaerobic glycolysis is significantly reduced compared to its aerobic counterpart, however this process is more rapid and can occur in oxygen deprived tissues^[22]. Notably, some cancerous cells have been shown to preferentially undergo anaerobic respiration even under optimal conditions for aerobic respiration^[24-26]. This effect, which is thought to be due to metabolic reprogramming related to their hyperproliferative state, has been termed the “Warburg effect” after German physiologist and Nobel laureate Otto Warburg whose initial observations of increased glucose consumption coupled with increased lactate excretion from cancer cells led to the hypothesis of its existence^[27-29].

Cells have developed several mechanisms to increase or decrease glycolysis in response to metabolic needs. Furthermore, metabolic control of glycolysis occurs through various feedback mechanisms. Inhibition of insulin receptor signaling or key enzymes in the pathway (especially PFK) typically occur in fasting states or high energy states when the ratio of ATP to ADP is high. In these situations metabolism is shifted away from glycolysis and can instead result in a reciprocal induction of gluconeogenesis (see section 4 below)^[22,23]. Typically, glycolysis follows the general steps as reviewed above. However, there is some redundancy in the metabolic processes of the cell and some molecules may be synthesized in a different way and still be used in glycolysis. This can be seen in the way in which cells breakdown disaccharides like sucrose. If energy is needed, then the sucrose will be converted into fructose-6-phosphate molecules and continue through glycolysis^[22].

The TCA cycle

The TCA cycle allows for complete catabolism of organic molecules in the presence of oxygen, and results in the majority of ATP production in eukaryotes. The reactions of the TCA allow for breakdown of carbohydrates as well amino acids and fatty acids through various metabolites that can enter the pathway at different steps. For glucose metabolism the process begins with the production of acetyl Co-A in the mitochondrial matrix through oxidative decarboxylation of pyruvate in a reaction catalyzed by the pyruvate dehydrogenase complex (a complex of 3 component enzymes, 2 regulatory enzymes, and 5 coenzymes). Acetyl Co-A and oxaloacetate combine to form citrate in a condensation reaction catalyzed by citrate synthase. Citrate is then isomerized to isocitrate by aconitase which is subsequently converted to α -ketoglutarate by oxidative decarboxylation in a reaction catalyzed by isocitrate dehydrogenase. The α -ketoglutarate dehydrogenase complex catalyzes the conversion of α -ketoglutarate to succinyl Co-A and producing NADH. Succinyl Co-A is then cleaved to succinate by succinate thiokinase in a reaction that generates GTP via substrate level phosphorylation. Succinate is subsequently oxidized to fumarate by succinate dehydrogenase with FAD being reduced to FADH₂ in the process. Fumarate is then hydrated to malate in a reaction catalyzed by fumarase, with malate being oxidized to oxaloacetate by malate dehydrogenase producing another molecule NADH in the process.

There are many ways that the TCA cycle is regulated. The first regulatory step is known as the bridge reaction where pyruvate is converted to acetyl-CoA. If the cell has too many high energy molecules, then this “bridge reaction” will not occur and pyruvate will be utilized in other fashions. Other regulatory steps include the synthesis of citrate, and the oxidative decarboxylations of isocitrate and α -ketoglutarate all of which result in the production of high energy molecules (NADH, FADH₂, ATP, GTP) which then undergo oxidative phosphorylation. These steps will be inhibited if the concentration of the high energy molecules is increased. Similarly, if the concentration of low energy molecules (GDP, ADP, NAD⁺, FAD) were to accumulate then the reactions in the TCA cycle would increase^[22].

Oxidative Phosphorylation and the electron transport chain

Many of the products from glycolysis are then transported to the inner mitochondrial membrane where they donate electrons to a set of electron carriers known as the electron transport chain (ETC). As electrons transverse the ETC they lose energy and are coupled to the pumping of protons across the inner mitochondrial membrane which can subsequently be captured to drive the production of ATP through oxidative phosphorylation (OXPHOS) in a reaction catalyzed by the enzyme complex ATP synthase^[22,23].

Oxidative phosphorylation is regulated via several mechanisms. The enzymes succinate dehydrogenase and α -ketoglutarate dehydrogenase have roles in both OXPHOS and the TCA cycle, and are regulated by TCA intermediates like succinate, fumarate, and α -ketoglutarate. These two enzymes are also inhibited by high energy compounds and activated by low energy compounds. The pH of the mitochondrial matrix also regulates OXPHOS, as the ability to maintain the ETC and the subsequent proton pump is tied to maintaining a pH gradient^[22].

Gluconeogenesis

Gluconeogenesis is the synthesis of glucose, allowing the body to ensure blood sugar levels remain stable even in fasting states. The first step in gluconeogenesis is synthesizing PEP from pyruvate. This is a two-step process in which pyruvate is first converted to oxaloacetate by pyruvate carboxylase, then converted to PEP by PEP carboxykinase. PEP is converted to 2-phosphoglycerate, and subsequently to 3-phosphoglycerate, which is phosphorylated to produce 1,2-bisphosphoglycerate. Glyceraldehyde 3-phosphate is then synthesized by glyceraldehyde phosphatase dehydrogenase and converted to fructose 1,6-bisphosphate. Finally, glucose 6-phosphatase dephosphorylates glucose 6-phosphate to form glucose. Since this process is nearly the opposite of glycolysis, many of the enzymes between these two processes are the same, and gluconeogenesis is tightly regulated by many feedback mechanisms to maintain the glucose concentration and to avoid hypo/hyperglycemia. Not surprisingly then, one of the main regulators of gluconeogenesis is glucose itself; the other two main regulators are pyruvate and PEP. High concentrations of these two molecules in combination with lower levels of glucose leads to increased gluconeogenesis^[22].

Fatty acid synthesis and degradation

Fatty acid synthesis is not only important for long-term energy storage but also for structural components of cell membranes and eicosanoids. Fatty acid synthesis typically begins with a reaction between acetyl-CoA and malonyl-ACP to yield acetoacetyl-ACP and CO₂. This condensation reaction is facilitated by 3-ketoacyl ACP synthase (KAS III). Acetoacetyl-ACP subsequently undergoes reduction, hydration, and re-reduction to reduce the 3-keto group eventually yielding acyl-ACP, which can be used to initiate elongation of the fatty acid chain. This cycle continues until acyl-ACP's backbone reaches 16 or 18 carbons. After appropriate elongation acyl-CoA can be used for multiple different processes, including synthesis of glycerophospholipids and triacylglycerides, production of phosphatidate, and synthesis of phosphatidylcholine (PC). While lipogenesis can occur through the conversion of carbohydrates to acetyl-CoA, it can also take place by *de-novo* lipogenesis through the conversion of glycogen to fatty acids which typically occurs when glycogen storage is full^[22].

To release energy stored at fat, the molecule undergoes β -oxidation, or fatty acid oxidation. As fatty acids are unable to diffuse through the mitochondrial membrane, they are first converted to acylcarnitine which can enter through the carnitine antiports. Once in the matrix, acylcarnitine is converted to fatty-acyl-CoA. β -oxidation is largely the reverse reaction of lipid synthesis. Starting with acyl-SCoA there is oxidation, hydration and oxidation again to yield 3-ketoacyl-SCoA. The β -carbonyl is then cleaved by HS-CoA, resulting in a fatty Acyl-CoA molecule that now holds two less carbons than it did at the start of the cycle. Each cycle thus produces ubiquinol, NADH and acetyl-CoA which can all be used in aerobic respiration^[22].

Fatty acid synthesis and degradation are regulated largely by cellular energy dependence. Fatty acids serve as long-term energy storage molecules. During starvation where ATP production from the breakdown of glycogen cannot produce adequate amounts of energy, fatty acid degradation accelerates. On the other hand, if there are adequate supplies of ATP and glycogen storage is full, then fatty acid synthesis can occur^[23].

Amino acid synthesis and degradation

Amino acids and proteins remain a central aspect of cellular metabolism. While there have been over 300 amino acids described, only 20 are commonly found in mammalian proteins. Not surprisingly, these 20 amino acids are the only amino acids coded for by DNA^[30]. Of these, histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine are termed essential as they cannot be synthesized by humans. Amino acids serve various roles in metabolism. In addition to protein synthesis, they can be used for energy production and synthesis of hormones. In extreme situations where energy is scarce and fatty acid reserves have been exhausted, protein turnover becomes a main source of energy^[22].

Oxidation of proteins typically occurs in small quantities since the ammonia/ammonium byproduct is toxic and must be transported bound to *L*-glutamine. *L*-glutamine can leave the tissue and be transported to the liver for energy production with NH₄⁺ excreted as urea. Alternatively, proteins can be metabolized by the glucose-alanine cycle. When breakdown of muscle protein yields *L*-glutamate, a reaction with pyruvate occurs yielding alanine and α -ketoglutarate. Alanine is then transported to the liver where transamination occurs resulting in glutamate which subsequently undergoes deamination releasing NH₄⁺ into the urea cycle. Pyruvate is also a byproduct of the transamination reaction and can be used in the liver for gluconeogenesis.

Integration of metabolic processes

Cellular metabolism is intertwined and tightly regulated. Glycolysis and the TCA cycle produce many byproducts that may enter the ETC for oxidative phosphorylation or can be used for other purposes. For example, the oxidation of glyceraldehyde 3-phosphate which occurs in glycolysis also results in the production of NADH and H⁺. These molecules can serve as electron donors for the ETC. Similarly, FADH₂ which is a byproduct of the reaction that converts succinate to fumarate in the TCA cycle can also serve as an electron donor in the ETC.

Anaerobic and aerobic respiration are closely linked by the use of NAD⁺ and NADH. Production of lactate during anaerobic respiration is one of the main ways in which NADH and H⁺ are oxidized back into NAD⁺ which allows for the TCA cycle to continue without any significant changes. Ultimately, glycolysis, the TCA cycle, gluconeogenesis, fatty acid metabolism, and protein synthesis are all interconnected and exist in a highly regulated and interdependent environment designed to maintain homeostasis^[31-33].

ALTERATIONS IN METABOLISM OF MULTIPLE MYELOMA

Multiple changes in metabolism occur in myeloma cells which are summarized below and in Figure 1. Understanding the metabolic alterations in MM has important implications in the care of patients with MM. It sheds new light into our understanding of MM development and progression, and allows for the assessment of predictive or prognostic biomarkers for optimal management of myeloma patients. Importantly, it provides potentially novel therapeutic targets for the treatment of MM.

Over the last decade, several technologies such as mass spectrometry, ¹H-nuclear magnetic resonance (¹H-NMR) spectroscopy and mass spectrometry, and ¹³C stable isotope resolved metabolomics (SIRM) have been used to determine metabolic alterations in monoclonal gammopathy of undetermined significance (MGUS) patients, newly diagnosed MM (NDMM) and relapsed/refractory MM (RRMM) and to compare metabolic changes in drug resistant MM cells. Steiner *et al.*^[34] used mass spectrometry to analyze 188

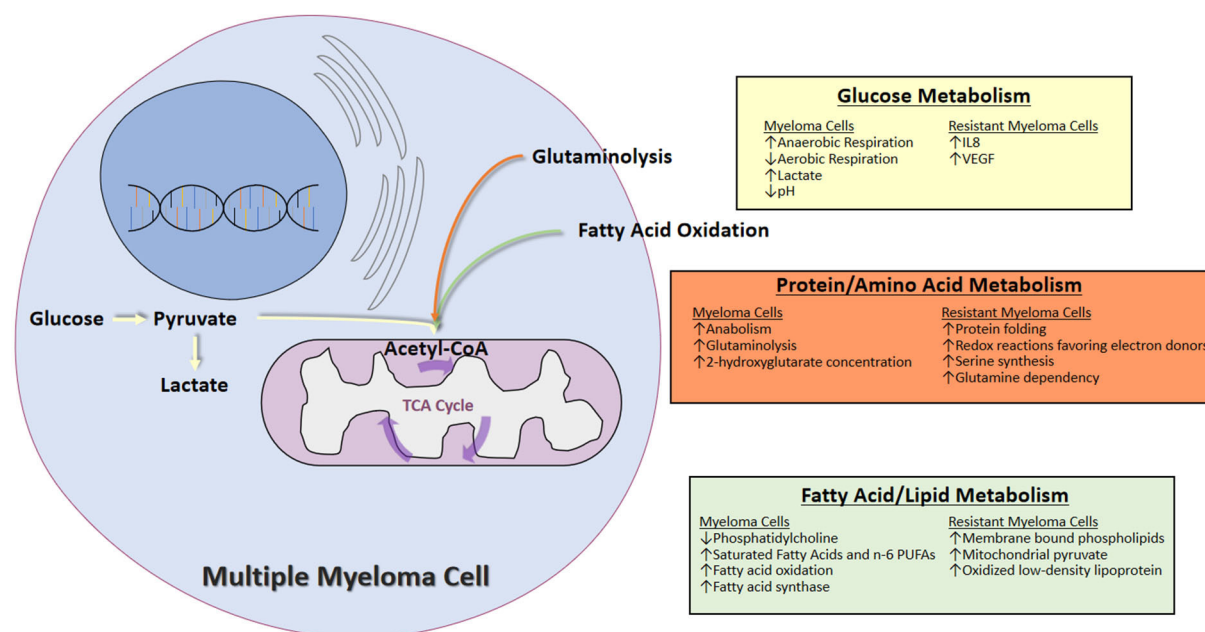

Figure 1. Summary of the metabolic changes in multiple myeloma cells and in resistant myeloma cells

endogenous metabolites in peripheral blood plasma samples of healthy controls, patients with MGUS, NDMM, or RRMM. The metabolomic profile was quite different between healthy controls and patients with MGUS, NDMM or RRMM with significant alterations in amino acid, lipid and energy metabolism. Eight plasma metabolites - free carnitine, acetylcarnitine, glutamate, asymmetric dimethylarginine (ADMA) and four PC species - were different between MGUS and NDMM patients, demonstrating that metabolic changes occur during MM development and progression^[34].

High-resolution ¹H-NMR spectroscopy and mass spectrometry provides quantitative analysis of metabolite concentrations and reproducible information with minimal sample handling. Puchades-Carrasco *et al.*^[35] performed ¹H-NMR spectroscopy metabolomic analyses of serum samples of MM patients and healthy subjects, and also compared the metabolic profiles of MM patients at the time of diagnosis and after achieving complete remission. Compared to healthy subjects, MM patients at the time of diagnosis exhibited higher levels of isoleucine, arginine, acetate, phenylalanine, and tyrosine and decreased levels of 3-hydroxybutyrate, lysine, glutamine, and some lipids. Interestingly, when myeloma patients achieved complete remission, the levels of lysine, citrate, lactate dehydrogenase (LDH), and choline went up whereas glucose level decreased in comparison to those at the time of diagnosis^[35].

A similar study using ¹H-NMR spectroscopy was performed by Ludwig *et al.*^[36] to characterize the metabolic profile within the bone marrow using filtered plasma derived from bone marrow aspirates of healthy donors and patients with MGUS or MM. This study found that the essential amino acids isoleucine and threonine were significantly decreased in the bone marrow of MGUS and MM patients as were the nucleotide-breakdown products, hypoxanthine and xanthine, suggesting an increase in anabolism. The products of arginine metabolism, creatinine and urea, were also significantly altered. The authors suggested that alterations in bone marrow metabolism are an early and consistent feature during the development of MGUS and MM^[36].

Recently, Gonsalves *et al.*^[37] performed ¹³C SIRM using U[¹³C₆]-Glucose and U[¹²C₅]-Glutamine in human MM cell lines to determine the contribution of carbon substrates from glutamine into the TCA cycle of clonal plasma cells in comparison with those from glucose. Their results suggest that glutamine is the main

contributor of carbon substrates to the TCA cycle whereas glucose is an important contributor of carbon substrates for the formation of lactate in clonal plasma cells^[37]. This was also supported by the finding that clonal bone marrow plasma cells in MM patients have higher glutamine uptake compared with the remainder of bone marrow mononuclear cells. Additionally, 2-hydroxyglutarate (2-HG) - an oncometabolite of glutaminolysis - is significantly increased in the bone marrow supernatant of MM patients compared to that of MGUS patients. Similarly, levels of 2-HG in the bone marrow supernatant or in the peripheral blood plasma of patients with smoldering multiple myeloma was associated with higher risk of progression to MM, and correlates with the percentage of bone marrow plasma cells expressing c-MYC^[37]. These results demonstrate the utility of measuring 2-HG levels in BM supernatant or peripheral blood plasma of SMM patients as a potential biomarker for disease progression and for identification of patients who may benefit from early therapeutic intervention.

To characterize the lipid profile of MM cells, Hossen *et al.*^[38] sorted single MM and normal plasma cells using flow cytometry and performed matrix-assisted laser desorption/ionization-imaging mass spectrometry. They found that PC (16:0/20:4) was significantly decreased in MM cells compared to normal plasma cells, which is likely due to the decrease of its integrated fatty acids or to increased metabolism of C_{16:0}.

The development of drug resistance is also associated with metabolic alterations in MM. Zub *et al.*^[39] performed global proteomic and transcriptomic profiling on melphalan sensitive and resistant RPMI8226 MM cell lines. Glycolysis was found to be the most significantly altered pathway. Gluconeogenesis, glutaryl-CoA degradation, isoleucine and tryptophan degradation, TCA cycle, ketolysis and ketogenesis were also significantly altered when MM cells develop resistance to melphalan. Specifically, the glycolytic and pentose phosphate pathway enzymes were up-regulated in the melphalan resistant cells, whereas the TCA cycle and ETC proteins were down-regulated. Additionally, the melphalan-resistant cells displayed increased tolerance to overall oxidative stress, but were sensitive to mitochondrial electron transport inhibitors. It was further demonstrated that lactate accumulation, Interleukin-8 and vascular endothelial growth factor (VEGF) signaling, as well as aldo-keto reductase played a role in the development of drug resistance to melphalan in MM cell lines^[39]. Similarly, in MM cell lines resistant to proteasome inhibitors (bortezomib and carfilzomib), complex proteomic changes, particularly in redox and energy metabolism were observed^[40]. Proteins involved in metabolic regulation, redox homeostasis, and protein folding and destruction were upregulated in proteasome inhibitor-resistant MM cell lines, which exhibited metabolic adaptations that favored the generation of reducing equivalents such as NADPH^[40]. The glucose metabolism was rewired in bortezomib-resistant MM cells, leading to higher activity of both the pentose phosphate pathway and serine synthesis pathway and an increased anti-oxidant capacity in bortezomib-resistant cells^[41]. Interestingly, the expression of 3-phosphoglycerate dehydrogenase (PHGDH), which catalyzes the rate-limiting step of serine synthesis, was up-regulated in bortezomib-resistant MM cells. Consistent with increased serine synthesis observed in bortezomib-resistant MM cells, serine starvation enhances the cytotoxicity of bortezomib. These data suggest that interfering with serine metabolism could be a novel strategy to improve bortezomib therapy and PHGDH could be a potential biomarker for bortezomib resistance^[41].

To identify therapeutic targets for the prevention and treatment of drug resistance, Maiso *et al.*^[42] performed metabolic profiling of multiple myeloma cells in normoxic and hypoxic conditions. It was found that in hypoxic conditions, intermediates of the TCA cycle and the ETC were reduced whereas intermediates of glycolysis were elevated. Specifically, glucose 6-phosphate, fructose 6-phosphate, fructose 1,6-bisphosphate, pyruvate, and lactate were significantly increased in hypoxic cells. Gene expression profiling further demonstrated that the main pathways altered by hypoxic culture were those involved in glucose metabolism and the TCA cycle including key metabolic genes such as hexokinase 2 (HK2) and lactate dehydrogenase A (LDHA). Interestingly, bortezomib treatment inhibited HK2 activity but not lactate activity, suggesting LDHA may play a role in modulating drug resistance of MM cells in hypoxic conditions.

TARGETING METABOLIC PATHWAYS FOR THE TREATMENT OF MULTIPLE MYELOMA

The alterations in metabolism provide potentially therapeutic targets for the treatment of MM.

Targeting glycolysis for the treatment of MM

Glucose is the most abundant energy producing molecule in the human body and as such is broken down to produce energy for the body to maintain its regulatory functions. MM exhibits significant alterations in glucose metabolism. This was demonstrated by the fact that myelomatous bone and soft tissue lesions have elevated glucose uptake on positron emission tomography (PET) scans. Total lesion glycolysis and metabolic tumor volume, parameters measurable using ^{18}F -FDG PET CT scan, are highly associated with progression-free and overall survival and can significantly improve the prognostic value of both the GEP70 and International Staging Systems^[43]. These data suggest that targeting specific aspects of glucose metabolism may offer a novel avenue for therapy.

Like many other tumors, MM cells demonstrate enhanced glycolysis and lactate production (e.g., aerobic glycolysis) instead of proceeding through the TCA cycle. Enhanced glycolytic flux confers tumor cells a growth advantage and plays an important role in maintaining myeloma cell survival and proliferation and in inducing chemoresistance. Many genes are involved in the enhanced glycolysis seen in MM. The PI3K/AKT pathway, a cytoplasmic chemical messaging system, has been linked to increased glucose metabolism and may be part of the reason why glycolytic intermediates are upregulated in myeloma cells^[44-47]. Subsequently, it was found that a serine/threonine protein kinase, mTOR, regulated PI3K/AKT signaling^[45]. Hypoxia-inducible factor-1 (HIF-1) is a transcription factor that is upregulated in the bone marrow microenvironment (where hypoxic conditions are standard), in myeloma cell lines, and CD138+ plasma cells isolated from MM patients^[48,49]. HIF-1 has been shown to play a key role in the accumulation of increased glycolytic metabolites in MM^[42,50,51]. HIF1- α (a subunit of HIF-1) induces transcription of several genes related to the response to hypoxia including genes that upregulate glycolytic enzymes and lactate production^[42]. HIF1- α expression is increased in drug resistant myeloma cells, and is associated with increased risk for metastatic disease and worse prognosis in various cancers^[42,50-53]. Drug resistance and disease relapse are thought to be due to the minimal residual disease cells that reside in the hypoxic bone marrow microenvironment. Maiso *et al.*^[42] showed that specific inhibition of LDHA and HIF1- α can restore drug sensitivity to anti-myeloma agents and inhibit tumor growth suggesting that targeting HIF1- α or LDHA can be used to inhibit myeloma growth and overcome drug resistance.

Pyruvate kinase M2 (PKM2) is a key factor regulating aerobic glycolysis and promoting tumor cell proliferation and survival^[54]. Recently, Gu *et al.*^[55] showed that never in mitosis gene A (NIMA)-related kinase 2 (NEK2) regulates splicing of PKM and increased the PKM2/PKM1 ratio in myeloma cells to promote aerobic glycolysis and oncogenic activity.

LDH is a key enzyme that regulates glycolysis and the conversion of pyruvate and NADH to lactate and NAD⁺ respectively^[56]. LDHA has been shown to be upregulated in MM cells by the proliferator-activator receptor-g coactivator-1 β acting on the LDHA promoter. This increase has been shown to significantly potentiate glycolysis metabolism resulting in increased cell proliferation and tumor growth^[42,57].

MM cells exhibit increased activity in glucose transporters and in key glycolytic enzymes such as HK. Most of the work targeting glucose metabolism in MM has focused on the GLUT family. Up-regulation of GLUT1, GLUT4, GLUT8, and GLUT11 has been shown to increase glycolytic metabolites in myeloma cells^[58]. Myeloma cells rely on the insulin-responsive glucose transporter GLUT4 for basal glucose consumption, maintenance of Mcl-1 expression, growth, and survival^[58]. Ritonavir is an FDA-approved HIV protease inhibitor and has a selective off-target inhibitory effect on GLUT4. Treatment with ritonavir elicits dose-dependent abrogation of both glucose uptake and proliferation on KMS11 and L363 myeloma cells^[58]. Interestingly, a subset of myeloma

cells survives glucose deprivation or ritonavir treatment likely by engagement of mitochondrial oxidative phosphorylation. Metformin is an FDA approved anti-diabetic medication that targets mitochondrial complex 1. The combination of ritonavir and metformin effectively elicited apoptosis *in vitro* in MM cell lines and primary human myeloma cells and showed anti-myeloma activity *in vivo* in a xenograft model of MM^[59]. Further analysis of the combination showed that it suppressed AKT and mTORC1 phosphorylation, and down-regulated the expression of Mcl-1 in myeloma models^[59].

Hexokinases catalyze the first irreversible step of glycolysis and play a critical role in the regulation of glycolytic activity. HK2 interacts with the voltage dependent anion channel in the outer membrane of mitochondria, where it catalyzes the conversion of glucose to glucose 6-phosphate^[60]. HK2 has been shown to be overexpressed in a variety of cancers including MM^[61,62], suggesting that HK2 could be a viable target for inhibiting the proliferation of multiple myeloma cells^[62-65]. Notably, treatment with bortezomib or vincristine, downregulated the expression of GLUT-1 and hexokinase, and induced apoptosis in OPM2 MM cells^[66].

An additional approach to targeting glucose consumption has been with the use of the novel purine analogue 8-aminoadenosine (8-NH(2)-Ado). Shanmugam *et al.*^[67] showed that treatment of the MM1S myeloma cell line with 8-NH(2)-Ado reduced glucose consumption through regulation of the GLUT4 transporter.

Targeting amino acid metabolism for the treatment of MM

In addition to MM cells being dependent on glucose, myeloma cells are also dependent on glutamine for energy equivalents through a process known as glutaminolysis. This process is especially prevalent in chemotherapy resistant myeloma cells. Bajpai *et al.*^[68] showed that when glucose metabolism is inhibited in myeloma cells exposed to various anti-myeloma agents, (bortezomib, melphalan, or carfilzomib), the resistant myeloma cells became preferentially dependent on glutamine and thus less likely to undergo apoptosis. Using glutamine as a primary energy source also affects the bone marrow microenvironment in MM patients. Specifically, the T-cells and NK cells in the tumor microenvironment are suppressed by the nutrient deprivation, hypoxia, and decreased pH that results from increased dependence on glutamine as an energy source^[69].

Glutaminolysis breaks down glutamine into alpha-ketoglutarate which then enters TCA cycle. Glutamine can be converted to glutamate, a reaction termed glutamine anaplerosis. Alpha-ketoglutarate can be further broken down to 2-HG which is associated with c-MYC overexpression^[37,70]. 2-HG is an oncometabolite, and elevated levels of 2-HG in smoldering MM patients are associated with increased risk of progression to MM^[37]. Glutamine is crucial for the survival and proliferation of certain cancer cells, and starvation of glutamine induces cancer cell death^[71]. Effenberger *et al.*^[72] recently showed that *in vitro* cultures of MM cells are dependent on glutamine for survival and that this is dependent on MYC protein expression. Notably, when these cells were treated with the glutaminase inhibitor benzophenanthridinone 968 apoptosis was induced. Additionally, MM cells show high expression of the glutamine transporters SNAT1, ASCT2, and L-type amino acid transporter 1 (LAT1); and inhibition of the ASCT2 transporter exhibits anti-myeloma activity^[73]. Furthermore, high expression of LAT1 is associated with high proliferation and poor prognosis in newly diagnosed MM patients, and predicts poor overall survival independent of the International Staging System^[74]. These data demonstrate that inhibition of glutaminolysis serves as a potential therapeutic approach in the treatment of MM^[71,72].

Targeting fatty acid metabolism for the treatment of MM

Fatty acids and lipids play important roles in the development and pathogenesis of MM through direct influence on the metabolism of myeloma cells, functioning as intercellular messengers, or acting as mediators of the pathological immunologic pathways^[75]. Analysis of plasma or erythrocyte membrane lipid

composition provides a simple, suitable model to study fatty acid metabolism. Jurczynszyn *et al.*^[75] measured the fatty acid composition of RBC membranes in MM patients and compared them with healthy controls. MM patients exhibited higher levels of saturated fatty acids and n-6 polyunsaturated fatty acids (PUFA) and lower levels of monounsaturated n-3 PUFA and trans-fatty acids, than controls. It was suggested that the fatty acid content of the RBC membrane could serve as a diagnostic and/or predictive biomarker in MM. Similarly, increased plasma levels of saturated fatty acids and n-6 PUFA were observed in MM patients compared to healthy controls, indicating increased synthesis of these fatty acids in MM patients^[76]. Recently, it has been shown that several myeloma cell lines (U266, RPMI8226, and NCI-H929) increase fatty acid oxidation as a mechanism to maintain metabolic hemostasis and viability during conditions of decreased glycolysis and increased lactate accumulation^[77-79].

Fatty acid synthase (FAS) expression was up-regulated in human myeloma cell lines as well as primary myeloma cells and contributes to myeloma cell proliferation and survival. Inhibition of fatty acid β -oxidation with etomoxir or *de novo* fatty acid synthesis with orlistat significantly reduced myeloma cell proliferation. The combination of 50 mmol/L etomoxir and 20 mmol/L orlistat resulted in an additive inhibitory effect on myeloma cell proliferation. Interestingly, the inhibitory effect was associated with reduced levels of p21 protein and phosphorylated retinoblastoma protein^[79]. These data suggest that inhibition of fatty acid metabolism provides a potential therapeutic approach in the treatment of MM, however O'Connor *et al.*^[80] recently showed that etomoxir loses its specificity at concentrations above 5 mmol/L and results in increased ROS production so these experiments must be interpreted with caution.

Obesity is associated with increased risks of myeloma incidence and mortality. To understand the molecular mechanisms by which adipocytes contribute to myeloma cell survival and progression, Bullwinkle *et al.*^[81] co-cultured MM cell lines with adipocytes harvested from normal, overweight, obese, or super obese individuals. It was found that MM cells proliferated faster, displayed increased pSTAT-3/STAT-3 signaling, and had enhanced adipocyte endothelial tube formation and cell adhesion when co-culturing with conditioned media from obese and super obese individuals.

FUTURE DIRECTIONS

Several areas of future research provide promise in the development of novel treatments for MM.

Lactate research

As the primary molecule thought to induce the hypoxic microenvironment surrounding many cancer cells, lactate is one of the most heavily researched metabolites in MM cells. In 1991 it was discovered that high serum LDH levels could identify myeloma patients that were at increased risk for early progression after treatment^[82]. Furthermore, LDH has been identified as a marker that identifies higher risk patients^[83]. The increased anaerobic respiration in the hypoxic microenvironment of myeloma cells is thought to be linked to the HIF1- α transcription factor, and leads to an increase in lactic acid production. In MM, HIF1- α activity increases glycolytic metabolites, inhibits production of TCA intermediates, and activates IL-6 which all contribute to tumor growth and survival^[84,85]. Notably, hypoxia has been shown to promote myeloma cell dissemination from the bone marrow to the peripheral blood through the downregulation of E-cadherin and the upregulation of the epithelial to mesenchymal transition proteins SNAIL, FOXC2, and TGF β 1^[86]. Hypoxic conditions also promote upregulation of VEGF leading to increased angiogenesis in a mechanism that is thought to be related to HIF1- α activation^[86-89].

Transporters of lactate are also possible metabolic targets in myeloma. The MCT family of transporters are involved in lactate transport in and out of the cell. MCT1 and MCT4 are preferentially expressed in myeloma cells. Inhibition of MCT1 with α -cyano-4-hydroxycinnamic acid led to reduced lactate incorporation and induced apoptosis in myeloma cell lines^[90,91]. Increased lactate is secreted out of MM cells through the MCT

transporters leading to an acidification of the bone marrow microenvironment. This results in inhibition of MCTs in T-cells and thus accumulation of intracellular lactate and H⁺, which-together with their reduced access to glucose by overconsuming tumor cells-leads to decreased T-cell activation^[92].

OXPHOS in multiple myeloma

Since oxidative phosphorylation is the last step in ATP synthesis for aerobic respiration it has been a particular focus of research in cancer metabolism. Given the increase in glycolysis during the progression of myeloma reviewed above, it might be predicted that OXPHOS increases as well. However, it has been found that OXPHOS activity is decreased during increased glycolysis in MM. This is thought to occur because the TCA cycle is not producing enough electron carriers to supply the OXPHOS mechanism to operate at a normal rate of ATP production^[90]. Given these conditions, energy production shifts to anaerobic respiration since other mechanisms, like ketosis, are evolutionarily reserved for starvation and extreme cases, meaning that lactate is the main source of energy in myeloma cells.

While many groups have investigated the role of metabolism in myeloma, relatively few have focused on the role of oxidative phosphorylation in MM. The complex 1 inhibitor, IACS-010759, has been tested in leukemia cells where it led to decreased proliferation and increased apoptosis in leukemia cells^[93,94]. This compound is actively being tested in clinical trials of relapsed AML (NCT02882321), and advanced solid tumors and lymphomas (NCT03291938).

Similarly, inhibitors of complex III have been explored as possible anti-cancer agents. Inhibition of complex III leads to an increase in ROS which can combat tumor proliferation and metastasis as well as induce apoptosis in MM. Previously, Arihara *et al.*^[95] demonstrated that reactive oxygen species have antimyeloma activity. Using CP-31398, an activator of p53 which also induces the formation of ROS, the investigators demonstrated decreased MM proliferation and increased apoptosis in a p53 independent fashion, and this effect was synergistic with carfilzomib. Notably, no additional hematologic toxicity was seen with the agent in animal studies^[96].

Fatty acid research

It is established that resistant MM cells can increase lipogenesis as a mechanism of chemotherapy resistance^[42,79,97]. PUFAs have previously been shown to enhance chemotherapeutic drug effects by selectively inducing apoptosis in multiple cancer cell lines^[98-103]. Specifically, administration of two PUFAs, eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) to four MM cells (L363, OPM-1, OPM-2 and U266) resulted in induction of apoptosis through increased caspase-3 activation, and mitochondrial membrane perturbation with no effect on normal human peripheral mononuclear cells^[104]. Similarly, studies by Dai *et al.*^[105] examined the effects of EPA and DHA on the myeloma cell lines MM1S and MM1R and found that treatment with these agents resulted in increased apoptosis which was enhanced by the addition of dexamethasone. Notably, this synergy with dexamethasone was observed in the MM1R cell line which is inherently dexamethasone resistant. As glucocorticoids are known to increase lipogenesis, and remain a mainstay of MM therapy, these data suggest that EPA and DHA may resensitize cells that have acquired resistance to glucocorticoids. Additional studies on MM cell lines showed that treatment with EPA or DHA decreased MM cell proliferation through induction of lipid peroxidation. This effect was inhibited by superoxide dismutase, or cyclooxygenase/lipoxygenase inhibitors suggesting a role for superoxides, prostaglandins, and leukotrienes in MM proliferation^[106]. Similarly, Wang *et al.*^[107] examined the expression of FAS in bone marrow from MM patients and matched healthy volunteers and found 70% of MM patients had elevated FAS while none of the healthy volunteers had detectable levels. Treatment of the FAS expressing MM cell lines U266 and RPMI8226 with the FAS inhibitor cerulenin resulted in induction of apoptosis evidenced by increased Annexin V staining suggesting FAS as a possible target of anti-myeloma therapy. These studies are admittedly preliminary but warrant additional research in this area.

Other metabolic targets

Other studies have been focused on TCA intermediates. Sanchez *et al.*^[108] were able to identify dichloroacetate (DCA) as a possible target for cancer therapy. DCA is an activator for pyruvate dehydrogenase which allows for increased production of TCA intermediates and consequently, increased OXPHOS for ATP production. Subsequently, DCA was found to inhibit glycolysis in multiple myeloma and increase sensitivity to bortezomib.

CONCLUSION

The study of metabolism's role in MM remains in its infancy, and many avenues remain unexplored. With combination therapies being the norm in myeloma management and acquired resistance to conventional therapies remaining a challenge, the potential exists for additional adjunctive therapies in MM patients. Targeting metabolic pathways is a novel area with preclinical data suggesting efficacy. Targets such as the GLUT and MCT transporters, IGF-1, FAS, and metabolites of the ETC and OXPHOS warrant additional exploration as possible novel anti-myeloma strategies, but care must be taken to minimize adverse effects when targeting ubiquitous pathways. Ideally, future preclinical and clinical studies will help to elucidate metabolism's role in myeloma development and progression, and may lead to the discovery of novel therapies for patients suffering from this disorder.

Abstract

The emergence of novel systemic therapies has spurred a dramatic paradigm shift in lung cancer treatment. Research has revealed greater intracranial efficacy in targeted agents and immune checkpoint inhibitors (ICI) compared to conventional chemotherapy. Concurrently, advances in stereotactic radiosurgery (SRS) have contributed to the increased use of this highly localized, minimally-invasive treatment modality for local tumor control. In this era of precision medicine, the combination of these novel agents and SRS demands further prospective exploration - particularly as questions regarding their sequence of administration and the risk of neurotoxicity remain unanswered. Presently, although data are limited and largely retrospective, literature supports the concurrent administration of ICI and radiation, with no observed increases in immune-related adverse events or acute neurologic toxicities. In the case of patients with driver mutations, newer generations of tyrosine kinase inhibitors (TKI) display improved intracranial efficacy and are currently preferred alone upfront in patients with asymptomatic brain metastases (BM) due to lack of data. Evidence of combining TKI and SRS is limited with mixed results. In this review, we explore the evidence regarding the use of novel systemic agents and SRS for treatment of lung cancer BM. Clinical practice will continue to be refined as larger, prospective studies yield results.

Keywords: Lung cancer; stereotactic radiosurgery, brain metastasis, tyrosine kinase inhibitors, immunotherapy

INTRODUCTION

Lung cancer remains the leading cause of cancer-related mortality^[1]. Eighty-five percent of diagnoses represent non-small cell lung cancer (NSCLC)^[2]; the remaining 10%-14% are diagnoses of small cell lung cancer. Brain metastases (BM) are diagnosed in approximately 10% of lung cancers at time of diagnosis^[3] and approximately 40%-50% will be diagnosed with BM during the course of their disease^[3,4]. BM in lung cancer are known to be associated with poor prognosis. Historically, standard treatment for BM from lung cancer involves neurosurgical resection^[5], radiotherapy and/or chemotherapy^[5,6].

Recent advances in NSCLC, including molecular analysis, matched targeted therapies and immunotherapy, has altered the standard of care. These novel approaches have shifted the paradigm in lung cancer^[7] and improved median overall survival in lung cancer patients with BM^[7,8]. Survival now ranges between 9-15 months and can be as high as 46 months in patients with favorable prognostic factors such as good performance status and epidermal growth factor receptor (EGFR) and/or anaplastic lymphoma kinase (ALK) positivity^[9]. In addition, over the past decade, standard of care in radiotherapy for BM has increasingly favored SRS^[10,11]. Precise delivery of high-dose radiation localized to the tumor results in higher local tumor control^[10] and fewer side effects such as neurocognitive damage^[11] compared to whole brain radiotherapy (WBRT).

The trifold advancement in targeted therapies, immunotherapy and SRS has revolutionized the treatment of BM in lung cancer. Employing these novel therapies, lung cancer patients are living longer, becoming more likely to develop brain metastases. Certainly, the use of these therapies - either individually or in combination - is anticipated for the treatment of lung cancer BM.

In this review, we discuss the current evidence regarding the use of SRS employed alone and in combination with novel therapies for treatment of lung cancer BM.

BRAIN METASTASIS IN LUNG CANCER LACKING A DRIVER MUTATION

SRS

SRS, typically delivered in a single fraction, serves as a key modality for delivering high-dose radiation to smaller target sites (usually < 3 cm)^[12], sparing adjacent structures from exposure and mitigating the harmful effects of radiation^[11].

For single BM, SRS has demonstrated efficacy and safety. Therefore, both surgical resection plus postoperative radiation and SRS alone are reasonable options and treatment should be individualized as comparative data is lacking^[13]. Surgery plus postoperative radiation is preferred for a single, large and symptomatic BM to allow for decompression, lower morbidity and higher local control^[13]. One small retrospective study found similar survival when comparing surgical resection vs. SRS for solitary BM^[14]. However, more local recurrence was demonstrated in the surgery group^[14].

For surgically-resected brain metastases, post-operative SRS (post-SRS) is the current standard of care. Some concerns with post-SRS include radiation necrosis and leptomeningeal disease (LMD) recurrence. The hypothesis behind LMD recurrence is the intra-operative seeding of viable tumor cells, which is supported by a study where post-SRS demonstrated higher rates of LMD compared to adjuvant WBRT^[15]. A new approach, pre-operative SRS (pre-SRS), is being evaluated as a potential method to decrease radiation necrosis and LMD. Potential benefits of pre-SRS include: (1) better local tumor control through improved delineation when contouring an intact metastasis compared to an irregularly-shaped surgical cavity; (2) reduced risk of radiation necrosis, as there is no need to treat surrounding brain tissue and the majority of the treated BM will be resected; (3) reduced risk of LMD as a result of a potential sterilizing effect via the intraoperative seeding of treated tumor cells; and (4) the potential to treat more patients, as with post-

SRS some patients are lost to follow-up. A potential disadvantage includes reduced wound healing^[15]. Asher *et al.*^[16] evaluated pre-SRS in 47 patients, demonstrating its safety and efficacy with local control rates of 85.6% at 12 months. One retrospective study evaluating pre- and post-SRS cohorts of 180 BM patients (including approximately 40% with NSCLC) showed similar rates of local recurrence and overall survival. However, pre-SRS was associated with significantly reduced rates of radiation necrosis and LMD^[17]. Clinical trials currently comparing pre-SRS and post-SRS in BM include NCT03741673 and NCT03750227.

SRS plays a major role in patients with multiple small BM (< 3 cm) or surgically inaccessible BM. Younger lung cancer patients of high Karnofsky performance status with limited BM and a low burden of extracranial disease may derive the most benefit from SRS^[10,18]. Generally, SRS use has been limited to patients with few, small, easily radio-accessible BM^[2]. Although a multi-center retrospective analysis demonstrated a survival advantage for patients treated with SRS possessing fewer than four BM ($n = 189$ for NSCLC) compared to WBRT (adjusted HR for NSCLC, 0.58; 95%CI: 0.38-0.87; $P = 0.01$)^[19], Yamamoto and colleagues recently evaluated SRS alone in 1,194 patients with up to ten lesions (largest tumor < 10 mL in volume and < 3 cm in longest diameter; total cumulative volume ≤ 15 mL)^[20]. Their group found no difference in overall survival (10.8 months) or treatment-related adverse events (9%) between patients with two to four tumors and patients with five to ten tumors^[20]. These results suggest expanding SRS for the treatment of patients with up to ten BM^[2,5]. Further data propose total BM volume as potentially more significant than the total number of BM^[10].

Adverse effects of SRS

Overall, the adverse effects of SRS are consistent with known toxicities of intracranial irradiation. Both acute (developing over weeks to months) and late-onset (developing over months to years) toxicities may result. Certainly, the risk, severity and incidence of radiation-induced toxicities is highly dependent on the site, dose, fractionation and volume of tissue irradiated along with the patient's comorbidities^[21]. Acute toxicities are uncommon and include nausea, headache, dizziness, seizure or new transient focal deficits^[22]. Patients are usually treated with a short course of glucocorticoids.

The most common delayed adverse effect of SRS treatment to BM is radiation necrosis, occurring in approximately 5%-10% of patients^[23]. However, this risk rapidly increases with increasing BM size and/or volume as well as with a history of radiation to same lesion^[21,23-25]. A study suggests employing multifractionated SRS in three to five fractions rather than single fraction SRS as a means of decreasing the risk of radiation necrosis and improving local control^[26]. The use of fractionated SRS also allows for the safe treatment of larger BM (> 3 cm)^[26,27]. Data on long-term effects of SRS on neurocognition is limited but reassuring^[25].

SRS in combination with immunotherapy

Immune checkpoint inhibitors (ICIs) have become a routine part of the treatment of advanced NSCLC lacking a driver mutation, administered with chemotherapy doublet or alone in patients with $\geq 50\%$ expression of programmed cell death-ligand 1 (PD-L1)^[8]. Most patients with advanced NSCLC and BM are eligible to receive ICIs - either alone or with chemotherapy.

Concerns to using ICIs to treat BM include: (1) pseudo-progression with the potential of symptom aggravation; and (2) steroid use for symptomatic BM which may reduce ICI activity, as demonstrated by a decreased objective brain response with the addition of steroids during ICI treatment in melanoma^[28]. Present data on ICIs for BM from advanced NSCLC is limited. Most ICI clinical trials in NSCLC excluded patients with untreated or unstable BM, yet included stable and treated BM, comprising 6%-17% of included patients^[29]. Overall, in the small subgroups of BM patients included in these trials, ICI appears safe^[29]. However, outcomes were mixed as some trials demonstrated benefit over chemotherapy and others did not^[29]. A rationale for positive response to ICIs includes the inflammatory microenvironment of BM, with

the presence of significant tumor-infiltrating lymphocytes (TILs). In a series of 116 BM specimens (including 61 from NSCLC BM), more than 50% of all specimens had dense TIL infiltration - also associated with improved survival^[30].

Radiation therapy (RT) also induces an antitumor immune response by upregulating PD-L1 and inflammatory cytokines as well as facilitating T-cell infiltration^[31]. Localized RT may induce an abscopal effect, which reflects the regression of non-irradiated metastatic lesions due to systemic anti-tumor response. The dose and fractionation of RT plays a role in its effects on the immune system. Schaeue *et al.*^[32] found that fractionated treatment with medium-sized radiation doses of 7.5 Gy per fraction yielded the best tumor control and anti-tumor immune responses. Dewan *et al.*^[33] showed that 5×6 Gy and 3×8 Gy protocols of RT were more effective in inducing immune-mediated abscopal effects than a single ablative dose of 20 Gy when combined with an anti-CTLA-4 antibody. These preclinical data suggest a better systemic anti-tumor effect with hypofractionated (e.g., fractionated SRS) than conventional RT. Most data regarding the abscopal effect are from treating systemic disease; if the same impact occurs in the treatment of BM is uncertain. Although based on small studies, there is growing evidence in favor of an abscopal effect when treating BM^[34].

RT alone is a poor inducer of immune-mediated local and abscopal responses; but, evidence suggests these responses are enhanced by combining radiation with ICI^[31,35,36]. Although data regarding the combination of ICI and radiotherapy in BM due to NSCLC are limited and mostly retrospective, data indicate that combining ICI and radiation in BM is safe with similar adverse events^[37,38] and support a concurrent administration of ICI with radiation over a sequential administration^[38]. While most studies demonstrated similar adverse events with combination ICI-radiotherapy, the role of ICI in radiation necrosis remains controversial. One retrospective study with 61% NSCLC patients showed that the incidence of symptomatic radiation necrosis after stereotactic radiation was higher in patients who received ICI - especially those with melanoma^[39]. Other retrospective studies including patients with NSCLC and BM did not report a higher incidence of radiation necrosis with combination ICI-radiotherapy^[37,38,40].

Many questions regarding the combination of ICI and RT remain unanswered including the optimal timing, the impact of steroids and neurotoxicity. Questions such as these should be investigated through prospective trials. Current clinical trials evaluating the combination of ICI and radiation therapy in NSCLC BM include NCT02978404 (Nivolumab + SRS), NCT02858869 (Pembrolizumab + SRS) and NCT02696993 (Nivolumab + SRS/WBRT and Nivolumab + Ipilimumab + SRS/WBRT). These phase I and phase II trials include other malignancies and are expected to finish by 2020.

BRAIN METASTASIS IN LUNG CANCER WITH DRIVER MUTATIONS

In NSCLC, sensitizing EGFR mutations are found in 10% of Caucasians as well as up to 50% of Asians^[41]. ALK-rearrangement is found in 2%-7%^[42] and ROS proto-oncogene 1 (ROS1) occurs in 1%-2% of patients^[43]. The incidence of BM is higher in patients with driver mutations. The rates of BM present at diagnosis is 24.2% and 23.8% in EGFR-mutated and ALK-rearranged lung cancers, respectively, and increasing to > 45% of patients at three years post-diagnosis^[44]. ROS1-rearranged NSCLC also has a high incidence of BM (36%) and is the common first site of progression^[45].

First- (erlotinib, gefinitib) and second-generation (afatinib) anti-EGFR TKI have demonstrated improved survival and brain response rates of over 50% in EGFR-mutated patients compared to EGFR wild-type patients^[5]. The third-generation anti-EGFR TKI, osimertinib, demonstrated an even higher rate of intracranial response (91% vs. 68% in patients with measurable BM lesions), a lower rate of central nervous system (CNS) progression and longer progression-free survival when compared to first generation anti-EGFR TKI in the FLAURA trial^[46,47]. Though first- and second-generation anti-EGFR TKI have activity in patients with BM, these agents have a much lower intracranial concentration as compared with osimertinib^[5]. Given

the high intracranial activity of osimertinib, it is preferred as the initial therapy for patients presenting with asymptomatic BM in EGFR-mutated NSCLC. Osimertinib has not yet been evaluated with SRS, but it is reasonable to use SRS in the case of isolated intracranial progression and continue to use osimertinib. A clinical trial is open to evaluate osimertinib with or without SRS for EGFR-mutated NSCLC with BM (NCT03497767). The trial is expected to be completed in 2022.

If osimertinib is unavailable, first- or second-generation anti-EGFR TKI can be used in patients with asymptomatic BM, but not alone. Preclinical studies have shown a sensitizing effect of radiotherapy on EGFR expression and an enhanced radiation response through the inhibition of EGFR^[48,49]. Although limited, clinical data is not yet reflective of preclinical data, but shows promise for future trials. A meta-analysis including 363 patients and another retrospective study of 351 patients with EGFR-mutated NSCLC (treated with first- and second-generation anti-EGFR TKI) suggested upfront intracranial radiation demonstrates better overall survival^[50,51]. SRS followed by anti-EGFR TKI resulted in the longest overall survival, with WBRT followed by anti-EGFR TKI demonstrating intermediate overall survival and anti-EGFR TKI followed by SRS or WBRT at intracranial progression resulting in the shortest median overall survival^[50,51]. Based on these data, for patients with asymptomatic BM started on a first- or second-generation anti-EGFR TKI, upfront SRS is appropriate - particularly given its better outcomes compared to delaying radiation. The concurrent use of anti-EGFR TKI with SRS or WBRT is more controversial, demonstrating mixed results. A phase III study found decreased overall survival with WBRT + SRS + erlotinib compared to WBRT + SRS^[52]. Another retrospective study found similar survival in patients receiving a concurrent administration of radiation + anti-EGFR TKI vs. patients receiving radiation followed by anti-EGFR TKI^[53]. At this point, due to the absence of data, we recommend stopping TKI administration during SRS treatment and resuming after completion.

ALK-directed TKIs have also demonstrated intracranial activity. In a retrospective analysis, the first-generation ALK inhibitor, crizotinib, showed an intracranial disease control rate of 56% in untreated BM and 62% in previously treated BM^[54]. Despite this intracranial efficacy, approximately 20% of patients progressing on crizotinib developed BM^[54]. Second-generation ALK-directed TKIs (ceritinib, alectinib, brigatinib) have better intracranial efficacy. Alectinib was compared to crizotinib in two phase III trials (J-ALEX and ALEX) and showed improved survival and superior CNS activity with an incidence rate of CNS progression at 12 months of 4.6% with alectinib compared to 32% with crizotinib in patients without BM at baseline^[55-57]. Brigatinib is also superior to crizotinib in the frontline setting, as seen in the ALTA trial, with an intracranial response rate of 78% with brigatinib vs. 28% with crizotinib^[58]. Crizotinib, ceritinib, alectinib and brigatinib are all approved as first-line therapies for ALK-positive advanced NSCLC. However, alectinib is preferred per National Comprehensive Cancer Network guidelines^[8]. Alectinib alone is appropriate in asymptomatic BM.

In patients who progress on crizotinib, ceritinib, alectinib or brigatinib are all appropriate as they have not been directly compared in terms of BM efficacy. In a small case series, alectinib also showed intracranial response in ceritinib-resistant patients^[59]. In the setting of alectinib-resistant disease, options include switching to lorlatinib, which has documented CNS activity in patients who have failed second-generation inhibitors^[60] or local therapy (such as SRS) if only oligometastatic disease is present^[61].

Crizotinib is the standard first-line treatment for patients with ROS1-rearranged NSCLC^[8], but as previously discussed, it has poor intracranial activity. Other approved TKIs include ceritinib and lorlatinib that demonstrate better intracranial activity^[62,63]. There are no data available on the combination of radiation therapy and TKI in ROS1-rearranged NSCLC.

In one study, patients with EGFR-mutated or ALK-rearranged NSCLC who had oligo-progression on erlotinib or crizotinib were considered for local ablative therapy to the sites of progression and continuation

of the TKI^[64]. The TKI was stopped on the days of radiation and restarted with the same dose^[64]. Twenty-five of 51 patients who progressed were deemed suitable for local therapy and most received stereotactic radiation^[64]. Ten of the 25 patients had intracranial progression^[64]. Post local ablative therapy, the median progression-free survival was six months^[64]. Minimal grade three and four adverse events were seen^[64]. Another study of ALK-rearranged NSCLC showed that combining stereotactic radiation with crizotinib is safe and can achieve durable control, although the study only included extracranial sites of progression^[65]. A retrospective study showed prolonged overall survival (49.5 months) of NSCLC patients with BM when treated with ALK-directed TKI therapy and brain radiation^[66]. In the ALEX trial, patients with previous radiation to BM had higher intracranial response rates (86% *vs.* 79%) compared with patients without prior radiotherapy^[57]. In summary, data on the safety and outcome of combining radiation with ALK-directed TKIs is limited and favors SRS over WBRT.

An ongoing clinical trial is evaluating ALK inhibitors and other targeted therapies in combination with stereotactic brain treatment in patients with stage IV oncogene-driven (EGFR, ALK, or ROS1) NSCLC (NCT02314364).

CONCLUSION

The development of novel, targeted agents and immunotherapy has advanced the systemic treatment of lung cancer. These therapeutics demonstrate far greater intracranial efficacy than conventional chemotherapy - transformative for BM treatment. However, this paradigm shift in treatment warrants the careful consideration of systemic therapy as a frontline approach. While SRS remains an important aspect of the management of BM, its role combined with novel systemic therapies is largely unclear. Limited available evidence suggests combination is safe with favorable outcomes, but the sequence of administration remains uncertain. Many clinical trials are underway that aim to further address these questions. As the results of these studies emerge, clinicians will gain further evidence-based insight into the clinical management of patients with lung cancer BM.

Abstract

Contralateral axillary metastasis (CAM) is a rare entity normally treated as a systemic disease. Recent publications have proposed aggressive surgical treatment with benefits to the patients in terms of survival. We present a case of a 74-year-old patient with a history of unilateral breast cancer, recurrence on the ipsilateral breast and then development of a CAM. The patient was treated with aggressive surgical treatment, but she developed an early recurrence of the disease with distant metastasis. There is limited evidence of the correct management of CAM, although proposed to treat it as a loco regional disease, individualized and multidisciplinary management is the best option for these patients.

Keywords: Breast cancer, contralateral axillary metastasis, lymphatic routes blockage

INTRODUCTION

Contralateral axillary metastasis (CAM), posterior to a unilateral breast cancer, is a rare entity. The reported incidence is between 1.9% and 6% in different publications^[1,2]. Although rare, it is very clinically relevant, as lymph node metastasis is the most important prognostic factor in breast cancer. Correct identification of the primary origin of axillary metastasis is a priority; however, sometimes it can be a true challenge. There are many controversies about the pathophysiology and appropriate management of CAM because the contralateral axilla is considered a distant metastasis, thus stage IV disease, with limited therapeutic

strategies involved. Some authors have advised about a multidisciplinary and more aggressive approach to treat CAM, such as a loco regional spread breast cancer rather than distant metastasis^[3,4].

CASE REPORT

A 74-year old female, with an oncologic history of Hodgkin lymphoma (HL) stage IV B, with supra diaphragmatic and infra diaphragmatic adenopathies and bone marrow infiltration, was treated with chemotherapy twenty years ago.

The patient presented, in 2007, a left breast lesion on the upper outer quadrant (UOQ) detected by mammography. An ultrasound (US) and magnetic resonance imaging (MRI) study confirmed and classified the lesion as a BI-RADS 5. A core needle biopsy (CNB) was performed and the histopathology analysis (HA) reported an invasive ductal carcinoma (IDC), grade two, negative estrogen receptor (ER), positive progesterone receptor and negative human epidermal growth factor receptor type two (HER2/neu). A lumpectomy and sentinel lymph node biopsy (SLNB) with one step nucleic acid amplification (OSNA) technique, were performed. The SLN was negative and the size of the tumor was 1.5 cm. Classified as a stage IA, complement treatment with radiotherapy (RT) and hormonal therapy with Anastrozole was decided for five years.

In 2016, a lesion of 2 cm in the surgical scar of the left breast was identified. Although the lesion was classified as an IDC, this time it was triple-negative (TN) by immunophenotype and with a Ki-67 of 35%. A total left mastectomy and SLNB were indicated, with one positive lymph node in the OSNA analysis, thus requiring an axillary lymph node dissection (ALND). A total of 15 lymph nodes were excised without disease. Adjuvant systemic chemotherapy (ASC), with doxorubicin, cyclophosphamide, methotrexate and paclitaxel, was indicated.

The surgery was complicated with a chronic seroma, and it was managed with conservative measures for six months without success; thus, requiring surgical treatment. During the procedure, in August 2017, a suspicious lesion was observed in the surgical bed of the mastectomy. A biopsy was taken, reporting metastatic infiltration of carcinoma in the pectoralis major. A wide local excision of the pectoralis major muscle was performed and the HA reported an IDC of 3.5 cm, grade three, TN, Ki67 of 75% and free margins. With this result, the patient underwent ASC with Capecitabine plus RT.

In March 2018, suspicious right axillary lymph nodes were identified during a computer tomography scan [Figure 1]. The study, complemented with US and MRI, identified an intramammary lymph node

Figure 2. Positron emission tomography computer tomography showing multiple metastatic disease

in the UOQ of the right breast. Surgical treatment was determined and 43 out of 45 of the right ALND were positive, seven of them with capsular rupture. In addition, the intramammary lymph node was also positive for IDC, TN immunophenotype with a Ki67 of 63%. ASC and RT to the whole breast, axillary and supraclavicular region was decided.

During controls, in May 2018 the patient complained of a lump in the left inguinal area, when performing the physical exploration, a three cm lymph node was identified. A CNB reported metastatic carcinoma compatible with breast cancer. A positron emission tomography (PET) scan revealed multiple abnormal lymph nodes in the cervical, supraclavicular, mediastinal, retroperitoneal and inguinal regions. In addition, two bone lesions, one in the pelvis and another in the humeral bone were described as well as unspecific pleural nodules [Figure 2].

Treatment with carboplatin and gemcitabine was administered. However, a new PET revealed disease progression with new muscular, hepatic, subcutaneous and bone lesions. The patient was admitted to the hospital for severe respiratory insufficiency due to bilateral pleural effusion; finally, she died on October 10th of 2018.

DISCUSSION

One of the main explanations of CAM is aberrant drainage due to blockage of normal lymphatic routes. Perre *et al.*^[5] described this theory; they studied 23 patients with breast cancer who underwent lymphoscintigraphy before and after surgical treatment with or without radiotherapy. Only one patient presented drainage to the contralateral axilla before treatment; however, this same event presented in four patients after ALND of the opposite axilla and in one patient after radiotherapy. In a more recent publication, van der Ploeg *et al.*^[6] observed, in patients with previous ALND for breast carcinoma, contralateral axillary drainage in four out of 12 of them, during lymphoscintigraphy and SLNB. This finding becomes more relevant because two of the four involved lymph nodes were positive for metastasis. Both patients underwent ALND on the same side and reported alive and free of disease for 22 and 36 months after the procedure. In these two publications, the authors concluded that this mechanism of drainage reflects regional dissemination to the node on the direct pathway, making the “crossover metastasis” effect. However, a different outcome would be in cases of untreated breast cancer, where CAM means dissemination beyond the regional nodes.

Other risk factors for CAM have been described, including obstruction of the ipsilateral lymphatic drainage, bulky tumor in the breast, extensive tumor burden in the axilla, and as mentioned before, previous surgery and/or radiotherapy^[3,7].

There are challenges in the clinical scenario of CAM. Contralateral spread from the original tumor is not the only possibility. An occult second primary in the contralateral breast and axillary metastasis from the extramammary site should be considered^[8]. Although it is possible to have certainty of the tumor origin with a biopsy of the axillary node, to discard an occult second primary in the contralateral breast is not always an easy task. MRI has been proposed to be a good technique to identify occult primary breast carcinoma (OPBC). In a prospective analysis carried out by Buchanan *et al.*^[9], 69 patients with occult OPBC, underwent breast MRI, identifying 80% (55 of 69) of suspicious lesions and proved to be breast carcinoma in 49% of them (34 of 69). Although MRI has its limitations, due to false positive results, the authors of this study support that OPBC is a primary indication for the use of MRI.

CAM is an uncommon event in breast cancer and has a poor prognosis. AJCC 8th edition classifies CAM as stage IV disease because contralateral axillary lymph nodes are not considered a regional extent of the disease, but a distant metastasis^[10]. However, several publications have questioned this affirmation and proposed that treatment of CAM should be aggressive and multidisciplinary as it is in the case of locally advanced breast cancer, rather than treated as a distant metastasis^[3,4,8]. A systematic review analyzed 48 patients with CAM, 23 had complete follow up data during a mean time of 50.3 months with an overall survival of 82.6%. An important fact is that 92.1% of patients received surgical treatment and 88.9% systemic treatment^[11].

The patient of the case had many risks factors, like conservative surgery, radiotherapy in the left breast and an ipsilateral recurrence treated with mastectomy and SLNB. After completing ALND, 15 lymph nodes were negative for metastasis. However, CAM was identified two years later.

History of HL has been described as a risk factor for breast cancer, with an excess risk of 40% even after 40 years. The main risk factor is mantle radiotherapy, especially in young women in the “peri-pubertal” period, corresponding as the highest breast radio sensitivity period^[12,13]. The patient in our case was treated with chemotherapy exclusively and after menopause, thus we cannot assume a specific risk association.

It is important to mention that even though this patient received aggressive surgical treatment, chemotherapy and radiotherapy, the disease progressed as a systemic disease in a short period of time. This reflects the complexity of the case and that different approaches should be taken into account when treating these patients.

In conclusion, CAM are an unusual form of metastasis in unilateral breast cancers. The assumption of a disseminated disease prompt to systemic therapies rather than an aggressive surgical treatment. There are many controversies regarding the appropriate management and the prognostic influence on these patients. Unfortunately, there is poor evidence for the adequate treatment, due to the rarity of the event. An individualized and multidisciplinary approach is encouraged for these patients, so a positive impact on survival is achieved.

Abstract

Aim: To correlate the microcalcifications' characteristics, such as morphology and elemental compositions, with the occurrence of bone metastatic lesions at 5 years from diagnosis.

Methods: In this retrospective study, we enrolled 70 patients from which we collected one breast biopsy each. From each biopsy, paraffin serial sections were obtained to perform histological classifications, immunohistochemical analyses and Energy Dispersive X-ray evaluation.

Results: Microcalcifications analysis showed a significant association between the presence of calcium crystals made of magnesium substituted hydroxyapatite and the development of bone metastasis from 5 years from diagnosis. No significant association was observed by evaluation the morphological appearance of microcalcifications. Immunohistochemical analysis displayed a significant association between the expression of bone morphogenetic proteins 2 and pentraxin-3, two osteoblast induction factors, and the formation of bone metastatic lesions.

Conclusion: Results here reported highlighted the possible use of breast microcalcifications as a negative prognostic marker of bone metastatic diseases. In particular, the association between elemental composition of breast microcalcifications and the formation of bone lesions can lay the foundation for the development of new *in vivo* diagnostic tools based on the analysis of microcalcifications and capable to predict the formation of bone metastasis.

Keywords: Microcalcifications, breast cancer, bone metastasis, breast osteoblast-like cells, bone morphogenetic proteins 2, pentraxin-3

INTRODUCTION

Bone metastasis from breast cancer represent the main disability associated to breast cancer^[1,2]. Indeed, the occurrence of bone metastatic lesions affected the patients' quality of life by inducing pain, hypercalcemia, bone fracture and spinal compression^[2]. Also, the progression of metastatic lesions is often the cause of the patient's death^[2].

In this context, the early identification of breast cancer lesions with high propensity to form bone metastasis could improve the patient's survival allowing to clinicians to choose the more appropriate therapeutical protocol.

In the last years, several studies investigated the cellular and molecular mechanisms involved in the breast cancer osteotropism^[3-6]. In particular, our group described, for the first time, a new breast cancer cell type showing an osteoblast-like phenotype, the breast osteoblast-like cells (BOLCs)^[7]. As the real osteoblasts, it is demonstrated that these cells are capable to product calcium crystals made of hydroxyapatite (HA) of magnesium substituted hydroxyapatite (MgHAp) in a process similar to the physiological mineralization^[7]. Several molecules have been associated to the process of the formation of microcalcifications in breast cancer. Among them, deserve particular mention the bone morphogenetic proteins 2 (BMP-2) and pentraxin-3 (PTX3). BMP-2 is currently considered the most powerful osteoblast induction factor^[8], whereas it is recently demonstrated the ability of PTX3 to induce both osteoblast proliferation and activity^[9,10]. In particular, studies of Scimeca *et al.*^[7] highlighted the essential role of PTX3 in bone metabolisms founding a correlation between the impairment of PTX3 expression and the inhibition of osteoblast activity. In these reports authors suggested a direct role of PTX3 in the assembly of HA crystals. Surprisingly, the presence of BOLCs into breast cancer lesions is also associated to the development of bone metastatic lesions at five years from diagnosis. Therefore, the presence of microcalcifications made of HA or MgHAp in breast lesions could be considered as a negative prognostic factor for bone metastatic diseases as well as the BOLCs.

Starting from these considerations, the aim of this study was to correlate the microcalcifications' characteristics, such as morphology and elemental compositions, with the occurrence of bone metastatic lesions at 5 years from diagnosis.

METHODS

In this retrospective study, we enrolled 70 patients from which we collected one breast biopsy each. Our study protocol was approved by independent ethical committee. From each biopsy, paraffin serial sections were obtained to perform histological classifications, immunohistochemical analyses and energy dispersive X-ray (EDX) evaluation. Exclusion criteria were history of previously or concomitant other neoplastic diseases, autoimmune diseases, viral chronic infections (HBV, HCV, and HIV), and any antitumoral treatment received before biopsy.

Histology

After fixation in 10% buffered formalin for 24 h, breast tissues were paraffin embedded. Four μm thick sections were stained with haematoxylin-eosin (H&E)^[11].

EDX microanalysis

The EDX microanalysis is a technology that performs the elemental and chemical analysis of a sample in a transmission electron microscope. When the electron beam in an electron microscope hits a thin sample,

some atoms of the sample will be excited or ionized. When they return into their ground state, they will emit characteristic X-rays. The X-ray emission at different wavelengths may then be measured by a photon-energy-sensitive detector^[12,13].

The EDX detector system performs a simultaneous display of all mid-energy (1-20 keV) X-rays collected during any individual analysis period. Therefore, it is possible to detect those elements with N.A. > 10. The minimal detectable elemental concentration, which requires some signal averaging, is approximately 0.1 mmol/kg of dry specimen (i.e., 10 ppm), whereas spatial resolution ranges from about 10 nm to a few micrometers^[12,13].

All breast samples underwent ultrastructural microanalysis. Following to the identification of microcalcifications, six-micrometer-thick paraffin sections were embedded in Epon resin as previously described^[12]. Briefly, sections were de-paraffinized, hydrated, osmium tetroxide-fixed, dehydrated in ethanol and propylene oxide and infiltrated in Epon. The embedding capsules were positioned over areas containing microcalcifications identified by Toluidine Blue staining previously. Unstained ultra-thin sections of approximately 100-nm-thick were mounted on copper grids for microanalysis. EDX spectra of microcalcifications were acquired with a Hitachi 7100FA transmission electron microscope (Hitachi, Schaumburg, IL, USA) and an EDX detector (Thermo Scientific, Waltham, MA, USA) at an acceleration voltage of 75 KeV and magnification of 12,000. Spectra were semi-quantitatively analyzed by the Noram System Six software (Thermo Scientific, Waltham, MA, USA) using the standardless Cliff-Lorimer k-factor method^[12,13]. The EDX microanalysis apparatus was calibrated using an X-ray microanalysis standard (Micro-Analysis Consultants Ltd., Cambridgeshire, UK).

Immunohistochemistry

We employed immunohistochemical techniques to study the expression of molecules associated to microcalcifications production, PTX3 and BMP-2. Briefly, antigen retrieval was performed on 3- μ m-thick paraffin sections using EDTA citrate pH 7.8 buffers for 30 min at 95 °C. Sections were then incubated for 1 h at room temperature with the following primary antibodies diluted 1:100: BMP-2 (clone N/A; Novus Biologicals, USA) and PTX3 (clone MNB1; Abcam, UK). Reactions were revealed by HRP-DAB Detection Kit (UCS Diagnostic, Italy). To assess the background of immuno-staining we included a negative control for each reaction by incubating the sections with secondary antibodies (HRP) and detection system (DAB). Reactions have been set-up by using specific control tissues as indicated in the data sheets.

Statistical analysis

Separate χ^2 tests were used to assess the associations between morphological appearance and experimental groups and between elemental composition and experimental groups. Difference between the expression of biomarkers evaluated by immunohistochemistry were evaluated by Mann Whitney test. Immunohistochemical values were reported as mean value \pm standard error.

RESULTS

Histology

The study of H&E sections allowed us to classify breast biopsies in ductal infiltrating carcinomas according to Nottingham Histological system^[14]. Specifically, we observed 15/70 G1 infiltrating carcinomas, 38/70 G2 infiltrating carcinomas and 17/70 G3 infiltrating carcinomas. Also, based on the presence of metastatic lesions at 5 years from diagnosis, biopsies collected in the study were classified as follow: 30 infiltrating carcinomas of patients with clinical evidence of bone metastasis (BM+) (59.65 \pm 1.23 years) and 40 infiltrating carcinomas of patients without clinical evidence of bone metastasis (BM-) (57.91 \pm 0.96 years). Microcalcifications were detectable in 63.3% of BM+ and in 62.5% of BM-. From morphological point of view, we observed 63.3% of psammomabodies and 36.7% of polymorphous calcifications in BM+ and 62.5% of psammomabodies and 37.5% of polymorphous calcifications in BM- [Figure 1A-C].

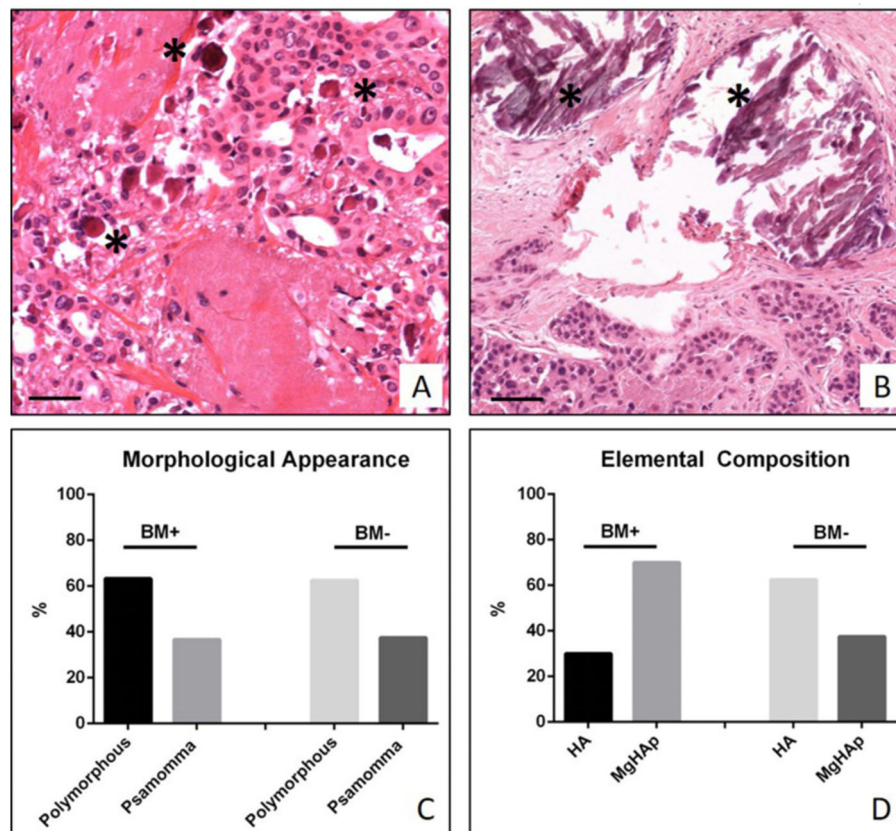

Figure 1. Study of breast microcalcifications. A: Representative image of ductal infiltrating breast carcinoma with several psammoma bodies (asterisks); B: image shows a ductal infiltrating breast carcinoma with polymorphous calcifications (asterisks). Scale bars represent 100 μ m for all images; C: graph displays the percentage of psammoma bodies and polymorphous calcifications in BM+ and BM- patients; D: graph displays the percentage of hydroxyapatite (HA) and Magnesium substituted hydroxyapatite (MgHAp) in BM+ and BM- patients

EDX microanalysis

Analysis of the elemental composition of microcalcifications revealed the presence of two form of calcium crystals in our samples: HA, and MgHAp [Figure 1D]. Statistical analysis shows a significant distribution of these types of calcifications in BM+ and BM- [Figure 1D]. In particular, calcifications of BM+ group were 70% MgHAp and 30% HA, whereas in BM- group we noted 37.5% of MgHAp and 62.5% of HA [Figure 1D].

Immunohistochemistry

We employed immunohistochemical techniques to study the expression of two osteoblast induction factors, BMP-2 and PTX3. Immunohistochemical positivity was evaluated on digital images (Iscan Coreo, Ventana, Tucson, AZ, USA) by a semi-quantitative approach. Specifically, immunoreactions for BMP-2 and PTX3 were evaluated by counting the number of positive breast infiltrating cells (out of a total of 500 in randomly selected regions). Our results showed a significant increase of BMP-2 expression in BM+ breast lesions as compared to BM- group (BM+ 205.6 ± 17.57 ; BM- 131.8 ± 14.17 ; $P = 0.030$) [Figure 2A and B]. In agreement with this, we also observed a significant increase of PTX3 expression in patients of BM+ group as compared to those of BM- (BM+ 209.0 ± 19.32 ; BM- 135.6 ± 13.10 ; $P = 0.0024$) [Figure 2C and D].

DISCUSSION

In the last years, numerous studies highlighted the role of breast microcalcifications in the patho-physiogenesis of both breast cancer occurrence and progression^[3-6,15,16]. In particular, we recently demonstrated the presence of breast cancer cells with an osteoblast phenotype (breast osteoblast-like cells-

Figure 2. Immunohistochemical analysis of bone morphogenetic proteins 2 (BMP-2) and pentraxin-3 (PTX3). A: Graph shows the number of BMP-2 positive breast cancer cells in BM+ and BM- patients; B: representative image of BMP-2 expression in a ductal infiltrating breast carcinoma; C: graph shows the number of PTX3 positive breast cancer cells in BM+ and BM- patients; D: image displays the PTX3 expression in a case of ductal infiltrating breast carcinoma. Scale bars represent 100 μm for all images

BOLCs) able to product microcalcifications made of HA or MgHAp^[7]. Noteworthy, the breast cancer lesions characterized by the presence of BOLCs showed high propensity to form bone metastasis^[7]. Thus, the presence of microcalcifications in breast lesions could represent a negative prognostic marker for metastatic diseases. Starting from these considerations, the aim of this study was to correlate the microcalcifications' characteristics, such as morphology and elemental compositions, with the occurrence of bone metastatic lesions at 5 years from diagnosis. To this end, we retrospectively collected breast cancer lesions of patients with (BM+) or without (BM-) clinical evidence of bone metastatic lesions. Our results clearly indicate that elemental composition, but not morphological appearance, of breast microcalcifications can predict the presence or development of bone metastatic lesions. In particular, according with the data reported by Bonfiglio *et al.*^[15], in this study the breast cancer lesions of BM+ patients were frequently characterized by the presence calcifications made of MgHAp. Thus, the presence of MgHAp could play an active role in breast cancer progression. Indeed, as hypothesized in our previously study, the ability of HA to bind Mg can support the neoplastic progression by inhibiting the activity of DNA repair enzymes that require Mg as co-factor. These data further support the hypothesis that the bone metastatic process of breast cancer can be driven by BOLCs. Indeed, we also noted that breast cancer cells of BM+ patients acquired the capability to express two of the most important osteoblast induction factors such as BMP-2 and PTX3. BMP-2 is a member of TGF-β superfamily that which regulate numerous process in bone metabolisms^[8]. Specifically, BMP-2 is involved in both mesenchymal stem cells recruitment and differentiation into mature osteoblasts^[8]. In a recent paper, Scimeca *et al.*^[7] demonstrated the expression of BMP-2 by BOLCs. PTX3, also known as TNF-inducible gene 14 protein, is a molecule involved in several process of innate immunity^[17,18]. It is also demonstrated that PTX3 have a role in the extracellular matrix formation as well as bone formation^[9]. In

this context, the expression of BMP-2 and PTX3 in BM+ lesions can provide a scientific rationale for BOLCs development and microcalcifications formation. Also, it is known that both BMP-2 and PTX3 are involved in the EMT phenomenon. Thus, it is possible to speculate that these molecules have role both in BOLCs generation that in the production of HA or MgHAp crystals by the BOLCs themselves.

In conclusion, results here reported highlighted the possible use of breast microcalcifications as a negative prognostic marker of bone metastatic diseases. In particular, the association between elemental composition of breast microcalcifications and the formation of bone lesions can lay the foundation for the development of new *in vivo* diagnostic tools based on the analysis of microcalcifications and capable to predict the formation of bone metastasis. In this scenario, the *in vivo* analysis of elemental composition of microcalcifications by RAMAN spectroscopy could improve the clinical armamentarium available for the diagnosis and stadiation of breast cancer.

Abstract

Aim: This study focuses on the stomach as an unusual but not rare site of metastasis of breast cancer.

Methods: We performed a literature search on gastric metastasis from breast cancer searching for reviews from 2000 to 2018 and case reports from 2013 to 2018. We found 11 reviews and 36 case reports and we compared their findings about important aspects of gastric metastasis, such as disease free survival, overall survival, symptoms, endoscopic findings, therapy, histology, and immunohistochemistry.

Results: The incidence of stomach as site of metastasis of breast cancer ranges from 5% to 18%. Reviews and case reports reached similar conclusions about several of the aforementioned aspects: invasive lobular breast cancer (ILC) is mainly responsible for gastric metastases; disease free survival can vary greatly ranging from 0.5 months to 30 years; gastric metastases usually present with non-specific symptoms, even though five patients in case reports were asymptomatic; linitis plastica is the most common endoscopic finding; immunohistochemistry is essential for differentiating primary gastric cancer from metastasis; the preferred treatment is systemic therapy, but surgery is still an option in case of emergency; median overall survival of patients with gastric metastasis from breast cancer is 24 months.

Conclusion: Breast metastasis to the stomach should be considered in any patient suspecting gastric neoplasm previously treated for breast carcinoma, especially if the treated carcinoma was ILC.

Keywords: Gastric metastasis, breast cancer, immunohistochemistry, stomach

INTRODUCTION

Breast cancer is the most common malignant tumor in the female population. Different histologies metastasize to different organs^[1]: ductal cancer metastasizes mainly to lungs, bones and liver, while lobular cancer has a tendency to metastasize to the gastrointestinal system^[2,3]. Gastric metastases from breast cancer are not common, but the autoptic incidence is not negligible, and varies from 5% to 18%^[3,4]. Gastric metastases are metachronous in most cases and even in patients with a known history of breast cancer it may be difficult to correlate the two diseases to a common cause, since the gastric disease often presents only several years after the treatment for the breast tumor^[5,6]. This late manifestation of the disease may lead to erroneous diagnosis in clinical practice and a correct identification of the disease becomes possible only after performing surgery, even though this approach is used only in limited cases. With this study we want to compare current clinical practice found in case reports with the results presented in recent reviews.

METHODS

We performed a literature search aimed at finding reviews published from January 1st 2000 to October 31st 2018 about gastric metastasis from breast cancer and case reports on the same argument from January 1st 2013 to October 31st 2018. The results presented in the reviews and in the case reports were compared with the aim of analyzing eventual similarity and differences in the findings discussed therein.

Characteristics of the included studies are summarized in [Table 1](#)^[7-17], whereas characteristic of patients from case reports (2013-2018) are reported in [Tables 2-4](#)^[9,14,18-51].

RESULTS

Part 1. Reviews

The search for reviews about gastric metastasis from breast cancer was carried out using the combination of words (gastric OR stomach) and (metastasis OR metastases) and (breast) for the PubMed database, using the filter for reviews. Articles written in languages other than English, articles about primary gastric cancer with breast metastasis and about primary breast cancer metastasizing in organs other than the stomach were excluded. The time span considered went from January 1st 2000 to October 31st 2018 and 11 articles fulfilling the criteria were found as a result of the search. The main aspects of the included studies are summarized in [Table 1](#).

Incidence

Nine of the articles reported the incidence of gastric metastasis from breast cancer: the incidence ranged from 0.3% to 35%, with the value 2%-18% reported in 3 articles.

Breast histology

Nine reviews reached the same conclusion that the most common histological type of breast cancer responsible for gastric metastasis is the lobular cancer. Two of the articles also reported the occurrence of metastasis associated with different types of cancer, with lobular cancer being identified as the cause of metastasis in 83% of the cases.

Disease Free survival

Nine of the reviews cited interval time from the appearance of the primary breast cancer to the presentation of gastric metastasis, however the time intervals were not specifically defined, as for example two articles reported “many years” and one article “few months to several years”. Other articles reported a median disease free survival of 5 years, but gastric metastasis may occur up to 30 years after the primary tumor.

Table 1. Summary of reviews from 2000 to 2018

Study	Incidence	DFS	Symptoms	Endoscopy	CT	Breast histology biopsy	Gastric histology	Gastric metastasis receptor	Therapy	Surgery	Palliation	Survival
Pectasides <i>et al.</i> ^[7] , 2009	0.3%-18%	Many years	Non specific: dysphagia, dyspepsia, anorexia, abdominal pain, early satiety, nausea, vomiting, bleeding	Linitis plastica, negative in 50%		Lobular 83%	Signet ring morphology	Positive CK7, GCDFFP-15, CEA, ER, PgR, Negative CK20	Chemotherapy or endocrine therapy	Only for complications, obstruction or bleeding		
Ayantude <i>et al.</i> ^[8] , 2007	7.4%-18%	Few months to several years	Non specific: nausea, vomiting, epigastric pain, anorexia, dyspepsia, bloating	Linitis plastica, normal mucosa in 30%	Thickened visceral wall, other metastasis	Lobular	Signet ring morphology	Positive CK, GCDFFP-15, CEA, ER, PgR, Negative CK20	Systemic therapy, hormonal therapy	Only for emergency situation, bypass for obstruction	Radiotherapy, brachytherapy, stenting or dilatation	
Villa Guzman <i>et al.</i> ^[9] , 2017	2%-18%	4-5 years	Inexpressive	Diffuse infiltration		Lobular	Signet ring	Positive ER, PgR, CK7, CK18, Negative HER2, CK20	Systemic therapy	Obstruction, bleeding		
Reiman <i>et al.</i> ^[10] , 2001	6%-18%		Nausea, vomiting, epigastric pain, anorexia, weight loss, dysphagia, melena, hematemesis, iron deficiency anemia, guaiac positive stools	Linitis plastica		Lobular	Signet ring		Systemic therapy, radiotherapy, endoscopy			
Critchley <i>et al.</i> ^[11] , 2011	8%-35%	7 years		Normal in 50%		Lobular			Systemic therapy, hormonal therapy	obstruction, mass effect		
Namikawa <i>et al.</i> ^[13] , 2013		50-78 months	Epigastric pain, melena, anemia, nausea, vomiting	3 patterns: localized, PET diffuse, external compression*	PET has low sensitivity				Systemic therapy	Emergency, bypass for obstruction		
Weigt <i>et al.</i> ^[12] , 2015		75.6 months	Epigastric pain, dysphagia, vomiting, gastrointestinal hemorrhage	Sub-mucosal type lesion, solitary lesions*					Systemic therapy	Obstruction, bleeding	Endoscopic hemostatic procedures, stents	
Barranco <i>et al.</i> ^[14] , 2017	2%-18%		Non specific: anorexia, dyspepsia, epigastric pain, vomiting	Linitis plastica								
Jones <i>et al.</i> ^[15] , 2007	2%-18%	Many years	Dyspepsia, anorexia, epigastric pain, early satiety, vomiting, bleeding	Linitis plastica, normal mucosa in 50%		Lobular 83%			Systemic therapy	Bypass for obstruction	Endoluminal stent, endoscopic or endovascular therapy for bleeding	28 months
Aurello <i>et al.</i> ^[16] , 2004	0.7%-15%	Majority within 5 years, 7 years, 30 y	Weight loss, nausea, vomiting, epigastric pain, early satiety	Discrete nodules, linitis plastica		Lobular			Individualized, systemic therapy	Intestinal obstruction, bleeding, perforation		2 year
Ellis <i>et al.</i> ^[17] , 2009	15%	0-369 months (84 epigastric pain, early satiety, vomiting, bleeding)	Dyspepsia, anorexia, epigastric pain, early satiety, vomiting, bleeding	Linitis plastica (lobular type); discrete nodules (ductal type)		Lobular	Negative Signet ring in 50%	ER, PgR, E-cadherin	Medical therapy			

ER: estrogen receptor; PgR: progesterone receptor; HER: human epithelial receptor; CK: cytokeratin; GCDFFP-15: gross cystic disease fluid protein 15; CEA: carcinoembryonic antigen

Symptoms

Ten articles reported the most common presentation symptoms related to gastric metastasis: they are often non specific, with epigastric pain as the most frequently reported, followed by nausea, vomiting, dyspepsia and dysphagia. Other reported symptoms are anorexia, early satiety, weight loss, and bleeding that may manifest as hematemesis, melena or iron deficiency anemia. One article used the term “inexpressive” to describe these symptoms.

Endoscopy

All the studies reported the main endoscopic findings, and the majority of them agreed that the most common presentation is linitis plastica. Because linitis plastica is caused by the infiltration of tumor cells in submucosa, the overlying mucosa is normal, thus resulting in negative exam results in 50% of cases, as reported in two studies, or 30%, as reported by Ayantude. Two articles discussed different patterns of

presentation, but they analyzed all gastric metastases from other primary tumors and not only the ones related to breast cancer.

Alternative instrumental tools

Other instrumental tools were not frequently cited. Ayantude and Aurello mentioned that computed tomography (CT) is commonly used to evaluate thickened visceral wall or the presence of other metastases. Namikawa observed that PET has a low sensitivity in diagnosing metastasis, but it may be useful to evaluate response to treatment in those tumors with intense FDG (F-18 fluorodeoxyglucose) uptake.

Gastric biopsy/histology

Two articles reported that gastric biopsy may be negative in 30% or even in 50% of the cases because the tumor cells infiltrate the submucosal layer and not the mucosal layer, which shows a normal histological aspect; there is thus a need for performing deeper biopsy in order to study also underlying layers, which is essential in this particular metastatic pattern. The most common reported histological pattern is signet ring cells, as cited in seven articles, which in some cases may be confused with tumor of gastric origin.

Gastric metastasis receptor

Immunohistochemistry is essential for differentiating gastric metastasis from primary tumor; positivity for estrogen and progesterone receptors in gastric metastasis is reported in seven articles, and they are the main receptors that direct the diagnosis to a secondary tumor of breast origin. Metastases of breast tumor

also show positivity for other receptors, such as CK7, CK18, GCDFP-15 and CEA, which are reported in five articles, and they are negative for CK20 and CDX2, which are usually expressed in intestinal cells, and also negative for E-cadherin and HER2, indicating a probable lobular breast cancer origin.

Therapy/Surgery/Palliation

Ten articles reported that the main therapy for gastric metastasis from breast origin is systemic therapy, either chemotherapy or hormonal therapy; surgery is reserved only in case of complications or emergency, such as bleeding, perforation or obstruction. In this latter case, a more conservative approach is advised and three articles suggest to perform a simple bypass instead of a gastrectomy. Endoscopy can prove very useful and must be considered before surgical approach in case of obstruction and bleeding to put stents or to perform dilatation; also bleeding can be managed conservatively either with endoscopic hemostatic procedures or by embolization radiologists.

Survival

Only two articles mentioned overall survival and they are approximately concordant, with Jones reporting a survival of 28 months, and Aurello reporting 2 years.

Part 2. Case reports

We also performed a review of the literature focusing on case reports of gastric metastasis from breast cancer from January 1st 2013 to October 31st 2018 because we wanted to update the aforementioned reviews with the latest current clinical practice present worldwide. We found 36 reports for a total of 69 patients. Data were not reported entirely in all the case reports, so we analyzed and compared only mentioned data. All the patients were females except one male^[43]. The median age of the patients was 58 years, with a range from 33 to 86 years. For the case reports that reported the age of the patients, 34 (59%) patients were > 55 years old, whereas 14 (41%) were < 55 years.

Breast tumor/receptor

The most common histological type of breast cancer was ILC (invasive lobular cancer), that was found in 42 cases (63%); other histological type of breast tumor were IDC (invasive ductal cancer) in 16 (24%), mixed in 2 (4%), and tubular in 6 cases (9%). In one case^[30] breast tumor was not found at instrumental research after the diagnosis of gastric metastasis. Breast cancer tumor had ER positive in 34 (92%) cases and negative in 3 (8%); PgR was positive in 29 (80%) and negative in 7 (20%), and HER2 was negative in 21 (75%) cases and positive in 7 (25%). The most common receptor status is ER+/PgR+/HER2-.

Disease free survival

Usually gastric metastases from breast tumor occur several years after primary cancer; 54 (83%) patients had metachronous disease, whereas only 10 (17%) had synchronous tumors.

Time of presentation of gastric metastasis from primary breast cancer varies from 0.5 months to 20 years later, with a median time of 61 months (about 5 years). This explains the difficulty to reconduct the gastric disease to breast tumor, because in many cases there was a long time between the manifestations of the two disease.

Symptoms

Gastric metastasis mostly presented with non specific symptoms in 45 cases, such as epigastric pain (28), nausea and/or vomiting (14), dyspepsia (3), dysphagia (3), anorexia (5), weight loss (12), hematemesis or melena (13), anemia (3). Five patients^[24,37,49] were totally asymptomatic, and diagnosis of gastric metastasis in these cases was incidental during exams in follow up. In one case^[37] elevated CEA and CA15-3 rose suspiciously for metastasis and then PET scan confirmed gastric localization.

Endoscopy

At endoscopy the most common presentation was linitis plastica, present in 21 cases (37%), whereas ulcers were found in 16 cases (28%). In three of these latter cases^[27,28,41] the first presentation was perforation, which resulted in elevated morbidity and mortality. Polyps or nodules were present in 4 patients (7%).

Gastric tumor/receptor

Histological study of gastric metastasis showed in the majority of cases adenocarcinoma with signet ring cells. In six (9%) patients initial gastric biopsies suspected a primary gastric cancer so they were submitted to surgical treatment; only after histological study of the specimen it was clear that they were metastases from breast cancer and not primary tumor of the stomach.

Immunohistotype is essential to diagnose and differentiate primary gastric cancer from metastatic tumor; the mainly studied receptors were ER, that was positive in 50 (91%) cases and negative in 5 (9%); PgR, positive in 28 (61%) cases, and negative in 18 (39%); HER2 negative in 25 (70%) and positive in 11 (30%); CK7 positive in 21 (91%) and negative in 2 (9%) cases; CK20 negative in 20 (95%) and positive in only 1 case (5%); CDX2 negative in 7 cases (100%); GCDPF-15 positive in 9 (75%) and negative in 3 cases (25%); GATA-3 positive in 4 cases, Mammoglobine positive in 6 cases (86%) and negative in 1 (14%); E-cadherin positive in 3 (37%) and negative in 5 cases (63%).

In 45 cases immunohistological study of the biopsies from gastric lesions or gastric wall were taken before starting any treatment; considering patients who underwent gastrectomy, nine^[23,26,27,28,35,42,43,45] were taken after surgical treatment whereas three^[23,28,43] were done before, but authors decided to perform surgery because they suspected primary gastric cancer or they couldn't exclude it.

In two patients^[22,43] immunohistological pattern of gastric metastasis was different from the one of primary breast cancer; in one patient^[40] pattern changed during treatment history, passing to a luminal A type and then to a triple negative.

Other metastasis

Gastric metastasis is usually part of a systemic disease and presents with other localization of malignant cells; considering all case reports, 56 patients (81%) presented with other metastases at time of diagnosis.

Therapy

The preferred treatment is systemic therapy, as chemotherapy, endocrine therapy or a combination of both of them; 41 of the patients were subjected to chemotherapy with or without hormonal therapy. Combination of surgery and chemotherapy was used in 10 patients^[23,28,29,35,37-39,41,43,45]; two of them^[28,29] were submitted to neoadjuvant chemotherapy followed by surgery in the belief of a primary gastric cancer. Surgical treatment alone was chosen in 7^[26,27,42] patients, with three^[27,42] of them in an emergency setting for bleeding and perforation. Endoscopic stenting for obstruction was used successfully in 2 patients^[19,22].

Survival

Median overall survival was 24 months, in line with data given by current literature. In some papers survival at follow up was the only data cited, and the media of these data was 28 months. Patients submitted to chemotherapy had an OS of 23 months; patients subjected to surgical treatment alone had an OS of 45 months. Those subjected to surgery plus chemotherapy had an OS of 91 months. We must consider the fact that for this latter group only two patients were considered and that they had stomach as the only site of metastasis. However, due to the paucity of number of cases considered, this data can be misleading.

Part 3. Comparison between reviews and case reports

The final results from the review and the case reports show that the breast cancer that is responsible for most of the metastasis is the lobular type (83% vs. 63%). Both summaries report that the time of presentation of

gastric metastasis is very variable, and ranges from few months to many years (20 years vs. 30 years), and that median disease free survival is 5 years.

Symptoms related to gastric metastasis are reported in both studies as non specific, such as epigastric or abdominal pain, nausea or vomiting, dysphagia, dyspepsia, anorexia, weight loss, and bleeding that may manifest as hematemesis, or melena or anemia. Interestingly, in five patients^[24,37,49] of case reports there were no symptoms and diagnosis of gastric metastasis was based on other signs, such as elevated serum markers or incidental findings at instrumental routine follow up.

Regarding endoscopic findings, the principal pattern is linitis plastica in both studies; reviews say that in 30%-50% of cases endoscopic findings are negative, but this aspect is not present in the majority of case reports.

The most common histological pattern found in gastric metastasis is adenocarcinoma with signet ring cells; this pattern can be confused with primary gastric cancer, as said in the reviews; indeed in three case reports^[37-39] preoperative findings showed this pattern on gastric biopsies and surgical treatment was performed.

Immunohistochemistry is mainly based on expression of ER and PgR. They are reported as positive in reviews, and, in the case reports, 50 (91%) tumors had ER positive and 28 (61%) had PgR positive; other receptors are HER2 and E-cadherin, whose absence is related to lobular cancer (negative in reviews, in case reports 25 (70%) tumor had HER2- and 5 (63%) had E-cadherin-); positivity for CK7, GCDPF-15 and MGB and absence of CK20 and CDX2 are also related to breast cancer origin. Systemic therapy is the treatment of choice in the reviews and even in case reports (used in 41 patients). Surgery is usually performed in case of complications such as perforation or bleeding; in three cases patients were submitted to emergency laparotomy, two^[28] for perforation and septic shock and one^[42] for bleeding and hemorrhagic shock. Main surgical intervention is gastrectomy (performed in 13 patients), whereas in one patient^[41] only resection and biopsy were performed in the setting of a perforation. Bypass, that is considered the best option according to reviews, was not even considered in case reports. Indeed obstruction can be managed conservatively by endoscopic stenting as mentioned in reviews, and this was performed in two patients^[19,22]. No embolization was performed in case reports. Median overall survival is similar (about 2 years) in the two summaries. Unfortunately reviews didn't subdivide OS by type of treatment.

DISCUSSION

Breast cancer is the most common malignancy in women and the leading cause of cancer-related death in female gender. Global incidence increased about 3.1% every year in the past 30 years, with an increase of the number of cases in Middle East, south Asia, southeast Asia, and central Latin America, and also mortality increased at an annual rate of 1.8%^[1]. Malignant proliferation may arise from ductal or lobular epithelium: the most frequent is the ductal type that includes 75%-82% of all cases^[4,52,53]. Other less frequent types are lobular carcinoma (4%-10% of all cases), phyllodes, or tubular cancer.

Metastases are possible either in ductal and lobular carcinoma, but they may develop in different organs: ductal carcinoma metastasizes more frequently to the lung, the brain and the liver, whereas lobular cancer tends to metastasize to the gastrointestinal (GI) tract, gynecologic organs, peritoneum and bones^[2,3]. Breast cancer, melanoma and lung cancer, represent the most frequent malignancies metastasizing to GI tract^[15,16,53]: the common sites of GI metastasis from breast tumor are colon and rectum (45%), stomach (28%), small intestine (19%), and esophagus (8%)^[53]. Median overall survival of patients with gastric metastasis ranges from 24 to 36 months^[53].

Incidence

Gastrointestinal metastases from breast cancer are rare, among them the stomach is the second most common site. In McLemore *et al.*^[53], 2005 study, which regarded 12,001 patients, gastric involvement represents 28% of all cases. The incidence of breast cancer metastasis to the stomach is reported to be from 0.1% to 6%, but in autopsy series the estimated incidence is found to be higher, from 5% to 18%^[3,4]. Gastrointestinal metastases are usually associated with other concurrent tumor localization: in a retrospective study lead by Taal *et al.*^[3], 1992 up to 94% of patients present with disseminated disease, that involve the skeleton (60%), liver (20%), and also the lung (18%)^[4]. In our study 81% of the patients had other metastases at time of diagnosis.

Metastasis

Gastrointestinal metastasis from breast cancer can be synchronous or more frequently metachronous, with a mean time of presentation reported to be from 6 to 7 years^[5], but in literature time can vary from 2 to 30 years^[5,6]. In our study there were 54 cases with metachronous presentation and only 10 patients with synchronous disease.

Studies report three main mechanisms of dissemination of malignant breast cells to the upper GI tract: lymphatic spread, hematogeneous route, and direct invasion from surrounding organs^[3,4,54,55]. The first type is more common in esophageal metastasis: the typical presentation is stricture or submucosal nodules with normal overlying mucosa, that makes endoscopic diagnosis difficult^[54,55]. Also the infiltration of paraesophageal lymphonodes can result in compression of the esophageal lumen with consequent intramural infiltration^[56]. Hematogenous spread is typical of esophagus, stomach or duodenum which results in stenosis or mass localized intramural or in the submucosal layer, that may become ulcerated. The most common pattern of presentation is linitis plastica-like; in this situation malignant cells are trapped from blood stream to the submucosal or subserosal layer with diffuse infiltration that cause diffuse thickening and rigidity of the organ wall^[4,54,55,57].

An important role in metastatic pathway is played by chemokines. CXCR4 and CXCR7 are the main chemokine receptor expressed in breast cancer cells involved in transendothelial migration (TEM), and they are responsible for the chemotaxis to certain target organs^[58]. CXCR4+ tumors are associated with more distant metastasis than CXCR4-tumors, even though this association is not statistically significant^[59]. Their ligands are CXCL12 and CCL21; the first is implied in modulating integrin expression, metalloproteinase production, tumor angiogenesis, tumor cell adhesion and apoptosis^[60,61]. Metalloproteinases are essential to degrade extracellular matrix to permit invasion of the cells attracted in metastatic sites by chemokines from the bloodstream^[60]. CXCL12 promotes homing of tumor cells to secondary sites and then recall endothelial stem cells for blood vessel formation and subsequent proliferation^[61].

Circulating breast tumor cells pass from blood or lymphatic stream to areas that express CXCL12, thereby metastatizing in many organs such as bone marrow, lymph nodes, liver and lung^[59,61].

An interesting hypothesis suggested by an article by J. Carlos Villa Guzman highlights the implication of inflammation response in tumorigenesis. Chronic inflammation induced by *Helicobacter Pylori* is associated with higher expression of chemokines and interleukins that may attract tumor cells to gastric or colon mucosa with subsequent proliferation and develop of metastatic disease^[9]. Even though these mechanisms are not fully understood, this hypothesis offers an interesting start point for other future studies.

Lobular breast cancer

Breast cancer metastases are more frequently related to lobular type than ductal type; in 83% of all metastases the primary breast cancer has lobular histotype^[4]. According to the study of Borst *et al.*^[62], 1993

Figure 1. Endoscopy showing localized lesion at gastric corpus. Biopsy confirmed the presence of gastric metastasis from breast cancer

the incidence of lobular carcinoma metastasis is higher in organs such as gastrointestinal system (4.5% vs. 0.2% in ductal carcinoma); gynecologic organs (4.5% vs. 0.8%); peritoneum-retroperitoneum (3.1% vs. 0.6%); bone marrow (21.2% vs. 14.4%). We found 42 cases with gastric metastasis from lobular carcinoma, whereas 16 cases were related to ductal carcinoma. The propensity of lobular breast cancer to give metastasis seems to be correlated with mutations of E-cadherin genes; the impaired function of the produced protein determines loss of adhesion among epithelial cells. Cells are initially separated from each other so that they can invade the surrounding tissue and then enter in the lymphatic system or in the bloodstream, leading to the progression of metastatic disease^[63,64].

Symptoms

Gastric metastases of breast cancer have no specific symptoms and may often be confused with primary gastric cancer or other conditions, such as effects of chemotherapy, radiotherapy, oral medications, liver metastasis or hypercalcemia^[4,57]. These symptoms include anorexia, dysphagia, feeling bloated soon after eating, bleeding (melena, hematemesis), dyspepsia, epigastric pain andretch^[65,66]. Common findings in blood tests are iron deficiency anemia or abnormal high levels of CA 15.3 that would arise the suspect for a relapse of primary breast cancer^[9,67]. Gastric metastases usually occur many years after primary breast cancer, so when the patient presents with these vague symptoms it's difficult to reconduct them to the primary causative disease. In our case reports, nine^[23,28,29,35,37,38,39,43,45] of the patients had a wrong initial diagnosis and they were submitted to surgical treatment in the suspect of a primary gastric cancer.

Diagnosis (instrumental)

Endoscopy is the main diagnostic tool when patients present with symptoms related to upper GI disease. Gastric metastases from breast cancer show three main different patterns: localized pattern (in about 18% of cases, as large ulcers and polyps [Figure 1], diffuse infiltration (57% of cases, such as linitis plastica-like with diffuse infiltration of the submucosal and seromuscular layer with a fibrotic reaction that causes narrowing lumen, rigidity, wall thickening with reduced peristalsis), and external compression (in 25% of cases)^[4,68,69]. Gastric metastases are usually localized in submucosal and seromuscular layers; in more than 50% of cases endoscopy study is negative^[70]. In one case report^[18] first histological examination of gastric biopsies was negative; after synchronous diagnosis of primary breast cancer, endoscopy was repeated and biopsies of submucosal layer were performed again, showing gastric metastasis from lobular cancer. Also in another patient^[19] initial gastric biopsies were negative, reporting only mild chronic gastritis. Endoscopic ultrasound showed thickening of the muscularis propria so biopsies were repeated focusing on this layer: muscular wall was infiltrated by malignant cell from lobular breast carcinoma.

Figure 2. CT scan showing gastric wall thickening at gastric fundus (A-D)

In literature CT scan study is not mentioned as one of the main diagnostic source to establish the nature of primary cancer, but it is used to evaluate wall thickening despite a normal aspect in endoscopic study and other site of metastasis^[54] [Figure 2].

A new useful diagnostic approach to differential diagnosis is magnifying endoscopy with narrow-band imaging (ME-NBI); it shows alterations in the framework of microvessels that are characteristic of metastatic pattern in comparison to primary malignancy of the stomach^[51].

The sensitivity of PET is lower for the diagnosis of gastric cancer due to physiological absorption of F-18 fluorodeoxyglucose and involuntary movements by the gastric wall [Figure 3]; early cancers, signet-ring cell carcinoma and poorly differentiated non-solid adenocarcinoma are characterized by high false-negative rates. There are also some scenarios of non-specific FDG accumulation correlated to mucosal inflammation, as in superficial gastritis and erosive gastritis, leading to false positives^[71].

Histology

Differentiation of primary gastric cancer from gastric metastasis is crucial; from the histological point of view, the first important difference is the localization of tumor cells: mucosa is generally involved in gastric cancer, while submucosal layer is usually affected in metastatic disease^[4,15]. In gastric metastasis malignant small cells with monomorphic, round nuclei and vacuolated cytoplasm typically array in chords, named “Indian files”, and infiltrate the serosal, muscular and submucosal layer^[57].

An additional difficulty is that they share signet ring cell-like morphology, thus lobular metastasis can mimic primary gastric cancer. However breast signet-ring cell carcinoma may show some morphological differences from gastric and colonic signet-ring cell carcinoma. The first shows a single, well-circumscribed univacuolated intracytoplasmatic lumina, with a central eosinophilic inclusion, whereas the latter has an extended, globoid, and optically clear cytoplasmatic acid mucin that pushes the nuclei against the cell membrane^[72].

Figure 3. Pet scan showing pathological F-18fluorodeoxyglucose accumulation in the gastric fundus (A-E)

Therefore differentiation of primary gastric metastasis requires to evaluate the infiltration of the serosal, muscular and submuscular layers by cells that organize in a typical Indian file pattern^[57] with a signet ring appearance^[73].

Immunohistochemistry

Immunohistochemical analysis is the most important tool for differentiating between primary gastric cancer and gastric metastasis from breast cancer; the main markers currently employed are estrogen receptor (ER), progesterone receptor (PgR), mammaglobin (MBG), cytokeratin 7 (CK7), cytokeratin 20 (CK20), human epithelial receptor 2 (HER2), gross cystic disease fluid protein 15 (GCDFP-15), and GATA-3. A new marker is HFN4A, which is discussed below.

The expression of ER and PgR is highly indicative of breast carcinoma metastasis. Primary gastric cancer can express ER in up to 30% of cases and PgR in up to 20% of cases, but also gastric metastasis from breast carcinoma sometimes show negative ER and PgR rate even if primary breast cancer is ER and PgR positive^[66,74]. Expression of ER, PR and HER2 status can change between primary tumor and metastatic

lesions in up to 42% and this change does not correlate with an impairment of overall survival^[75]: ER and PR status are different in 14.6% and 16.7% of cases respectively, while HER2 changes in about 8.3% of cases. During treatment it can be useful to take several biopsies to modify chemotherapy or endocrine therapy in the light of ER, PR and HER2 status^[70]. Following chemotherapy, in particular anthracycline-based ones, the level of expression of ER, PR and HER2 can change^[75]; these modifications imply a change also in tumor progression and aggressiveness and a resistance to endocrine therapy or trastuzumab, producing a change in clinical strategy. In our study the male patient^[43] had different patterns between gastric metastasis and primary breast tumor (ER-/PgR- in the stomach and ER+/PgR+ in the breast), one^[22] had different expression of HER2 (HER2- in the breast, HER2+ in the stomach) and one patient^[40] showed a change in receptor status during treatment passing from a Luminal A type to a Luminal B and then to a triple negative.

Combination of CK7/CK20 is also useful to distinguish between metastasis from breast carcinoma and primary gastric tumor; CK20 is expressed in gastric, colorectal, pancreatic and in transitional cell carcinomas, but it's negative in breast cancer^[76]. The CK7+/CK20- pattern is typical of adenocarcinoma of the breast, lung, and ovary, while CK7-/CK20+ is expressed in intestinal adenocarcinoma. CDX2 is a tumor suppressor gene that is implied in intestinal cell proliferation, differentiation, adhesion and apoptosis; it's an important marker of intestinal differentiation, usually expressed in gastric cancer and in intestinal metaplasia^[77,78].

Mammoglobine (MGB) is a 93-amino acid glycoprotein and a recent marker for breast cancer with a sensitivity of 93.1%. It can be useful in diagnosis of gastric metastasis from breast tumor in combination with other receptor expression^[79,80]. GCDFP-15 is never expressed in gastrointestinal cancer, but it's found in malignant tumor from the breast, and also salivary gland, external genitals, eyelid, apocrine duct of the bronchial tubes and gynecologic adenocarcinoma^[81]. MGB is more sensitive than GCDFP-15 but has less specificity^[79]. GATA-3 is a nuclear transcription correlated to breast glandular epithelial cells and shows the highest sensitivity in comparison to MGB and GCDFP-15^[81].

Diagnosis of metastatic disease stems from the analysis of all these markers. Gastric metastases are usually positive for ER, PgR, mammoglobine, GCDFP-15, GATA-3 and CK7 and negative for CK20. Gastric cancer is normally positive for CK20, but it's usually negative for GCDFP-15, ER and PgR, even if ER and PgR expression is controversial.

HNF4A (hepatocyte nuclear factor 4 alpha) was introduced as a new marker to differentiate gastric metastasis from primary malignant tumor. HNF4A is a nuclear transcription factor correlated with invasion, metastasis and epithelial-to-mesenchymal transition, due to activation of MMP-14 and promoting tumor angiogenesis, migration and invasion^[82]. A recent Brazilian study shows that HNF4A has positive expression in all patients with primary gastric adenocarcinoma, negative in all cases of primary breast carcinoma and also negative in all gastric metastases from breast carcinoma. In combination with ER and PR expression, it exhibits high sensitivity (100%) and specificity (96%)^[83].

Therapy

Establishing the primary site of malignancy determines the right treatment. Gastric metastasis from breast cancer are considered as a systemic disease because they usually present along with other metastatic localization, therefore the appropriate therapy is systemic, such as chemotherapy or endocrine therapy, whereas for primary gastric cancer first line therapy involves surgery^[5,15,84]. Chemotherapy, hormonal therapy or a combination of both of them lead to a remission rate of 32% to 53% and a prolonged survival of 2 or 3 years^[3].

In case of metastatic disease surgery is considered in case of obstruction, bleeding or perforation of gastric wall^[85] even if more conservative treatments (endoscopic hemostatic procedures or stent) can be performed

in patients with low performance status^[12]. The surgical option must be as little invasive as possible, for example a palliative bypass can be considered in case of outlet obstruction^[15].

Many studies, such as the one conducted by McLemore *et al.*^[53], 2005 report a lack of survival benefit from surgical treatment; palliative surgery can be associated with a prolonged median survival in some cases, but other factors can affect this difference such as biased patient selection for surgical palliation. In literature, few studies show surgical resection in patients with unique localization with reported improvement in overall survival: the study published by Taal *et al.*^[4], 2000 patients with complete remission of primary breast cancer that underwent gastric resection for solitary gastric metastasis shows a survival time of 38 months to be compared with 14.38 months for patients who didn't undergo resection^[3]. This can be explained considering that for patients submitted to surgical treatment the stomach is the unique localization without other metastasis or peritoneal carcinomatosis. In these patients the disease is not as advanced as in those candidates for systemic therapy. Therefore enhanced survival is due to patient clinical conditions and not strictly related to the type of treatment. In general, surgery does not offer an increase in survival but may have role in palliation^[53]. In our study surgery was also used to perform final diagnosis; gastric biopsies were confounding, thus authors performed gastrectomy to rule out the origin of the gastric disease^[23,28,29,35,37-39,43,45].

CDH1 mutation

As mentioned before, E-cadherin is a transmembrane glycoprotein involved in calcium-dependent adhesion; when E-cadherin is mutated, this leads to loss of cell adhesion, cell migration and subsequently tumorigenesis^[86]. An important gene mutation that is both associated with breast cancer and gastric cancer is CDH1, that encodes E-cadherin. Families with CDH1 mutations have a cumulative risk of developing hereditary diffuse gastric cancer (HDGC) of 70% and 56% in males and females, whereas female members have a cumulative risk of 42% for lobular breast cancer by age 80^[87]. Other gene mutations related to breast cancer but not to gastric cancer are BRCA1, BRCA2, and TP53; both BRCA1 and TP53 are associated with invasive ductal carcinoma, BRCA2 with both ductal and lobular carcinoma while CDH1 is only associated with lobular breast carcinoma^[88]. CDH1 is a gene mutation that is mutually exclusive with BRCA1/2 germline mutations. Screening for CDH1 should be suggested to women who have a personal or a family history of a combination of diffuse gastric cancer and lobular breast cancer (with at least one diagnosed before the age of 50), bilateral lobular carcinoma diagnosed at a young age, or family history of multiple lobular carcinomas with onset before 50 years old without gastric tumour^[89]. Sometimes diagnosis of lobular breast cancer with early onset might be the first manifestation of HDGC; so in patients with a history of multiple LBCs at a young age, especially with bilateral manifestation, it's advisable to perform a test for gene mutations^[90]. When CDH1 mutation is diagnosed, therapeutic management for the stomach and the breast is quite different: usually prophylactic total gastrectomy is advised because of the high risk of DGC, whereas prophylactic mastectomy is not performed, considering various genetic penetrance for LBC, but female patients should undergo to yearly mammography and breast MRI from age 35 years onwards^[86].

In conclusion, gastric metastases are a rare but not unusual site of secundarism from breast cancer^[3,4]. They usually arise several years after diagnosis of primary tumor and sometimes this can mislead the diagnosis^[5,6]. The differential diagnosis between primary gastric cancer and gastric metastasis is crucial and made possible only by histology and immunohistological patterns. Systemic therapy is the treatment of choice because the disease is usually not only localized to the stomach but presents other concurrent metastases^[5,15,84]. Surgery still has a role in case of complications or for definitive diagnosis when preoperative biopsy is not diriment and there is still a suspicion for primary gastric cancer^[85], even though this latter case is progressively decreasing thanks to innovation in instrumental tools for diagnosis. Breast metastasis to the stomach should be considered in any patient suspected of gastric cancer previously treated for breast carcinoma, especially if the treated carcinoma was ILC.

DECLARATIONS

Authors' contributions

Made substantial contributions to conception and design of the study and performed data analysis and interpretation: D'Angelo F, Rampini A, Cardella S

Performed data acquisition: Rampini A, Cardella S

Performed administrative, technical, and material support: Nigri G, Valabrega S

Data review: Antonlino L, Aurello P, Ramacciato G

Meeting Abstracts

Open Access

Meeting abstracts of Colossal Facet Conference - 2nd World Congress on Cancer 2018 “Oncology and Cancer therapeutics in the 21st century”

Bologna, Italy; 23-25 Jul 2018; Published: 18 Apr 2019

Correspondence to: Dr. Ciro Isidoro, Department of Health Sciences, Università del Piemonte Orientale “A. Avogadro”, Novara 28100, Italy. E-mail: ciro.isidoro@med.uniupo.it

Editorial note

This Special Issue of Journal of Cancer Metastasis and Treatment is dedicated to the proceedings of the 2nd World Congress on Cancer 2018 held in Bologna (Italy) in July 23-25. The theme of the Conference Cancer-2018 was “Oncology and Cancer therapeutics in the 21st century”.

Goal of the meeting was to share the foremost updated knowledge on the biology and the novel therapeutic options in Cancer. The conference focused on the mechanisms of cancer development, on the relationship between tumor microenvironment, metabolism and Cancer progression, novel technologies for early detection, and on novel pharmacological approaches to treat cancer patients. Major topics included epigenetics, inflammation, drug resistance, cancer stem cells, autophagy, cell metabolism, experimental models, biobanking, immune response, cachexia, molecular diagnosis, biomarkers, patient clinical care and complementary phytotherapy.

This Special Issue will cover the researches at the cutting edge in the study of the biology and clinical care of Cancer presented at the Conference.

Invited Speakers, Poster presenters and participants can contribute to this special issue with either an extended abstract (no page limit), Commentary, Original articles and (mini) review articles. Inclusion of schemes, Figures and Cartoon summarizing the results is strongly encouraged. An “ad hoc” editorial team will oversee the peer review of research and review articles.

Ciro Isidoro, Guest Editor

Keywords: Autophagy, biobanking, biomarkers, cachexia, cancer metabolism, cancer therapy, cell death, drug resistance, epigenetics, metastasis

1. Autophagy in cancer: epigenetic regulation and therapeutic opportunities

Ciro Isidoro, Chiara Vidoni, Alessandra Ferraresi, Eleonora Secomandi, Letizia Vallino

Department of Health Sciences, Università del Piemonte Orientale, Italy, Novara 28100, Italy.

Autophagy, lysosome-effected degradation pathway that eliminates damaged and redundant cellular self-constituents, plays a pivotal role in maintaining cell homeostasis. Autophagy is a stress-response triggered under nutrient- and energy-restricted situations, as well as in response to damaging and harmful injuries. Autophagy play an important role in preventing tumorigenic transformation by cooperating with the systems for the quality control of the proteome and of the genome. Defective autophagy may facilitate carcinogenesis, and in cancer cells autophagy may serve a survival function allowing to cope with damages induced by anti-cancer treatments or with the lack of oxygen and nutrients. The composition of the tumour environment impacts on autophagy in cancer cells. In fact, the metabolic cross-talk with stromal cells and their soluble factors, including inflammatory cytokines, can modulate the availability of nutrients, energy and growth factors that eventually modulate autophagy. Autophagy in cancer cells is also modulated epigenetically by changes of the chromatin structures and the presence of microRNA. The fact that autophagy constitutes the integrated response to all metabolic stresses and that can be epigenetically modulated offers the possibility to treat cancer through the use of autophagy-targeted epigenetic modifiers.

Biography

Ciro Isidoro is Professor of Pathology at the School of Medicine of Università del Piemonte Orientale (Novara, Italy). He received his doctoral degree in Biological Sciences from the University of Torino (Italy) and his doctoral degree in Medicine and Surgery from the University of Piemonte Orientale (Novara, Italy). He is Visiting Professor at the Faculty of Medicine, Siriraj Hospital, of Mahidol University (Bangkok, Thailand), Visiting Professor at the Department of Cell Biology of the Oklahoma City University Health Sciences Center (US), and Professeur Honoraire at the Faculté de Medecine et de Pharmacie de l'Université de Franche-Comté, Besancon (France). He is member of the Scientific board of the «Integrative Cancer Research Center of the Georgia Institute of Technology» (Atlanta, US). **Ciro Isidoro** has co-authored > 120 peer-reviewed original articles published in international journals. He serves as Co-Editor in Chief of the Journal of Traditional and Complementary Medicine and Associate Editor of Autophagy, Molecular Carcinogenesis, BMC Cancer, and other journals. His fields of expertise include the subjects “autophagy regulation in cancer” and “mechanisms of anticancer activity of dietary products”.

2. Understanding parasites in the United States

Omar M. Amin

Parasitology Center Inc, Scottsdale, AZ 85259, USA.

This Power Point presentation is based on our work at Parasitology Center, Inc. (PCI), in Scottsdale, Arizona, USA and covers the diagnosis, pathology, and treatment of human parasitic infections in the United States based on our own patient history and cases diagnosed. A brief introduction to laboratory procedures, misdiagnoses/mistreatment, and impact on public health is made. The presentation begins with a quiz which is answered at the end. A systematic treatment of protozoan, helminth (worm), and arthropod parasites follows, emphasizing epidemiology and exposure, symptoms, gross pathology, and herbal and allopathic remedies including our own anti-parasitic herbal product Freedom/Cleanse/Restore.

All topics are presented with illustrated and labeled pictures of the various kinds of parasites and their gross pathology in human tissues, when applicable. The presentation is followed by a brief discussion of case histories as tested by us at PCI as well as by a treatment of intestinal pathogenic bacteria, also tested by us, that usually cause GI symptoms similar to those caused by intestinal parasites.

3. The new oncological theory and its importance in the war with cancer

Andrei P. Kozlov

Biomedical Center, Peter the Great St.Petersburg Polytechnic University and Research Institute of Pure Biopreparation, St. Petersburg 195251, Russia.

Earlier I formulated the concept of the possible evolutionary role of tumors (A.P. Kozlov, “Evolution by Tumor Neo functionalization”, Elsevier/Academic Press, 2014). This concept suggests that heritable tumors at earlier stages of progression supply evolving multicellular organisms with extra cell masses for the expression of newly evolving genes. After expression of novel genes in tumor cells, tumors differentiate in new directions and give rise to new cell types, tissues and organs.

In the presentation, the bulk of data supporting the positive evolutionary role of tumors will be reviewed, obtained both in the lab of the author and from the literature sources. The new concept supports the possibility of sustaining a stable tumor mass as a strategy in cancer therapy.

As a result of experimental confirmation of nontrivial predictions of the new concept a new class of genes - Tumor Specifically Expressed, Evolutionarily New (TSEEN) genes - was discovered. Examples of TSEEN genes will be presented. TSEEN genes may represent the new targets in the war with cancer.

4. Discovery of a novel PRMT5 inhibitor to treat pancreatic and colorectal cancers

Tao Lu

Department of Pharmacology and Toxicology, Indiana University School of Medicine, 635 Barnhill Drive, Indianapolis, IN 46202, USA.

Recently, we discovered that protein arginine methyltransferase 5 (PRMT5) functions as a novel activator of the nuclear factor κ B (NF- κ B), a culprit in pancreatic ductal adenocarcinoma (PDAC) and colorectal cancer (CRC). In this study, we adapted the AlphaLISA technique into a PRMT5-specific high throughput screen, and discovered PR5-LL-CM01 as a novel small molecule inhibitor of NF- κ B. Treatment of PDAC and CRC cells with PR5-LL-CM01 inhibited tumor cell proliferation, anchorage-independent growth, as well as cell migration. Furthermore, PR5-LL-CM01 greatly impeded tumor growth in PDAC and CRC *in vivo* xenograft models. Importantly, PR5-LL-CM01 exhibited more potent anti-tumor effect than the commercial PRMT5 inhibitor, EPZ015666, in both PDAC and CRC. Our study has established PR5-LL-CM01 as a potential basis for novel drug development to treat PDAC and CRC in the future.

Biography

Dr. Tao Lu is a tenure-track Assistant Professor and principle investigator at Department of Pharmacology and Toxicology, and a member of Simon Cancer Center at Indiana University School of Medicine. She

obtained her Ph.D. degree from University of Toledo, School of Medicine, and finished her postdoctoral training with the world renowned scientist Dr. George Stark at Cleveland Clinic, Ohio. Her research focuses on the discovery of novel regulators of NF- κ B, particularly, on the epigenetic regulation of NF- κ B and its role in cancer therapeutics. She won multiple awards at international scientific meetings. Dr. Lu has published near 50 papers with 2 were highlighted by F1000 Prime. She currently holds 2 provisional patents regarding NF- κ B regulation and serves as the editorial board member of 8 scientific journals.

5. Using a multiplexed immunofluorescence assay to uncover an immunosuppressive mechanism of tumor-associated macrophages in the pancreatic tumor microenvironment

Anna Juncker-Jensen, Jun Fang, Judy Kuo, Mate Nagy, Qingyan Au, Eric Leones, Flora Sahafi, Raghav Padmanabhan, Nicholas Hoe, Josette William

NeoGenomics, Aliso Viejo, CA 92656, USA.

Background: Pancreatic ductal adenocarcinoma (PDAC) is characterized by an excessive amount of desmoplastic stroma seeded with inflammatory cells and it is one of the most aggressive forms of cancer with no current specific therapies. Tumor-associated macrophages (TAMs) are a major component of the tumor microenvironment (TME), and in most solid cancers increased TAM infiltration is associated with a poor prognosis. TAMs can be described as classically activated M1 types with pro-inflammatory antitumor functions, vs. alternatively activated M2 types with immunosuppressive pro-tumor functions. The immunosuppressive functions of M2 TAMs can be exerted through release of cytokines and growth factors as well as via direct recruitment of T regulatory cells (Tregs), a subset of lymphocytes responsible for immune tolerance of the system to the tumor. While the differentiation from M1 to M2 in PDAC has been shown to be associated with a worse prognosis^[1], not much is known about PDAC TAM polarization and its potential correlation to Treg recruitment.

Methods: For this study we have used MultiOmyx, a proprietary, multiplexing assay with similar staining characteristics as standard IHC stains but with the significant advantage that up to 60 protein biomarkers can be interrogated from a single FFPE section^[2]. MultiOmyx protein immunofluorescence assays utilize a pair of directly conjugated Cyanine dye-labeled (Cy3, Cy5) antibodies per round of staining. Each round of staining is imaged and followed by novel dye inactivation chemistry, enabling repeated rounds of staining and deactivation.

Results: Using the pan macrophage marker CD68 in combination with either M1 marker HLA-DR or M2 marker CD163 we confirmed the presence of M1 (CD68+HLA-DR+) and M2 (CD68+CD163+) populations in 9 stage IIB non-metastatic PDAC FFPE samples, the vast majority being of the M2 subtype. Moreover, we found a positive significant correlation (Pearson's correlation $P < 0.05$) between the presence of M2 TAMs and Tregs (CD3+CD4+FoxP3+), but not between M1 TAMs and Tregs. Moreover, in a spatial nearest neighbor analysis we found M2 type TAMs to be in closer proximity to Tregs compared to M1 type TAMs.

Conclusion: We demonstrate a positive significant correlation between the presence of M2 TAMs and Tregs in the TME of PDAC, suggesting a possible pathway in which TAM polarization plays an immunosuppressive function by recruiting Tregs. PDAC is one of the most aggressive forms of cancer with a 5-year survival rate below 5% and no current specific therapies. An increasing number of studies show accumulation of immune suppressor cells such as MDSCs and TAMs in PDAC patients. Hopefully,

a greater understanding of the phenotypes and functions of subsets of these cell types, will result in new cancer immunotherapy strategies for PDAC.

6. Stereotactic radiosurgery for brain metastasis: the end of whole brain radiotherapy?

Leonardo Frighetto^{1,2}

¹*Department of Neurosurgery, Radiotherapy and Radiosurgery Unit, Hospital Moinhos de Vento, Porto Alegre, RS 90035-004, Brazil.*

²*Coordinator, Neurosurgery Residency Program, Federal University of South Frontier, Zona Rural, Realeza 85770-000, Brazil.*

The objective of this presentation is to evaluate the applications of stereotactic radiosurgery (SRS) alone or in association with whole brain radiotherapy (WBRT) in the management of metastatic brain disease. Special attention was given to the influence of these treatment modalities on intracranial progression, local control, functional preservation, quality of life and survival. WBRT alone or following microsurgery has been the gold standard treatment of brain metastasis. The limited disease concept of oligometastatic brain disease, opened space to the use of focal therapies, such as SRS. Furthermore, delaying neurocognitive and cerebellar deterioration related to WBRT, is a worthwhile goal in brain metastasis patients. Moreover, SRS is more effective in the treatment of tumors considered resistant to WBRT such as melanoma and renal cell carcinoma. Analysis of the available data, including prospective randomized control trials in which SRS-alone was compared with WBRT+SRS, for patients with 1-4 brain metastasis, have proved that there was no significant difference in survival, neurologic death, functional independence and quality of life between the two treatment modalities. The omission of WBRT significantly increased the intracranial progression in new sites, requiring frequent monitoring in order to detect new lesions before they became symptomatic. Level 1 data has also demonstrated better neurocognitive function in patients not submitted to WBRT. The favorable outcomes demonstrated with SRS, have made possible its application in the focal treatment of surgical cavities. Therefore, the use of the SRS alone approach for oligometastatic brain disease may allow the majority of patients to avoid WBRT.

Biography

Leonardo Frighetto is the scientific coordinator of the Stereotactic Radiosurgery Unit at Moinhos de Vento Hospital and coordinator of the Neurosurgery Residency at the Federal University of the South Frontier, in Brazil. After finishing a fellowship at the Department of Stereotactic and Functional Neurosurgery at the University of California Los Angeles, he participated in the development of one of the first Stereotactic Radiosurgery Units in Brazil. The hospital is accredited by the Joint Commission International and affiliated to Johns Hopkins Medicine International. He also served as the President of the Brazilian Society of Radiosurgery from 2012 to 2014.

7. Role of *ERCC5* polymorphism and risk of breast cancer in Thailand

Malinee Pongsavee¹, Kamol Wisuwan²

¹*Department of Medical Technology, Faculty of Allied Health Sciences, Thammasat University, Patumthani 12121, Thailand.*

²*Department of Pathology, Ubon Ratchathani Cancer Hospital, Ubon Ratchathani 34000, Thailand.*

Breast cancer is a major public health problem around the world, including Thailand and it has the highest ranking among female cancer. Polymorphism of *ERCC5* gene (excision repair cross-complementary group 5 gene or *ERCC5*) was reported to associate with an increased risk of breast cancer. This study aims to investigate the relationship between *ERCC5* polymorphism and the breast cancer risk in the lower northeastern region women of Thailand. One hundred fifty samples from breast cancer patients and 122 samples from healthy control group were analysed. Genomic DNA was extracted from white blood cell of all samples. The real-time polymerase chain reaction was used to demonstrate genetic polymorphism of *ERCC5*. The results showed that the *ERCC5* rs751402 polymorphism variant AG was associated with an increased risk of breast cancer ($P < 0.05$). This study demonstrated that *ERCC5* rs751402 genotype AG was associated with breast cancer risk in the lower northeastern region women of Thailand.

8. The RNA Disruption Assay as a tool to predict pathologic complete response and improved disease-free survival in breast cancer patients after neoadjuvant chemotherapy

Amadeo Mark Parissenti^{1,2,3,4,5}

⁴*Rna Diagnostics, Inc., Sudbury, ON P3E 2H3, Canada.*

⁵*Rna Diagnostics, Inc., Toronto, ON M4T 1L9, Canada.*

We have observed that a variety of mechanistically distinct chemotherapy drugs can induce the degradation of ribosomal RNA into high molecular weight fragments in multiple tumour cell lines in a dose- and time-dependent manner - a phenomenon we term “RNA disruption”. Moreover, we have developed the RNA disruption assay (RDA) to quantify ribosomal RNA degradation in tumour cell lines and tissues. Interestingly, chemotherapy agents cannot induce RNA disruption in chemo-resistant cell lines, suggesting RDA may be useful clinically in monitoring tumour response to chemotherapy in real time. Consistent with this view, we observed that high mid-treatment tumour RNA disruption in patients with locally advanced breast cancer is associated with a pathologic complete response (pCR) and improved disease-free survival after epirubicin/docetaxel neoadjuvant chemotherapy. Moreover, we and our collaborators have recently shown that high tumour RNA disruption after only one cycle of neoadjuvant trastuzumab-based chemotherapy predicted for a post-treatment pCR in patients with Her2+ breast cancer. The BREVITY clinical trial (Breast Tumour Response Evaluation for Individualized Therapy) will soon be accruing patients in Germany, Italy, Ireland, the United States, and Canada to further assess the utility of RDA to predict response and survival after neoadjuvant chemotherapy. The patient eligibility criteria, trial design, timing of tumour biopsies, and both primary and secondary study endpoints will be discussed. RDA may enable oncologists to identify patients with chemo-resistant tumours early in neoadjuvant chemotherapy,

reducing the toxic side-effects of the ineffective regimen, and enabling patients to move to potentially more beneficial downstream or alternative treatments.

Biography

Dr. Parissenti is a professor of biochemistry at Laurentian University and the Northern Ontario School of Medicine in Sudbury, ON Canada. The RNA Disruption Assay was developed through Dr. Parissenti's collaborations with clinical researchers from the Canadian Cancer Trials Group and Rna Diagnostics, Inc. More information on RNA disruption and RDA can be obtained at <http://rnadiagnostics.com>.

9. ULLB-0005, a novel protein for cancer treatment

Sudeep Kumar

Unichem Laboratories Ltd, Pilerne Industrial Estate, Goa 403511, India.

Recombinant protein derived from a natural fungal protein, which has high binding specificity toward the carbohydrate antigen. The natural Amino acid sequence has been modified to make more stable and soluble protein. Modified sequence has been cloned and express in *E. coli*. The protein was purified through different column chromatography and was characterized as a single protein. Promising cytotoxicity was observed in different cancer cell line, with a good safety profile in human PBMCs with ULLB-0005. The efficacy of the Molecule as antitumor agent was assessed in respective xenograft immuno-compromised mice models *in vivo*. As expected the molecule showed strong anti-cancer activity in immune-compromised mice model in various cancers which was observed in the reduction of tumor volume. Mechanistic study showed strong apoptotic signal by modulating phosphatidyl serine externalization, mitochondrial membrane depolarization, cell cycle arrest, ultimately leading to death in cancer cells. Inhibition of proliferation and migration was observed in human endothelial cells, suggesting potential antiangiogenic effect. Single dose Pharmacokinetic study was performed for the molecule in BALB/C MICE with i.v., i.p. and i.m. route.

To elulate this novel protein as a combination with chemotherapy further studies was conducted and found that the molecule showed good synergy in *in vitro* with approved chemotherapeutic agents for Breast and Pancreatic cancer. The inhibition potential of novel protein was determined for CYP3A4, CYP2C9, CYP2D6, CYP1A2 & CYP2C19 using Cytochrome P450 inhibitor screening kit. None of these enzyme get inhibited in the presence of molecule.

Biography

Dr. Sudeep Kumar did his Post Doc in Biotech from Valencia, Spain. He has more than 20 years of experience in Biopharma. He has worked from R&D to tech transfer and manufacturing of different recombinant proteins from bacteria and mammalian cell culture. He is dealing with different regulatory agencies for approval and faced WHO, USFDA and other regulatory audits. He also actively involved with clinical research team for Preclinical and clinical trials of recombinant proteins and vaccine. He established the VLP technology platform for different vaccine in India in collaboration with Novavax. At present his major research area to develop new recombinant protein for different cancer.

10. Relevance of FoxO3a in tamoxifen resistant breast cancer

Catia Morelli¹, Marco Fiorillo², Pietro Rizza¹, Michele Pellegrino¹, Alessandra Nigro¹, Elena Ricci¹, Marilena Lanzino¹, Michael Lisanti², Sebastiano Andò¹, Diego Sisci¹

¹*Department of Pharmacy and Health and Nutritional Sciences, University of Calabria, Rende, Cosenza 87036, Italy.*

²*Translational Medicine, School of Environment and Life Sciences, Biomedical Research Centre (BRC), University of Salford, Greater Manchester M5 4WT, UK.*

Resistance to endocrine treatments is a major clinical challenge in the management of estrogen receptor positive (ER+) breast cancers (BC). Although multiple mechanisms leading to endocrine resistance have been proposed, the poor outcome of this subgroup of BC patients demands additional studies. Here we show that the expression of FoxO3a transcription factor is reduced in ER+ BC cells that developed resistance to Tamoxifen (Tam), TamR cells, due to its hyper-phosphorylation and degradation mediated by a hyperactive ERK1/2 pathway. On the other hand, FoxO3a silencing counteracts Tam induced growth inhibition in wtMCF-7, demonstrating that FoxO3a is a mediator of cell response to Tam.

FoxO3a re-activation in TamR/FoxO3a inducible clones, developed to express a constitutively active FoxO3a under tetracyclines control, re-established the sensitivity to the antiestrogen, inhibiting proliferation and cell cycle progression, as well as restoring Tam dependent apoptotic response.

Proteomics analysis unveiled novel interesting and potential mediators of the anti-proliferative and pro-apoptotic activity of the transcription factor, while Kaplan-Meier survival curves showed that high levels of FoxO3a transcripts strongly correlate to a positive response to Tam therapy in BC patients. Finally, FoxO3a induction by the anti-convulsant Lamotrigine (LTG), strongly reduced tumor mass in TamR-derived mouse xenografts.

Altogether, our data indicate that FoxO3a is a good prognostic factor in ER+ BC, predicting a positive response to endocrine therapy, and a key target to be exploited in combination therapy. In this context, LTG might represent a valid candidate to be used as an adjuvant to Tam therapy in patients at risk.

Biography

Catia Morelli has completed her PhD from University of Calabria, Cosenza, Italy, after a 4 years training period (1999-2003) at the Kimmel Cancer Center, Thomas Jefferson University, Philadelphia, PA (USA). She is now Researcher at the Department of Pharmacy and Health and Nutritional Sciences at the University of Calabria, recently awarded as Department of Excellence by the Italian Ministry of Education, University and Research. She encounters more than 35 papers in reputed journals and she is also co-founder of NanoSiliCal Devices, a spin-off company of the University of Calabria, developing silica-based nanosystems to be employed in targeted therapy (<http://www.nanosilicaldevices.com/en/>).

11. Deciphering human B cell repertoire with next-generation sequencing technology

DuckKyun Yoo¹, Wonjun Yang¹, Kihyun Kim¹, Sangil Kim¹, Sung Min Kim¹, Hyori Kim², Jinhee Kim³, So Young Chang³, Meehyun Ko³, Ji-Young Min³, Haejun Han⁴, Taehoon Ryu⁴, Jungeun Kim⁴, Junho Chung^{1,5,6}

⁵Samsung Biologics, Incheon 21987, South Korea.

⁶GSK Vaccines Research & Development, Rockville MD 20850, USA.

Next-generation sequencing (NGS) has allowed a massive increase in capacity to sequence genomes at relatively low cost and in a short time frame. It has revolutionized multiple aspects of biological research and is actively being adopted into profiling human B cell receptor (BCR) repertoires. Several NGS platforms are currently available, with average read lengths of 75 bp to 8,500 bp and different error rates.

Using NGS, we successfully constructed database of human BCR repertoire from convalescent patients who recovered from severe fever with thrombocytopenia and middle east respiratory syndrome. Afterwards, we developed algorithms for analyzing the diversity, enrichment pattern, accumulation of somatic hyper-mutation in BCR repertoire. Through *in silico* analysis we selected clones of interest and prepared recombinant antibodies using a mammalian transient expression system. Their reactivity to viral coat proteins and virus-neutralizing capability was confirmed in *in vitro* and *in vivo* experiments.

Currently we are investigating the clinical value of BCR repertoire profiling in autoimmune disease patients including Neuromyelitis Optica and various cancers.

Biography

Junho Chung has completed his MD, PhD from Seoul National Univ. College of Medicine, South Korea. He is the professor of Seoul National Univ., in the Department for Biochemistry and Molecular Biology. He has published more than 95 papers in reputed journals and has been serving as a vice-editor-in chief of Journal of Cancer Research and Clinical Oncology.

12. Biobank in Pilsen, Czech Republic, efficient tool for cancer research and personalised treatment

Judita Kinkorová, Ondřej Topolčan

Department of Immunochemistry, University Hospital Pilsen, Pilsen 304 60, Czech Republic.

Biobank in University Hospital (UH) Pilsen is newly established (opened in April 2017) hospital integrated biobank, based on previous high quality sample collection. Since 2000 the hospital repository started to collect and store systematically biological material of patients for research in the UH. The main diagnoses for sample collection are oncological samples of breast cancer, colorectal cancer, liver and kidney carcinoma, and prostate cancer.

To be a fully-fledged biobank the following activities have been realised: collection and storage high quality biological material (blood, serum and plasma) of oncological patients, collection management and storage of related data, implementation of ethical, social and legal issues, harmonization of IT systems, implementation of relevant requirements for providing biological material to the Czech Republic and abroad, preparation of education and training programmes and courses, active participation on BBMRI - ERIC activities, and cross-boarder collaboration in the BRoTHER project.

Currently is the biobank ready to implement aspects of personalised medicine in practice. Regarding the high quality aspects the selected long and short term stability of tumor markers are studied. Together

with the standard diagnostic procedures like biomarkers, imaging techniques, and clinical stage (multidisciplinary approach), new diagnostic algorithms based on multiparametric and multidisciplinary approach for selected diagnoses are created and brings benefits both for the patient and the hospital.

Personalized medicine approach in University Hospital is closely connected with the education programme realised at Faculty of Medicine in Pilsen Charles University.

Biography

Judita Kinkorová has completed his PhD from Academy of Science of the Czech Republic in Prague. She is the associate professor, in the Department for immunochemistry University Hospital Pilsen and a manager of biobank in University Hospital Pilsen. She has published more than 40 papers in reputed journals and has been serving as an editorial board member of EPMA Journal.

13. TM4SF5-mediated hepatic carcinogenesis

Jung Weon Lee

Department of Pharmacy, College of Pharmacy, Seoul National University, Seoul 08826, Korea.

Diverse functions of cancer cells including proliferation, migration and invasion critically and greatly depend on extracellular environment during their survival and metastasis. The environment consists of extracellular matrix proteins, neighboring cells, and soluble factors, including of cytokines, chemokines, and growth factors. Efficient dissemination of a cancer cell from a primary tumor mass and invasion through the environment can result in a successful metastasis. Therefore, identification of biological cancer marker(s) playing roles in diverse cancerous functions would be beneficial for clinical and therapeutic purposes, and can be performed in 2D flat, 3D cell and tissue cultures, and animal models. Transmembrane 4 L six family member 5 (TM4SF5) is a transmembrane glycoprotein of the transmembrane 4 L six family, a branch of the tetraspan(in) family, highly expressed in many types of cancers including hepatic cancer, and shown to cause epithelial-mesenchymal transition. TM4SF5 in hepatocytes is induced by TGF β 1-mediated Smad and EGFR activation and involved in liver fibrosis. Transgenic animal showed that overexpression of TM4SF5 in liver caused inflammatory, fatty, and fibrotic phenotypes, indicating that TM4SF5 expression following actions by TGF β 1 prevalent in chronic liver injury situation may lead to playing regulatory roles in functions for different metabolic pathways. Further, disease-prone TM4SF5 transgenic mice showed enhanced expressions of CD34, HIF1- α , AFU, and AFP in the livers. A small calchone compound, TSAHC and chimeric anti-TM4SF5 antibody could successfully block the TM4SF5-mediated regulation of metabolic activities, fibrosis, and xenograft tumor formation.

Biography

Dr. Jung Weon Lee is a Professor at Dept. of Pharmacy, Seoul National University (SNU), Korea. He got Ph.D. in Pharmacology, University of North Carolina at Chapel Hill, NC, USA. He had a postdoc period at Memorial Sloan-Kettering Cancer Center, NY, USA. In 2001, He came back to Korea, and in 2009 moved to Dept. of Pharmacy, SNU. His researches focus on how cellular functions occur at the molecular levels. His researches focuses on the roles of a tetraspanin, TM4SF5, in metabolic disorders, fibrosis, tumorigenesis and metastasis, and on the anti-TM4SF5 reagents to block TM4SF5-mediated diseases (Lab homepage: <http://www.snupharm.ac.kr/jwl/>).

14. The histone methyl transferase DOT1L is a key functional partner of estrogen receptor alpha for regulation of gene transcription in hormone-responsive breast cancer

Giovanni Nassa^{1,2}, Annamaria Salvati¹, Giorgio Giurato^{1,2}, Roberta Tarallo¹, Francesca Rizzo¹, Lorenza Mautone¹, Domenico Rocco¹, Tuula Anneli Nyman³, Alessandro Weisz¹

¹Laboratory of Molecular Medicine and Genomics, Department of Medicine, Surgery and Dentistry “Scuola Medica Salernitana”, University of Salerno, Baronissi, SA 84084, Italy.

²Genomix4Life S.r.l., University of Salerno, Baronissi, SA 84084, Italy.

³Proteomics Core Facility, Institute of Clinical Medicine, University of Oslo, Oslo 0315, Norway.

Estrogen Receptor alpha (ER α) is a key mediator of estrogen signaling in hormone-responsive breast cancer (BC) and target of endocrine therapies, where resistance to treatment is a major problem in clinical management of these patients. A better understanding of the molecular mechanisms of ER α actions in cancer may lead to identification of new therapeutic targets against endocrine therapy-resistant tumors. We recently identified the epigenetic writer DOT1L (DOT1 Like Histone Lysine Methyltransferase) as novel a nuclear partner of ER α in hormone-responsive BC cells. To investigate the functional role of this enzyme in mediating receptor actions in target cell nuclei, physical and functional ER α -DOT1L interaction on chromatin was mapped by Chromatin Immunoprecipitation coupled to Mass Spectrometry (ChIP-MS) and Sequencing (ChIP-Seq), transcriptome profiling (RNA-Seq) coupled to gene silencing and pharmacological inhibition of either protein. Cellular and functional assays were also used to evaluate the impact of the ER α -DOT1L complex in hormone-responsive BC cell functions. ChIP-MS confirmed co-recruitment of the two factors on chromatin in a multiprotein complex. Gene expression profiling and Nascent RNA-Seq before and after DOT1L pharmacological inhibition showed that this enzyme is involved in ER α -mediated transcriptional regulation of several estrogen responsive genes, including ER α itself. ChIP-Seq mapped co-occupancy of several chromatin sites by both proteins, including the ER α gene promoter itself. These results reveal that physical and functional association between ER α and DOT1L is a key molecular event in hormonal control of BC cell functions, suggesting that this enzyme might represent a potential drug target against hormone-responsive tumors.

Biography

Dr. Giovanni Nassa completed his PhD at University of Campania “Luigi Vanvitelli” and presently is fixed-term Researcher (RTDa) of General Pathology at the Department of Medicine, Surgery and Dentistry “SMS” of the University of Salerno. AIRC Fellow during the early stages of his career, he was also visiting scientist and FEBS fellow at the Institute of Biotechnology and Biomedicum of the University of Helsinki. He published more than 30 papers in international peer-review journals, with research mainly focusing on the epigenetic mechanisms underlying hormone-responsive breast cancer pathogenesis and loss of response to endocrine therapy during progression.

15. IL-4 as a potential treatment for cancer-induced muscle wasting

Paola Costelli

Department of Clinical and Biological Sciences, University of Turin, Turin 10126, Italy.

Skeletal muscle wasting, one of the most relevant features of cancer cachexia, is mainly associated with marked alterations of protein turnover. Few years ago the observation that also myogenesis is impaired in

cancer hosts was reported. In particular, Pax7⁺ cells accumulate in the muscle of tumor-bearing animals without proceeding into differentiation and fusing with existing myofibers. Such impairment was proposed to depend on persistently expressed Pax7 due to NF- κ B hyperactivation. The reduced myogenesis does not depend on an intrinsic defect of muscle stem cells, since they can easily differentiate *in vitro* and can fuse with damaged myofibers in an experimental model of muscle dystrophy. However, myogenic precursors isolated from mice bearing the C26 tumor cultured in proliferation medium spontaneously differentiate to adipocytes.

To investigate the mechanisms underlying such “adipogenic drive”, mice bearing the C26 carcinoma were treated intraperitoneally with IL-4, a cytokine previously shown to inhibit adipogenesis in muscle. The results obtained show that muscle wasting was partially prevented in tumor-bearing animals receiving IL-4, in terms of both tissue weight and myofiber cross sectional area. The improved muscle phenotype is associated with reduced levels of phosphorylated ERK, in agreement with previous data. The spontaneous adipogenic differentiation is markedly reduced in primary cultures of myogenic precursors isolated from the C26 hosts treated with IL-4 in comparison to those obtained by untreated animals. This observation suggested that IL-4, by inhibiting adipogenesis, could force myogenesis. Consistently, when IL-4 is administered to tumor-bearing animals in which muscle damage was induced by injection of BaCl₂, regeneration occurred faster than in the untreated C26 hosts.

On the whole these results suggest that primary cultures of myogenic precursors isolated from tumor-bearing animals are committed to differentiate to adipocytes, but can be forced through myogenesis by adequate stimuli. By contrast, the muscle microenvironment existing *in vivo* in the tumor host is able to inhibit both myogenic and adipogenic differentiation of these precursors, that indeed accumulate in the tissue. Preliminary data suggest that the lack of IL-4 production could play a role in this regard.

16. Lenvatinib in anaplastic thyroid cancer

Alessandro Antonelli¹, Silvia Martina Ferrari¹, Ilaria Ruffilli¹, Giusy Elia¹, Francesca Ragusa¹, Sabrina Rosaria Paparo¹, Claudia Caruso¹, Poupak Fallahi²

¹Department of Clinical and Experimental Medicine, University of Pisa, Pisa 56126, Italy.

²Department of Translational Research and New Technologies in Medicine and Surgery, University of Pisa, Pisa 56126, Italy.

The oral multitargeted tyrosine kinase inhibitor lenvatinib acts against VEGFR1-VEGFR3, FGFR1-FGFR4, PDGFR α , RET and v-kit Hardy-Zuckerman 4 feline sarcoma viral oncogene homolog (KIT) signaling networks involved in tumor angiogenesis.

The antitumor activity of lenvatinib (1 nmol/L, 100 nmol/L, 1 μ mol/L, 10 μ mol/L, 25 μ mol/L and 50 μ mol/L) has been investigated in primary anaplastic thyroid cancer (ATC) cells, in the human cell line 8305C (undifferentiated thyroid cancer) and in an ATC-cell line (AF), *in vitro*; and *in vivo* in AF cells injected in CD nu/nu mice.

Lenvatinib significantly reduced ATC cell proliferation ($P < 0.01$, ANOVA), increasing apoptosis ($P < 0.001$, ANOVA). Furthermore, lenvatinib inhibited migration ($P < 0.01$) and invasion ($P < 0.001$) in ATC, inhibited EGFR, AKT and ERK1/2 phosphorylation and down-regulated cyclin D1 in ATC cells. Moreover, lenvatinib significantly inhibited 8305C and AF cell proliferation, increasing apoptosis.

AF cells were injected subcutaneously into CD nu/nu mice and tumor masses were evident after 20 days. Tumor growth was significantly inhibited by lenvatinib (25 mg/kg/day), as the VEGF-A expression and microvessel density in AF tumor tissues.

In conclusion, we show for the first time the antitumoral effect of lenvatinib in primary human ATC cell cultures obtained from patients. These results could open the way to the clinical use of lenvatinib in the treatment of patients with ATC.

Biography

Prof. Antonelli is currently Director of the Immuno-Endocrine Section of Internal Medicine and Associate Professor in the Department of Clinical and Experimental Medicine, University of Pisa, Azienda Ospedaliera-Universitaria Pisana, Pisa, Italy.

He graduated in Medicine cum laude at the University of Pisa in 1982, where he received the post-graduate Specialization in Endocrinology in 1985 and in Occupational Health in 1987. He received also the post-graduate Specialization in Oncology (at the University La Sapienza, Rome, Italy) in 1992.

His researches have been published in more than 320 articles on International journals (Impact Factor > 1200; H index 60).

17. Novel inducers of noncanonical and immunogenic cell death

Marc Diederich

Department of Pharmacy, College of Pharmacy, Seoul National University, Seoul 151742, South Korea.

Apoptosis was most often considered as the most important type of cell death and numerous compounds triggering this programmed form of cell demise were explored. Over the last 10 years, other cell death modalities were also described, and proof of concept was provided that such compounds are efficiently able to target cancer cells that already became resistant to conventional apoptosis inducers. Moreover, the interplay between different cell death modalities gained interest^[1]. We became interested to assess the anticancer effect of compounds that were shown to kill cells by triggering various necrosis-related phenotypes^[2,3]. We believe that these compounds provide a more efficient therapeutic outcome. For our research we essentially investigated compounds of natural origins from both marine^[4-6] and terrestrial sources^[7-10]. Multiple forms of regulated necrosis and the in-depth elucidation of the corresponding cell signaling pathways allowed to better predict the immunogenic potential of cancer cells dying by non-canonical cell death mechanisms^[11-13]. This presentation will cover the effect of various natural and hemisynthetic compounds while describing their cell death-inducing activity leading to secretion or exposure of immunogenic cell death markers^[14-16].

Biography

Marc Diederich earned his PhD in molecular pharmacology in 1994 from the University Henri Poincaré Nancy 1, France. After training at the University of Cincinnati, USA, he focused his research on cancer and leukemia cell signaling pathways and gene expression mechanisms triggered by natural compounds with epigenetic-, anti-inflammatory- and cell death-inducing potential. He directs the Laboratory for molecular and cellular biology of cancer (LBMCC) at Kirchberg Hospital in Luxemburg. He was appointed associate Professor of Biochemistry at the College of Pharmacy of Seoul National University in 2012. In 2017, he was tenured and promoted to full professor at SNU.

18. Co-expression of immune checkpoint genes at the cancer/antigen-presenting-cell side of the immunological synapse

Raya Leibowitz-Amit¹, Amir Herman², Adi Layani¹, Paula Dobosz¹, Yehezkel Sidi¹, Dror Avni¹

¹*Oncology institute and cancer research center, Sheba medical center, Tel-Hashomer 52621, Israel.*

²*Orthopedics department, Assuta medical center, Ashdod, Tel Aviv 69710, Israel.*

Introduction: The interface between T lymphocytes and cancer cells or antigen-presenting cells (APC), termed “the immunological synapse” (IS), comprises of both co-inhibitory and co-stimulatory checkpoint proteins that modulate the signal transmitted to T lymphocytes, leading to either activation, anergy or exhaustion. Monoclonal antibodies against checkpoint proteins (designated “checkpoint inhibitors”) have anti-neoplastic activity in several malignancies, but not all cancers and not all patients within a given cancer respond.

Methods: We analysed the tumor cancer genome atlas database for the expression of 15 checkpoint mRNAs suggested from the literature to be expressed at the cancer/APC side of the IS in 28 tumor types. The Spearman rho correlation co-efficient for the co-expression of each pair of checkpoint mRNAs was

calculated. For each cancer type, we calculated the average correlation co-efficient of any combination of 2-15 mRNAs.

Results: The number of co-expressed checkpoint genes with an average Spearman rho co-efficient of above 0.5 was significantly different between tumor types, ranging from 10 to 0. Thyroid carcinoma, testicular cancer and melanoma were the three tumors with the highest number of co-expressed checkpoint mRNAs, whereas in acute leukemia there were no co-expressed checkpoint mRNAs, as predicted. Similarly, the nature and mix of co-stimulatory and co-inhibitory checkpoint mRNAs was different between different tumor types, with each tumor exhibiting a different “network” of checkpoint co-expression with differing strengths of correlations.

Conclusion: Our bioinformatic analysis indicates that both co-inhibitory and co-stimulatory checkpoint mRNAs are co-expressed in solid malignancies in varying extents in different cancers. We propose that the differences in these “checkpoint networks” formed on the cancer side of the IS take part in determining cancer immunogenicity. It is tempting to speculate that these networks may also take part in determining the potential of a tumor type to respond to the currently-available immune checkpoint inhibitors.

Biography

Raya Leibowitz completed her PhD and her MD at the Tel-Aviv university, Israel. She is currently a senior medical oncologist (clinician-investigator) at the Sheba medical center and an assistant professor at the department of oncology, faculty of medicine, Tel-Aviv university. Her major scientific work until now (first and last authorship) was published in *Nature Medicine*, *Cancer Research*, *Annals of oncology* and *Molecular Cancer*. Among other grants, she was a recipient of the “melanoma research alliance young investigator award”, the “Gerald Kirsh” humanitarian award and the “Conquer Cancer foundation” merit award twice.

19. Sunitinib in thyroid cancer: a review of the literature

Giusy Elia¹, Silvia Martina Ferrari¹, Ilaria Ruffilli¹, Francesca Ragusa¹, Sabrina Rosaria Paparo¹, Claudia Caruso¹, Poupak Fallahi², Alessandro Antonelli¹

¹Department of Clinical and Experimental Medicine, University of Pisa, Pisa 56126, Italy.

²Department of Translational Research and New Technologies in Medicine and Surgery, University of Pisa, Pisa 56126, Italy.

Sunitinib is a multi-targeted tyrosine kinase inhibitor (TKI), acting on different receptors for platelet-derived growth factor receptors and vascular endothelial growth factor receptors, c-KIT, fms-related tyrosine kinase 3 and RET, leading to tumor vascularization reduction, tumor cell apoptosis, and causing tumor shrinkage.

It has been approved for the treatment of pancreatic neuroendocrine tumors, imatinib-resistant gastrointestinal stromal tumor and renal carcinoma.

In vitro studies have been conducted on the RET/PTC1 cell, showing that sunitinib is able to target the cytosolic MEK/ERK and SAPK/JNK pathways inhibiting cell proliferation and causing stimulation of sodium/iodide symporter gene expression.

Also *in vitro* and *in vivo* studies conducted on anaplastic thyroid cancer cells have shown the efficacy of sunitinib, also as first- and second-line TKI therapy in patients with advanced dedifferentiated thyroid cancer, or medullary thyroid cancer.

The most frequent adverse events are fatigue, decreases in blood cell counts (especially leukocytes), diarrhea, hand-foot skin reaction, nausea, hypertension and musculoskeletal pain. A dose of 37.5 mg/day sunitinib is well-tolerated, and effective.

To sum up, although sunitinib is promising in the therapy of differentiated thyroid carcinoma, until now no phase III studies have been published. Further prospective researches are needed to evaluate the real effectiveness of sunitinib in aggressive thyroid cancer.

Biography

Giusy Elia is graduated in Biology applied to Biomedicine in 2012 and specialized in Clinical Pathology and Clinical Biochemistry in 2017 at the University of Pisa (Italy). Her areas of interests range from Immunology, Pharmacology to Biochemistry. Her researches have been published on International journals (HI = 5).

20. Vandetanib in anaplastic thyroid cancer

Silvia Martina Ferrari¹, Poupak Fallahi², Ilaria Ruffilli¹, Giusy Elia¹, Francesca Ragusa¹, Sabrina Rosaria Paparo¹, Claudia Caruso¹, Alessandro Antonelli¹

¹*Department of Clinical and Experimental Medicine, University of Pisa, Pisa 56126, Italy.*

²*Department of Translational Research and New Technologies in Medicine and Surgery, University of Pisa, Pisa 56126, Italy.*

Anaplastic thyroid cancer (ATC) represents about 1% of thyroid cancer (TC), and it is one of the most aggressive human tumors, representing approximately 15%-40% of TC deaths. The multimodal treatment, that includes debulking, chemotherapy, and hyperfractionated accelerated external beam radiotherapy, is the most effective treatment, with a median survival of 10 months. New drugs have been recently evaluated in ATC, but until now no significant improvement of survival has been observed.

Vandetanib is an oral once-daily multi-tyrosine kinase inhibitor, inhibiting the activation of RET, EGFR, VEGFR-2, VEGFR-3, and slightly VEGFR-1, and with a potent anti-angiogenic activity.

Its antitumor activity was tested at different concentrations (1 nmol/L, 100 nmol/L, 1 µmol/L, 10 µmol/L, 25 µmol/L and 50 µmol/L) in primary ATC cells, in the 8305C continuous cell line, and in AF cells; and in 8305C cells in CD nu/nu mice.

Vandetanib decreased significantly ATC cells proliferation ($P < 0.01$, ANOVA), inducing apoptosis dose-dependently ($P < 0.001$, ANOVA), and inhibiting migration ($P < 0.01$) and invasion ($P < 0.001$). Vandetanib inhibited EGFR, AKT and ERK1/2 phosphorylation and down-regulated cyclin D1 in ATC cells.

In 8305C and AF cells, vandetanib inhibited significantly the proliferation, inducing also apoptosis. 8305C cells were injected sc in CD nu/nu mice and tumor masses became detectable 30 days after. Vandetanib (25 mg/kg/die) inhibited significantly tumor growth and VEGF-A expression and microvessel density in 8305C tumor tissues.

In conclusion, we show the antitumor and antiangiogenic activity of vandetanib in ATC, paving the way to a future clinical evaluation.

Biography

Silvia Martina Ferrari is graduated in Biological Sciences cum laude in 2002 and specialized in Clinical Pathology in 2007 at the University of Pisa (Italy). Her principal areas of expertise are autoimmune thyroid disorders, chemokines and cytokines, type 1 diabetes, systemic autoimmune disorders, HCV-associated thyroid disorders and thyroid cancer. Her researches have been published in more than 158 articles on International journals (HI = 38). She serves as an editorial board member and is Referee and Reviewer of many scientific International journals.

21. Mitochondrial dynamics and chemoresistance in ovarian cancer

Youngjin Han¹, Yong Sang Song^{1,2}

¹Cancer Research Institute, Seoul National University, Seoul 03080, South Korea.

²Department of Obstetrics and Gynecology, College of Medicine, Seoul National University, Seoul 03080, South Korea.

Various cellular and acellular components constitute tumor microenvironment affecting metabolism and malignant phenotypes of cancer. Hypoxia and increased level of reactive oxygen species (ROS) are frequently observed in many types of malignant tissues composed of cancer cells and surrounding tumor microenvironment, including ovarian cancer. In response to the increased level of ROS, cancer cells activate antioxidant mechanisms to counterbalance increased ROS. PGC1 α is a key molecule critical for mitochondrial biogenesis and upregulation of antioxidant enzymes. In our previous research, we reported that PGC1 α is associated with cisplatin-resistance in tumor spheres. Tumor sphere cells acquired stem cell-like properties together with increased production of ROS. ROS was shown to be important for maintaining stemness and PGC1 α expression of the tumor sphere cells in ovarian cancer. Decreased sensitivity to cisplatin was observed in both tumor sphere and PGC1 α -overexpressing cells, while silencing PGC1 α sensitized the tumor sphere cells to cisplatin. Along with upregulation of PGC1 α expression in tumor sphere cells, mitochondrial fission was increased in comparison to their parental cells. Similar to the in-vivo environment of the malignant tumor, tumor spheres exhibit hypoxia at the core. The center of tumor spheres is exposed to hypoxia like *in vivo* tumor. As the tumor sphere grows larger in size, a hypoxic gradient towards the core of the sphere is created. Next, we investigated the effect of hypoxia on mitochondrial dynamics. Mitochondria, dynamic intracellular organelles, go through incessant processes of fission/fusion and biogenesis by various stimuli in tumor microenvironment. Under hypoxic (< 1 % O₂) culture conditions, mitochondrial fission was increased together with increased resistance to cisplatin in ovarian cancer cells. Inhibition of mitochondrial fission enhanced sensitivity of cancer cells to cisplatin. Our findings suggest that PGC1 α -induced mitochondrial biogenesis and alteration of mitochondrial dynamics by hypoxia could cause the cisplatin resistance of ovarian cancer cells. The changes in mitochondrial biogenesis and dynamics of cancer cells adapted to tumor microenvironment could be a novel therapeutic target to overcome chemoresistance in ovarian cancer.

Biography

Prof. Yong Sang Song is with the Department of Obstetrics and Gynecology, College of Medicine, Seoul National University, Korea. He received MD, College of Medicine, Seoul National University, Korea from 1977 to 1983; the MS and the PhD, Postgraduate School Seoul National University, Korea. His major interests are molecular mechanisms of tumors, especially the role of tumor microenvironment in cancer cell metabolism and chemoresistance and precision medicine in ovarian cancer. He is particularly interested in the impacts of components of tumor microenvironment in ovarian cancer progression. He has published more than 300 papers in the science citation index journals.

22. A strategy for the prevention of thyroid cancer with a focus on the experience of managing radio-induced thyroid cancer after the Chernobyl Accident

Valentina Drozd^{1,2}, Daniel Igor Branovan¹, Michael Fridman³, Nikolay Shiglik¹, Sergey Vershenya², Igor Makarov², Maxim Lushik⁴, Larisa Danilova⁴

¹New York Ear, Nose and Throat Institute, New York, NY 10003, United States.

²LTD MedEx-lab, Minsk 220013, Belarus.

³Republican Centre for Thyroid Tumors, Minsk 220013, Belarus.

⁴Belorussian medical academy for postgraduate education, Minsk 220013, Belarus.

One of the lessons learned from Chernobyl is the dramatic increase in incidence of thyroid cancer in Belarus. However the incidence of thyroid cancer has been steadily increasing during the last 30 years worldwide most markedly in the Republic of Korea, France, Italy, Australia, and USA. Analyzing this problem, some scientists have recently identified this epidemic of thyroid cancer as “overdiagnosis” and “overtreatment”. On the other hand, overall incidence-based mortality for thyroid cancer in USA from 1994 to 2013 substantially increased (1.1% per year), and it increased even faster for patients diagnosed with advanced-stage papillary thyroid cancer (2.9% per year). These findings are consistent with a true increase in the occurrence of thyroid cancer. The main factors contributing to this increase continue to be debated. The experience of managing radio-induced thyroid cancer after the Chernobyl Accident has shown that radiation exposure and the usage of drinking water with a high concentration of nitrates were significantly associated with high incidence of thyroid cancer. Better understanding of the combined impact mechanism of radiation and nitrates exposure and maybe other endocrine disruptors will give us more opportunities to develop new ways of thyroid cancer preventing.

The rising incidence and optimization of management of nodular goiter are also actual problems for Belarus. Surgery for treating of low-risk thyroid papillary microcarcinomas and nodular goiter might be an overtreatment and it is important to develop a less traumatic modalities. To ablate small thyroid nodules (less than 2 cm in diameter), we started to use new originally developed low-cost device for bipolar radiofrequency ablation - «Thyrablator» designed as a sterile disposable needle for the fine needle biopsy (20-gauge). The first experience showed a promising efficacy and safety of new device - «Thyrablator» as a minimally invasive treatment of thyroid lesions.

More studies are needed to better verify the causes of the epidemic of thyroid cancer in the world and to concentrate our efforts on the prevention and development of new minimally invasive approaches for the treatment of nodular goiter and early forms of thyroid cancer.

23. Reducing PD-L1 expression with epigenetic modifiers enhances immunotherapy

Tessa Knox¹, Eva Sahakian², Debarati Banik¹, Melissa Hadley¹, Erica Palmer¹, Jennifer Kim¹, John Powers², Fengdong Cheng¹, Vincent Gallub¹, Sarthak Shah¹, Alejandro Villagra¹

¹The George Washington University, Washington, DC 20052, USA.

²H. Lee Moffitt, Tampa, FL 33612, USA.

Histone deacetylases (HDACs), were originally described in a limited context as histone modifiers. New evidence has demonstrated that HDACs are also involved in a diverse range of cellular processes that are

not restricted to the chromatin environment, such as the regulation of the cell cycle/apoptosis and, more recently, a modulator of immune response. However, much remains unknown about the mechanism of action of HDACs and their roles in the immune-biology of cancer. The non-specific nature of pan-HDAC inhibitors results in a narrow therapeutic window of use, limiting the dose and duration due to toxicity. Our group has focused in one specific HDAC, HDAC6, and shown that both the genetic abrogation and pharmacological inhibition of this HDAC modulates the expression of a variety of immune-regulatory proteins in the tumor microenvironment, including PD-L1, PD-L2, MHC class I, B7-H4 and TRAIL-R1. We have previously demonstrated that both pharmacological inhibition and/or genetic abrogation of HDAC6 plays a critical role in the immune check point blockade by down-regulating the expression of PD-L1 and other check-point modulators such as PD-L2, B7-H4, *etc.* Moreover, we have also observed that *in vivo* inhibition of HDAC6 reduces tumor growth in B16 and SM1 murine melanoma models within syngeneic immunocompetent hosts. Additionally, we have found that the combination of low doses of the HDAC6i Nexturastat A and checkpoint immune blockade therapies, including anti-PD-1 and anti-CTLA4, result in an important improvement in anti-tumor responses in our murine model as evidenced by the reduction of tumor growth when compared to treatment with individual stand-alone agents and the improved modulation of various immune markers. Our studies have also demonstrated that tumors treated with stand-alone check point inhibitor treatments, specifically anti-PD-1, results in a substantial increase in the production of IFN γ and IL-2, resulting in the upregulation of PD-L1 and other critical checkpoints in the immune blockade. Similar levels of IFN γ and IL-2 were found in the combination subject groups, however, the levels of PD-L1 and PD-L2 were more comparable to the non-treated group. Overall, our evidence suggests that HDAC6i has the potential for use as an adjuvant in ongoing therapeutic options involving the immune check-point blockade.

24. Trisenox disrupts MDM2-DAXX-HAUSP complex, degrades MDM2, and activates p53 in acute leukemia cells

Paul Bernard Tchounwou, Sanjay Kumar

Cellomics and Toxicogenomics Research Laboratory, NIH/NIMHD-RCMI Center for Environmental Health, College of Science, Engineering and Technology, Jackson State University, Jackson, MS 39217, USA.

Trisenox (TX) has been successfully used in the treatment of both de novo and relapsed acute promyelocytic leukemia (APL) patients. It inhibits APL cells growth efficiently through cell cycle arrest and apoptosis, however exact molecular mechanisms of action poorly understood. In present study, we found a new target of TX action that involves the activation of p53 and p21 expression through association with death domain-associated protein (DAXX), disruption of MDM2-DAXX-HAUSP complex and degradation of MDM2 in APL cells. TX-induced stress signal is transmitted by protein kinase (ATM & ATR) and phosphorylation of CHK1 & CHK2 at Ser 345 and Thr68 residues leading to complex disruption and accumulation of p53 in APL cells. TX-induced p53 caused cell cycle arrest by regulating expression of p21, cyclins and cyclin dependent kinases proteins and forcing cells to undergo apoptosis by apoptotic proteins expression modulation, mitochondrial membrane depolarization leading to caspase 3 activation. Our immunoprecipitation studies also showed that the complex molecules were well associated in APL cells, and TX disrupted their associations leading to accumulation of p53. We further studied the functional role of p53 in disruption and expression of complex molecules in p53-knock down APL cells using lentiviral shRNA approach. Taken together, our findings showed that TX activates p53, through association of DAXX, disruption of MDM2-DAXX-HAUSP complex, MDM2 degradation in APL cells leading to cell cycle arrest and apoptosis. This novel target of TX activity may be useful for designing new APL drugs.

Biography

Dr. Paul B. Tchounwou is Associate Dean of the CSET, Presidential Distinguished Professor, and Director of the NIH-funded RCMI-Center for Environmental Health. He is an internationally recognized biomedical scientist whose research focuses on the mechanisms of action of xenobiotic compounds and cancer therapeutic drugs. He is author of 228 peer-reviewed publications and 507 scientific presentations. He is the Editor-in-Chief of Environmental Toxicology (New York, USA) and of International Journal of Environmental Research and Public Health (Basel, Switzerland). He has received several awards for excellence including the 2003 Millennium Award for Research Excellence conferred by the White House (Washington DC).

25. The potential role of milk's amino acid- and miRNA signaling in the pathogenesis of prostate cancer

Bodo C. Melnik¹, Swen Malte John¹, Pedro Carrera-Bastos², Loren Cordain³, Gerd Schmitz⁴

¹*Department of Dermatology, Environmental Medicine and Health Theory, University of Osnabrück, Osnabrück 49074, Germany.*

²*Center for Primary Health Care Research, Lund University, Lund Se-22100, Sweden.*

³*Department of Health and Exercise Science, Colorado State University, CO 80523, USA.*

⁴*Institute for Clinical Chemistry and Laboratory Medicine, University Hospital Regensburg, Regensburg 93053, Germany.*

Epidemiological studies reported a dose relationship between cow's milk intake and prostate cancer (PCa). Lactose intolerance protects against the development of common cancers and a lower incidence of lactose intolerance in comparison to the general population has been reported in PCa patients. Daily milk consumption during adolescence in comparison to less frequent milk consumption increased the risk of advanced PCa in adulthood by 3.2. An increased risk for PCa has also been observed for patients with a history of severe acne, which is another milk-induced disease, pointing to common underlying signaling pathways. Several components of milk such as dairy protein, calcium, galactose, miRNAs, androgen precursors and estrogens derived from high-yield dairy cows have been implicated to play a role in milk-induced PCa. We provide translational evidence, that milk's essential amino acids via enhancing the secretion of insulin and insulin-like growth factor 1 result in AKT-stimulated mouse double minute 2-mediated degradation of the tumor suppressor p53. Moreover, milk exosomal miRNA-125b, which survives pasteurization, may directly repress TP53 mRNA. Milk-derived miRNA-148a via depletion of DNA methyltransferase 1 and hypomethylation of cancer-germline genes may promote epithelial-mesenchymal transition and cancer stem cells. Although boiling and ultraheat treatment of milk eliminates milk's miRNA signaling, milk's amino acid signaling is not affected by thermal procedures. We recommend that patients with severe acne vulgaris, adults with a history of severe acne, as well as individuals with a family history of PCa should refrain from pasteurized cow's milk to prevent PCa.

Biography

After his medical studies at the University of Münster, Germany, Bodo C. Melnik was visiting scientist at the University of California San Francisco from 1982-1984. From 1984-1990, he was resident at the Department of Dermatology, University of Düsseldorf. He is currently Associate Professor at the Department of Dermatology, Environmental Medicine and Health Theory, University of Osnabrück, Germany, member of the European Society for Dermatological Research and coeditor of the Journal of Translational Research. His research interests are milk signaling and milk microRNA signal transduction in diseases of civilization such as acne and prostate cancer.

26. Human-enzyme mediated, systemic depletion of amino acids for cancer prevention and treatment

John DiGiovanni

Division of Pharmacology & Toxicology, College of Pharmacy and Live STRONG Cancer Institutes, Dell Medical School, the University of Texas at Austin, Austin, TX 78712, USA.

Significant differences exist between the metabolism of normal and malignant cells. We have recently evaluated two potential therapeutic enzymes that degrade critical amino acids required for tumor growth. These engineered human enzymes, one that degrades cystine/cysteine [Cyst(e)inase] and one that degrades methionine (Methioninase), are currently under investigation for anticancer activity with promising preclinical results for prostate cancer as well as several other cancers. Depletion of extracellular cystine/cysteine leads to depletion of intracellular cysteine, decreased levels of intracellular glutathione (GSH) and increases in intracellular ROS leading to activation of cellular signaling pathways and cancer cell death. Depletion of extracellular methionine leads to reductions in intracellular *L*-methionine, *S*-adenosylmethionine and polyamines as well as reduced levels of cysteine and GSH and cancer cell death. Both enzymes given i.p. significantly reduced serum levels of their respective amino acid targets and significantly inhibited tumor growth *in vivo*. These and other studies on the mechanisms associated with their potential anticancer activity will be presented. In addition, studies are underway to identify agents that would synergize with one or both of these enzymes for enhanced therapeutic efficacy. Promising results have been obtained through targeting parallel antioxidant defense pathways and mitochondrial metabolism and these results will also be presented. Research supported by NIH NCI grant CA189623.

Biography

John DiGiovanni received his BS degree in Pharmacy and his PhD degree in Pharmacology from the University of Washington, Seattle, Washington. He did his postdoctoral work at the McArdle Laboratory for Cancer Research, University of Wisconsin, Madison, WI in carcinogenesis and cancer biology. Dr. DiGiovanni joined the University of Texas at Austin (UT Austin) in January of 2010 and is Professor in the Division of Pharmacology and Toxicology, College of Pharmacy. He holds the Coulter R. Sublett Endowed Chair in Pharmacy. He also has adjunct appointments in the Department of Nutritional Sciences (College of Natural Sciences) and the Department of Pediatrics (Dell Medical School). In addition, Dr. DiGiovanni is Director of the Center for Molecular Carcinogenesis and Toxicology (CMCT) at UT Austin and is Associate Director for Basic Research in the LiveSTRONG Cancer Institutes, Dell Medical School at UT Austin. He is the Editor-in-Chief for the journal Molecular Carcinogenesis. Dr. DiGiovanni has published more than 250 research articles in prestigious peer-reviewed journals and more than 50 invited reviews/book chapters.

27. Cancer stem cells and miRNA in osteosarcoma

In the last years, several studies have identified the presence inside many types of tumors of a subpopulation of stem-like cells, a biologically unique subset of cells, which are probably involved in tumor progression and in the resistance to the antineoplastic treatments. These cells are defined as cancer stem cells (CSCs) and their uncomplete eradication represents a possible explanation as why many therapies seem to have an initial effect, but the patient later relapses. On the other hand, there are a lot of researches about the role of microRNAs (miRNAs) in several cancerous process (i.e., growth, invasion and metastases) and in the maintenance of stemness. On the base of this, we have studied the presence of CSCs inside the primary and aggressive bone malignancy which primarily affecting children and young adults, the osteosarcoma (OS). In this study, we have shown not only the presence of the CSCs population inside different high grade types of OS (i.e., telangiectatic OS, small cell OS and conventional OS), but also the preliminary results about the possibility to find a profile of miRNA expression, as “miRNA codes”, which can be analogue to all the analyzed subtypes of OS. These results could be important to identify a common molecular code among the three highly malignant forms of OS that could be used in the design of new and more effective treatments against the highly aggressive types of OS.

Biography

2011 she has obtained her Master's Degree in Biology at the University of Florence, Florence, Italy. 2016 she has completed her PhD from University of Florence, Florence, Italy, in the field on pathophysiology of bone. 2016-present she is a Post-Doc researcher, at the Department of Surgery and Translational Medicine, University of Florence, Florence, Italy. 2013-present she's carrying on researches on primary bone cancers (i.e., osteosarcoma, Ewing's sarcoma and giant cell tumor). Her interest are focused on cancer stem cells and on miRNAs involved in these bone diseases. She has published several papers in reputed journals and she has attended national and international meetings on this topic.

28. Vitamin E δ -tocotrienol induces apoptosis in prostate cancer cells through activation of the ER stress-autophagy axis and rewiring of mitochondrial metabolism

Fabrizio Fontana, Marina Montagnani Marelli, Michela Raimondi, Roberta Manuela Moretti, Monica Marzagalli, Raffaella Longo, Maurizio Crestani, Patrizia Limonta

Department of Pharmacological and Biomolecular Sciences, Università degli Studi di Milano, Milano 20133, Italy.

Prostate cancer is androgen dependent in its early stage and responds to the androgen deprivation therapy; however, it often progresses to the castration-resistant prostate cancer (CRPC) stage in which cancer cells become resistant to therapies. Preliminary experiments performed in the authors' laboratory demonstrate that vitamin E-derivative δ -tocotrienol (δ -TT) exerts a proapoptotic activity in CRPC cells while sparing normal prostate epithelial cells. These studies were performed to investigate the molecular mechanisms underlying this activity: (1) in CRPC cells, δ -TT induces endoplasmic reticulum (ER) stress (expression of ER stress markers such as BiP, PERK, p-eIF2 α , IRE1 α , ATF4 and CHOP) and autophagy (expression of autophagy markers such as LC3- II and p62). Using the ER stress inhibitors salubrinal and 4-PBA and the autophagy flux inhibitors 3-methyladenine and chloroquine, we confirmed that the effect of δ -TT is

mediated by both these mechanisms. Moreover, treatment of CRPC cells with salubrinal impairs δ -TT-induced LC3-II expression, demonstrating that this compound triggers the ER stress-autophagy axis; (2) in CRPC cells, the expression levels of the proteins of the respiratory chain complexes are increased compared to non-tumoral cells, supporting a reprogramming of the OXPHOS system. In these cells, δ -TT: decreases the expression levels of the proteins of the respiratory chain complexes, specifically of complex I; decreases the mitochondrial activity as well as the mitochondrial activity/mass ratio; decreases both ATP production and oxygen consumption. These data demonstrate that δ -TT exerts a significant proapoptotic activity in CRPC cells through activation of the ER stress-autophagy axis and rewiring of mitochondrial metabolism.

⁴Dell Pediatric Research Institute, University of Texas at Austin, Austin, TX 78712, USA.

Natural compounds ingested through the diet can modulate key molecular signaling, inhibit cancer cell proliferation and induce apoptosis. According to the World Health Organization, an increased consumption of natural compounds could prevent about one-third of all cancer deaths. Libraries of natural compounds incorporate phytochemicals characterized by vast molecular diversity and are essential to identify combinations that synergistically contribute to improving treatment outcome. Given the very large number of possible combinations, high-throughput screening methods are paramount to identify the most efficacious compound combinations. In this study, we used high-throughput screening to test the outcome of natural compound combinations on prostate cancer. The *in vitro* screen identified ursolic acid, curcumin and resveratrol as top-hits. These compounds were then administered via the diet to a mouse allograft model of prostate cancer. Combinations of the compounds greatly improved outcome, *in vivo*. This outcome was, at least in part due to the modulation of glutamine metabolism, as determined via untargeted metabolomics and metabolic flux analysis, induced by compound combinations. Moreover, the combinations affected levels of ASCT2 and activation of STAT3, mTORC1 and AMPK. Overall, the high throughput approach is effective for identifying combinations of natural compounds that can synergistically contribute to chemoprevention and therapeutic outcome.

30. The effects of water extract of *Ruta graveolens* on glioblastoma and melanoma cells is selective and depends on REST/NRSF expression

Heterogeneity and recurrent relapse of tumors, drugs resistance and the lack of selectivity of current chemotherapy calls for new drugs.

Here we report that RGWE is able to kill a number of glioblastoma (GBM) cell lines and cancer stem cells as shown by MTT and trypan blue assay. In particular, we analyzed U87MG, U138, C6 cell lines as well as 3 cancer stem cells originated from patients affected by GBM. RGWE, differently to temozolomide and cisplatin, does not show any toxic activity towards differentiated neurons. Interestingly, differently to GBM cells responsive to RGWE, T98G GBM cell line, unresponsive to RGWE, do not express the transcription factor REST/NRSF, encoding a zinc finger protein that function as a master regulator of neural cell differentiation in normal physiological conditions. NRSF is highly expressed in embryonic stem cells but reduced rapidly in neuron progenitors and maintained at very low levels after differentiation. In contrast, in neuroepithelial tumors, high levels of NRSF are expressed in medulloblastomas, neuroblastomas and multiform glioblastoma and are correlated with the proliferation and severity of these tumors. We observed that down regulation of REST/NRSF in U87MG and C6 cells by means of siRNA, prevents RGWE cytotoxic effects.

We also found that human melanoma cell lines, HNCB and A375 expressing high and low levels of REST/NRSF respectively, respond differently to RGWE. HNCB (REST^{high}) cells die upon RGWE administration whereas A375 (REST^{low}) cells are unresponsive. RGWE stimulation is able to affect also cell migration as shown by wound assay. Upon siRNA-mediated REST down-regulation, HNCB cells show unresponsiveness to RGWE's effects.

Finally, we evaluated the effects of RGWE in the tube formation assay on Matrigel, an angiogenic assay. We found that RGWE is able to impair tubule network formation when administered to human endothelial cells, HUVEC.

31. A natural agent bitter melon exerts strong efficacy against pancreatic cancer in combination with gemcitabine in patient derived xenografts

Rajesh Agarwal

Department of Pharmaceutical Sciences, University of Colorado Skaggs School of Pharmacy and Pharmaceutical Sciences, Colorado 80045, USA.

Pancreatic cancer (PanC) remains the 4th leading cause of cancer related-deaths in U.S. resulting in a dismal survival rate of < 5%. This generates a critical need for identifying novel non-toxic agents aimed at

effective PanC management with minimal patient distress. Bitter melon (*Momordica charantia*), a dietary agent, is actively being examined for its anti-cancer efficacy against a panel of malignancies. Recent data from our group highlights the anti-PanC potential of bitter melon juice (BMJ); its role in PanC-cancer stem cell (CSC) self-renewal/ kinetics and gemcitabine (GEM) resistance in PanC cells. Combinations for BMJ and GEM *in vitro* also showed synergism in AsPC1 and synergistic effect in BxPC3 PanC cells. As patient-derived xenografts are gaining importance, we next assessed the efficacy of BMJ and GEM alone, or in combination; tumor growth was significantly inhibited in all treated groups with GEM and Combo displaying comparable efficacies followed by BMJ. Notably, tumor regrowth determination with subsequent treatment washout period showed maximum tumor regrowth in GEM group comparable to controls; however, BMJ consistently showed a prolonged inhibitory effect and Combo group remained close to BMJ, suggesting no apparent antagonistic interference. In mechanistic evaluations, in tumor tissues, minimal expression levels of Ki67 and VEGF were observed in BMJ and Combo groups by study end compared to controls and GEM groups. Together, these results show strong BMJ efficacy as a single agent as well as being a perfect combinatorial candidate with GEM for PanC management and treatment. Supported by NCI R01 grant CA195708.

Biography

Rajesh Agarwal completed his Ph.D. from Lucknow University, India in 1981. He is currently Professor and Vice Chairman, Department of Pharmaceutical Sciences, University of Colorado. He has over 360 peer-reviewed publications and several book chapters, has been an invited speaker across the globe, has over three hundred presentations in national and international scientific meetings, is an active member of several National Institutes of Health, USA grant review committee, and is an editorial board member of several lead cancer journals.

32. The mitochondrial-targeted compound SS-31 improves cachexia by increasing muscle energetics

Riccardo Ballarò^{1,2}, Marc Beltrà^{1,2}, Paola Costelli^{1,2}, Hazel Szeto³, Fabio Penna^{1,2}

¹*Department of Clinical and Biological Sciences, Experimental Medicine and Clinical Pathology Unit, University of Turin, Turin 10126, Italy.*

²*Interuniversity Institute of Myology, Milano 20132, Italy.*

³*Weill Cornell Medicine, New York, NY 10016, USA.*

Cachexia is a complex syndrome that frequently complicates the management of cancer patients^[1]. This syndrome is characterized by progressive wasting of body mass, mainly due to the depletion of both adipose and muscle tissue^[2]. Together with increased protein degradation, also mitochondrial impairment likely contributes to muscle wasting^[3]. Indeed, alterations of mitochondrial morphology and function have been observed in the skeletal muscle of tumor-bearing animals with cachexia^[3].

The aim of the present study was to investigate if selective targeting of mitochondria with SS-31 could exert positive effects on muscle wasting in mice bearing the C26 tumor treated or not with chemotherapy (oxaliplatin+5-fluorouracil; C26 and C26 OXFU, respectively).

Both C26 hosts and C26 OXFU mice showed anorexia, body weight loss and decreased muscle mass and strength. In the C26 hosts, SS-31 partially prevented body wasting, anorexia and muscle mass. In the

skeletal muscle of both C26 and C26 OXFU animals, mitochondrial markers such as PGC-1 α , cytochrome c and SDHA were reduced and these alterations were not corrected by SS-31. In the C26 OXFU mice the reduced expression of mitochondrial markers was also associated with impaired muscle oxidative capacity and ATP content. These latter were improved by SS-31 in the C26 hosts but not in the C26 OXFU mice. Muscle wasting and mitochondrial impairments were associated with reduced protein synthesis in the C26 hosts. Consistently with improved muscle energetics, SS-31 administration partially corrected muscle protein synthesis in C26-bearing mice.

Overall, SS-31 administration could contribute to correct muscle wasting and to improve muscle energetics in tumor-bearing animals, suggesting that targeting mitochondria could be part of a multimodal therapy against cancer cachexia. In order to increase the translational value of the results, further analysis and treatment optimization are needed in order to demonstrate the effectiveness of SS-31 in C26-bearing mice treated with chemotherapy.

³Stephenson Cancer Center and Department of Cell Biology, The University of Oklahoma Health Sciences Center, Oklahoma City, OK 73104, USA.

Ovarian cancer emerges as a highly aggressive metastatic disease characterized by a high grade of lethality and it remains the most lethal gynecologic cancer with a five-year survival rate of about 30%-40%. Cancer progression is facilitated by pro-invasive factors released by the tumour microenvironment and modulating the epithelial-to-mesenchymal transition (EMT).

Lysophosphatidic acid (LPA), a bioactive phospholipid highly secreted in the ascitic fluid and plasma of ovarian cancer patients, stimulates the growth and promotes the tissue invasion of cancer cells. Resveratrol (RV), a polyphenol found in grapes and in a variety of natural products, is attracting the interest of many researchers thanks to its several anti-cancer properties.

Here we show that LPA induces the EMT through induction of the Hedgehog pathway and concomitant inhibition of autophagy in the cancer cells at the migration front. We found that RV and LPA regulate in an

opposite fashion the expression of BMI-1, a Polycomb transcriptional repressor belonging to the Hedgehog pathway, involved in cancer cell stemness and metastasis. Interestingly, BMI-1 silencing restores autophagy and halts ovarian cancer cell migration. Our data indicate that there is a functional cross-talk between autophagy and Hedgehog/EMT/cell migration processes and we propose BMI-1 as the joining mediator.

In conclusion, our findings indicate that RV elicits its anti-tumor effect through induction of autophagy and down-regulation of BMI-1, and that this process is sufficient to inhibit cancer cell migration and invasion.

Background: Glioblastoma Multiforme (GBM), a high-grade glioma (WHO grade IV), is the most aggressive form of brain cancer. Treatment options for GBM involving a combination of surgery, chemotherapy and radiation resulted in a poor survival outcome. Epigenetic mechanisms are increasingly implicated in GBM pathogenesis. Unlike genetic mutations, epigenetic changes are reversible and can be targeted by drugs. We evaluated whether different histone deacetylase Inhibitors (HDACis) are able to affect migration, invasion and vasculogenic mimicry in GBM cells.

Methods: We tested Varinostat (SAHA) and Trichostatin A (TSA) as inhibitors of class I and II HDACs, Entinostat (MS275) as selective inhibitor of class I HDACs (specifically of HDAC 1 and 3) and MC1568 as selective HDAC class II inhibitor. Tube Assay was used to evaluate the ability of HDAC is to interfere with vessels formation by human GBM U87MG and rat glioma C6 cell lines and by cancer stem cells (CSCs) isolated from human GBMs. U87MG directional cell migration and cell invasion have been assessed by Boyden chamber assay and using xCELLigence Real-Time Cell Analyzer. Trypan Blue exclusion test and MTT assay were employed to assess cell viability and cell proliferation.

Results: Our data show that sublethal doses of HDACis significantly decrease U87MG directional cell migration and that MS275 HDACi is able to impair U87MG matrigel invasion. Finally, we observed that HDACis inhibit significantly vasculogenic mimicry in U87MG, C6 and CSCs cells.

Conclusion: GBM depends on vascular networks to supply blood, oxygen, and nutrients. Tumor blood vessels can either be formed from pre-existing blood vessels (neo-angiogenesis) or from tumor cells (vasculogenic mimicry) due to a process of epithelial-mesenchymal transition; vascular mimicry provides a mechanism whereby GBM could escape anti-angiogenic therapies. Our results suggest that HDACis may be promising candidates for blocking vascular mimicry.

35. Resveratrol and Halofuginone Counteract TGF- β -Induced activation and proliferation of stromal fibroblasts by Up-regulating Autophagy

Eleonora Secomandi¹, Sami Ibazizen², Gwenael Rolin², Ciro Isidoro¹

¹Laboratory of Molecular Pathology and Nanobioimaging, Department of Health Sciences, Università del Piemonte Orientale, Novara 28100, Italy.

²Inserm UMR 1098, Engineering and Cutaneous Biology Team, Besançon 25020, France.

Cancer can be viewed as a wound that never heals. In this respect, keloids can be considered as the “benign” counterparts of cutaneous tumors. Keloids are pathological scars derived from an altered skin wound healing process and are characterized by hyper-activation and abnormal proliferation of stromal fibroblasts. Among the several pro-inflammatory cytokines involved in the pathogenesis of keloids, transforming growth factor- β (TGF- β) plays a crucial role in myofibroblast proliferation and differentiation. Resveratrol (RV), a naturally polyphenolic compound, is a strong autophagy inducer and inhibits oxidation, inflammation and collagen I deposition. Halofuginone (HF) is a synthetic halogenated derivate of febrifugine, well known for its anti-fibrotic therapeutic potential.

In the present work, we focused our attention on the role of autophagy in keloid formation and progression. We found that RV and HF counteract TGF- β -induced migration of keloid fibroblasts and, in parallel, an increase of autophagic flux is detected, suggesting autophagy as a putative mechanism responsible for slowing down cell motility. Moreover, HF reduces the number of Ki67+ cells, decreasing the proliferative capacity of keloid fibroblasts. Both RV and HF attenuate α -SMA and COL1 synthesis and limit the contraction capability of myofibroblasts within the collagen matrix, even in co-treatment with TGF- β .

36. The possible mechanism of the antioxidants on the antitumor effect of bortezomib in melanoma and myeloma cell lines

Angéla Takács¹, Eszter Lajkó¹, Ildikó Istenes², László Kőhida¹, Orsolya Láng¹

¹Department of Genetics Cell- and Immunobiology, Semmelweis University, Budapest 1085, Hungary.

²Department of Internal Medicine, Semmelweis University, Budapest 1085, Hungary.

Bortezomib is a proteasome inhibitor chemotherapeutic agent used to treat multiple myeloma; recently studies offer it as a promising drug to treat melanoma. Bortezomib-induced peripheral neuropathy (BIPN) is a dose-limiting side-effect, that can be treated with antioxidants, e.g., alpha-lipoic acid and thiamine.

The objective of our experiments was: to verify the cytotoxicity of bortezomib; to test and compare the influence of the antioxidants on the antitumor effect of bortezomib in melanoma and myeloma.

The cells were U266 myeloma, WM35 primary and A2058 metastatic melanoma. The concentrations were: (1) bortezomib: 20, 100 and 300 ng/mL; (2) alpha-lipoic acid: 10 and 100 μ g/mL (3) thiamine: 150 and 300 nmol/L. Impedimetry (xCELLigence SP) was used to evaluate the cytotoxicity. To study the cell cycle profile, Cell-ClockTM, a redox dye was applied and evaluated by ImageJ. Apoptosis was analyzed by flow cytometry after annexinV assay and phospho-p53 immunostaining.

Bortezomib was cytotoxic and blocked U266 cells in the G1 phase. Alpha-lipoic acid enhanced the cytotoxicity of bortezomib (20 ng/mL) in U266 cells, but counteracted bortezomib in melanoma cells.

Thiamine (300 nmol/L) with bortezomib antagonized the antitumor effect of bortezomib on myeloma cells. In every cell, bortezomib was apoptotic, which effect was decreased in melanoma by the co-treatments.

A good correlation between the apoptotic and the cell cycle arresting effect of bortezomib as well as the antagonism of the antioxidants was found. In conclusion, the combination therapy of bortezomib and a low dose of antioxidants could be offered for the treatment of BIPN in multiple myeloma.

Biography

³Oncology Unit, Department of Translational Medicine, Università del Piemonte Orientale “A. Avogadro”, Novara 28100, Italy.

The lack of nutrients and of growth factors has a great impact on the metabolic pathways involved in cancer cell proliferation. In this condition, cancer cells activate autophagy as a pro-survival pathway and eventually exit the cell cycle to undergo a dormant state. Presently, the potential benefit of nutrient starvation in the prevention and treatment of cancer is under clinical consideration. Resveratrol (RV), a dietary polyphenol acting as a protein (caloric) restriction mimetic, could substitute for amino acid starvation. Here we report on the changes of the global transcriptome in ovarian cancer cells subjected to amino acid starvation or to the protein-caloric restriction mimetic RV. Based on the Gene Ontology analysis, the mRNAs expressed in the two treatments affected different biological functions. The number of transcripts positively impinging on the autophagy pathway was higher in RV-treated than in starved cancer cells. Our data support the view that RV treatment can be more effective than and can substitute for nutrient starvation to induce a dormant-like state in cancer cells.

38. Resveratrol abrogates IL-6 - induced ovarian cancer cell motility by limiting glucose availability and up-regulating autophagy

Chiara Vidoni¹, Alessandra Ferraresi¹, Suratchanee Phadngam¹, Andrea Castiglioni¹, Alessandra Galetto², Ciro Isidoro¹

¹Laboratory of Molecular Pathology and Nanobioimaging, Department of Health Sciences, Università del Piemonte Orientale “A. Avogadro”, Novara 28100, Italy.

²Unit of Oncology, Department of Translational Medicine, Università del Piemonte Orientale “A. Avogadro”, Novara 28100, Italy.

In this work, we investigated whether glucose uptake plays a role in ovarian cancer cell migration. IL-6, a cytokine released by cancer-associated fibroblasts and cancer cells, promotes ovarian cancer metastasis. We have previously found that Resveratrol (RV), a naturally polyphenolic compound, counteracts IL-6-induced cancer cell migration, through the epigenetic up-regulation of autophagy. Here, we show that IL-6 stimulates glucose-uptake along with cell migration. We found that in the presence of glucose, IL-6-induced mitochondrial oxidative stress with production of anion superoxide and inactivation of ATG4, the cysteine protease that processes LC3 needed for autophagosome formation. RV reduced glucose uptake, prevented the formation of anion superoxide, rescued ATG4 function and increased the level of autophagosome formation. RV-mediated up-regulation of autophagy was more pronounced at the migration front, leading to a reduced cancer cell motility. These data indicate that IL-6 promotes ovarian cancer cell migration by promoting glucose uptake which is metabolized to produce mitochondrial oxidative stress that eventually inhibits autophagy, and RV may counteract this action by limiting the glucose uptake and the production of anion superoxide.

39. Warty Carcinoma of the uterine cervix - do we know it

Angel Yordanov¹, Strahil Strashilov², Milena Karcheva³, Polina Vasileva⁴, Ilko Iliev¹, Stanislav Slavchev⁵, Yoana Ivanova⁴

¹Clinic of Gynecologic Oncology, Medical University Pleven, Pleven 5803, Bulgaria.

³Department of Epidemiology, Medical University Pleven, Pleven 5803, Bulgaria.

⁴Department of Obstetrics and Gynecology, Medical University Pleven, Pleven 5803, Bulgaria.

⁵Clinic of Gynaecology, University Hospital “St. Anna”-Varna, Varna 9002, Bulgaria.

Introduction: Warty carcinoma of the uterine cervix is a rare subtype of squamous cell carcinoma that usually occurs in women over 48-50 years. Warty carcinoma is not as aggressive as the other subtypes, and has a better prognosis. It is also a slow-growing tumor. The prognosis depends on a set of several factors that include: the size of the tumor and the extent of its invasion, stage of cancer, FIGO grade, involvement of the regional lymph nodes, whether the tumor is occurring for the first time, or is a recurrent tumor, response to treatment.

Aim: The aim of the study was to explore the prognosis of this type of cervical cancer.

Methods: For ten year period (2008-2017) in the Clinic of Gynecologic oncology at the UMHAT - Pleven, Bulgaria were operated 714 cases with Carcinoma of the uterine cervix and 14 of which were histologically diagnosed as a Warty carcinoma. Radical abdominal hysterectomy was performed on all patients with pelvic lymph node dissection with postoperative telegamma therapy. Patients were investigated by retro- and prospective analysis for overall and recurrence-free survival rate.

Results: Warty carcinoma was 1.94% of all cervical carcinomas, treated in our clinic. The mean age of the patients was 48 years (29 to 72 years) and 57% of them were peri- and postmenopausal and 43% were in women under the age of 45. According to the FIGO staging systems for cervical cancer, patients were staged as follows: in stage IB1 - 43% and in stage IB2 - 57%. In 29% the tumor size was under 2 cm, in 14%

the size was 2-4 cm and in 57% the size of the local tumor is above 4 cm. Never the less the high percentage of locally advanced process (patients with tumor above 4 cm), only in one case there was local spreading of the tumor to the uterine cavity and in one case there lymph node metastasis. Lymphovascular space invasion was not seen in any patient. Our patients are free of tumor recurrence or occurrence of symptoms for a period of 9.4 years (112 months), to 4 months after the surgical procedure.

Conclusion: Warty carcinoma of the cervix has good clinical prognosis and it is possible to rethink for not so aggressive surgical treatment and even for fertility sparing surgery when it is necessary.

40. Peptide based targeted drug delivery of mono- and dual-drug conjugates to prostate cancer cells

Michael Firer^{1,2}, Oranit Bashari¹, Boris Redko³, Anna Cohen¹, Galia Luboshits¹, Gary Gellerman^{2,3}

¹Department of Chemical Engineering, Ariel University, Ariel 40700, Israel.

²Ariel Center for Applied Cancer Research, Ariel University, Ariel 40700, Israel.

³Department of Chemical Sciences, Ariel University, Ariel 40700, Israel.

Targeted drug delivery (TDD) systems are becoming important in cancer therapy for the specific delivery of cytotoxic drugs into the target cells. This strategy bypasses the disadvantages of traditional chemotherapy such as non-specific toxicity and development of drug resistance and may also reduce drug doses. TDD systems commonly consist of a targeting moiety (such as an antibody, protein or peptide) chemically conjugated to a linker which has been coupled to a cytotoxic compound. In order for targeted nanoparticles to be effective therapeutics, a number of design issues need to be considered. This presentation will discuss selection of appropriate peptides derived from phage display libraries as targeting moieties, focusing on our results in the development of peptide-drug-conjugates (PDCs) for prostate cancer therapy. Based on our previous studies in TDD systems, we defined a series of phage selection criteria which enabled the choice of candidate peptides for testing *in vitro* and *in vivo*. Using the selection criteria, two lead peptides, P10 and P12 were used to build mono- and dual-drug PDCs which were shown to be target specific and effective against a variety of prostate cancer cells. These results demonstrate several important principles in the tailored design and selection of both the peptides and cytotoxic drugs suitable for incorporation into effective PDCs. We are now using these principles to design PDCs for other cancers.

41. Pregnancy-associated breast cancer is it always possible to keep the pregnancy

⁴Department of Surgical Diseases, Medical University-Pleven, Pleven 5803, Bulgaria.

Introduction: Pregnancy-associated breast cancer can occur in any moment during gestation, lactation, or even within 1 year after delivery. The incidence of that cancer is 1:3000 to 1:10000 pregnancies. The diagnosing process is often hard due to the pregnancy-related physiological changes of the breast.

Case presentation: We present the case of a 41-year old woman, diagnosed with breast cancer during pregnancy, in 20th week of gestation; the cancer was found due to presence of multiple pathological fractures of the spinal cord.

Discussion: Despite the fact that treating breast cancer during pregnancy is done following the same principals as the management of breast cancer in non-pregnant patients taking into account that the aim of the treatment is to provide the best curative treatment with minimal or no harm to the fetus maximizing the gestational period and ensure safe delivery of the fetus, is not always easy to keep the pregnancy.

Conclusion: In conclusion, with the increasing birth age for women, PABC will be a more common disease. We have to focus our thinking on it. Elective termination of pregnancy has not proven to improve the outcome in breast cancer. Therefore, it is not routinely recommended. The decision to terminate has to be individualized based on the oncologic situation and maternal concerns.

Cachexia is a frequent feature in cancer patients. Its occurrence is associated with reduced tolerance to anti-cancer treatments, impaired survival and bad quality of life. This syndrome is mainly characterized by loss of body weight, depletion of muscle mass and metabolic alterations^[1]. The loss of muscle mass and function is also associated with autophagy deregulation and mitochondrial impairments^[1] that could be exacerbated by anti-cancer treatments^[2]. In this regard, exercise could represent a promising non-pharmacological approach to correct muscle wasting in cancer cachexia^[3]. The main goal of the present study was to investigate if mild exercise could improve muscle wasting in mice bearing the C26 tumor, in the presence or in the absence of chemotherapy treatment [oxaliplatin+5-fluorouracil (OXFU)]. Although chemotherapy increased the lifespan of C26-bearing mice, it resulted in muscle wasting more severe than that observed in the untreated C26 hosts. Such wasting pattern was associated with increased levels of molecules accepted as markers of autophagy and mitophagy, while the expression of markers of mitochondrial content and dynamics decreased. Consistently, C26 OXFU mice showed impaired muscle oxidative metabolism (SDH total activity) and reduced protein synthesis. Moderate exercise in OXFU-treated C26-bearing mice exerted beneficial effects on the loss of both muscle mass and function, partially restoring the expression of markers of autophagy and mitophagy, increasing mitochondrial content and dynamics and improving muscle oxidative capacity.

On the whole, chemotherapy administration could contribute to muscle wasting in cancer patients, enhancing the alterations of metabolism due to tumor growth. In this regard, moderate exercise may support cancer patients under chemotherapy regimen preserving muscle mass and function.

43. Mouse mammary carcinomas secrete extracellular vesicles - *in vitro* and *in vivo* study

Yuko Ito, Nabil Eid, Masa-Aki Shibata, Yoshinori Otsuki, Yoichi Kondo

Department of Anatomy & Cell Biology, Division of Life Sciences, Osaka Medical College, 2-7 Daigakumachi, Takatsuki, Osaka, 569-8686, Japan

Many types of cells including cancer cells secrete extracellular vesicles (EVs). EVs are small vesicles released by donor cells that can be taken up by recipient cells. EVs contain receptor proteins, proteolytic enzymes, miRNAs, and mRNAs which are transferred into the target cells, and then affect various cell functions. EVs are categorized depending upon where in the cells they originate: vesicles that are derived from multivesicular bodies are referred to as exosomes (50-100 nm in diameter) and those from the plasma membranes as microvesicles (500-1000 nm in diameter). There are numerous *in vitro* studies, however, little is known about EVs *in vivo*. Here we show the chemical and ultrastructural features of EVs derived from cultured mouse mammary carcinoma cells and their tumors in mice formed upon inoculation. BJMC338 tumors show a low metastatic propensity, while BJMC3879 tumors show a high metastatic propensity, especially to lymph nodes and lungs. Both EVs contain premature vascular endothelial cell growth factor C, and inoculated tumors demonstrated that EVs were in their lumen and surrounding connective tissue. Many exosomes were accumulated in the cytoplasm, Golgi complex and r-ER of tumor cells. These observations suggest that mouse mammary carcinoma cells in tumors secrete EVs.

44. Epithelial splicing regulatory protein 1 expression is an unfavorable prognostic factor in prostate cancer patients

The objective of this study was to evaluate the role of epithelial splicing regulatory protein 1 (ESRP1) expression in predicting prognosis and disease progression in a large cohort of PC patients with long-

term follow-up. The ESRP1 participates in the epithelial-mesenchymal transition, a necessary prelude to disease progression in prostate cancer (PC). The prognostic role of ESRP1 has been studied in various human primary tumor tissues and has been described to be tumor-specific. However, little is known about the prognostic value of ESRP1 in PC. A preliminary investigation into the clinical significance of ESRP1 was conducted using The Cancer Genome Atlas PC dataset. Tissue microarrays of radical prostatectomy specimens from 514 PC patients at the National Cancer Center of Korea were immunohistochemically stained for ESRP1. PC samples were grouped into high and low expression of ESRP1 based on the immunohistochemistry results. The median follow-up period was 91.2 months. The immunohistochemistry was interpreted semi-quantitatively using *H*-score, defined by the intensity (0, 1, 2 and 3), and the percentage of expressed areas (0-100%). The prognostic significance of ESRP1 expression was analyzed using the Cox proportional-hazards model ($P < 0.05$). After adjusting for clinicopathological variables, high expression of ESRP1 was significantly associated with worse biochemical recurrence-free survival [hazard ratio (HR): 1.37; 95% confidence interval (CI): 1.02-1.83; $P = 0.037$] and shorter cancer-specific survival (HR: 3.43; 95% CI: 1.12-10.54; $P = 0.031$). PC patients with high expression of ESRP1 appear to have increased risk of biochemical recurrence and cancer-specific death. The expression of ESRP1 in patients with poor survival outcomes indicates that there may be an opportunity to predict response to androgen deprivation therapy based on ESRP1 expression.

Despite the fact that overall rates of gastric cancer (GC) continue to decline worldwide, the majority of patients are still diagnosed with advanced disease in Western countries. New strategies for early diagnosis and new therapeutic methods in GC need to be explored. Epigenetic control using inhibitors of DNA methylation, such as 5-aza-2'-deoxycytidine (also known as Decitabine), may offer new possibilities in GC therapy. Our research group previously identified 86 differentially expressed genes (DEGs) by microarray analysis comparing GC cell lines treated with Decitabine and non-treated cells. Among the upregulated

DEGs identified by this methodology, *NRN1* was selected for further analyzes. This study aimed to evaluate, compare and correlate *NRN1* mRNA and methylation levels of GC and adjacent non tumor samples from patients with primary gastric adenocarcinoma. The mRNA level was assessed by quantitative reverse transcription PCR. DNA methylation analysis was assessed by Ion Torrent PGM sequencer. A total of 12 CpG sites were evaluated in *NRN1* promoter region. GC samples showed a significant increased DNA methylation at five specific CpG sites of *NRN1* promoter region compared with adjacent non tumor samples ($P < 0.05$), besides no difference in *NRN1* mRNA levels between these groups. At this time, no significant correlation between mRNA and methylation levels, as well as, significant clinicopathological associations were observed. Although different mechanisms may be involved in gene regulation, *NRN1* methylation seems to play an important role in gastric carcinogenesis. This study is still in progress and new samples and other gene regions will be incorporated in our analyzes.

46. A semi-comprehensive analysis of gene amplification in breast cancers using multiplex ligation-dependent probe amplification and fluorescence in situ hybridization

Akishi Ooi

Kanazawa University, Kanazawa 920-1192, Japan.

Gene amplification is a common event in breast cancer. The aim of the present study was to determine the amplification status of 22 genes that are reportedly frequently amplified in breast cancers. A total of 320 formalin-fixed and paraffin-embedded invasive ductal cancer tissues were screened by multiple ligation-dependent probe amplification, and 885 genes with “gain” or “amplified” status were further examined for the respective gene amplification by fluorescence *in situ* hybridization (FISH). In the FISH analysis, 116 of 320 tumors (36%) displayed gene amplification of at least 1 of the 22 genes. The frequencies of gene amplification were as follows: *ESR1* (5 cases, 1.5%), *EGFR* (one case, 0.3%), *ZNF703* (25 cases, 7.8%), *FGFR1* (24 cases, 7.5%), *ADAM9* (17 cases, 5.3%), *IKBKB* (10 cases, 3.1%), *PRDM1* (5 cases, 1.5%), *MTDH* (15 cases, 4.7%), *MYC* (29 cases, 9.0%), *CCND1* (39 cases, 12%), *C11ORF30* (19 cases, 5.9%), *CDH1* (1 case, 0.3%), *CPD* (9 cases, 2.8%), *MED1* (25 cases, 7.8%), *ERBB2* (35 cases, 11%), *CDC6* (14 cases, 4.3%), *TOP2A* (12 cases, 3.8%), *MAPT* (1 case, 0.3%), *PPM1D* (10 cases, 3%), *BIRC5* (6 cases, 1.9%), *CCNE1* (3 cases, 0.9%), and *AURKA* (1 case, 0.3%). In addition to the frequent co-amplifications of genes closely located on the same chromosome region, such as 8p11, 8q24, 11q13, or 17q12-21, co-amplification of genes located in different chromosomes was also found. The co-amplification of *ZNF703/FGFR1* (8p11) and *CCND1* (11q13) in single cells was found in 11 tumors, occurring in the same amplicons in 5. The co-amplification of *ZNF703/FGFR1* and *ERBB2* (17q12-21) in single tumor nuclei but different amplicons was observed in 11 cases, and that of *CCND1* and *ERBB2* was noted in 5 cases. The co-amplification of *MYC* (8q24) with *CCND1* or *ERBB2* in single nuclei was found in three and two tumors, respectively. The amplifications of *ESR1* and *ERBB2* as well as *EGFR* and *ERBB2* were found in one tumor each, although in different cancer cells. Amplified genes are attractive potential targets for therapy, so a precise and feasible analysis of the gene amplification status is clinically valuable.

47. Spinless metal isotopes are able to suppress DNA Polymerase Beta in WERI/Y79 retinoblastoma cells: beyond the cytostatic effect

Kirill V. Ermakov, Alexander A. Bukhvostov, Anton S. Dvornikov, Dmitry A. Kuznetsov

Department of Medicinal NanoBioTechnologies, School of Medicine, N. I. Pirogov Russian National Research Medical University, Moscow 117997, Russian Federation.

Nuclear spin possessing isotopes (^{25}Mg , ^{43}Ca , ^{67}Zn) promote the marked magnetic isotope effects (MIE) on DNA Polymerase Beta (DNAPolB) in *ex vivo* survived human retinoblastoma (RB) cells. In *N*-ethyl-melamide chase experiment, the RB in situ catalytic activity of DNAPolB has been selectively estimated as a function of MIE. A resulted enzyme function breakdown leads to a sharp decrease of cancer cell viability. This study a paramagnetic chemotherapy path is all about.

Abstract

Autophagy is a conserved lysosomal-dependent catabolic process that maintains the cellular homeostasis by recycling misfolded proteins and damaged organelles. It involves a series of ordered events (initiation, nucleation, elongation, lysosomal fusion and degradation) that are tightly regulated/controlled by diverse cell signals and stress. It is like a double-edged sword that can play either a protective or destructive role in cancer, by pro-survival or apoptotic cues. Recently, modulating autophagy by pharmacological agents has become an attractive strategy to treat cancer. Currently, a number of small molecules that inhibit autophagy initiation (e.g., ULK kinase inhibitors), nucleation (e.g., Vps34 inhibitors), elongation (e.g., ATG4 inhibitors) and lysosome fusion (e.g., chloroquine, hydroxyl chloroquine, *etc.*) are reported in pre-clinical and clinical study. Also a number of small molecules reported to induce autophagy by targeting mammalian target of rapamycin (e.g., rapamycin analogs) or adenosine 5'-monophosphate-activated protein kinase (e.g., sulforaphane). The study results suggest that many potential "druggable" targets exist in the autophagy pathway that could be harnessed for developing new cancer therapeutics. In this review, we discuss the reported autophagy modulators (inhibitors and inducers), their molecular mode of action and their applications in cancer therapy.

Keywords: Autophagy, cancer, ATG, ULK inhibitor, Vps34 inhibitor, mammalian target of rapamycin inhibitors, lysosome fusion inhibitors

INTRODUCTION

Autophagy is a natural cellular process that occurs for the maintenance of cellular homeostasis. During autophagy, catabolic degradation occurs to recycle unnecessary, dysfunctional cellular components,

Table 1. Characteristics of three types of autophagy

Sl. No.	Type	Mechanism	Biological effects	Markers
1	Macroautophagy (commonly referred as autophagy)	Autophagosome formation	Cell killing and survival	Beclin1, Atg5, Atg12, LC3-I and LC3-II
2	Microautophagy	Vacuole invagination process	Cell killing and survival	Hsc70 multi-vesicular bodies and multi-vesicular lysosomes
3	Chaperon mediated autophagy	Receptor mediated process	Selective cell killing, T-cell activation	LAMP-2A, Hsc70

damaged organelles and protein aggregates^[1]. It also removes intrusive pathogens to protect our body from various infectious diseases and other disorders including cancer^[2,3]. The autophagic process occurs when the cells are in stress conditions such as starvation or hypoxia. Based on these cues, the cytoplasmic contents (cargo) get sequestered within the autophagosome and then fuse with lysosome for cargo degradation. Three forms of autophagy have been reported: (1) chaperon mediated autophagy; (2) microautophagy; and (3) macroautophagy^[4] [Table 1].

The type and mode of action differs from one another based on how and what target cargoes are subjected to lysosomal degradation. In chaperone mediated autophagy, the substrate with the targeting motif KFERQ is recognized by the chaperone Hsc70, and moves the individual protein substrate to lysosome degradation^[5]. While, microautophagy is responsible for basal degradation of the cytoplasmic content by the direct invagination into lysosome^[6]. On the other hand, macroautophagy, an ubiquitous pathway in eukaryotic cells, starts with the formation of double membrane structures called autophagosomes in which cargo sequestration occurs^[3]. The early autophagosome is formed from components derived from endoplasmic reticulum, which acquires V-ATPase and LAMP to become late autophagosome^[7,8]. Finally, the late autophagosome fuses with the pre-existing lysosomes to become the autolysosome^[9]. The autolysosome contains unrecognizable cytoplasmic materials as they are in degradation and recycling process^[10]. The multi-step process of macroautophagy (here onwards referred to as autophagy; Figure 1) is regulated by autophagy related genes, which were originally found in autophagy defective yeast mutants.

Autophagy is initiated through diverse signaling pathways in response to major stress response and plays a pro-survival role by nutrient recycling. The stress factors include low cellular energy levels, amino acid deprivation, growth factor withdrawal, hypoxia conditions, ER stress, oxidative stress, organelle damage and infection^[11]. Over a period of stress, the cells employ autophagy process either to move contents or to degrade harmful components such as damaged mitochondria or invading pathogens through the process of lysosomal degradation^[12]. Aberration in autophagy process has been implicated in a wide range of diseases including neurodegenerative disorders that involve the accumulation of pathogenic proteins, inflammatory disorders and cancer^[4,13]. The following sections discuss various signaling pathways involved in the autophagy process, their role in cancer and other diseases; also small molecule inhibitors that target the autophagy process that are useful for cancer therapy are detailed along with the mode of interaction with their targets, if known.

AUTOPHAGY PROCESS

Initiation step

Autophagy is a multi-step process involving, initiation, nucleation, elongation/expansion and closure steps^[14]. The initiation of phagophore formation is governed by multi-protein complex known as ULK complex (Unc-51-like kinase 1, FIP200, ATG101 and ATG13), that integrates upstream nutrient and energy status and thereby initiates the process of autophagy [Figure 2]. Each protein of the ULK complex has a unique role; ULK1, a serine-threonine protein kinase, plays a key role in the scaffold formation of ULK1-ATG13-FIP200 complex^[15]; ATG13, an adaptor protein mediates interaction between ULK1 and FIP200, and directly binds to LC3 as well. Another protein, ATG101 which is a subunit of ULK complex recruits downstream Atg proteins that are essential for autophagy^[16,17].

Figure 1. Cartoon representation of pathways involved in autophagy and the chemical inhibitors/inducers of the process. Autophagy involves 4 steps: (1) initiation; (2) nucleation; (3) expansion and closure; and (4) degradation and recycling. Small molecule modulators that affect different steps of autophagy are shown in red color (inhibitors) and green color (inducers)

Initiation step of autophagy process in normal nutrient conditions (e.g., sensed by the levels of growth factors, amino acids and glucose) is regulated by a negative autophagy regulator mammalian target of rapamycin (mTOR) that phosphorylates two subunits, ULK1 and Atg13 of ULK complex. The complex of mTOR that consists of mTORC1, Raptor and MLST8 as subunits directly binds ULK1 protein and thereby leads to ULK complex dissociation^[18]. Upon nutrient starvation, mTORC1 dissociates from ULK complex and hence ULK1 gets activated and phosphorylates ATG13, ATG101 and FIP200 in order to initiate the phagophore formation [Figure 3]. Investigations suggest that phosphorylation of ULK1 plays a vital role in the regulation of autophagy initiation process and at least 30 phosphorylation sites have been reported. However, the molecular basis and the molecules involved in ULK1 phosphorylation are yet to be completely unraveled^[18].

In contrast to mTORC1, adenosine 5'-monophosphate (AMP)-activated protein kinase (AMPK) indirectly activates ULK complex by phosphorylating TSC2 and raptor. Recently, AMPK has also been shown to directly interact with and phosphorylate ULK1 in a nutrient-dependent manner. Several phosphorylation sites, including Ser555, Ser637 and Ser757 were reported. AMPK phosphorylation site Ser555 is thought to recruit phospho-binding protein to the ULK complex^[19]. During glucose starvation, AMPK targeting phosphorylation sites on ULK1 are triggered and contributes to ULK1 activation [Figure 2]. AKT is a serine/threonine kinase that acts as a sensor of growth factor levels in the cell and is activated in nutrient rich condition. Upon activation, AKT phosphorylates Ser9 of GSK3, which acts as inhibitory cue for GSK3. Dephosphorylation of Ser9 activates GSK3 and eventually the activated GSK3 phosphorylates TIP60 at Ser86^[20]. Further, TIP60 acetylates ULK1 and thereby increases the kinase activity of ULK1 [Figure 2]. Finally, accumulation of activated ULK complex initiates the phagophore formation^[20].

Nucleation step

Phagophore formation starts with the nucleation step of autophagy process, where protein subunits including Vps34, Beclin1, Ambra1, ATG14 and p150 coordinate with each other and form a nucleation complex^[21].

Figure 2. Diagrammatic representation of various signals leading to the formation of autophagy initiation - ULK complex

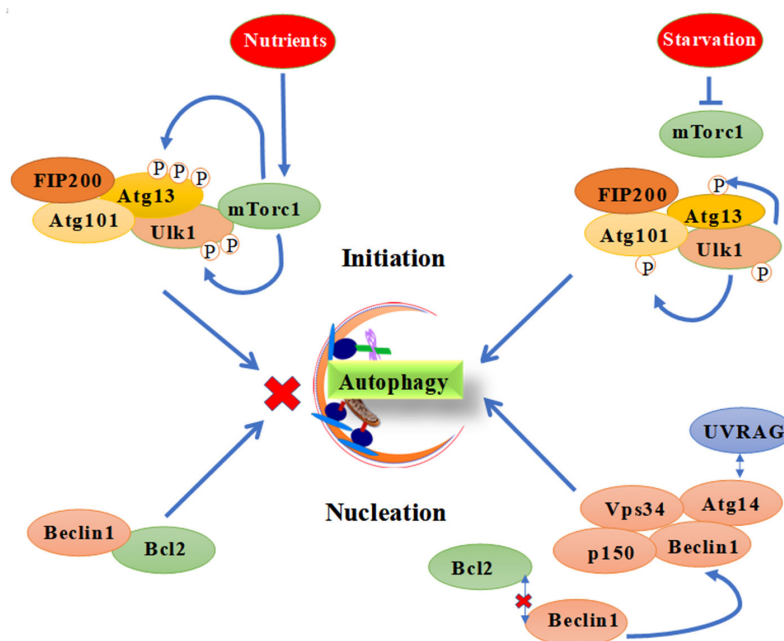

Figure 3. Schematic representation of molecules involved in the (1) initiation; and (2) nucleation process leading to the autophagosome formation during autophagy

During nucleation, vesicular sorting protein 34 and its enzymatic product phosphatidylinositol-3-phosphate, an essential component play a vital role in recruiting other autophagy protein subunits such as WIPI-1, DFCP1, ATG5 and LC3. The effectors WIPI-1, WIPI-2 and DFCP1, binds to PI3P via WD repeats and FYVE domains, respectively^[21,22]. In nucleation process, Vps34 associates with the phagophore membrane via p150 [Figure 3] that is anchored by myristic acid. Beclin-1 is the third important component for phospholipid kinase activity. Activity of Beclin-1 is affected by many different binding partners. Beclin1 dissociates from the anti-apoptotic factor Bcl2, which leads to the activation of Vps34. The association of beclin1 with Vps34 is stabilized by the other two components - UV radiation-associated resistance gene and beclin-1-associated autophagy related key regulator^[23].

Elongation step

In elongation step, the maturation of the autophagosome takes place with the help of two ubiquitin like conjugation system [Figure 4]. In the early step of autophagosome maturation, Atg12 is activated by Atg7

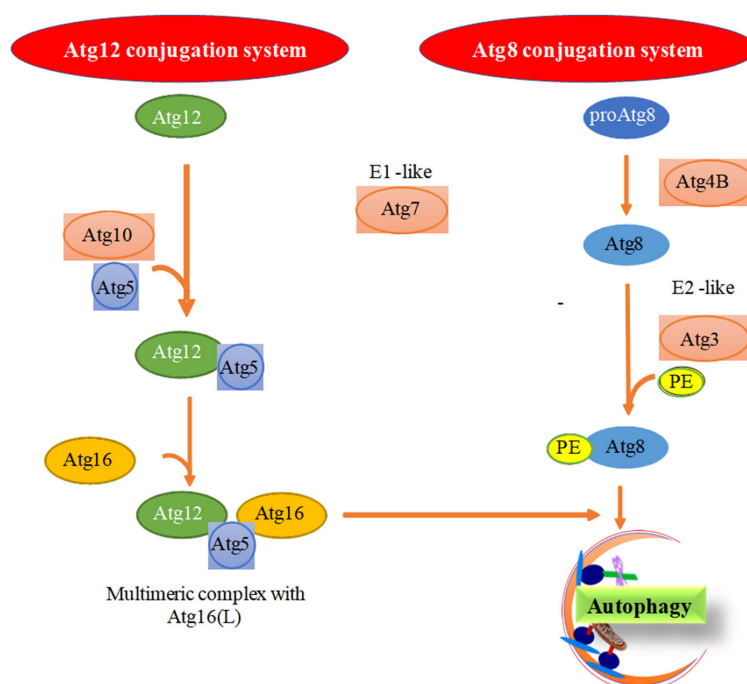

Figure 4. Two ubiquitin like conjugation system is involved in the autophagophore elongation/maturation process

and transferred to Atg10 thereby forming a covalent linkage with Atg5^[24]. This Atg12-Atg5 conjugate complexes with Atg16L and forms autophagy elongation complex. Carboxy terminal Gly residue of Atg12 is involved in the formation of thioester linkage with the active site Cys residue of Atg5 and Atg10, and also involved in amide linkage with Lys residue of Atg5^[25]. Elongation complex forms a dimer which provides a site for LC3 lipidation, a process required for association of LC3 with autophagosome membrane^[26]. Although, Atg12 does not possess similarity with ubiquitin, it forms an ubiquitin-like fold and is involved in autophagy elongation step. For the autophagosome maturation, LC3 lipidation is very essential and acts as a second ubiquitin-like conjugation. This conjugation occurs in a series of reactions including proLC3-I cleavage by Atg4B, LC3-I activation by Atg7, transfer to Atg3 and finally conjugation with PE. Like Atg12, carboxy terminal Gly of LC3 is involved in thioester linkage with Cys residues of Atg7 and Atg3, and an amide linkage with PE^[27]. These reactions are similar in LC3 homologues GABARAP, GATE-16 and mAtg8L. Completion of these maturation steps leads to autophagosome-lysosome fusion^[28] and then degradation of the cargo.

Fusion and degradation step

Degradation and recycling of cellular components is a central function of all living cells to meet cell demands. In final stage of autophagy, matured autophagosome fuses with multivesicular endosomes and lysosomes. Degradation of cytosolic components is not a random process and thus several proteins such as Vps34/SKD1 and Rab11 involvement is necessary to accomplish autophagosome-lysosome fusion process^[29]. A recent study has reported that components of HOPS complex (homotypic fusion and protein sorting) plays a major role in the formation of autophagosome-endosome fusion. Moreover, dysfunction or absence of subunits of the ESCRT III complex and proteins required for biogenesis of endosomes severely affects the fusion process^[30]. The fusion of inner membrane of autophagosome delivers the cytosolic proteins to lysosomes, where hydrolysis takes place to complete the degradation of the cargo.

ROLE OF AUTOPHAGY IN VARIOUS DISEASES

Dysregulation in the autophagy process results in various diseases. Defects or deregulation is especially important in cancer, ageing related disease, neurodegenerative diseases and lysosomal storage diseases^[2].

In aging process, the functional role of autophagy is expulsion of aggregated protein which increases the lifespan; in the case of defective autophagy process, the formation of vacuoles and improper fusion of vacuoles with the lysosomes results in impaired protein flux^[31]. In infectious disease, the functional role of autophagy is to remove the bacterial and viral pathogens through sequestration in autophagic vacuoles and then degradation. This provides immunity against pathogens^[32]; while a defective autophagy process provides a conducive environment for pathogens. In lysosomal storage disorders, the removal of lysosomal stock such as fatty acids, cholesterol are defective and an increased number of autophagosomes and reduced organelle turnover occur^[33]. In the case of neurodegeneration disorders, the neuronal protein aggregates are removed by autophagic process; while, in the defective process the protein aggregates accumulate in neurons leading to neurodegeneration^[34].

Role of autophagy in cancer

Autophagy is a complex process that responds to a variety of stressful environments such as nutrient deprivation, abnormal protein accumulation and damaged organelle, and thereby maintains the cellular homeostasis^[35]. Autophagy plays a cyto-protective role by clearing the damaged organelles, misfolded proteins and ROS, thus confining the genomic instability and aberrant mutations that ultimately leads to cancer. Consequently, autophagy machinery can be defined as cell survival mechanism in normal and as death mechanism in cancer cells.

However, deregulation of autophagy has been reported in a variety of diseases including cancer. Many reports have shown that autophagy plays dual role in cancer development. In early stage of cancer, autophagy suppresses/abolishes tumor formation by clearing the damaged proteins and organelles, and thereby induces cell death; whereas in advanced cancers, the stress mediated properties of autophagy has been hijacked by tumor cells to meet their increased metabolic requirements that are indispensable for tumor survival and rapid proliferation. Hence, autophagy has been reported as a tumor promoter in advanced cancers. Additionally, the regulation of autophagy through diverse signaling mechanisms can contribute upregulation/downregulation of tumor suppressor/oncogenes, and that can lead to inhibition/induction of cancer development^[36,37]. For example, negative regulation of tumor suppressor genes through different signaling mechanisms (i.e., mTOR, AMPK, *etc.*) could induce autophagy and suppression of cancer initiation; whereas, activation of oncogenes could lead to inhibition of autophagy and promotion of cancer development.

It has been widely reported that autophagy modulates cancer growth and development, and this depends on cancer type, stage, and genetic context. A basal level of autophagy is considered as a cancer suppressive mechanism in normal cells. However, abnormal levels of autophagy in stressful conditions (i.e., Hypoxia, ROS, *etc.*) lead to inhibition of break down of damaged organelles and proteins, and subsequent cancer development. Nonetheless, it has been reported that mutation in autophagy related proteins leads to tumor suppression/promotion in a variety of cancers. For example, BECN1 related proteins (e.g., BIF-1 *etc.*) have been found abnormal/absent in gastric and colorectal cancer^[38,39]. Further, mutation in UVRAG protein reported to reduce autophagy, and consequent colorectal cancer development^[40]. On the other hand, an unexpected high basal-level of autophagy has been reported in several types of RAS-activated cancers (e.g., pancreatic cancers) and inhibition of autophagy in these cancers hinders the tumor formation^[41].

In order to identify alterations of different genes that are involved in autophagy signaling pathways, we have analyzed 1,087 cancer patient samples data from Cbioportal database (<http://www.cbioportal.org/>). Through this data analysis, we have noticed that mTOR gene shows high alterations with 12% (altered/profiled ratio = 128/1,087) and PIK3C3 shows 9% (altered/profiled ratio = 97/1,087) alterations. Further we also observed the alterations of other genes including ULK1 (5%), UVRAG (5%), beclin1 (2.7%), ATG4B (4%), ATG16L1 (2.1%), ATG5 (4%) and ATG12 (2.8%). Altogether, these studies explain that cell transformation and deregulation of many signaling pathways are connected directly or indirectly with autophagy modulation. These evidences,

suggest that autophagy has a dual role in cancer and is dependent on biological factors such as the driving oncogene, tumor suppressor involved and tumor type. Hence, autophagy is considered as a double-edged sword, by both protecting from and promoting cancer^[42,43].

Autophagy acts as a tumor suppressor during tumorigenesis

Autophagy is widely documented as a tumor suppressive mechanism, as its deregulation leads to genomic instability, aberrant mutations, tumor formation and metastasis^[44]. Primarily, the role of beclin1 in autophagy has been studied extensively. For example, mice having monoallelic deletion of beclin1 gene induce tumor formation. As is evident, the allelic loss of beclin1 was found in 40%-75% in breast, ovarian, and prostate cancers^[44,45]. It is well documented that Beclin-1 promotes autophagy by binding to Vps34 via its conserved domain that was reported essential for tumor suppression. Recently, phosphorylation of multiple tyrosine residues of beclin1 has also been observed, which leads to a decrease in the activity of beclin1/PI3KC3 complex and thereby the reduction of autophagy^[46].

The reduction of beclin1 protein levels is also reported in many brain cancers. A study conducted to investigate beclin1 mRNA expression in different histotypes of brain tumors reported the expression levels vary based on the type of tumor. After examining mRNA expression in 212 primary brain tumors, the study identified low expression in most high-grade ependymal neoplasms, astrocytic and atypical meningiomas; whereas, high expression in low-grade tumors and medulloblastomas^[47]. Additionally, monoallelic deletion/mutations in UVRAG protein and decreased expression levels of Bif-1 were also reported in colon, gastric, breast, prostate and bladder cancers^[38]. The reported results clearly indicate that autophagy related protein Beclin-1 and its regulators (i.e., UVRAG and Bif-1) mediate tumor suppression.

Further, deregulation of several proteins of PI3K/Akt pathway were also reported to impair autophagy mechanism and can lead to tumorigenesis. For example, phosphatase and tensin homolog protein was reported to inhibit Akt survival pathway, and thereby induces autophagy mechanism. However, a mutation in PTEN gene leads to constitutive activation of Akt and inhibition of autophagy, leading to cancer formation^[44,48]. Furthermore, the accumulations of p62 aggregates were reported to cause several cancers owing to impaired autophagy mechanism. Another study by Kang *et.al.*^[49], identified the frameshift mutations with mononucleotide repeats in ATG genes in gastric and colorectal carcinomas. Further, this study suggested that these mutations are associated with cancer progression by autophagy deregulation. The study investigated the expression of BNIP3 (Bcl-2/adenovirus E1B 19 kDa-interacting protein), a key regulator of mitochondrial autophagy in breast cancer and reported that BNIP3 expression is significantly lost in invasive breast cancers and suggested that breast cancers cells shows high proliferation with low BNIP3 expression. Thus, collectively these evidences suggest that autophagy plays essential role in tumor suppression and conversely its deregulation leads to cancer.

Autophagy acts as a cell survival mechanism in cancer cells

Genome-wide screening studies show that many genes are involved in the regulation of autophagy either through suppression or enhancement of autophagy^[50]. High throughput analyses also contribute to the understanding of autophagy regulation at protein level and in terms of protein-protein interactions. Further, research in yeast and animals suggests that stress-induced autophagy under nutrient-limiting condition promotes cell survival by influencing the bioenergetics of the cell. A study conducted in human prostate cancer cells PC3 and LNCaP, and breast cancer cells MCF7 shows that autophagy acts as a survival mechanism in hypoxic tumor cells. Hypoxia inducible factor1, a positive regulator of autophagy enhances tumor metabolism and metastasis^[51], and thereby limits the radiation and chemotherapy. Hypoxia inducible factor1 is involved in the induction of BNIP3 and BNIP3L which disrupts beclin1-bcl2 complex, and releases beclin1 to induce autophagy. Further, BNIP3 induced autophagy acts as an adaptive survival mechanism in hypoxia tumors^[52]. *In vitro* and *in vivo* studies also reported that autophagy acts as survival mechanism in squamous cell carcinoma by protecting endoG-mediated apoptosis^[3].

Figure 5. Mammalian target of rapamycin (mTOR) inhibitors

Additionally, it has been reported that RAS-activating mutations induce high basal-level of autophagy, and consequently assist in the development of lung, colon, and pancreatic cancers; hence inhibition of autophagy in these cancers hinders the tumor growth^[44,48,53]. Genetic studies carried on mice also disclosed that deletion of autophagic gene FIP200 inhibits the cell growth in mammary tumors^[41]. Moreover, mutations in BRAF protein reported to induce high levels of autophagy in CNS tumor^[53], melanoma^[54] and thyroid cancers^[45]; while, inhibition BRAF lead to impaired autophagy and decreased cell proliferation and cancer growth. All together, these studies suggest that inhibition of autophagy could be an appropriate strategy for the treatment of cancer and targeting the autophagy pathway with small molecules would be fruitful.

AUTOPHAGY MODULATORS FOR CANCER THERAPY

mTOR inhibitors

The mTOR, a member of PI3K family, is critical for serving as a primary regulator of cell growth, proliferation, metabolism and survival^[55]. The catalytic subunit of both mTOR1 and mTOR2 complex is involved in many oncogenic signaling pathways. The hyperactive characteristic of mTOR in many human cancers led to target this protein kinase as therapeutic target. Therefore, inhibiting mTOR has gained much attention in anti-cancer therapy. Rapamycin [Figure 5] with two binding moieties is the first generation inhibitor of mTOR. In order to form ternary complex, one binding moiety of rapamycin binds with FKBP12 and the other binds with mTOR^[56]. Initially, rapamycin was recognized as immunosuppressant which blocks T-cell activation and later on the anti-cancer activity was documented. Several rapalogs were generated by replacing C-40-O with different moieties and among them Temsirolimus is the first to get FDA approval for cancer treatment^[57]. Recent studies have shown that rapamycin can also act as a cytostatic agent, slowing or arresting the growth of various cancer cell lines.

Pan-PI3K inhibitors

PI3K is an essential subunit of PI3K-AKT-mTOR pathway involved in cell proliferation and survival; it is a well known protein kinase for the induction of autophagy. In several cancers including diffuse intrinsic pontine glioma, glioblastoma, paediatric high-grade glioma, breast cancer and cutaneous melanoma, over activation of this pathway has been observed and hence inhibition of PI3K has become an important target in several cancers^[58]. PI3K inhibitors including 3-methyladenine (3-MA) and wortmannin [Figure 6] are well characterized as autophagy inhibitors based on their inhibitory effect on the autophagy induction. Besides inhibiting PI3K with an IC₅₀ of 60 µmol/L, 3-MA has also been reported as inhibitor of Vps34 with an IC₅₀ 25 µmol/L. Cell culture studies revealed that 3-MA suppresses cell migration and leads to cancer cell death

Figure 6. Pan-PI3K inhibitors

under normal as well as starvation conditions^[56]. Surprisingly, prolonged treatment (upto 9h) with 3-MA has shown autophagy flux promotion by increasing the autophagic markers levels such as LC3 protein^[59].

Wortmannin, a fungal metabolite is a selective, irreversible and potent inhibitor of PI3K that inhibits autophagic sequestration. It has been demonstrated that the lower concentration (nanomolar) of wortmannin potently and specifically inhibits PI3K; whereas, higher concentrations can inhibit the ataxia telangiectasia gene-related DNA-dependent protein kinase. At physiological pH (6-8.5), wortmannin compete with ATP and ATP analogs binds to PI3K, this suggests that wortmannin binds in the substrate binding site of PI3K. More importantly, site directed mutagenesis studies shows that Lys802 is essential to form nucleophilic interaction^[60]. These observations of wortmannin interactions with PI3K provide the molecular basis for designing better inhibitors for PI3K kinase family proteins to treat cancer via autophagy inhibition.

Ly294002, an inhibitor of PI3K class family proteins is derived from the flavonoid quercetin. Ly294002 is not completely selective for PI3K family proteins, and additionally act on other unrelated proteins and lipid kinases^[61]. Ly294002 binds at the ATP binding site and is more stable in solution than wortmannin. More importantly, this compound shows its inhibitory effect with IC_{50} values of 0.5, 0.97 and 0.7 $\mu\text{mol/L}$ for PI3K α , β and δ targets, respectively^[61,62]. To improve the selectivity and specificity, many Ly294002 analog were synthesized; SF1126 a prodrug of Ly294002 entered into clinical trial but was recently halted.

CLR457, a potential inhibitor of all PI3K isoforms is an orally bioavailable inhibitor with antineoplastic activity. It has been extensively characterized by *in vitro* biochemical methods and *in vivo* tumor xenograft studies^[63]. Dose limiting toxicity studies show that CLR457 potently inhibited PI3K isoforms including p110 α (IC_{50} = 89 nmol/L), p110 β (IC_{50} = 56 nmol/L), p110 δ (IC_{50} = 39 nmol/L) and p110 γ (IC_{50} = 230 nmol/L). However, the characteristics such as poor tolerability and limited antitumor activity of CLR457 resulted in the termination of clinical development.

Recently, omipalisib (GSK2126458) is presented as an autophagy inhibitor that specifically binds to PI3K in PI3K/mTOR signaling pathway. It directly targets Akt phosphorylation by PI3K and reverse phosphorylation of Akt by mTOR. It is an orally bioavailable dual ATP-competitive inhibitor of PI3K and mTOR with high potency^[64]. The indirect inhibition of Akt by omipalisib induces cytotoxicity and promotes autophagic cell death at 0.5 $\mu\text{mol/L}$ dose. Further, investigations carried out to know whether the mechanism of cell death occurs through autophagy or apoptosis reported that there is no significant difference in treated and untreated cells when apoptosis markers were used^[65]. Cell culture studies reported that GSK2126458 arrests cell cycle at G1 phase and affects proliferation of several cell lines such as breast cancer cell lines T47D and BT474 with IC_{50} values of 3 and 2.4 nmol/L, respectively. Currently, omipalisib is in clinical trials for idiopathic pulmonary fibrosis and solid tumors. The difficulties in PI3K inhibitors such as lower solubility of wortmannin and broad spectrum inhibition of Ly294002 and limited antitumor activity of CLR457, further necessitate the identification of new inhibitors for PI3K.

Figure 7. Pan-mTORC inhibitors

Pan-mTORC inhibitors

Activation of mTORC1 and mTORC2 is important in many cancers. Compounds with ATP competitive mechanism inhibiting both mTORC1 and mTORC2 offer better alternative to rapalogs. Torin 1 [Figure 7], is a commercially available autophagy inhibitor that is selective and highly potent ATP-competitive inhibitor of both mTORC1 and mTORC2. Torin 1 shows more efficacy towards blocking the phosphorylation of mTORC1 and mTORC2, when compared with rapamycin a well-known classical mTOR allosteric inhibitor. *In vitro* kinase assay reveals that Torin 1 has an IC_{50} of 3 nmol/L, 3 μ mol/L, 1.8 μ mol/L and 1 μ mol/L for mTOR, hVps34, PI3K- α and DNA-PK, respectively. The results show that Torin 1 is more selective for mTOR inhibition over other kinases^[60]. Second generation ATP-competitive inhibitor, Torin 2 is a potent and selective inhibitor of mTOR with better pharmacokinetics profile to overcome the limitations of Torin 1. *In vitro* studies revealed that Torin 2 reduced cell proliferation in several cancer cell lines and exhibited combinatorial response with AZD6244, an inhibitor of MEK kinase in the molar ratio of 1:50. Torin 2 shows inhibition of several PI3KK family proteins including mTOR, ATM, ATR and DNA-PKs with an IC_{50} value of less than 10 nmol/L^[66]; whereas, Torin 1 inhibits only mTOR, ATR and DNA-PK. Further, effects of Torin 2 in autophagosome formation were examined and found to induce autophagy^[66].

AZD8055 is another novel ATP-competitive inhibitor of mTOR kinase (IC_{50} of 0.8 nmol/L) that shows approximately 1000-fold selectivity against other kinases^[67]. Remarkably, in xenografts studies, AZD8055 shows substantial growth inhibition and suggests that AZD8055 can be a potent therapeutic drug in many human cancer treatments^[67]. AZD8055 treated acute myeloid leukemia cells have shown significant decrease in cell cycle progression and cell proliferation in blast phase. More interestingly, AZD8055 treatment results in decreased growth of leukemic progenitors but not normal immature CD34+ cells^[68]. Another independent study also revealed that AZD8055 treated chronic lymphoid leukemia (CLL) cells show significant reduction in CLL cell proliferation and increase in apoptosis. Currently, this inhibitor is in phase 1 clinical trials.

WYE-354, another heterocyclic compound is a powerful dual ATP-competitive kinase inhibitor that selectively blocks mTORC1/2 activity with an IC_{50} value of 4.3 nmol/L. Although it displays a weak inhibition of PI3K α , it has no inhibitory effect on other proteins/kinases. *In vitro* analysis revealed that WYE-354 potently blocks several cancer cell proliferation including LNCap, A498, MDA-MB-231, MDA-MB-361, MDA-MB-468 and HCT116 cell lines. Mechanistically, WYE-354 arrests cell cycle at G1 phase and induces

Figure 8. Dual PI3K/mTOR inhibitors

apoptosis by activation of caspase cascade. Autophagy inhibition by shRNA and autophagy inhibitors such as bafilomycin A1 and 3-MA, notably sensitized WYE-354 mediated anti-colon cancer cell activity. *In vivo* studies, further witnessed that WYE-354 administration in severe combined immunodeficient mice inhibited growth of xenografts^[69]. PP30 is an adenine-mimetic pyrazolopyrimidine scaffold compound that selectively inhibits mTORC1 (IC_{50} = 8 nmol/L) and mTORC2 (IC_{50} = 80 nmol/L).

PI3K/mTOR inhibitors

mTOR shares high sequence homology with the hinge region of PI3K, as they belong to the same family of phosphatidylinositol 3-kinase. Hence, several small molecules target both mTOR and PI3K simultaneously. PI-103 [Figure 8] belongs to pyridofuroprymidine class of compounds and is a multi-target inhibitor that inhibits PI3K and mTOR. Studies using human leukemia cell lines including MV4-11, OCI-AML3 and MOLM14 clearly indicated that PI-103 treatment arrested the cell cycle at G1 phase and eventually reduced the cell proliferation in these cells. The effects of PI-103 in AML patient samples have shown that 82% reduction of AML progenitor clonogenicity. The significant increase in apoptosis is also observed in blast cells when treated with 1.0 μ mol/L of PI-103. On the other hand, PI3K/Akt and mTOR inhibition has also been shown when the AML blast cells treated with RAD001 and IC87114 (RAD + IC); but the mechanism of antiproliferative effect is yet to be elucidated. At the same time, this study also reported that inhibitory effect of PI-103 is not much higher than that of RAD + IC in AML blast cells^[70].

PKI-587, a dual ATP competitive inhibitor of known therapeutic targets PI3K (PI3K- α and PI3K- γ) and mTOR is an orally bioavailable inhibitor^[56]. It shows potent inhibitory efficacies of PI3K- α , PI3K- γ and mTOR with IC_{50} values of 0.4, 5.4 and 1.6 nmol/L, respectively. PKI-587 not only inhibits wild type PI3K, but also exhibits inhibitory activity against most commonly occurring mutants including H1047R and E545K of PI3K with an IC_{50} value of 0.6 nmol/L for both forms. In *in vitro*, PKI-587 has exhibited excellent antitumor activity in over 50 human cancer cell lines^[71]. In *in vivo*, PKI-587 showed inhibition of tumor growth in MDA-MB-261, BT474, HCT116, H1975 and U87MG xenograft models, when administrated intravenously.

A novel inhibitor apitolisib, also known as RG7422/GDC-0980 is an orally available dual PI3K and mTOR inhibitor with excellent pharmaceutical and pharmacokinetics properties. The GDC-0980 inhibition of PI3K and mTOR overexpression has shown significant reduction in tumor cell growth by inducing apoptosis. In

cell free assays, GDC-0980 treatment results in the inhibition of class 1 PI3K isoforms α , β , δ and γ at low nanomolar IC_{50} values of 5, 27, 7 and 14 nmol/L, respectively and mTOR inhibition with K_i value of 17 nmol/L. These preclinical data show high potency and selectivity of GDC-0980 inhibitory activity. However, GDC-0980 has less effectiveness than everolimus in metastatic renal cell carcinoma^[72].

NVP-BGT226, a potent orally bioavailable dual inhibitor of PI3K and mTOR signaling pathways, blocks cell cycle at G0/G1 phase and induces autophagy and apoptosis. It is shown that NVP-BGT226 suppresses the growth of primary myeloma and common myeloma cell lines at nanomolar concentrations. Specifically, NVP-BGT226 inhibits PI3K α , β and γ isoforms with IC_{50} values of 4, 63 and 38 nmol/L, respectively. The analysis of NVP-BGT226 effects in hepatocellular carcinoma (HCC) shows cell growth and proliferation inhibition with potent cytotoxic activity. Hence, the capabilities of NVP-BGT226 in targeting PI3K and mTOR may represent it as an anticancer agent in HCC^[73]. NVP-BEZ235, an imidazo[4,5-c]quinoline derivative, is a dual kinase inhibitor of PI3K and mTOR that binds to the ATP binding site and halts cell cycle at G1 phase. When the compound is given orally to animal models, it displayed disease stasis of human cancers^[74]. Although co-crystallization studies of this compound with targets are ongoing, docking studies revealed that NVP-BEZ235 forms H-bond with ATP binding cleft residues including Val851, Asp933, and Ser774 of PI3K α homology model. This compound has entered phase I clinical trials for the treatment of breast cancer, advanced solid tumors and Cowden syndrome.

Unc-51-like kinases inhibitors

ULK belong to serine/threonine kinase family proteins, and play a crucial role in autophagy regulation^[34]. Humans contain four ULK kinases including ULK1, ULK2, ULK3 and ULK4. Among them, ULK1 is well studied and it is utmost important for autophagy initiation. Under nutrient deprivation, ULK1 is activated by several up-stream signals (e.g., AMPK, *etc.*) and then initiates autophagy process by recruiting various other proteins (i.e., FIP200, ATG101 and ATG13 for ULK complex) to the on-site of autophagy initiation. Thus, ULK1 and its associated proteins (i.e., ULK complex) play essential roles in cell survival mechanism under nutrient deficiency^[75]. However, disruption of ULK1 and its associated protein complex lead to autophagy inhibition and cell death. As cancer cells generate energy and nutrients through autophagy mechanism and eventually help in cell survival and tumor progression, disruption of ULK1 function by developing small molecule inhibitors has become an attractive approach to treat cancer^[75,76]. As a proof of concept, few ULK1 inhibitors have been reported in the literature [Figure 9].

MRT67307 and MRT68921 are two closely related derivatives with different substitution pattern on the pyrimidine ring. MRT67307 inhibits ULK1 and ULK2 with an IC_{50} of 45 and 38 nmol/L, respectively. This compound led to the identification of MRT68921, that has 15-fold improved inhibition of ULK1 (IC_{50} = 2.9 nmol/L) and 30-fold improved inhibition of ULK2 (IC_{50} = 1.1 nmol/L), when compared with MRT67307. Studies using MRT67307 and MRT68921 in MEFs cells show that these compounds are able to block autophagic flux. In addition, MRT68921 treated cells show significant increase in SQSTM1 level and decrease in LC3-2/LC3-1 ratio. These results suggested that MRT68921 treatment efficiently inhibits ULK-mediated autophagy^[77]. However, the molecular basis of this block remains to be elucidated. SBI-0206965 is a potent and specific inhibitor of ULK1 with an IC_{50} of 108 nmol/L and also selectively inhibits ULK2 with IC_{50} of 711 nmol/L, but with less efficacy when compared with ULK1. Inhibition of ULK1 in NSCLC cells results in anti-proliferative effect^[51]. Specifically, SBI-0206965 suppresses phosphorylation events in cells that are mediated by ULK1. SBI-0206965 at 10 μ mol/L concentration shows high selectivity and inhibits only 10 out of 456 kinases.

In 2015, Lazarus *et al.*^[75] reported the first crystal structure of ULK1 in complex with multiple inhibitors. The structure consists of an N-terminal kinase domain, a serine-proline rich region, and a C-terminal interacting domain. They used a standard 32 P-ATP radioactive assay to screen a collection of 746 compounds against ULK1 that led to the identification of several pyrazole aminoquinazolines as ULK1 inhibitors. For example,

Figure 9. ULK1 inhibitors

the identified compound 2a showed dose dependent inhibition with IC_{50} of 160 nmol/L when re-tested in *in vitro* assay. Further, co-crystallization of this compound with ULK1 demonstrated that compound 2a [Figure 10] bound in the ATP binding site by making hinge region interaction with its amino pyrazole core group. Moreover, they observed that the aniline moiety made contacts with Asp165 of DFG motif, and the cyclopropyl substituent moiety fitted into the pocket close to the gate keeper residue methionine. Quinazoline ring interacts through position 6 and 7 with the backbone of kinase. In conformity with this steric obstruction, no compounds with substituents at these positions showed activity against ULK1.

Further, modifications made to these series of compounds led to the identification of compound 2b with improved potency with an IC_{50} of 8 nmol/L^[56]. However, the co-crystallization of this compound in similar condition (as of compound 2a) with ULK1 produced different space groups that indicate compound 2b produced conformational changes in the kinase domain, which led to the improved activity. Detailed analysis revealed that there were major changes in the conformation of interlobe loop, the side chain of Asp165 (DFG loop residue) and methionine of gatekeeper residue^[75]. Testing of compound 2b against a small panel of kinases showed non-selectivity, suggesting the need for improving the selectivity and potency against ULK1.

Vacuolar protein sorting 34 inhibitors

Vps34 is a lipid kinase that belongs to subgroup of class III PI3K family protein. The major function of this family protein is to phosphorylate the 3-hydroxyl group of inositol ring of phosphatidylinositol (PtdIns) lipid substrates to generate PtdIns3P^[22,79,80]. Vps43 interacts with multiple protein subunits and forms Vps34 complex I (i.e., Vps34, Vps15, Beclin 1, and Atg14L) that precisely catalyzes the phosphorylation of PtdIns to PtdIns3P and anchors with intracellular membranes. Further, the membrane-bound PtdIns3P interacts with proteins that contains FYVE, PX, or WD40 domain and involves in vesicle trafficking and autophagy mechanism. Thus, Vps34 complex is essential for initiation/induction of autophagy during nutrient deprivation through regulation of mTOR pathway. Therefore, the disruption of Vps34 complex leads to autophagy inhibition and cancer cell death. Hence, Vps34 has become an attractive drug target for cancer therapy and a number of inhibitors have been reported in the literature, and few compounds have entered into clinical studies.

Recently, Dowdle *et al.*^[81], identified a hit containing bisaminopyrimidine core as a potent and selective Vps34 kinase inhibitor using high-throughput screening of compound libraries. Optimization of this

Figure 10. A: Superimposition of the binding mode of compound 2a (PDB ID: 4WNO) and compound 2b (PDB ID: 4WNP) in ULK1; B: binding mode of compound 2c (PDB ID: 5CI7) in ULK1. Hydrogen bond interactions are represented in black dotted lines. Compound 2c with a diaminopropyl group, a closely related pyrimidine analog of MRT67307, showed dose dependent inhibition with an IC₅₀ of 120 nmol/L. Co-crystallization of compound 2c with ULK1 [Figure 10B] showed that it has similar orientation with the diaminopropyl group occupying a similar space as that of quinazoline of compound 2a. The main difference in the kinase is the movement in the β sheet in the N-terminal lobe with Gly23 towards the inhibitor, which allows Ile22 to twist away from the bulky diaminopropyl substituent on the pyrimidine. The other difference is the gatekeeper methionine moves towards iodine group, to adopt a suitable dipole-dipole interaction. A flexible region involving Ile22 was required to pack above the aminopropyl group^[78]

compound led to the identification of 4-aminopyridine-containing PIK-III inhibitor [Figure 11] with improved potency and selectivity^[81]. Additional biochemical testing and profiling of this compound showed that PIK-III is at least 100-fold selective for Vps34 as compared to related kinases including PI3K α , mTOR, and additional 44 protein kinases. Moreover, they also demonstrated that PIK-III inhibited the co-localization and distribution of PtdIns3P specific lipid binding domain (FYVE) fused with GFP with an IC₅₀ of 55 nmol/L concentration and that is > 10,000 times more potent than the non-selective Vps34 inhibitor 3-MA.

Co-crystallization of PIK-III with human Vps34 kinase [Figure 12A] revealed that the overall structural geometry was comparable to that of PI3K γ and *Drosophila melanogaster* Vps34 structures^[81]. Further, analysis revealed that the structure appears like a typical lipid and protein kinase structure that has a relatively narrow active site with hydrophobic pocket appropriate for binding co-planar aromatic compounds. Binding mode of PIK-III to Vps34 structure demonstrated that the cyclopropyl group occupied the hydrophobic pocket that was formed with side chains of Phe612, Pro618 and Phe684. Two hydrogen bond interactions were observed between PIK-III acceptor/donor and backbone amide & carbonyl oxygen of Ile685. In addition, solvent mediated hydrogen bond network bridges were observed between aminopyrimidine moiety of PIK-III and side chains of Asp671 and Asp644. Superimposition of Vps34 and PI3K α active site revealed that in both the structures the hydrophobic cavity was enclosed/covered with P-loop residues, however their relative orientations were quite different with respect to their hinge regions. In Vps34 it is relatively displaced towards hinge region, whereas in PI3K α structure it is wider and proximal to hinge region. In Vps34 structure, the relative orientation of Phe612 has significant role as it allows cyclopropyl group to fit into the hydrophobic pocket to acquire optimal interaction with hinge region. Whereas, in PI3K α structure the corresponding phenylalanine was replaced with methionine residue and it doesn't allow the cyclopropyl group to fit into the pocket. Thus, this structural difference makes an ideal tool for developing selective inhibitors of Vps34 and also to explicitly measure pharmacological consequences of VPS34 inhibition *in vivo*.

Further, docking and structure-activity relationship (SAR) study led to the identification of compound 3a with greater potency and improved metabolic stability providing an excellent candidate for *in vivo* pharmacokinetics evaluation^[80]. Compound 3a showed exceptionally selective activity over other lipid and protein kinases (> 100-fold against more than 280 kinases evaluated, except TAK1 and PI3K δ). Co-crystallization of compound 3a with Vps34 [Figure 12] revealed that its binding mode is similar to that

**Figure 11.** Vps34 inhibitors

of PIK-III. Moreover, compound 3a prevented the degradation of various autophagy substrates (p62, NCOA4, NBR1, NDPS2 and FTH1) as that of PIK-III. Pharmacokinetics profile of compound 3a revealed that it is rapidly absorbed and showed moderate mean systemic clearance (30 mL/min/kg) with good oral bioavailability ($F\% = 47$). Oral administration of compound 3a to RKO colon cancer bearing mice at 50 mg/kg twice a day for 7 days showed time-dependent accumulation of LC3-II with reduced autophagy capacity without reduction of tumor volume. Hence, additional studies with long term drug administration need to be evaluated.

Pasquier *et al.*^[82], reported a series of tetrahydropyrimidopyrimidinone derivatives [Figure 11] as Vps34 inhibitors using a cell based high-throughput phenotype screening campaigning. The reported compounds comprise/contain a pyrimidinone moiety with a morpholine group as hinge binder and shown to have Vps43 inhibition in kinase profiling assay panel. However, these compounds also showed cross-reactivity with class I PIKs (isoforms α , β , δ , and γ) and at a lower concentration level, with mTOR. Further, evaluation of these compounds activity against Vps34 using GFP-FYVE cell based assay revealed that compound 3b shows higher cellular potency compared to other compounds^[82]. Hence, compound 3b was selected as advanced hit for back screening. Additional screening of tetrahydropyrimidopyrimidinone derivatives and SAR studies focused on potency and selectivity over lipid kinases. Substitution at 1-position of the pyrimidinone scaffold led to the identification of compounds 3c, 3d and 3e [Figure 11] with enhanced Vps34 enzymatic potency, substantial GFP-FYVE cellular potency, attractive ligand efficiency (LE) and ligand lipophilicity efficiency (LLE) values. Moreover, these compounds also showed favorable *in vitro* ADME properties and sensible microsomal stability.

X-ray co-crystal structure of compound 3c [Figure 12C], 3d and 3e with human Vps34 demonstrated that all the compounds adapted a DFG-in conformation and were involved in hinge region interaction via oxygen atom of the morpholine ring. Moreover, this moiety was also involved in making promising vander Waals interactions with adjacent residues. The aromatic ring of pyrimidinone moiety was stacked in between Ile634 and Ile760 side chains, whereas carbonyl function of this moiety was involved in making hydrogen bond interaction with catalytic Ly636 side chain, and water mediated H-bond interactions with Asp644 and Tyr670 side chains. The (2S)-trifluoromethyl group of tetrahydropyrimidine ring was pointed towards the hydrophobic pocket under the P-loop residues Phe612 to Ala619. Compounds 3c-e show difference only at their N-substituent that points towards the exit of the ATP binding site. Further, modification of hinge binder moiety led to improved selectivity, and replacing the trifluoromethyl moiety on

Figure 12. 3D binding mode and interaction of PIK-III (PDB ID: 4PH4) (A), compound 3a (PDB ID: 5ENN) (B), compound 3c (PDB ID: 4UWF) (C) and compound 3f (PDB ID: 4UWL) (D) with Vps34. Hydrogen and water mediated hydrogen bonds are represented in black dotted lines

tetrahydropyrimidinone ring gained Vps34 potency and lost selectivity against other lipid kinases. From the final step of optimization, compound 3f was selected as Vps34 inhibitor for *in vivo* pharmacological study.

In vitro studies revealed that compound 3f displayed IC_{50} values of 2 and 82 nmol/L on Vps34 enzymatic assay and GFP-FYVE cellular assay, respectively. Biophysical characterization using surface plasmon resonance and isothermal titration calorimetry demonstrated that the compound 3f has a binding affinity (K_D) of 2.59 and 2.7 nmol/L, respectively. Moreover, compound 3f showed good physiochemical/drug-like properties (such as LE = 0.41, and LLE = 6.22). Further, co-crystallization of compound 3f with Vps34 [Figure 12D] revealed that methyl group of morpholine moiety points towards Met682. Like compound 3e, water mediated hydrogen bonds were observed between carbonyl oxygen atom and Asp761 of Vps43. Thus, this binding orientation provided enhanced Vps34 selectivity and potency. *In vivo* pharmacokinetics (PK) profiles of compound 3f disclosed a good oral bioavailability (F% = 85) with maximal plasma concentration observed at 0.5 h and reasonable systemic clearance. Moreover, PK/PD experiments using GFP-FYVE H1299 tumors xenografted in SCID mice revealed that compound 3f had sustainable inhibition (> 80%) of granular staining, and a dose dependent target modulation.

Lysomotrophic agents

Chloroquine [Figure 13], a widely used inhibitor of autophagy which inhibits last stage of autophagy is initially discovered to treat malaria and inflammatory diseases. Although, the mode of action of bafilomycin A1 and lysosomal protease inhibitors were well characterized, mode of action of chloroquine still remains unclear. However, it is believed that chloroquine inhibits autophagic flux through rising pH and thereby inactivates lysosomal hydrolases^[83]. Currently, chloroquine (CQ) and hydroxychloroquine (HCQ) are being investigated as autophagy modulator in Phase II/III trials for cancer therapy^[84]. Recent *in vitro* and *in vivo* studies revealed that chloroquine affects the endo-lysosomal system and golgi complex thereby modulates autophagic flux through decreasing autophagosome-lysosome fusion^[85]. This study invalidated lysosomal degradation function of chloroquine.

Figure 13. Lysomotrophic inhibitors

HCQ, a derivative of CQ is a 4-aminoquinoline that has antimalarial and anti-inflammatory activities; it is currently being investigated as the inhibitor for autophagy. Several clinical trials of HCQ in combination with other anti-cancer drugs (e.g., temozolomide, bortezomib, temsirolimus, vorinostat, doxorubicin, *etc.*) showed partial response and stable disease outcome for various cancers (melanoma, colorectal cancer, myeloma and renal cell carcinoma)^[86]. As a drug, this basic compound alkalinizes acidic environment of lysosomes and thereby prevents autophagosome-lysosome fusion. HCQ is proved to be threefold less toxic than CQ and can augment the cytotoxicity of a number of chemotherapies and targeted therapies. A recent meta-analysis of clinical trials of CQ and HCQ concluded that their use in cancer patients has better treatment response, when used in combination with existing anti-cancer therapy^[87].

Based on the 4-aminoquinoline core structure of CQ and HCQ, Lys05 was designed; it was more potent in *in vitro* and *in vivo* as a single agent. The increased activity of Lys05 was due to the bivalent aminoquinoline rings, C7-chlorine and a short triamine linker. Lys05 trihydrochloride is water soluble and shows potent anti-tumor activity in several human cancer cell lines as a single agent. Intermittent high dose or chronic daily dosing of Lys05 at lower doses have shown early blockage of autophagy in melanoma and colon cancer xenograft models^[88]. Comparative study in cancer cells also revealed that HCQ at 100 $\mu\text{mol/L}$ cannot show complete deacidification of endovascular compartment; whereas 50 $\mu\text{mol/L}$ of Lys05 has shown complete deacidification. Further, in mice models Lys05 at high dose (80 mg/kg, i.p.) causes Paneth cell dysfunction with loss of lysozyme biosynthesis and bowel pseudo-obstruction^[88,89]. Studies evidenced that high dose of Lys05 is associated with intestinal toxicity and it has been also observed that high dose of HCQ also causes low grade nausea and constipation in patients. Lys05 is a new lysosomal inhibitor that has a potential to be further developed as a drug for cancer treatment.

Autophagy inducers

In addition to the above agents/compounds that were designed to modulate the autophagy process by specifically interacting with targets in autophagy pathways, there are other agents that induce autophagy. Particularly, naturally occurring compounds have multiple modes of action and targets different pathways. Some of them induce autophagy by targeting autophagy pathway signaling molecules and are discussed in this section [Figure 14].

Curcumin

Curcumin, a natural compound of golden spice turmeric shows numerous activities including anti-inflammatory, antimicrobial, antioxidant, hypoglycemic and wound healing activities. Considering these activities, curcumin has been investigated in many clinical conditions such as multiple myeloma, breast cancer and non small cell lung cancer. Although, it has proven efficacy in several clinical aspects, curcumin has therapeutic limitations due to rapid systemic elimination, rapid metabolism and poor absorption. Curcumin showed anticancer effects by sensitizing chemotherapy and radiation therapy^[90]. In gastric cancer cell lines SGC-7901 and BGC-823, curcumin significantly inhibited cell proliferation by exhibiting autophagy induction. The studies have reported that curcumin induces autophagy by its dual functionality in up-regulation of p53 and p21, and down-regulation of PI3K/Akt/mTOR signaling pathways^[91]. Another recent investigation also reported that curcumin induces autophagy in human pancreatic cancer cell lines^[91].

Figure 14. Autophagy inducers

Curcumin treatment of human lung adenocarcinoma cell line A549 showed autophagy induction by means of increased AMPK phosphorylation^[92].

Quercetin

Quercetin, a well-known cancer therapeutic agent and autophagy modulator is abundantly present in vegetables and fruits, and suppress tumor proliferation^[93]. It has been shown that quercetin suppresses Akt/mTOR and Bcl-2 signaling pathways and activates LC3, ERK and caspase. Studies in human neuroglioma cells U87 and *in vivo* studies revealed that quercetin nanoparticles significantly inhibit neuroglioma cell proliferation by inducing autophagy and apoptosis. Cell proliferation assay of neuroglioma cells showed that quercetin nanoparticles treatment with 10-50 µg/mL gradually reduced cell viability^[94]. A recent study reports that quercetin modulate p-STAT3/Bcl2 pathway and there by induces protective autophagy in ovarian cancer^[95].

Obatoclax mesylate

Obatoclax, a small molecule indole bipyrrole compound is an inhibitor of Bcl2 family proteins and exhibited anticancer activity in acute lymphoblastic leukemia^[96]. In addition to its involvement in apoptosis, obatoclax has also been involved in triggering cell death via autophagy induction^[97]. Primarily, this compound plays a key role in stimulation of necrosome assembly on autophagosome membrane to induce autophagy. Co-immunoprecipitation studies indicated that obatoclax enhances the interaction between Atg5 and necrosome components including FAD, RIP and RIP3. The same study investigated the role of obatoclax with 200 nmol/L concentration in rhabdomyosarcoma cells to unravel whether cell death occurs via apoptosis or autophagy and noticed little DNA fragmentation when the most of cell lost their viability.

Spermidine

Spermidine is a polyamine present in most of the mammalian cells and has important roles in several cellular activities under physiological conditions. It is well known for its longevity-promoting activity in association with autophagy enhancement. A study conducted in differentiated rat pheochromocytoma PC12 and human embryonic kidney 293 cells, revealed the possible role of spermidine in autophagy. After treating the cells with spermidine, the cell death analysis and caspase activity assays indicated that spermidine restricts neuronal injury via inhibiting caspase-3 dependent Beclin1 cleavage. Eventually, this mechanism elevates dysregulated autophagy flux levels^[98]. Very recent immunoprecipitation and immunohistochemistry studies in human chondrocytes and *in vivo* study conducted in mice reported that the cells treated with spermidine (100 nmol/L) showed autophagy activation and promoted chondrogenesis^[98]. However, spermidine role in cancer is still controversial as some studies reported that spermidine do not induce tumorigenesis^[99], whereas some studies established that spermidine synthase inhibitors show little cell growth reduction in cancer cell lines^[100].

Sulforaphane

Sulforaphane, an organic isothiocyanate compound derived from glucosinolates shows both cytoprotective and cytotoxic activities. It activates nuclear factor E2-related factor 2 signaling that elevates the expression of antioxidant response proteins in oxidative stress. A study in murine osteosarcoma cells reported that sulforaphane induces apoptosis through cell cycle arrest and inhibits tumor cell growth^[101]. It has also been reported that the treatment of sulforaphane initiates various cellular processes in human prostate cancer^[102]. To investigate whether sulforaphane is reducing the cell growth or encourages cell death, a study was conducted in human lens cell line and reported that sulforaphane reduced the cell viability in human lens cell line and promotes cell death. The study also revealed that sulforaphane promotes ER stress and autophagy induction via MAPK signaling^[103], and longer treatment with sulforaphane has shown significant decrease in AMPK phosphorylation at thr-172^[104] in human prostate cancer cells.

FDA approved drugs with autophagy modulation activity

In addition to the above discussed autophagy modulators, few FDA approved drugs (for different indications) are reported to have additional autophagy modulator activities [Table 2]. This section is intended to list out these drugs and provide brief information and mode of autophagy modulation by these drugs. Some of these drugs are already used as anticancer agents, while some are used for other indications. These data suggests that some of the approved anticancer drug may be partly working through autophagy modulation. Moreover, understanding the exact molecular mode of action of these drugs could help to repurpose these drugs for cancer therapy in the future.

Temozolamide, an alkylating agent is a FDA approved drug for the treatment of glioblastoma multiforme in combination with radiotherapy^[105]. Recent studies have investigated the role of temozolamide in autophagy modulation and reported that it induces autophagy in glioblastoma cancer cells through EGFR independent manner^[106]. Temozolamide also showed cytotoxicity in PI3K/AKT/mTOR pathway inhibited adenoma cells^[107]. Gefitinib which targets tyrosine kinase activity of EGFR and binds competitively to the ATP binding site is a FDA approved drug for treating the patients with non-small cell lung cancer (NSCLC)^[108]. Gefitinib induces autophagy in lung cancer cells through blocking of PI3K/AKT/mTOR pathway^[109] and also exhibited autophagy induction in combination with clarithromycin in NSCLC cells^[110].

Metformin, a biguanide antihyperglycemic agent is FDA approved for treating non-insulin-dependent diabetes mellitus. It controls glucose level by means of decreasing hepatic glucose production and also by increasing insulin-mediated glucose uptake. It is reported that metformin is involved in autophagy induction by AMPK dependent manner. Several cancer models have shown significant growth inhibition upon metformin treatment^[111]. A study also reported that metformin promotes autophagy and selectively inhibits esophageal squamous cell carcinoma cell growth by down regulating STAT3 signaling^[112]. Studies on human multiple myeloma cells show that metformin inhibits the cell proliferation by promoting autophagy and cell cycle arrest and this study suggested metformin dual repression of mTORC1 and mTORC2 via AMPK activation^[113].

Bortezomib is a proteasome inhibitor that specifically inhibits nuclear factor kappaB and is a FDA approved drug to treat multiple myeloma^[114]. Bortezomib has shown anticancer activities in several human cancers including prostate cancer, colon cancer, ovarian cancer and breast cancer. Studies have explored the possible role of Bortezomib in autophagy and found that it promotes cancer cell death through blockage of autophagic flux in ERK phosphorylation dependent manner^[115]. Sodium phenylbutyrate is a chemical chaperon that inhibits histone deacetylase and is FDA approved drug to treat urea cycle disorders. Sodium phenylbutyrate is also under clinical investigation in several human diseases including hemoglobinopathies, motor neuron diseases, cancer and cystic fibrosis^[115]. Sodium phenylbutyrate has been shown to reduce dithiothreitol or tunicamycin induced autophagy^[116].

Table 2. FDA approved drugs for various human diseases that are reported to have autophagy modulating activity

Sl. No.	Drug	Mode of action	FDA approved use	Nature of the modulator
1	Temozolomide	Alkylating agent	Glioblastoma multiforme	Autophagy inducer
2	Rapamycin	Inhibits mTOR	Transplant rejection	Autophagy inducer
3	Metformin	Activates AMPK	Type 2 Diabetes	Autophagy inducer
4	Gefitinib	PI3K/AKT/mTOR pathway	Metastatic non-small cell lung cancer (NSCLC)	Autophagy inducer
5	Bortezomib	Activates AMPK	Multiple myeloma	Autophagy inhibitor
6	Sodium Phenylbutyrate	Improves cathepsin D and B activities and lysosomal-autophagic function	Urea cycle disorders and acute promyelocytic leukemia	Autophagy inhibitor
7	Carbamazepine	Reduces inositol and Ins (1,4,5)P3 levels	Epilepsy	Autophagy inducer
8	Verapamil	Inhibits Ca ²⁺ channel lowers intracytosolic Ca ²⁺ levels	Hypertension	Autophagy inducer
9	Rilmenidine	Reduces cAMP levels	Hypertension	Autophagy inducer
10	Choloroquine and Hydroxychloroquine	Inhibits lysosomal function	Malaria, Lupus and rheumatoid arthritis	Autophagy inhibitor
11	Pantoprazole	Proton pump inhibitor, increased endosomal pH	Erosive esophagitis	Autophagy inhibitor
12	Celecoxib	Inhibits cyclooxygenase 2	Rheumatoid arthritis and osteoarthritis	Autophagy inhibitor

Carbamazepine is a FDA approved anticonvulsant drug for the treatment of epilepsy. Evidences indicate that carbamazepine diminishes hepatocellular death in autophagy dependent manner. A study on SW480 colon cancer cell lines revealed that carbamazepine decreases β -Catenin and VEGF levels, resulting in antitumor activity^[117]. Verapamil and Rilmenidine are well known drugs for the treatment of hypertension and now these drugs are under investigation to unravel their role as autophagy modulators in cancer. Autophagy induction has been observed upon treatment with verapamil in COLO 205 cells with cytoprotective activity^[118]. It has been observed that Rilmenidine promotes autophagy in an mTOR independent manner, however the reduction in disease progression has not been observed^[119].

Pantoprazole is a protein pump inhibitor used to treat certain esophagus and stomach related problems. Various studies reported that pantoprazole sensitized cancer cells to anticancer drugs by suppressing autophagy induction in time- and dose-dependent manner^[120-122]. Celecoxib is a nonsteroidal anti-inflammatory drug that is FDA approved for Rheumatoid arthritis and osteoarthritis treatment. Recent studies have evaluated celecoxib activities in cancer and reported its antitumor effects in solid tumors. Also autophagy reduced significantly upon treatment with celecoxib in imatinib resistant chronic myeloid leukemia cells^[123]. All together, although these drugs have proven to be useful in various human diseases, currently many studies are investigating their impact in cancer though autophagy modulation.

CONCLUSION

Autophagy is a conserved cellular process that is essential for the cells to cope-up with adverse conditions, such as the lack of nutrients or bacterial/viral infections. In such conditions, autophagy plays a pro-survival role by recycling the cellular components by lysosomal degradation and also helps in the removal of pathogenic organism by sequestration and degradation. Because of its central role in maintaining cellular homeostasis, alterations in the autophagic process through aberrant signaling has been linked to several disease states such as cancer and neurodegeneration, among others. In cancer, autophagy has the role of a double edge sword, with tumor suppressing activity during the initial stages of cancer development and pro-survival effects in the later stages of cancer development.

The relevance of autophagy modulation in cancer is increasingly appreciated and many therapeutic targets involved in autophagy process have been identified. In this review, we highlighted the role of promising autophagy signaling pathway/biomarkers that could be modulated for cancer therapy. Further, we also

reviewed and analyzed the available autophagy inducers/inhibitors. Except for the mTOR targeting rapalogs, no other autophagy targeting agents are approved in the clinics for cancer treatment. Currently, chloroquine and hydroxychloroquine are being clinically tested as autophagy modulators either alone or in combination with other anti-cancer therapeutics (e.g., temozolomide, bortezomib, temsirolimus, vorinostat, doxorubicin, *etc.*). Eventhough hydroxychloroquine shows partial response and improves treatment outcomes in various cancers such as melanoma, colorectal cancer, myeloma and renal cell carcinoma, dose related toxicity may preclude its widespread use as autophagy modulator. However, this may change soon as several groups are developing molecules to various drug targets such as ULK and Vps34 within the autophagy signaling pathway. Developing selective autophagy modulators with minimal cross-talk with other targets will be challenging and crucial for making autophagy modulation as a successful strategy for cancer therapy. Moreover, patient selection based on the alteration in the autophagy signaling pathways could pave way for better treatment outcomes for autophagy modulators.

The importance of autophagy related research can be fathomed from the ever increasing number of publications (90 articles in the year 2000, 2050 in 2010 and 6700 articles in 2018; scopus data) and the fact that 2016 Nobel prize in Physiology or Medicine was awarded to Prof. Yoshinori Ohsumi for his research on Autophagy in yeast. Eventhough, we have made big strides in understanding the autophagy process, the complete molecular machinery of autophagy, the signaling process involved and their roles in various disease conditions are not yet completely elucidated in humans. Future research should hold promise as well as provide insights in these directions for identifying better treatment for cancer and other diseases.

DECLARATIONS

Abstract

Circulating biomarkers - nucleic acids, proteins, and metabolites - have been used in several adult oncologic processes to affect early detection, measure response to treatment, and offer prognostic information. The identification and validation of biomarkers for pediatric brain tumors, however, has been meager by comparison. Early detection and serial screening of pediatric brain tumors has the potential to improve outcomes by allowing for rapid therapeutic interventions and more targeted therapies. This is particular resonant for pediatric brain tumors where treatment success is heavily dependent on early surgical intervention. This highlights the need for biomarker development in pediatric neuro-oncology. The authors reviewed current circulating biomarker targets in various biofluid reservoirs and discuss the current barriers to biomarker development in pediatric neuro-oncology patients.

Keywords: Pediatric, brain tumor, biomarker, miRNA, biofluid, overview

INTRODUCTION

Pediatric brain tumors are the leading, oncologic cause of death in children under 10 in North America. Roughly 4,600 children are diagnosed with brain tumors every year in the United States, and maximal, safe surgical resection remains the primary treatment modality^[1-3]. Five-year survivals can vary by as much as 70% with some of the most common pediatric brain tumors, depending on a surgeon's ability to achieve complete safe resection of the mass^[4-8]. This makes early diagnosis and intervention, potentially, critical to

ensuring favorable outcomes, as surgical resection is generally more successful when tumors are smaller, confined to a single location, and less entwined with critical neural structures.

Despite a general awareness of the importance of establishing a prompt diagnosis for pediatric brain tumor care, delay in time to diagnosis is common with pediatric brain tumor patients, as children have a unique capacity to tolerate intracranial volume and pressure changes with minimal outward symptoms^[9]. Additionally, the immature nature of the nervous system in infants makes clinical screening for brain tumor-related symptoms challenging. Widespread radiographic screening of children, be it with computed tomography or magnetic resonance imaging, is impractical due to the risks of radiation exposure to the developing central nervous system, neurotoxic effects of early anesthetic exposure, and prohibitive diagnostic costs^[10-12].

As such, a minimally invasive, reliable, and cheaply implemented screening tool has become a great clinical need for physicians and researchers seeking to improve early tumor detection, develop minimally invasive methods for molecular stratification of tumors, and allow for reliable post-treatment screening in pediatric brain tumor populations. Numerous permutations exist for researchers seeking to discover and validate novel biomarkers, as potential tumor markers need to be examined in different biofluid reservoirs and with different analytic techniques. Each variation in biomarker sampling and analysis exposes different advantages and limitations that researchers and clinicians must be cognizant of as they search for accurate and realistically deployable brain tumor biomarker assays. The authors will review here the history of biomarker development for pediatric brain tumors to date, the limitations and advantages of current target biofluids, promising biomarkers for the most prevalent pediatric brain tumors, and the major limitations of biomarker development in pediatric populations.

Historical biomarkers

Attempts to acquire objective evidence of a tumor from extra-tumor biofluids date back at least 100 years, beginning with cerebrospinal fluid (CSF) cytology. Tumor cytology is the oldest and most well-understood method for detecting and differentiating pediatric brain tumors via a biofluid^[13]. The use of cytology to diagnose tumors in a minimally invasive manner dates back to the 19th century^[14]. The process for acquiring CSF samples for cytologic analysis has the benefit of being relatively simple to perform and widely available in most regions of the world. In order to acquire a CSF sample, a lumbar puncture is performed with a sterile 20-22-gauge needle at or below the L2/L3 interlaminar space. Ventricular CSF samples have been used, as well, for CSF cytology; but the sensitivity of samples acquired from cerebral ventricular punctures is significantly lower than samples drawn from the lumbar cistern, likely due to sedimentation of tumor cells into the dependent lumbar cistern^[15]. CSF samples are then fixed and processed for light microscopic evaluation or flow cytometry. CSF cytology can provide pathologic diagnoses in many oncologic cases. Immunohistochemical assays are also possible, making the cytologic analysis of CSF somewhat comparable to tissue biopsy in the range of qualitative information it can provide. However, CSF cytology has a low sensitivity (45%), unless performed repeatedly on the same patient, making it an inaccurate and impractical brain tumor screening modality by itself^[16,17].

Arguably, modern pediatric intracranial tumor serum biomarker assay development began in the 1960s and 70s in the field of germ cell tumor diagnostics. Research with immunoperoxidase staining of testis germ cell tumors revealed excesses in alpha-fetoprotein (AFP) and beta human chorionic gonadotropin (βHCG) production within the tissues of some tumor types^[18]. Immunostaining and radioimmunoassay techniques quickly proliferated for these compounds; and by the mid-1970s, pathologists were able to utilize AFP, βHCG, as well as other proteins, to distinguish endodermal sinus tumors, choriocarcinomas, dysgerminomas, and teratomas on immunohistochemical review and via serum-based tests.

In 1979, Jeffrey Allen, MD and colleagues at Memorial Sloan-Kettering applied serum and CSF AFP/ β HCG radioimmunoassays for use in a group of 6 pediatric patients with biopsy proven intracranial germ cell tumors. This study was not powered to allow for statistical discrimination of the results, but it demonstrated, within individual cases, high correlations between serum AFP and CSF β HCG levels and the presence of intracranial germ cell tumors. Furthermore, those patients with elevated AFP or β HCG assay levels had complete normalization of their serum and CSF levels concurrent with successful tumor radiographic response to therapy^[19]. This work has been expanded upon numerous times since, and the correlations found in Allen *et al.*^[19]'s paper have proven to be robust within larger cohorts. AFP and β HCG serum and CSF assays have now become routine components of intracranial germ cell tumor diagnostics, in some cases obviating the need for tissue sampling entirely^[20-23].

The story of AFP/ β HCG serum and CSF assays is a rare success story in the realm of clinical oncologic biomarkers for pediatric brain tumor patients, and one that has, frustratingly, not been matched since. No other intracranial pediatric tumor has a widely accepted diagnostic peripheral biomarker capable - in select circumstances - of replacing tissue biopsy in the clinical evaluation algorithm^[23]. Even for intracranial germ cell tumors, AFP/ β HCG serum and CSF assays can provide false negatives, and research continues as we seek ever more reliable biofluid-based biomarkers.

CSF biomarkers

The most studied and fruitful biofluid target for pediatric oncologic biomarkers is CSF. A normally low-protein, relatively acellular biofluid^[24], CSF is a natural choice for mining biomarker data for central nervous system (CNS) pathologies as it lies in direct contact with the whole of the CNS's pial and ependymal surfaces. Cells, both pathologic and normal, shed proteins and nucleic acids, be they naked or within extracellular vesicles, into the extracellular spaces. These compounds and vesicles will accumulate within the local biofluid compartments. In the case of the CNS, intravascular spaces, parenchymal interstitial spaces, and the intraventricular/subarachnoid spaces represent the major extracellular compartments where biomarkers can collect. With diffusion into the intravascular spaces being limited by the blood brain barrier (BBB)^[25], the CSF and interstitial spaces, theoretically, should be the most rich in cytologic, genetic, and protein markers of tumor growth^[16]. Most CSF based biomarker studies have focused on detecting: (1) tumor cells; (2) cell-free tumor DNA; (3) non-coding RNA; or (4) tumor-related metabolites. The authors have already discussed CSF cytology (i.e., detecting tumor cells) in the previous section, so we will only focus on the last three biomarker sources going forward.

Cell-free DNA

Circulating, cell-free tumor DNA (cfDNA) analysis employs several techniques to identify specific genetic sequences or screen for arrays of genetic sequences within biofluids. Methods for detection of genomic alterations in cfDNA are mainly PCR-based assays: real-time PCR, methylation-specific PCR, droplet digital PCR, and next-generation sequencing (NGS). The latter two techniques have particularly improved the sensitivity of cfDNA detection compared to older PCR-based assays^[26]. While not specifically confined to use in the CSF, it has been most successful at correlating with brain tumor pathologies when examined in the CSF, due to the fact that non-CSF biofluids typically contain a very small percentage ($\leq 1\%$) of brain tumor genetic material in a sea of normal tissue genetic material^[27]. Within CSF, cfDNA has been shown to detect the presence of a CNS neoplasm at rates significantly higher than CSF cytologic analysis^[28], as well as identify clinically relevant mutations, even when present at strikingly low frequencies ($1:1 \times 10^7$), through the use of NGS techniques like duplex sequencing^[29].

CSF cfDNA has been shown in several studies of adult intracranial tumor patients to exceed CSF cytologic detection levels when specific mutations are screened for (EGFR for glioblastoma, KRAS for non-small cell lung cancer, BRAF p. V600E for melanoma, *etc.*)^[27,28,30,31]. Among pediatric brain tumor patients,

this biomarker has been only sparsely examined and almost exclusively in CSF. Despite cfDNA's limited utilization, to date, in pediatric brain tumor biomarker development, the authors feel that it bears special discussion, due to its potential as a low-risk diagnostic for midline gliomas.

Midline gliomas represent a one of the most difficult groups of pediatric primary brain tumors to treat. Characterized by a H3K27M histone mutation^[32], these tumors are generally aggressive and often not safely surgically accessible^[33], making it difficult for clinicians to acquire biopsies. This limits the amount of molecular information available to direct therapy and inform prognosis, and it elevates the clinical need for a safe, reliable method of extracting molecular information from these tumor patients.

Using cfDNA isolated from CSF samples from pediatric brain tumor patients, researchers have made significant progress towards the detection of diffuse midline glioma histone mutations important for prognostication. A study conducted by Huang *et al.*^[34] that reviewed CSF samples from 6 pediatric patients with diffuse midline gliomas found that the H3F3A mutation could be isolated or detected in up to 83% of patients, with a specificity of 100%. This methodology has, subsequently, been confirmed in a larger cohort of 48 patients in a multi-institutional study. In that study by Panditharatna *et al.*^[35], the authors found that the H3 p. K27M mutations in CSF strongly correlated with the presence of a diffuse midline glioma with the same H3K27M mutation. The amount of detectable genetic material also correlated with the response of that tumor to radiation therapy. The accuracy of the H3 p. K27M cfDNA was 87% in this study. Interestingly, Panditharatna's group also looked at the presence of the H3 p. K27M mutant genetic material in matched serum samples, as well. They reported comparable sensitivity and sensitivity results with serum as compared to CSF, though with markedly lower quantities of detectable cfDNA^[35].

CSF-based cfDNA does have important limitations that have yet to be overcome. While sensitivity for intracranial tumor detection with CSF-based cfDNA is superior to CSF cytology in general, its sensitivity for primary CNS tumors seems to be much less than for extra-CNS neoplasm. In a study of 53 adult patients with intracranial tumors, 62.5% of patients with metastatic CNS tumors had detectable tumor-specific mutant cfDNA in the CSF, while only 50% of patients with primary CNS neoplasms had detectable cfDNA in the CSF^[27]. cfDNA detection in the CSF may be limited by anatomic factors, such as tumor location relative to CSF cisterns. A study of 35 pediatric and adult patients with primary brain tumors found that 86% of tumors abutting a CSF cistern had detectable cfDNA in the CSF, but none of the tumors with entirely parenchymal locations had detectable CSF cfDNA^[36]. Tumor biology may also limit detection as some authors have noted low to absent rates of cfDNA detection even for some ependymomas with extensive surface contact with CSF^[37].

Non-coding RNA

Non-coding RNA, predominantly miRNA, are small (18-25 nucleotides) RNA that function to regulate mRNA pre- and post-translationally. miRNA form from a precursor RNA (pri-miRNA) that is cleaved by the RNase III nuclear enzyme Drosha into a 60-70 nucleotide intermediate known as pre-miRNA, which is then exported from the nucleus via Exportin-5. Once in the cytoplasm, pre-miRNA is cleaved again by Dicer, another RNase III enzyme, into miRNA, which then complexes with a transactivation-responsive RNA binding protein and Argonaute to form an RNA-induced silencing complex^[38]. This miRNA-enzyme complex is the active unit at the end of miRNA biogenesis, and it is capable of recognizing complementary mRNA and (1) inhibiting translation initiation via cap-40S association; (2) inhibiting translation initiation via 40S-AUG-60S association; (3) inhibiting elongation; (4) causing premature ribosome drop-off; (5) causing cotranslational protein degradation; (6) causing sequestration of mRNA in P-bodies; (7) causing increased mRNA degradation; (8) increasing mRNA cleavage; or (9) effecting transcriptional inhibition by interaction with promoter sequences or increased methylation of promoters^[39].

There are currently > 1,900 known human miRNA (miRbase.org) regulating at least 30% of human genes^[40]. Table 1 lists some of the more prominent miRNA implicated in pediatric brain tumor biology^[41-43]. These

Table 1. Summary of commonly implicated miRNA alterations in pediatric brain tumors

MiRNA	Tumor types	Regulation	Potential actions	Ref.
MIR-15B	Glioma	Upregulated	Modulates multi-drug resistance and cell migration	[16,47]
MIR-21	Glioma	Upregulated	Targets PTEN, PDCD4, Bcl2 and other tumor suppressor genes.	[42,47,48]
	Medulloblastoma	Upregulated		
	Ependymoma	Upregulated		
MIR-23A	Glioma	Upregulated	May regulate cell migration and apoptosis.	[44]
MIR-34A	Ependymoma	Upregulated	Regulates apoptosis through SIRT1	[42]
MIR-124A	Medulloblastoma	Downregulated	Modulates glycolysis and cell cycle through CDK6	[43,49]
MIR-125B	Glioma	Upregulated	SHH pathway modulation and apoptosis	[16,47-49]
	Medulloblastoma	Downregulated		
MIR-128A	Medulloblastoma	Upregulated	Tumor growth and apoptosis via MYC and Bcl2	[43]

MIR-518B	Glioma	Upregulated	Tumor suppressor acting through PDGFRB	[50]
	Ependymoma	Downregulated		

molecules are secreted into the extracellular spaces, predominantly in microvesicles, apoptotic bodies, and exosomes. Within these vesicles, the miRNA are protected from degradation by endogenous RNases, making them an unusually stable transcript compared to other forms of RNA. Furthermore, research has shown that extracellular vesicles from tumor patients tend to be particularly enriched with tumor-related miRNA^[44,45], and these extracellular vesicles can induced oncogenic protein expression changes in adjacent, normal cells^[46].

A myriad of miRNA have been detected in the CSF of adult brain tumor patients, most prominently miR-21, miR-15b, miR-125b, and miR-223^[16,44,48,49]. These markers individually or in combination with other miRNA have demonstrated high levels of specificity and sensitivity for gliomas and medulloblastomas^[47,49]. However, there are no published articles at the time of this review analyzing the miRNA in the CSF of pediatric glioma, embryonal, or ependymal tumor patients in isolation from adult populations. The composition and clinical applicability of miRNA in the CSF of pediatric brain tumor patients remains a significant knowledge gap, at present, in the field of pediatric neuro-oncology.

Tumor metabolites and proteins

Aberrations in tumor metabolism and cell signaling pathways relative to normal tissues tends to lead to an accumulation of well-characterized small molecules that can be used to predict the presence of a malignancy; and in certain instances, even predict the molecular signature of that malignancy^[51]. Dyscrasias have been identified in all of the major metabolic cycles employed by cancer cells, including glucose metabolism, the pentose phosphate pathway, amino acid metabolism, and fatty acid metabolism, as well as many proliferative signaling pathways, such as the PI3K/AKT and WNT/ β -catenin pathways^[8,16]. Lactate, isocitrate, citrate, and D-2-hydroxyglutarate are metabolites known to accumulate in gliomas utilizing aerobic glycolysis as their dominant ATP source^[52]. D-2-hydroxyglutarate, in particular, has been shown to be elevated in the CSF of patients with IDH1 mutant gliomas, and its detection in the CSF may be a surrogate for this prognostically important mutation^[53].

As with CSF-based miRNA, very little research has been done examining the use of CSF metabolites to diagnose, track, and molecularly subtype pediatric brain tumors. What work has been done revolves around monoamine metabolism in pediatric brain tumors. In 1987, Bostrom and Mirkin looked at the concentrations of homovanillic acid (HVA), hydroxymethoxyphenylethyleneglycol (MHPG), and vanillylmandelic acid in the CSF of adult and pediatric patients with leukemia, glial, neuroectodermal, or retinoblastoma tumor histories. In their study, MHPG and VMA were significantly elevated among patients with primary CNS tumors or neuroblastoma cranial metastases, suggesting that these metabolites increased in response to disruption of the BBB or mass effect within the CNS^[54]. This work was followed in 2014 by a study by Varela *et al.*^[55] of 22 pediatric patients with posterior fossa astrocytomas, medulloblastomas,

and one case of an ependymoma. Ventricular CSF samples and serum samples were acquired and levels of MHPG, HVA, and 5-hydroxyindoleacetic acid were measured. The authors found that MHPG levels were significantly higher (19.4%) in astrocytoma patients versus medulloblastoma patients. However, none of the measured monoamine metabolites significantly varied from age-matched controls in this small study^[55].

Like tumor metabolite CSF biomarkers, most protein biomarkers investigated in CSF are part of well-defined aberrant tumor cell signaling pathways. One of the most well studied family of proteins influencing proliferation and differentiation in pediatric brain tumors is the insulin-like growth factor (IGF) family of mitogens, binding proteins, and receptors. The IGF mitogens are primarily synthesized in the liver and circulate in conjunction with any of 7 IGF binding proteins (IGFBP) to promote CNS development, among other functions. They have been implicated in the proliferation and formation of medulloblastomas and ependymomas in *in vitro* and murine models^[56,57], and IGF-1 levels have been shown to correlate with an individual's propensity for developing cancer^[58].

In a study of 35 CSF samples from pediatric patients, mostly medulloblastoma patients, IGFBP-3 levels were found to be significantly elevated in the CSF of medulloblastoma patients compared to control or ependymoma patients. This finding was comparable to mRNA levels for IGFBP-3 in the tumors themselves. The study did have several limitations that tempered the confidence that could be assigned to the results. The levels of IGFBP were overall highly correlated with total CSF protein levels, as has been the case with other CSF-based protein biomarkers for brain tumors^[59,60], suggesting that IGFBP may just be an indicator of BBB disruption, rather than a specifically oncologic biomarker. The authors did attempt to normalize IGFBP-3 levels to total CSF protein levels, and the significance of the finding remained. Another issue with the study was that correlation with tumor treatment could not be assessed, as follow-up CSF samples in all patients were taken within 2 weeks of surgical resection, potentially contaminating the samples with tumor cell slough and physiologic changes related to general anesthesia and surgery^[61]. Even so, this study suggests that the IGF signaling pathway may be leveraged in the future to identify and track disease in pediatric patients with medulloblastoma.

Another paper by Desiderio *et al.*^[62] examined changes in the CSF proteome of 14 pediatric brain tumor patients and 5 controls from the time of surgical resection and at 6 days post-surgery via top down liquid chromatography-mass spectrometry. The authors found a non-significant trend towards decreased LVV-h7 and VV-h7 hemorphins in the CSF of pediatric patients with brain tumors. In Desiderio *et al.*^[62]'s cohort, the LVV-h7 and VV-h7 protein suppression reversed in the same patients if they underwent a gross total resection of their tumor and had no metastatic tumor burden. These findings have yet to be verified in a follow-up study, and the results included CSF samples within the window of surgical contamination^[62].

A similar whole-CSF proteome approach was utilized by Saratsis *et al.*^[63] to search for biomarkers predictive of diffuse intrinsic pontine gliomas. In this study, 55% of patients with diffuse intrinsic pontine gliomas demonstrated elevated levels of cyclophilin A in their CSF, while no patients with alternate supratentorial gliomas or control patients had meaningfully detectable levels of the same protein. Those patients with elevated cyclophilin A levels also showed a greater tendency towards radiographic evidence of necrosis and rapid tumor progression, suggesting that cyclophilin A may be indicative of more aggressive forms of diffuse intrinsic pontine glioma^[63].

Lastly, a study of 33 pediatric medulloblastoma patients and 25 age matched controls in a multi-centered study of prostaglandin D2 synthase (PGD2S), a highly abundant glycoprotein found in CSF, found a 6-fold reduction in PGD2S levels in medulloblastoma patients compared to controls. This was a highly significant finding ($P < 0.00001$). The authors theorized that this may be related to a host response to the tumor, as it has been described in other brain tumor patients and in some demyelinating diseases. PGD2S CSF levels

remained suppressed after tumor patients went into remission, so it is unlikely that this protein would be useful for longitudinal screening of pediatric brain tumor patients^[64].

Limitations to CSF-based biomarkers

While relatively minimally invasive, accessing the lumbar cisterns in order to collect CSF samples is still a more difficult affair than phlebotomy, saliva collection, or urine sampling. The procedures involved in CSF sampling - lumbar puncture or ventricular puncture - require skilled, advanced practice medical personnel with knowledge of basic anatomy and sterile technique. In the case of pediatric patients, sedation is sometimes required in order to perform a lumbar puncture, and it is mandatory for ventricular access procedures. These technical difficulties currently limit the availability of patient CSF as a routine diagnostic medium and will likely frustrate attempts to use CSF-based biomarker assays for screening large populations of pediatric patients. This limits the availability of patient CSF as a routine diagnostic medium.

As has been stated earlier, CSF may also be an inappropriate source of biomarker molecules for more parenchymal based tumors, where tumor cells do not make direct contact with ependymal or pial surfaces and are, therefore, less likely to release genetic material and small molecules into CSF. In reality, 70% of pediatric brain tumors will arise in or near the 4th cerebral ventricle, making this potential limitation applicable to a minority of cases^[65].

In the same vein, though, the tendency of pediatric brain tumors to arise near the 4th ventricle in the posterior fossa makes lumbar puncture more perilous for patients, as drainage of CSF from the lumbar cistern, rarely, can create a pressure gradient across the infratentorial compartment in the setting of a large mass lesion. These pressure gradients, in severe cases, can lead to brainstem and cerebellar herniation through the foramen magnum, causing significant neural injury and even death^[66]. For this reason, routine lumbar punctures for the purposes of oncologic screening may not be deemed safe in many pediatric brain tumor patients.

Serum biomarkers

While CSF can be problematic to acquire, more peripheral biofluids, such as serum, urine, and saliva, can and are easily acquired from pediatric patients in ambulatory settings every day. In this sense, they are far more practical sources for pediatric brain tumor biomarker discovery than CSF; but discoveries in these media must be approached cautiously, as biomarkers in these biofluids are subject to dilution and filtration at multiple points between synthesis and their collection sites, sometimes greatly compromising the fidelity of the observed biomarker concentration^[67-69].

That being said, serum remains the most successful source of clinically relevant biomarkers in practice today. Examples of serum biomarkers in clinical use include prostate specific antigen, AFP, β HCG, alanine aminotransferase, aspartate aminotransferase, lactate dehydrogenase, and carcinoembryonic antigen^[70,71]. As is the case in adult oncology, most research into pediatric brain tumor peripherally circulating biomarkers has focused on protein biomarkers, similar to those just listed, but miRNA are also beginning to show promise as potentially specific and easily measured diagnostics for detecting, diagnosing, and tracking pediatric brain tumors. Due to their relatively rapid turnover in the peripheral blood stream, DNA and RNA based biomarkers are particularly well suited for gauging tumor response to therapy^[72].

Non-coding RNA

As with CSF, serum miRNA and other forms of non-coding RNA have been targeted for potential diagnostic and screening purposes in neuro-oncology. miR-21, miR-125b, miR-128, miR-15b, and miR-182 have all been implicated in adult glioma studies of miRNA signatures within patient sera^[73]. Serum miR-21 and miR-15b, in particular, have been shown to strongly predict glial tumors in adult patient populations, with combined

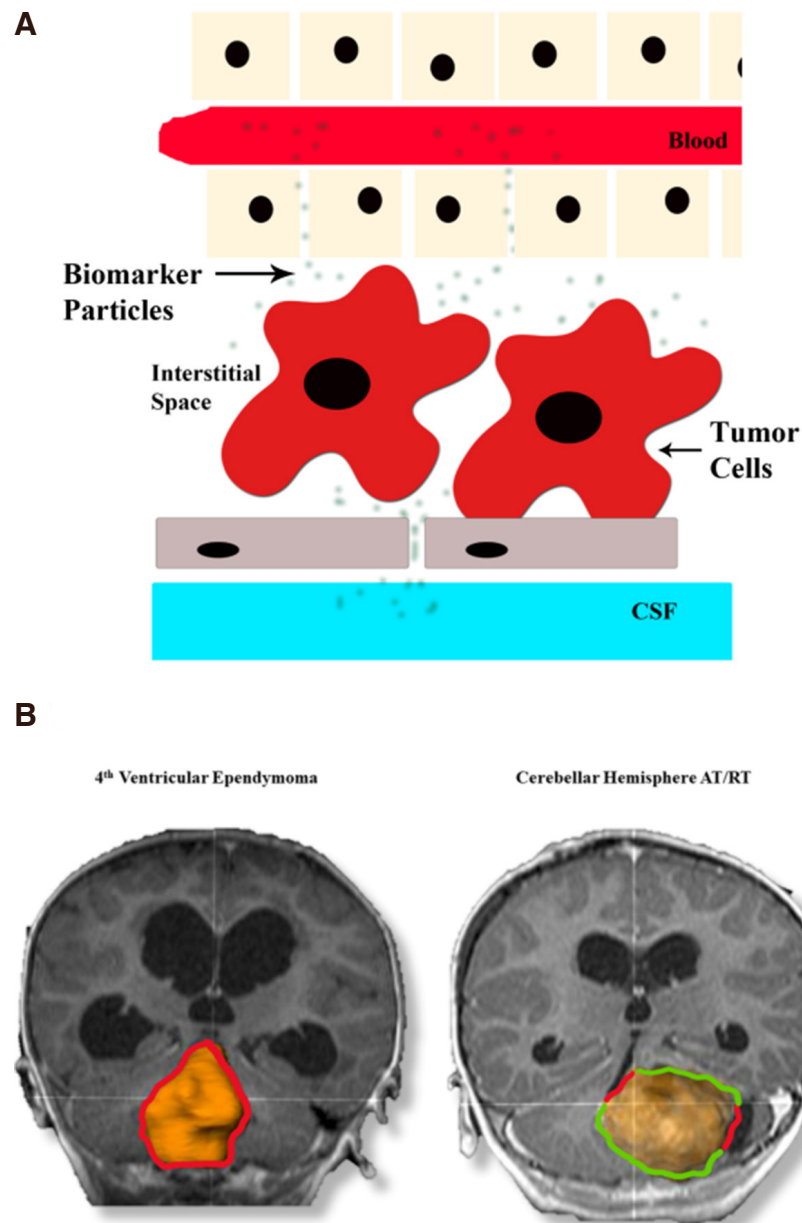

Figure 1. A: Schematic of diffusion of tumor nucleic acids, proteins, metabolites, and microvesicles into various extracellular compartments; B: Representative MRI images of an intraventricular (left) and mainly parenchymal (right) tumor with cerebrospinal fluid (CSF) contact points denoted in red and parenchymal contact points denoted in green

sensitivities and specificities of 100% in a series of 112 patients with gliomas, non-small cell lung cancer, and controls^[74]. Numerous studies examining serum miRNA signatures in gastric cancer, hepatocellular carcinoma, lung cancer, and breast cancer have also demonstrated the potentially powerful predictive value of serum miRNA in screening, risk-stratifying, and tracking cancer patients^[75-79].

In the realm of pediatric neuro-oncology, however, serum miRNA have only begun to be leveraged for tumor detection and screening. The first study to examine the potential utility of serum miRNA in detecting and screening pediatric brain tumors was done by this author and their colleagues (Bookland *et al.*^[41]) in a small cohort of pediatric juvenile pilocytic astrocytoma, ependymoma, and control patients. The authors identified four miRNA (miR-21, miR-15b, miR-23a, and miR-146b) that accurately predicted the presence, tumor nodule size, and response to therapy of juvenile pilocytic astrocytoma patients with a sensitivity of

86% and specificity of 100%. In particular, levels of miR-15b, miR-21, and miR-23a correlated strongly with tumor nodule volume (miR-15b, $R^2 = 0.86$; miR-21 $R^2 = 0.92$; miR-23a, $R^2 = 0.86$) and returned to normal levels within 24 h of gross total tumor resection. Interestingly, patients with tumors situated more deeply within the brain parenchyma demonstrated higher ratios of miRNA to tumor nodule volume than those more peripherally situated^[41]. These results further support the notion that oncologic miRNA serum levels may be affected by tumor anatomic location, just has been speculated with CSF biomarkers [Figure 1].

This pilot study evaluating the potential utility of serum miRNA as a biomarker for pediatric brain tumors is encouraging, but this initial work also highlighted significant barriers to serum miRNA development, including: (1) normalization of miRNA profiles; (2) low miRNA yields compared to tissue or CSF sources; (3) and a poor understanding of relative contributions tumor and host tissues make to the final serum miRNA signatures^[41,71]. One significant example of these challenges can be demonstrated in observing the effect that general anesthesia has on select serum miRNA levels. miR-125b, which has been implicated as an oncomir in gliomas and medulloblastomas^[80,81], is suppressed in humans and rodents after exposure to general anesthetic agents^[41,82]. Yet, few miRNA biomarker studies have controlled for the effects of anesthesia miRNA levels. Indeed, controlling for anesthesia in pediatric clinical trials is an ethically and technically complicated matter that adds a layer of complexity to serum miRNA interpretation of which clinical researchers must be cognizant. This example highlights the importance of developing a thorough understanding of the interplay between oncologically-relevant miRNA and the normal functions they regulate so that confounding host and external forces acting on miRNA of interest can be controlled.

Protein/small molecule

As mentioned previously, protein and small molecule serum biomarkers have been extensively studied, and they represent, perhaps, the most significant cohort of potential biomarkers for pediatric brain tumors. An exhaustive list of all proteins and small molecules implicated in pediatric brain tumor diagnostics and prognostics is beyond the scope of this brief review, but we will touch on some of the more widely reported biomarkers in the literature.

Osteopontin is an extracellular matrix protein expressed in a wide variety of tissues and involved in mineralization, immune modulation, cell migration, and anti-apoptosis^[83]. It has been shown to be overexpressed in atypical teratoid/rhabdoid tumors (AT/RT), as well as several other CNS tumors. In a series of 39 pediatric patients with AT/RT, medulloblastoma, epilepsy, or hydrocephalus, serum and CSF levels of osteopontin were shown to be significantly elevated in AT/RT patients versus medulloblastoma patients (~2:1 in serum) and versus control patients (~4:1 in serum). Serum osteopontin levels also correlated with AT/RT response to therapy, and higher serum levels were associated with a more malignant disease course^[84]. This work raises the possibility that osteopontin may be a highly specific and reliable biomarker for risk-stratifying AT/RT patients and gauging their response to therapy.

Another protein involved in a variety of carcinogenic signaling pathways, including proliferation, immunomodulation, migration, anti-apoptosis, and chemotherapy resistance, is metallothionein. Different isomers of metallothionein have been implicated *in vitro* in inducing chemoresistance in neuroblastoma, melanoma, rhabdomyosarcoma, and medulloblastoma cell lines^[85-87]. A group of researchers, using differential pulse voltammetry to measure serum metallothionein levels, attempted to exploit metallothionein's association with oncogenesis to see if it could be reliably detected at supernormal levels in pediatric solid tumor patients, including in 10 medulloblastoma patients and 4 ependymoma patients. All 38 pediatric solid tumor patients in this study had serum levels of metallothionein roughly 6-8-fold higher than adult controls ($P < 0.05$)^[88]. This work strongly suggests that serum metallothionein may be useful as a non-specific oncologic biomarker in pediatric patients, though additional work is needed to confirm the results with age-matched controls.

A larger study of 106 pediatric patients with brain tumors, including gliomas, medulloblastomas, and ependymomas, studied the relationship between serum levels of the pro-angiogenic growth factors and pediatric brain tumors. In this study, serum vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF) levels were measured at presentation and following surgical resection or debulking of the tumor. While the authors of the study found no statistically significant changes in bFGF levels between groups, serum VEGF was 16.4% higher ($P = 0.05$) in pediatric brain tumor patients compared to controls. Interestingly, subset analysis of only the glioma patients showed that serum VEGF levels were 16.4% lower ($P < 0.05$) than controls^[89]. This is a curious result given glioblastoma and other high-grade glial tumors are known to overexpress VEGF^[90]. The authors also found no statistically significant difference in serum VEGF or bFGF levels in any of the post-surgical patients, regardless of the degree of tumor resection achieved^[89]. These results are, in the end, difficult to reconcile; and this may reflect the extremely diverse collection of pediatric brain tumors included.

Behrends *et al.*^[91] in a study of 40 pediatric cancer patients, including 10 brain tumor patients, employed a less conventional method to identify humoral targets for biomarker development. In contrast to other biomarker development projects that rely on a priori knowledge of cell signaling proteins known to be abnormal in the disease process of interest, Behrend's group used SEREX technology to identify potential humoral targets, in some cases finding cancer antigens with no described function. The group utilized autologous sera and serially screened these sera against autologous cDNA expression libraries in 4 pediatric medulloblastoma patients. From this, the group identified 15 antigens. Humoral responses to these 15 antigens were then tested in the 40 pediatric cancer patients, as well as in 40 pediatric controls. Antibodies were found to 5 of the 15 antigens exclusively in pediatric cancer patients. The authors noted, though, that the humoral responses to these antigens was not uniform. Only 2-3 out of 5 medulloblastomas had detectable antibodies to any one antigen, and the humoral responses varied over time depending on response of the tumor to therapy. The authors also point out that humoral responses may change, as well, due to mutations in some tumors that support immune evasion^[91]. Taken in balance, SEREX screening for humoral biomarker targets is an innovative technique for identifying novel pediatric brain tumor biomarkers, but clinical application is likely to be limited by the marked variability in humoral response across patients.

Limitations to serum biomarkers in pediatric brain tumor patients

While familiar and easily accessible, serum sources for biomarkers do have significant drawbacks. As a peripheral biofluid, the milieu of serum proteins and genetic material is affected by every organ system in the human body. Even large amounts of oncologic biomarkers can easily be diluted out by normal serum components^[35]. Additionally, it is difficult to know what sources - host or tumor - are driving the targeted biomarker concentration levels. Studies have shown that even epigenetic factors, such as a change in diet, can significantly alter measured levels of some serum biomarkers for adult cancers^[38]. As with CSF, the location and biology of pediatric brain tumors also seems to play a part in serum levels of some presumptive biomarkers, with certain tumor-related proteins being undetectable outside of the BBB^[61,63].

Urine

Urine is a filtrate of serum via the glomeruli, and it represents a particularly easy and well-studied biofluid to obtain from children. Excreted oncologic biomarkers such as metanephrine and VMA have been employed clinically for decades as routine components in the work-up of several catecholamine producing solid tumors, including pheochromocytomas and neuroblastomas in both children and adults^[92].

A paper by Pricola Fehnel *et al.*^[93] in 2016 examined the use of urinary bFGF, MMP13 and TIMP3 levels as biomarkers for juvenile pilocytic astrocytomas. The study followed 21 astrocytoma, 17 medulloblastoma, and 21 control pediatric patients with serial urine samples pre-tumor treatment and post-tumor treatment. The authors also examined bFGF and TIMP3 levels in primary juvenile pilocytic astrocytoma cell line conditioned media. They found a significant elevation in bFGF and TIMP3 urine concentrations among the

astrocytoma patients, with a combined sensitivity and specificity of 100% and 95%, respectively. Conditioned media from cultured primary astrocytoma cells also showed relative enrichment of bFGF and TIMP3, concordant with the findings in patient urine samples. Among 9 patient samples where pre- and post-treatment imaging was available, bFGF and TIMP3 levels also significantly correlated with tumor volume changes on imaging^[93].

Another, earlier project from the same group looked at VEGF, MMP2, and MMP9 in urine and CSF samples from a cohort of 28 brain tumor patients ($n = 11$ pediatric, $n = 17$ adult) and 23 control patients. Urinary concentrations of VEGF, MMP2 and MMP9 were all significantly increased within the tumor patient cohort; and urinary VEGF and MMP2, in particular, had excellent sensitivity and specificities for the presence of a brain tumor. VEGF had 95.2% sensitivity and 89.5% specificity, while MMP2 demonstrated 82.1% sensitivity and 95.7% specificity. Both of these proteins were undetectable in the urine of 5 patients for whom follow-up imaging demonstrated complete resolution of their tumors^[94].

Both of these studies are very encouraging for the prospect of developing a clinically deployable and accurate laboratory assay for pediatric brain tumors. However, as with all biomarker sources, urine has special limitations as a diagnostic media that have still not completely been addressed in either of the aforementioned studies. Nolen *et al.*^[69] laid out in an extensive analysis of over 200 potential urinary biomarkers the effects of normalization methods, population variability, and temporal variability on measured biomarker concentrations. The authors of this study found that, while urine total protein had the smallest impact on biomarker variability, none of the normalization methods tested (urine creatinine, urine albumin, urine B2M) was clearly superior to the other. Additionally, the authors observed significant intra- and inter-day variability in urine biomarker concentrations; in most cases, the coefficients of variation exceeded 50%^[69]. These findings should prompt caution when interpreting urinary biomarker data, as robust differences in biomarker concentrations between diseased and normal states will be needed to consistently overcome such high levels of biomarker variability. Even so, the work by Pricola Fehnel *et al.*^[93] suggests that such high levels discrimination may indeed exist for some pediatric brain tumor urinary biomarkers.

Challenges of developing biomarkers from pediatric populations

Compared to the adult neuro-oncology world, the development of circulating biomarker candidates for pediatric brain tumor patients is still in its infancy. This is partially due to a significant statistical barrier to research within pediatric brain tumor patient populations. There are an estimated 4,600 new pediatric brain tumor diagnoses each year in the United States of America^[1]. This compares to an average of 22,172 new adult primary brain tumor diagnoses per year^[95]. As these statistics demonstrate, pediatric brain tumor cases are relatively rare, and individual institutions often do not have enough volume to organize large scale studies on their own. Multi-centered trials and novel screening assays are needed in order to create study populations with enough power to generate meaningful conclusions.

Another issue is the lack of comparative data across biofluids and pediatric brain tumor clinical stages for individual biomarker candidates. As mentioned in this review article, there exist significant theoretical and practical limitations to each biofluid currently targeted for biomarker discovery. Additionally, there is mounting evidence that tumor stage and location relative to the biofluid of interest can alter biomarker yields^[36,41,96]. A large study examining one or more biomarkers in multiple biofluids serially across early and late stages of brain tumor therapy will be needed to answer the question of which biofluid is most suitable for diagnosing and screening which pediatric brain tumors. This is a daunting ask given the difficulties researchers face accruing and maintaining large population pediatric brain tumor studies. A study by Pages *et al.*^[97] is currently underway examining the cfDNA in the CSF, serum, and urine of 192 pediatric brain tumor patients, but results are not available as of the production of this manuscript. It is hoped that this study and others to come like it may help to define the effect of biofluid choice on biomarker sensitivity and specificity for pediatric brain tumors.

Table 2. Summary of select works identifying circulating biomarkers for pediatric brain tumors

Source	Marker(s)	Method	Tumor type	Finding	Ref.
CSF	Type 1 collagen IGFBP4 Procollagen C-endopeptidase enhance 1 Glial cell-line derived neurotrophic factor receptor $\alpha 2$ Inter-alpha-trypsin inhibitor heavy chain 4 Neural proliferation and differentiation control protein-1	LC-MS/MS, RPPA, ELISA	Mixed Brain Tumors	Protein signatures may discriminate metastatic tumors from controls	[98]
CSF	H3F3A /HISTIH313 mutations	Sanger sequencing (DNA isolation, nested PCR) of cfDNA	Diffuse midline glioma	Feasibility and specificity of H3K27M detection in DNA from CSF	[34]
CSF	Prostaglandin D2 synthase	Proteomics MALDI-TOF/ELISA	Medulloblastoma	PGD2S ↓	[64]
CSF	Apolipoprotein A-II	SELDI-TOF mass spectrometry	Brain tumor	ApoAII level ↑	[59]
CSF	LVV VV-hemorphin-7	Proteomics LC-MS	Mixed Brain Tumors	LVV-/VV-h7 ↓ in tumor patients	[62]
CSF	c-Tau	ELISA	Medulloblastoma Ependymoma Astrocytoma	c-Tau ↑	[99]
CSF	CyclophilinA Dimethylarginase 1	Proteomics, mass spectrometry	DIPG	↑ cCypA and DDAH1	[63]
CSF	cfDNA	Genome-wide sequencing	High Grade Glioma JPA Medulloblastoma Ependymoma	cfDNA detected in 74% of tumor patient CSF	[36]
CSF, serum	Human chorionic gonadotropin	Enzyme immunoassay	Germinoma	HCG ↑ in patients with recurrence events	[22]
CSF, plasma	IGF, IGFBPs, IGFs	Microarray, RIA, western	Ependymoma Medulloblastoma	IGFBP-2/IGFBP-3 ↑ tumor patients	[61]
CSF, plasma	Osteopontin	ELISA, qPCR	Medulloblastoma AT/RT	Osteopontin ↑ in AT/RT recurrence	[84]
CSF, serum	AFP beta-hCG	Immunoenzyme	Germinoma NGGCT	↑ AFP in serum ↑ bHCG in CSF	[20]
CSF, serum	miR-371a-3p miR-372-3p miR-373-3p miR-367-3p	qRT-PCR	Germ cell tumors	miRNA ↑	[100]
CSF, plasma	H3K27M-mutant cfDNA	Digital drople PCR	Diffuse midline glioma	H3K27M mutant cfDNA correlates with treatment response	[35]
Blood/serum	ERCC2 methylation	Illumina Beadchip	Medulloblastoma	ERCC2 promoter methylation ↑ correlates with poor prognosis	[101]
Serum	Metallothionein	Differential pulse voltametry	Medulloblastoma Ependymoma	↑ in cancer patient's serum	[88]
Blood/serum	miRNA profile	qPCR	JPA	↑miR21, mir15b, miR23, miR146b correlated with tumor mural nodule size	[41]
Serum	VEGF bFGF	ELISA	High grade glioma	VEGF ↑	[89]
Urine, CSF	MMP-2 MMP-9 MMP-NGAL VEGF	ELISA	JPA	MMP-2, MMP-9, MMP-NGAL, VEGF levels ↑	[94]
Urine	bFGF TIMP3 MMP-13	ELISA	JPA	bFGF, TIMP3 ↑ MMP-13 ↓	[93]
Urine	Netrin-1	ELISA	Medulloblastoma	Netrin-1 ↑ in metastatic medulloblastoma	[102]

CSF: cerebrospinal fluid; cfDNA: cell-free tumor DNA; IGF: insulin-like growth factor; IGFBPs: IGF binding proteins; VEGF: vascular endothelial growth factor; bFGF: basic fibroblast growth factor

CONCLUSION

Pediatric brain tumors remain the most significant oncologic cause of death among children, and pediatric brain tumor diagnosis and longitudinal screening is heavily reliant on MRI - a very limited and expensive screening tool. The creation of reliable and easily deployed biomarker-based assays could dramatically improve pediatric brain tumor detection. Early detection could, in turn, improve current care by allowing for early surgery. Patient therapy could also be tailored based on biomarker-directed tumor risk stratification.

While there are currently many circulating biomarker candidates in CSF, serum, and urine, all the studies to date are hobbled by small cohort size and often mixed populations of tumor types [Table 2]. Follow-up multi-centered studies have failed to materialize for most biomarkers, leaving the validity of virtually all of these candidate pediatric brain tumor biomarkers in doubt. Hopefully, with continued interest, time, and collaboration, these current research needs will be met.

DECLARATIONS

Authors' contributions

Made substantial contributions to conception and design of the review and performed data collection: Bookland MJ

Performed data acquisition, as well as provided administrative, technical, and material support: Kolmakova A

Abstract

Circulating tumor cells (CTCs) have the potential to provide genetic information for heterogeneous tumors, which may be useful for monitoring disease progression and developing personalized therapies. However, the isolation of CTCs for molecular analysis is challenging due to their extreme rarity and phenotypic heterogeneity, which hinders the transformation of CTCs into traditional clinical applications. In order to achieve clinically significant CTC detection, devices utilizing novel microfluidics and nanotechnology have been developed to achieve high sensitivity and specificity capture of CTCs. In this review, we discuss these newly developed devices for CTC capture and molecular characterization for early diagnosis and determining ideal treatment regimen to better manage these cancers clinically. In addition, the potential prognostic values of CTCs as treatment guidelines and that ultimately contribute to realize personalized treatment are also discussed.

Keywords: Circulating tumor cells, sensitivity, treatment, precision medicine

INTRODUCTION

The main cause of cancer-related mortality is cancer metastasis. During this greatly complicated and multi-stage disseminative process, tumor cells (the seeds) detach from primary roots, shed into blood and lymph circulation, undergo the immune attack and shear stress, travel to preferable metastasis soil, and eventually seed and proliferate to develop metastases. On their way to the potential organs, these circulating tumor cells (CTCs) undergo epithelial-mesenchymal transition (EMT)^[1], thereby resulting in enhanced motility and migratory ability that facilitates vasculature invasion. Upon reaching a suitable niche, the CTCs undergo mesenchymal-epithelial transition (MET), subsequently reacquiring the stem cell properties and reactivating proliferative capability to colonize at metastatic sites^[2]. In order to prevent and surveil the development of metastasis disease, especially metastatic carcinoma, the detection and characterization of CTCs are of great interest to scientists. CTCs were first detected in cancer patient in 1869 by Australian physician named Thomas Ashworth. In the past couple of decades, numerous studies have suggested that the presence of CTCs in the blood of cancer patients has the clinical potential as a noninvasive diagnosis marker and a prognosis indicator known as a “liquid biopsy” to replace traditional invasive biopsy, whilst also facilitating technical advances for detection of CTCs.

CTC analysis has a variety of clinical applications, including real-time non-invasive monitoring of CTCs as biomarkers for new cancer therapies as well as identifying new potential therapeutic targets that directly inhibit cancer metastasis. Although the potential applications of CTC analysis appear to be very promising, due to the rarity (one CTC per billion hematologic cells) and heterogeneity (e.g., differences in morphology and gene expression) of CTCs in the blood of cancer patients, there are few commercially available techniques for clinical use. High sensitivity and specificity of CTC detection methods thus have a great impact on improving patient outcomes. Therefore, currently available technologies for CTC detection have become increasingly more sensitive and reliable, with the goal of early cancer detection and thus successful cancer treatment. An important new direction in this field is the development of devices and materials that provide information beyond CTC enumeration. Integrated devices allow for the separation of heterogeneous CTCs to facilitate a more in-depth characterization of these cells (e.g., phenotypic and molecular profiling) to develop a personalized treatment plan. Nanomaterials and microfluidic-based nanotechnologies may be the most promising strategies for implementing ideal CTC capture devices to replace traditional tools, primarily relying on their small size, high throughput capacity and large surface-to-volume ratio to solve the problem of CTC heterogeneity^[3]. In this review, we will provide an overview of current CTC isolation strategies and molecular characterization with brief insights into the potential clinical implications of CTC capture and characterization.

SENSITIVE CTC ISOLATION METHODS

CTCs may have the potential to predict the disease progression in patients with early-stage or advanced cancer, even before the formation of primary tumor. However, the extreme rarity of CTCs in blood poses a challenge for detecting CTCs from blood; for example, one study indicated that only 1.43% of 350 metastasis cancer patients had ≥ 500 CTCs/7.5 mL blood^[4]. Inability to draw large volume of blood from patients highlights the need for improved CTC isolation methods to achieve sensitive and specific CTC detection in small sample volumes. CTC isolation methods have been developed based on either biological (surface antigen, cytoplasmic protein, invasion capacity, *et al.*) or physical (size, density, deformability and charge, *et al.*) properties of tumor cells. We discuss the most popular technologies and latest advances in the following sections [Figure 1].

Detection of CTCs based on their biological properties

Immunomagnetic beads-based isolation

The most widely used enrichment method is a positive selection method based on the epithelial cell adhesion molecule (EpCAM) antibodies^[5-7]. So far, CellSearch System (Menarini Silicon Biosystems, Italy) is the first and also the only one being up to the standard of US Food and Drug Administration (FDA),

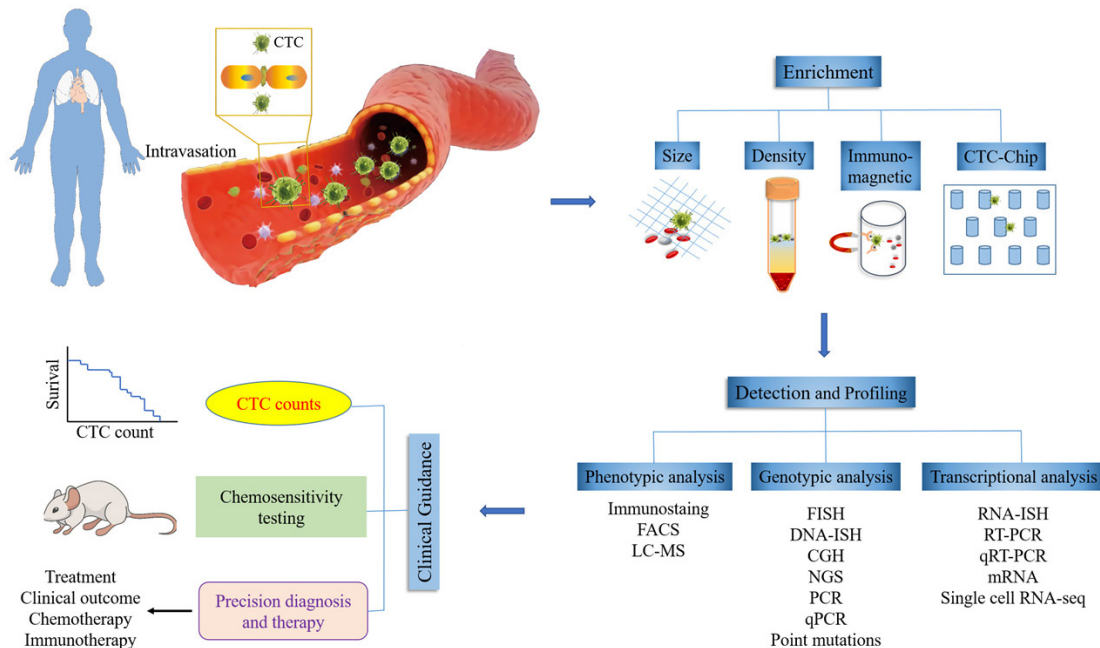

Figure 1. Illustration of current applications of CTC technologies. The CTCs exit the primary tumor and intravasate into the bloodstream. CTCs are enriched through various CTC isolation technologies such as size, density, immunomagnetic and CTC-Chip. Detection methods are utilized to detect CTCs based on phenotypic, genotypic and transcriptional analysis. The clinical applications of isolated and detected CTCs. The CTC count is associated with the potential of patient's survival. CTCs can be good chemotherapy monitoring markers for predicting drug sensitivity/resistance in preclinical and clinical settings. CTC: circulating tumor cells; FACS: fluorescence activated cell sorting; LC-MS: liquid chromatograph-mass spectrometry; FISH: fluorescence in situ hybridization; CGH: comparative genomic hybridization; NGS: next-generation sequencing; PCR: polymerase chain reaction; qRT-PCR: quantitative reverse transcription-polymerase chain reaction

which consists of the CellTracks Autoprep and the CellSearch Epithelial Cell kit, integrating EpCAM based immunomagnetically enrichment, 4',2-diamidino-2-phenylindole (DAPI) based cell nuclei staining, CD45-Allophycocyan specified leukocyte negative selection and cytokeratin 8,18,19-Phycoerythrin specified epithelial cells positive selection into an objective indicator (EpCAM+, DAPI+, CD45-, cytokeratin+) of CTC counts. In 2004, it was cleared for monitoring the outcome of therapies and optimizing clinical decision for breast cancer; later, it was also cleared for use in prostate and colorectal cancers. Through the CellSearch, which has become the benchmark for all other CTCs isolation methods, CTC counts have been associated with prognosis for progression-free survival (PFS) and overall survival (OS) in these three kinds of metastatic cancer^[8-10].

Although clinical correlations have been identified, methods for large scale isolation of CTCs from peripheral blood are lacking, therefore, efforts have been focused on improving the isolation sensitivity and efficiency. Talasaz *et al.*^[11], reported a magnetic sweeping device (MagSweeper, Stanford University, Stanford) consisting of a nonadherent plastic sheath covered magnetic rod with anti-EpCAM antibody functionalized beads, allowing for a ~60% capture efficiency to target cells and a purity of 100% for HLA-A2 cells. Ephesia technology integrated anti-EpCAM functionalized self-assembled magnetic beads with microfluidics, demonstrating a capture efficiency > 94%^[12]. Similar immunomagnetic platforms [Figure 2A] also included the Magnetic Sifter with magnetic pores incorporated into a microfluidic chip^[13]. Moreover, compared with CellSearch system, Adna Test (Qiagen, Hannover), a highly specific immunomagnetic cell-isolation system, with its improved antibody cocktails provided an effective approach to increase the efficiency of CTCs capture and complements the CellSearch for detection of CTCs^[14]. Mayo *et al.*^[15] utilized MACS cell separation platform (Miltenyi Biotec) based on a mixture of cytokeratin (CK) coated magnetic beads to isolate CTCs in lung cancer patients.

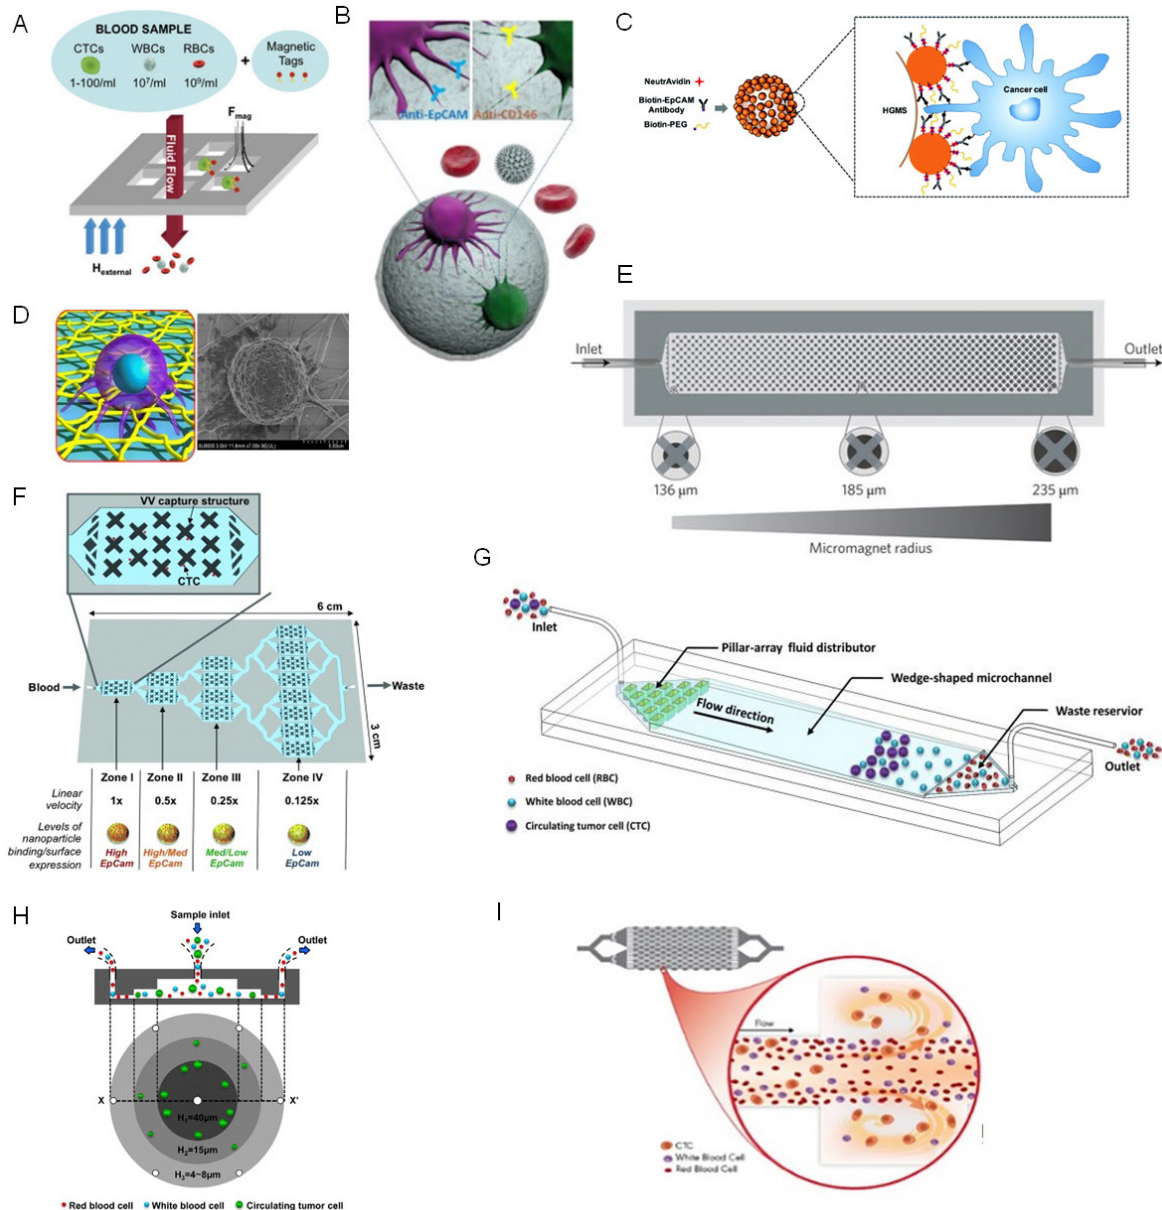

Figure 2. Strategies for CTC enrichment. A: A magnetic sifter device for CTC isolation when a magnetic field is applied. Magnetically labeled CTCs are captured at the edges of the pores, while unlabeled cells pass through the pores under fluid flow; B: dual antibodies (anti-EpCAM and anti-CD146) and biodegradable gelatin nanoparticle-coated microbeads for the capture of mesenchymal CTCs; C: a microfluidic device embedded a wedge-shaped microchamber for cell separation based on multiple biophysical properties; D: a 3D bionic cytosensor with PLGA nanofibers for CTC capture; E: vortex technology exploited for CTC isolating; F: a multizone velocity valley device for isolating heterogeneous CTCs in four different regions of varying linear velocities; G: the hollow glass microspheres with nanotopographical structures (NSHGMS) for excellent CTC isolation; H: a microfluidic device embedded a pyramid-shaped microchamber for size-based CTC separation; I: a MagRC approach for separating and in-line profiling of heterogeneous CTCs. However, a number of studies have shown that the levels of CTCs estimated by EpCAM-based methods including CellSearch, is uncorrelated with prognosis in patients with some types of carcinomas. Most of the evidence attributes this inconsistency to the large degree of heterogeneity in CTCs. Specifically, CTCs might undergo full (or partial) EMT during dissemination, resulting in several phenotypes including epithelial, mesenchymal or hybrid (epithelial/mesenchymal) CTCs. These subpopulations of cells may insufficiently bind to antibodies, thereby evading detection^[16,17]. Therefore, a lack of sensitive and specific biomarkers still hinders the isolation and detection of CTCs. Recent studies provide some probabilities. Here are some examples of successful markers. Glycan sialyl-Tn (STn) is often associated with cancer metastasis and expressed in metastatic colorectal and bladder tumors. Neves *et al.*^[18] fabricated a STn affinity-based microfluidic device for specifically isolating STn+ CTCs, following an enzyme-based method to recover viable CTCs for downstream analyses. It showed greatly higher isolation efficiency from the blood of patients with advanced bladder and colorectal cancers. Plastin3 (PLS3) is expressed in metastatic cancer cells but absent in normal cells^[19]. Similarly, telomerase which is expressed at high levels in almost all the cancer cells, but not in normal cells, plays an important role in cancer immortality by replenishing chromosome ends^[20]. Green fluorescent protein (GFP) fused adenoviral was employed as a probe to target telomerase in cancer cells, and this strategy was applied to detect and isolate CTCs in Non-Small Cell Lung Cancer (NSCLC) to evaluate response to radiation therapy and to potentially detect recurrence and progression of disease. Oncofetal chondroitin sulfate (ofCS) is expressed in both epithelial and mesenchymal tumor cells, as well as the cells that have undergone EMT, suggesting that it may be an ideal candidate for isolating and analyzing CTCs^[21,22]. Agerbæk *et al.*^[23] employed recombinant VAR2CA (rVAR2) to efficiently target ofCS expressed CTCs from patients with hepatic, prostate, pancreatic or lung cancer, allowing for isolation of a larger and more diverse population of CTCs compared to anti-EpCAM-antibody approaches. More recently, Ding *et al.*^[24] detected Folate receptor (FR) positive CTCs in peripheral blood from 200 patients with lung adenocarcinoma, and further determined that FR+ CTC number could be used for screening solitary pulmonary nodules (SPNs) in patients and diagnosing early-stage lung cancer with sensitivity of 70.2% and specificity of 79.3%. Meanwhile, more specific biomarker for specific subgroup of CTCs is of interest. Cyclooxygenase-2 (COX-2) has been implicated in transforming growth factor- β (TGF- β 1) mediated EMT progress^[25] and has a higher level of expression in subpopulations of mesenchymal CTCs correlated with distant metastases^[26]. These results suggested FR might be a novel biomarker for isolation and therapy targets. A subpopulation of tumor cells can express cluster of differentiation 146 (CD146) during EMT process, during which EpCAM expression is reduced. Therefore, Huang *et al.*^[27] [Figure 2B] designed dual antibodies (anti-EpCAM and anti-CD146) and biodegradable gelatin nanoparticle-coated microbeads to improve the capture of mesenchymal CTCs, achieving high efficiency (> 80%) and high cell viability (92.5%).

All aforementioned *ex vivo* detection systems require substantial quantities of blood. The GILUPI CellCollector (NANOMEDIZIN), approved by Conformite Europeenne in 2012, is another commercial EpCAM positive based selection device and is the first developed *in vivo* CTC isolation system to overcome the limitations of blood sample volume^[28-30].

Except those EpCAM-based positive selection, CD45 negative selection is applied to deplete the CD45+ cells, mostly using RosetteSep system (Stem Cell Technology, Vancouver), and to analyze the EpCAM-negative CTCs in combination with EPISPOT (Epithelial Immunospot assay, France). Ramirez *et al.*^[31] first evaluated the EPISPOT assay on a large cohort of metastatic breast cancer patients with a positive rate of 59% compared with the 48% positive rate using CellSearch, demonstrating its clinical prognostic relevance.

Microfluidic and nanotechnology-based CTC devices

Microfluidic devices enable efficient processing of complex blood samples with minimal damage to target cells. Owing to the synergistic benefits of the microfluidic devices and immunomagnetic separation, microchip-based immunomagnetic technologies are also commonly used for CTC detection. The most representative

microfluidic device based on anti-EpCAM for CTCs isolation is a microscope slide sized CTC-Chip with a mass of geometrically distributed microposts coated with anti-EpCAM^[32]. A 98% viability of captured CTCs was reported with minimal preprocessing and low flow stress^[33]. Ozkumur *et al.*^[34] developed an automated platform, termed “CTC-iChip”, combining the strengths of microfluidics and the benefits of magnetic-based cell isolation for single-cell separation. This CTC-iChip was able to detect the *EML4-ALK* gene fusion in lung cancer, suggesting that it could be a promising tool for clinical diagnosis. Then Stott *et al.*^[35] developed a microvortex-generating herringbone (HB)-Chip for effective capture of CTCs. The micromixer device was fabricated to enhance the cell-surface interaction. Subsequently, improvement was achieved by employing nanostructured substrates and chaotic micromixers, increasing the recovery rate up to 95%^[36].

For the sake of increasing the sensitivity of capturing exceedingly rare CTCs, many efforts have been made to fabricate nanostructures into the microfluidics to increase the interaction between ligands and cells; such devices include electropolymerized polymer nanodots^[37], electrospun TiO₂ nanofiber^[38], and silicon nanowires^[39-41]. More recently, Dong *et al.*^[42] [Figure 2C] utilized a nanotopographical surface (^{NS}HGMS), based on the CTC isolation technology of anti-EpCAM antibody modified Self-floating hollow glass microspheres (HGMS), to achieve excellent capture performance (93.6% ± 4.9% efficiency and 30 cells/mL detection limit in 20 min). A preferable method was based on a combination of advantages of different approaches. Wu *et al.*^[43] [Figure 2D] tactfully fabricated a 3D bionic cytosensor with electrospun polymers (PLGA) nanofibers crosswise stacked on Ni micropillars for better CTC filopodia climbing, subsequently coupled with immuno-selection by anti-EpCAM quantum dots, demonstrating a sensitive detection range and limit of 10¹-10⁵ cells/mL and 8 cells/mL, respectively, as well as a recovery range of 93.5%-105%.

However, fabricating these nanoscale substrates is time-consuming. Sheng *et al.*^[44] developed a microfluidic device combined with DNA aptamer modified gold nanoparticles (AuNPs) to enhance the capture performance without elaborate establishment for nanostructure. When compared with aptamer on the surface alone, the binding efficiency of AuNPs-aptamer showed a 39-fold increase and the capture efficiency rose from 49% to 92%. In order to profile the dynamic phenotypes of rare CTCs, Poudineh *et al.*^[45] [Figure 2E] fabricated a magnetic nanoparticles-enabled ranking cytometry (MagRC) approach to separate and in-line profile heterogeneous CTCs based on the longitudinal profile of magnetic field gradients. They demonstrated that this device was capable of profiling CTCs with higher sensitivity at a single-cell resolution in unprocessed blood from cancer patients compared to other previously developed magnetic sorting techniques. Similarly, an immunomagnetic nanoparticle-mediated binning and profiling approach [Figure 2F] was developed to separate CTCs with different phenotypes based on the differential expression of surface markers^[46]. The CTC subpopulations could be spatially sorted in different compartments of a fluidic chip, providing a powerful means to sort heterogeneous CTCs and investigate EMT in patient CTCs.

Detection of CTCs based on their physical properties

CTCs undergo cellular processes (EMT, MET, *et al.*) during dissemination, resulting in a number of phenotypes. Thus, it is important to determine which CTC fractions possess greater metastatic potential and/or stronger resistance to immune surveillance and medical treatment. In this case, CTCs would have better prognostic and therapeutic values. The aforementioned methods depend on specific markers of interest for isolation; however, subpopulations of CTCs lacking the markers may be unintentionally overlooked. Therefore, additional methods that could serve as complements to protein markers are urgently needed.

Size-based CTC isolation

Alternative methods that isolate CTCs dependent on physical properties have been developed to replace or complement the antibody-based isolation methods. Most of the CTCs are believed to be larger than normal blood cells (leukocytes, erythrocytes). And pores with ≈ 8 μm in diameter have been shown to be appropriate for CTC detainment.

Thanks to various advantages, such as retention of cell morphology, antigen independence, and high sensitivity and specificity, membranous filter devices, for example, isolation by size of epithelial tumor cells (ISET) (Rarecells Diagnostics, Paris, France), have caught more attention in CTC researches. In a comparative study, Bai *et al.*^[47] estimated the clinical effect of CTCs by using CellSearch system and ISET devices among patients with renal cell carcinoma (RCC), discovering that ISET was more appropriate for RCC patients. CTCBIOPSY (Wuhan YZY Medical Science and Technology Co., Ltd., China) is a commercial one-step ISET device which could complete automatic detection and identification within 10 min^[48]. The Parsortix technology (ANGLE plc) incorporated a microscope slide sized cassette for CTC separation based on cell size and compressibility^[49]. Owing to the excellent capture performance and the advantage of easy retrieval of viable CTCs for downstream analysis, the FDA clearance process of this device for diagnose is underway. The ClearCell FX system (Clearbridge BioMedics, Singapore), one of the first automated cell separation and retrieval systems, is a new label-free and size-based technology with extremely high recovery rates by dean flow fractionation^[50]. These devices, together with other similar size exclusion platforms, such as ScreenCell (ScreenCell, France) based on microporous membrane filter^[51], CellSieve™ (Creatv Microtech), and MetaCell (Ostrava, Czech Republic), constitute the next generation label-free CTCs enrichment technologies, demonstrating CTC isolation and detection with high efficiency, purity and viability.

Moreover, size difference can be combined with other physical features to improve capture yield. For example, a recent wedge-shaped microfluidic device [Figure 2G] based on the difference in size, as well as rigidity and nuclear/cytoplasmic ratio between CTCs and normal blood cells, was fabricated to enhance CTC isolation, exhibiting excellent capture performance with $\geq 85\%$ capture efficiency^[52]. Similarly, benefiting from those multiple biophysical properties, Liu *et al.*^[53] [Figure 2H] developed a pyramid-shaped microchamber to achieve a more than 85% capture efficiency and a 93% recovery yield. In addition, vortex technology has been exploited and validated for isolating CTCs based on differences in size, shape and deformability by inertial microfluidics and laminar micro-vortices. VTX-1 liquid biopsy system [Figure 2I] was developed for fully automated isolation and enumeration of CTCs with either high recovery mode or high purity mode in the vortex microfluidic chip^[54].

Density-based CTC isolation

The density of nucleated CTCs lies between plasma and red blood cells, and within the scope of white blood cells. Quantitative buffy coat analysis by centrifuging for separation was established by Stephen C. Wardlaw in 1983^[55]. AccuCyte separation based on this principle is the first step of the commercial RareCyte Platform (RareCyte, Inc. Seattle)^[56], coupled with fluorescence analyzing (CyteFinder system) and picking (CytePiker) to count and retrieve cells for downstream single-cell characterization, overcoming the limitation of capture methods which are dependent on sizes that might miss the small sized-CTCs and immunomarkers that might not be expressed on some subpopulations. Some commercial density gradient solutions, such as Ficoll-Paque (GE Healthcare) and Percoll (GE Healthcare), provide simple-to-use and inexpensive methods for separating CTCs in the mononucleocyte layer from granulocytes and erythrocytes. OncoQuick (Greiner Bio-One/Hexal Gentech, Germany) consists of a sterile tube with a porous barrier inserted above separation medium, allowing the simple, rapid and highly efficient enrichment of CTCs through density-based centrifugation and size-based separation.

Dielectrophoresis based CTC isolation

The overlap of size or density between CTCs and normal cells may affect the efficiency of these size-/density-based approaches. Electrical properties of CTCs have been applied to discriminate them from other normal cells using dielectrophoresis (DEP). Based on conventional DEP devices, microchips are used to manipulate electric fields to achieve higher capture efficiency and recovery rate. Nguyen *et al.*^[57] fabricated a microchip to guide target lung CTCs to sensing electrodes by DEP and hydrodynamic forces, achieving a LOD of 3 cells and an efficiency over 90% at 50 kHz electric field intensity within 10 minutes. The commercial

DEPArray TM cartridge (Menarini Silicon Biosystems, Italy) that contains an array of electrodes embedded with detection sensors is based on the same principle for isolating target cells for subsequent analysis.

MOLECULAR CHARACTERIZATION OF CTCs

Not all the CTCs are detectable and not all detected CTCs have the potential for metastases, indicating that CTC enumeration alone may not be an effective marker of progressive disease. A commonly used chemotherapy agent, isosfamide, was reported to decrease the number of lung cancer nodules but also increase CTC frequency in a pre-clinical model of osteosarcoma^[58]. Although a large number of clinical trials have suggested that CTC presence is associated with poor survival in patients with some metastatic cancers^[59]. Their characterization, including phenotyping and genotyping, could lead to a better understanding of heterogeneity of metastatic tumor and further facilitate the management of patients for individualized treatment.

Protein analysis of CTCs

Most CTC detection assays are compatible with identification systems for enumeration and follow-up characterization. The most common procedure consists of morphological analysis (size, shape, nuclear cytoplasmic ratio, cell shrinkage), immunohistochemical analysis^[4] [Figure 3A], and fluorescence immunocytochemistry (ICC). There are various markers that are useful for ICC analysis. For instance, DAPI (nuclear counterstaining), pan-keratin (positive marker), and CD45 (negative marker) are applied in the CellSearch system. Fluorescence channels and specific antibodies are now accessible for users to define the detection of more established markers, for example, epidermal growth factor receptor (EGFR)^[60], androgen receptor (AR)^[61], folate receptor (FR)^[62], and several EMT-related markers (such as vimentin) etc., which are not only the identification markers but also therapy-associated targets. Furthermore, the ELISPOT assay combines cell culture and an immunospot test to quantitatively and qualitatively detect single viable cells expressing-cancer associated marker proteins.

One of the more reliable analytical approaches is protein profiling of captured CTCs, which can shed light on the roles of CTCs in tumor metastases and disease progression. At present, proteomic analyses mostly rely on mass spectrometry and the sensitivity of this method is improved with appropriate sample preparation and targeted cell enrichment. High-resolution porous layer open tube based liquid chromatograph-mass spectrometry (PLOT-LC-MS) lead to identification of approximately 4000 proteins of 100-200 MCF-7 cells with zeptomole detection sensitivity. Recently, Zhu *et al.*^[63] incorporated the nanodroplet processing platform (nanoPOTS) with ultrasensitive LC-MS, allowing identification of 1500-3000 proteins from 10-140 cells. He subsequently combined CD45 negative selection and laser capture microdissection-based purification with nanoPOTS-LC-MS for studying protein expression of rare or single CTCs, identifying 164 and 607 protein groups of 1 and 5 spiked LNCaP cells, respectively^[64].

Because of these analytical advances, a wealth of information regarding disease metastasis and progression is being discovered. For example, a recent report about profiling of single live CTC protease activity demonstrated the increased expression of matrix metalloproteases (MMPs) secreted by CTCs relative to normal cells is capable of triggering proteolytic processes that assist in invasion and immune evasion^[65].

Gene analysis of CTCs

Fluorescence *in situ* hybridization (FISH) technology is highly commercial and easily accessible for analysis of genetic alterations (deletion, insertion, translocation and rearrangement) at the chromosomal level, and is widely used in CTC identification and characterization. For example, RNA-ISH has been utilized for detection of onco-miRNA (such as miRNA-21)^[66], while DNA-ISH has been used for quantifying copy number of cancer-related genes (such as HER2/*neu* gene)^[13]. Based on an optimized FISH method, Frithiof *et al.*^[67] [Figure 3B] performed a CellSearch-based CTC separation assay to quantitatively measure HER-2

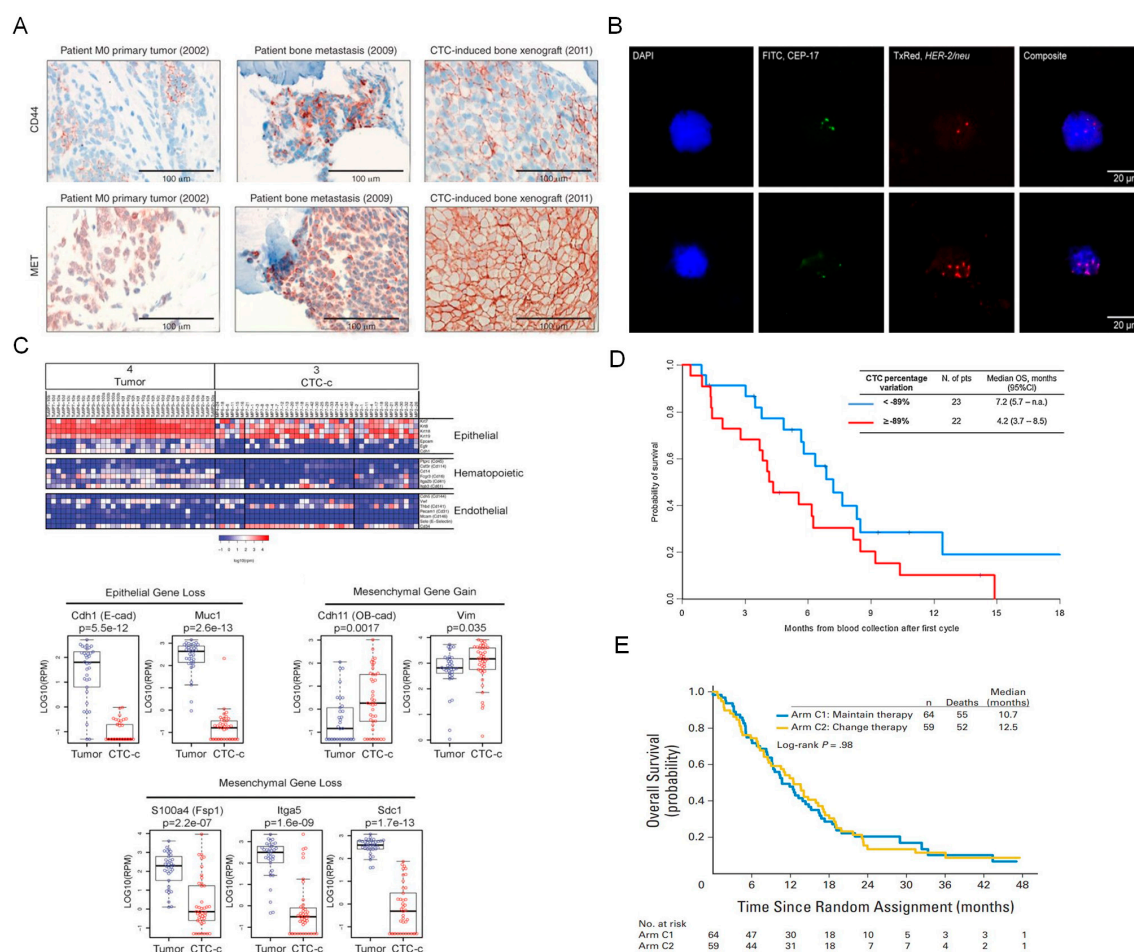

Figure 3. Molecular profiling and clinical application of CTCs. A: Immunohistochemical analysis of the expression of CD44 and MET in primary tumor (M0, nonmetastatic stage), bone metastasis and CTC-induced bone xenograft after transplantation of sorted CTCs; B: FISH images of a patient with metastatic breast cancer have no detectable HER-2 amplification (top panel), and the lower panel is HER-2 amplified CTC; C: the expression heatmap of epithelial, hematopoietic, and endothelial markers in primary tumors and classical epithelial CTCs (CTC-c). Epithelial and mesenchymal genes differentially expressed in CTCs vs. tumors; D: Kaplan-Meier curves of overall survival according to CTC change after one cycle of chemotherapy; E: overall survival (OS) and PFS in patients with metastatic breast cancer for whom therapy failed to reduce CTCs at first follow-up (approximately 21 days after first dose of chemotherapy), or randomly assigned to maintain the original chemotherapy (arm C1) or to switch to an alternative chemotherapy (arm C2). amplification in breast cancer CTCs. They validated that FISH was superior to protein evaluation of *HER-2* status in predicting breast cancer patients' response to *HER-2* targeted immunotherapy and found that one in six patients underwent CTC *HER-2* amplification during the treatment of metastatic disease.

Hybridization analyses, much like ICC analyses, are limited by the availability of both antibodies and microscope filters. Multiple polymerase chain reaction (PCR) targeting associated RNA and DNA for detecting assorted genetic mutations may overcome these limitations. Real-time PCR (RT-PCR) can be used to determine the differences of gene expression between CTCs and normal cells. And quantitative reverse transcription PCR (qRT-PCR) takes advantage of a reverse transcriptase reaction to convert RNA into cDNA before regular RT-PCR. Global or specific gene expression profiling of CTCs has been generated by real-time reverse transcription-PCR analysis, providing insights about mechanism of cancer and development of novel diagnostic biomarkers and therapeutic targets^[68]. These technologies following CTC isolation has been used for identification of various gene markers, such as ALDH1 (stem cell marker), phosphoinositide kinase-3 (PI3K α), TWIST1, TP53, and Akt2

(stem cell markers)^[69]. Mostert *et al.*^[70] performed a CTC isolation assay and mRNA expression profiling using the CellSearch technique in 142 metastatic colorectal cancer (mCRC) patients. They measured 95 mRNAs by RT-qPCR and found that 34 CTC-specific mRNAs were higher in patients with ≥ 3 CTCs compared with healthy donors. This CTC-specific gene panel for mCRC patients, such as *KRT19*, *KRT20* and *AGR2*, may aid in characterizing how CTCs with different expression profiles contribute to malignancy, thereby furthering the realization of individualized cancer treatment. Campton *et al.*^[71] developed a comprehensive and sensitive platform, named as AccuCyte®-CyteFinder® system, for identification and characterization of individual CTCs. Using the whole genome amplification (WGA) product, they confirmed that the TP53 gene, which is known to contain the R175H mutation in SKBR3, enables personalized, molecularly-guided cancer treatment.

Ampli11 TM (Menarini Silicon Biosystem), a product developed for single-cell WGA, can be used to amplify DNA for downstream genotyping analysis, including comparative genomic hybridization (CGH) and next-generation sequencing (NGS). Upon its development in 1992, CGH technology opened a new avenue in genomic investigation and, more particularly, in cancer gene analysis. In the past, CGH was applied for analysis of tumor tissues, but many studies have suggested that data from primary tumors alone is insufficient. Array CGH, which exploits ordered arrays of genomic DNA sequences, is widely used for analysis of CTCs, including identification of genomic alterations which include insertion/deletion, single-nucleotide variations, copy number variations (CNVs)^[72]; identification of candidate oncogenes or tumor suppressors; identification of novel biomarkers involved in metastasis, cancer progression and therapy response; and identification of subgroups of CTCs^[73]. High-throughput NGS is another strong technology to analyze heterogeneity of CTCs and reveal the mechanisms of metastasis, which might be the Achilles' heel in disease progression. Bertucci *et al.*^[74] utilized aCGH and NGS to compare DNA copy number and mutational profiles of 365 cancer-related genes between primary tumors and metastases and discovered a degree of divergence for actionable driver genes that might be extremely relevant with cancer metastasis. Profiting from whole genome amplification technology, the limited amount of single-cell genomic DNA sample can be amplified indistinguishable for sequencing.

Single-cell RNA sequencing was used to detect the heterogeneity of CTCs, unveiling the mechanism of drug resistance of androgen receptor (AR) inhibitors in prostate cancer^[61]. The technique was also used to identify conduct a transcriptomic analysis in pancreatic CTCs, finding increased expression of stromal-derived extracellular matrix (ECM) proteins, which facilitate cell migration and invasiveness, in CTCs from mice and humans with pancreatic cancer^[75] [Figure 3C].

Single-cell exome sequencing of isolated CTCs from cancer patient, revealed insertion/deletion and single-nucleotide variation in CTCs after whole genome amplification. The results showed cancer-type specific CNVs that are reproducible within cells of the same patient, or even between patients with the same type of cancer^[76].

CLINICAL IMPLICATIONS

Prognostic and diagnostic value of CTCs

Several studies have highlighted the correlation between CTC burden and treatment effect, indicating the prognostic value for patients receiving chemotherapy or surgery and the potential of surveillance of disease recurrence or metastasis [Table 1]. Several years after chemotherapy, patients with high-risk breast cancer with elevated CTC counts in their peripheral blood were reported to have worst survival prospect^[77]. Similarly, patients with colorectal cancer with elevated CTC counts were more likely to have recurrence after 3 years of curative resection, showing the relation between post-operative CTCs and poor prognosis^[78]. The prognostic value of CTCs was demonstrated by Nicola *et al.*^[79] [Figure 3D] in 60 patients with extensive SCLC. After assessment with the CellSearch system, the group isolated and analyzed CTCs in 90% (54/60)

of patients at baseline and demonstrated that CTC count was significantly associated with the number of organs involved. A reduction in CTC count of more than 89% after chemotherapy significantly improved the prognosis accuracy and was associated with a better outcome. They concluded that only the change of CTC count after the first chemotherapy cycle provided clinically relevant information. However, there were still some clinical trials (such as: gov NCT00382018) that failed to observe improved PFS or OS for cancer patients with decreased CTCs after therapies^[80] [Figure 3E]. Compared to either CTCs levels or cancer specific antigen levels alone, the combination of both two biomarkers provided a notably better predictive indicator for patients with advanced cervical cancer^[81].

Paired CTCs are correlated strongly with origin tumor cells, thus characterization of this subset of genes of CTCs might help to predict primary tumor origin. And CTCs detached from different parts within same tumor or even from different tumors are originally heterogeneous in nature. Gene expression profiling of CTCs from patients with different metastatic cancers showed the different but unique gene expression patterns of those cancer types, providing novel noninvasive diagnostic tools^[68] and essential information for personalized treatment.

On the other hand, CTCs undergoing certain transitions, such as EMT and MET, might generate new genetic alterations which are absent in the primary tumor, but related with potential distant tumor. Characterization of these subgroups of CTCs might assist in localizing specific distant metastatic sites. Additionally, some subgroup of CTCs may harbor changes that are undetectable in the tumor of origin, but are related to drug-resistance and management of treatment. Revealing the qualitative and quantitative divergence between the CTCs and the primary tumor or within CTCs by genotyping and phenotypic analysis is crucial for future studies of individualized medicine in metastatic disease. However, some changes present in CTCs homogeneously take place within primary tumor, suggesting CTCs, to some extent, might be a noninvasive and real-time indicator for following cancer progression and monitoring therapeutic response.

CTCs predict therapy outcome and provide personalized therapeutic targets

CTC enumeration can be a good marker for predicting drug sensitivity/resistance in preclinical and clinical settings. CTC quantity reasonably correlates well with clinical and instrumental tumor response. To investigate the clinical significance of CTCs in predicting the tumor response to chemotherapy, Wu *et al.*^[82] detected CTCs at baseline and during chemotherapy in 453 eligible lung cancer patients, indicating that disease control rate (DCR) of CTC-negative patients was significantly higher than that of CTC-positive patients; more importantly, patients also showed higher OS. The CTC status has been reported to be related to prognosis and is altered in response to chemotherapy in many other tumor types, such as colorectal cancer^[10], breast cancer^[83], osteosarcoma^[58]. Smerage *et al.*^[80] confirmed the prognostic significance of CTCs in patients with metastatic breast cancer, demonstrating that an increased number of CTCs was associated with poor prognosis. Early conversion to alternate cytotoxic therapies was ineffective in prolonging OS in patients with increased CTCs after receiving 21 days of first-line chemotherapy. For this population, a more effective treatment than standard chemotherapy is needed.

CTC characterization can generate predictions of drug potency and therapeutic efficacy before or during treatment according to analysis of targeted protein expression and signaling pathway activity. The development of immune check point inhibitors for cancer therapy, for example, anti-PD-L1, have achieved much success due to increased efficacy and decreased toxicity^[84]. However, PD-L1 expression detection for prediction of therapeutic response using tumor biopsies prior to treatment is invasive and insufficiently precise to guide treatment planning, resulting in some cancer patients being treated with an expensive but ineffective and toxic therapy. Instead, serial monitoring of patients treated with immune checkpoint inhibitors showed that a decrease of CTC score correlated with improved PFS and OS, and further demonstrated that RNA-based CTCs score during the immunotherapy has the potential to be a predictive biomarker for immunotherapeutic outcome^[85].

Table 1. Presence of CTCs and clinical outcome in cancer patients

Tumor type	Technique	Patient number	CTC cut-off	Patient Ratio	Baseline		Treatment		PFS		Post/During Therapy		Ref.
					P value	HR (95%CI)	P value	OS	HR (95%CI)	P value	HR (95%CI)	P value	
IBC (stage III)	CellSearch	63	≥1 CTC/ 7.5 mL	27%	NR	NR	NR	NR	4.22 (1.67-10.67)	log-rank P = 0.005	1.53 (0.41-5.79)	log-rank P = 0.54	[99]

Beyond enumeration alone, CTCs could provide crucial information of tumor malignancy via molecular characterization, leading to better treatment monitoring and molecular-/cancer cell-targeted therapies. The genotypic changes in CTCs provided the best suitable targeted therapy and enabled assessment treatment regimen efficacy over time. Epidermal growth factor receptor (EGFR) on the CTC surface has been verified as extremely significant in the process of tumor growth and progression. EGFR inhibitors (HER2 inhibitors, tyrosine kinase inhibitors, TKI and monoclonal antibodies) have been licensed for treatment of cancers caused by EGFR up-regulation, such as NSCL, breast, renal cell, squamous cell, colon and pancreatic cancers. However, in some cases, EGFR-targeted inhibitors are not effective due to the emergence of drug-resistance mutations. Mutation screening analysis of EGFR in CTCs may provide an explanation for drug-resistance mechanism and also reveal possibilities for diagnostic and therapeutic interventions^[60]. Inhibitors of other therapeutic molecular targets including mTOR, such as temsirolimus, and phosphoinositide 3-kinase (PI3K), such as ZSTK474, LY294002, have shown to have anti-proliferation in clinical trials^[86,87]. Most cell populations of the immune system play an important role in survival and seeding, or even enhancing the growth of tumorigenic subpopulations of CTCs. The molecular characterization of CTCs might assist in unveiling intercellular interaction mechanisms and providing potential therapeutic targets. For instance, the extracellular surface interacting protein, PD-L1, is one such target that is currently generating much interest^[84]. In consideration of costs and toxicity of anti-PD-L1 therapy, predictive biomarkers able to distinguish responders from non-responders are in urgent demand. Real-time CTC analysis provides significant information on drug resistance^[88]. In addition, CTCs are now regarded as a new cellular therapeutic target. Photodynamic therapy was used to selectively kill GFP-expressing CTCs by energy transfer between expressed GFP and pre-accumulated rose bengal (RB) in cells, demonstrating that clearance of CTCs could reduce metastasis and extend survival^[89].

CONCLUSION AND OUTLOOK

The potential clinical value of CTCs has been established. Advances in CTC isolation and molecular characterization offer the possibility for early detection and diagnosis, improve the satisfaction of therapies, as well as expand our knowledge about underlying mechanisms of cancer dissemination and progression.

Although the tremendous technical advances in CTC isolation and detection make it possible to analyze extremely rare CTCs, there are still many hurdles. First, a criterion to standardize different kinds of detection assays is urgently needed in clinical applications. Secondly, while the emergence of new predictive biomarkers leads to clearer recognition about tumor metastases and disease progression, novel targets for prognosis and treatment need to be further validated and standardized. The next frontier of CTCs detection lies in thorough characterization, which might rely on developing single-cell multi-omic technologies, including genomics, proteomics, transcriptomics etc.. Finally, research findings provide arguments in favor of the hypothesis that only a subpopulation (metastasis-initiating cells, MICs) of CTCs in patient blood is responsible for initiating carcinoma metastasis. A majority of cancer cells may never develop into metastatic phase, but instead maintain a dormant state or die from the anoikis, immune attacks and physical shear stress in the vasculature. However, our understanding about the requirements for CTCs being activated from latency into overt metastases is far from complete. Apart from CTCs, other noninvasive “liquid biopsies” might provide more supplementary information, including some cell-free components such as circulating tumor DNA (ctDNA)^[90], microRNAs (miRNA), exosomes, as well as long-coding RNA (lncRNA)^[91-94]. Recently, due to the success in immunotherapy of cancers, immune checkpoint blocker programmed death-ligand 1 (PD-L1), whose expression in CTCs correlate with tumor status^[95], has gained interest as a potential independent prognostic marker for PFS and OS^[96], extending the spectrum of noninvasive liquid biopsies^[97]. And, CTC detection may also have the potential to monitor the efficacy of anti-PD-L1 therapy^[98]. Comprehensive and systemic liquid biopsy analyses may contribute to thorough understanding of metastatic malignancy and better management of cancer patients.

DECLARATIONS

Authors' contributions

Huang QQ and Chen XX contributed equally to this work.

Abstract

Breast cancer (BC) is the leading cause of cancer-related deaths in women worldwide. However, the majority of cancer mortalities can be attributed to cancer cell metastasis to distal organs/tissues rather than the primary tumor mass itself. The microenvironment surrounding the main tumor mass, as well as its final migration destination, plays a crucial role in the survival, growth, proliferation, and progression of BC. Intercellular stromal cells and components of the microenvironment surrounding a tumor comprise a nurturing cubicle that provides a communication network of cross-talk and signaling between the tumor cells and the extracellular matrix (ECM) and interstitial cells. This network connection enables the tumor cells to engage in metastatic-associated activities such as cell adhesion, invasiveness, mobility, migration, cell shape change, cell-to-cell contact, and basement membrane degradation. An untapped therapeutic approach that might disable the communication network between cancer and stromal cells could possibly aid in providing this unmet need in treating metastatic disease. The intravenous administration of select protein-derived peptides to patients might have the potential to occupy, saturate, and block receptors and binding proteins at the interstitial/ECM communication interface with tumors.

Keywords: Alpha-fetoprotein, cancer, metastasis, breast, microenvironment, interstitium, extra-cellular matrix, stroma

INTRODUCTION

Breast cancer (BC) and its metastasis are worldwide public health issues causing financial, economic, social, and personal lifestyle problems in addition to their high mortality rate. An increased metastatic potential in

BC patients adds to their ultimate demise in both young and older women^[1]. However, there exists an innate flaw in BC cell survival and metastasis regarding its dependence on the microenvironment that surrounds the malignant tumor^[2]. This dependence presents a novel opportunity into an untapped therapeutic potential for BC patients with metastatic disease. The BC tumor mass maintains an intimate relationship with its microenvironment via a 2-way interchange of cross-talk and signaling communication cues between the two entities; this establishes a network-dependent connection^[3]. When tumor growth outpaces its blood and nutrient supplies, cells detach from the primary mass seeking out new fertile “nesting” grounds. The process of cell detachment, migration, and dissemination is the hallmark of metastases with its widespread cell dispersion throughout the body; this results in an increased lethality more than the primary BC tumor itself. In 1889, Stephen Paget^[4] proposed a “seed and soil” hypothesis in which break-away tumor cells seek out tissue/organ sites which are beneficial to resume new tumor growth in sites resembling their original microenvironments. Thus, migratory tumor cells seek out secondary nurturing destinations in which tumor cells grow unabated in distal target organs such as liver, lungs, bone marrow, and brain.

The tumor cells themselves first undergo an epithelial-to-mesenchymal transition that transforms the cell's phenotypic identity to adopt a migratory and invasive behavior^[5]. The dispersed migrating BC cells are attracted toward distal organ/tissue destinations under the influence of chemoattractant signals that determine their migratory gradient patterns and behavior. The chemotactic signals originate from a subfamily of secreted cytokines termed chemokines, most notably the CXCL12 ligand together with its cognate cell surface receptor, CXCR4. Such a 2-member complex is present on both tumor cells and stromal cells. Together, this chemokine/receptor complex forms an axis that can regulate cancer cell growth, proliferation, chemoresistance, angiogenesis, and metastasis^[6]. Hence, both the directive and the objective of the present report are to address the cancer cell-to-microenvironment interaction as a potential therapeutic intervention strategy targeted toward disrupting the communication signaling network both at primary tumor and its metastatic sites.

THE TUMOR MICRO-ENVIRONMENT COMPONENTS

The micro-environment surrounding the primary tumor mass and that encompassing the metastatic destination site have similar shared communication networks. The tumor cell-to-microenvironment connection serves as a signaling bridge between tumor cells and interstitial stromal components which sponsor two-way communication systems. Such signaling activities include nutrient supply, angiogenesis, cell adhesion, migration, cell-to-cell contact, adherens cell junction maintenance, invasiveness, and basement membrane proteolysis^[7]. Non-cellular constituents of the interstitium consists of multiple and diverse components such as: (1) metabolic by-products; (2) exosomes and microvesicles; (3) cell secreted and cell-surface proteins, co-factors and enzymes; (4) extracellular matrix components; (5) signaling molecules; and (6) endocrine and exocrine secretions such as cytokines. The non-malignant cell populations residing in the extracellular spaces and matrices consist of: (1) capillary and lymphatic cells of vessels and ducts; (2) extracellular matrix (ECM) cells; (3) stromal cells; (4) mesenchymal stem cells; (5) fibroblasts; (6) pericytes; (7) immune-associated cells (lymphocytes); (8) macrophages; (9) myofibroblasts; and (10) endothelial cells^[3,8,9]. Some of these constituent cells express and secrete various proteins involved in growth, cell movements, apoptosis, membrane proteolysis, and integrin and growth factor signaling. Thus, the cellular and non-cellular components of the institutional and ECM spaces represent an untapped source of potential molecular and cellular targets for cancer therapy. These will be addressed below.

CELL SIGNALING IN THE MICROENVIRONMENT

The tumor-to-microenvironment intracellular spaces offer a little-recognized cluster of molecular signaling targets with no place to hide. Hematologic and solid tumors are known to interact through microenvironments via cell surface chemokine receptors and their cognate ligands. As discussed above, the

major components in the extracellular signaling arena are the chemokine receptor complexes present on both tumor and ECM cells, which activate diverse intracellular signaling transduction events as discussed above^[10]. Such intracellular signaling systems can activate a variety of pathways such as ERK1/2, p38, JAK/STAT, SAPK/JNK, NF- κ B, mTOR, PI3K-AKT, and BT-kinases^[11]. Chemokine receptors, such as CXCR4 and CXCR7, represent members of the seven-transmembrane domain G-protein coupled receptor family that transmit intracellular activation of processes such as calcium flux, chemotaxis, transcription, cell cycle transition, and cell survival^[13]. The disruption, blockage, or dysregulation of chemokine receptors and associated proteins could lead to aberrant off-target signaling and de-sensitization of the chemokine receptor transactivation apparatus.

At present, the increasing insight and appreciation of the functional role of the microenvironment to cancer growth and metastasis is prompting further research to more fully elucidate and investigate the tumor cell-to-stroma cell dependency. The identification of metastasis-associated protein targets, both cell-bound and secreted, which occupy the extra-cellular matrix and spaces are key targets for disabling the communication lines between the tumor and the interstitium. The protein constituents which aid and abet this signaling complex display properties associated with processes such as cell adherence, cell-to-cell contact, invasion, immigration, matrix proteolysis, growth factor and receptor regulation, and ECM remodeling and restructuring. For example, a recent report has described the existence of a cancer cell-to-stromal macrophage EGF/CSF-1 paracrine signaling loop in the invasive spread of a primary rat mammary tumor [Figure 1]. The invasive response was inhibited by blocking the EGF and CSF receptors and/or macrophage function demonstrating that tumor migration invasiveness was dependent on the paracrine loop.

PROTEIN CONSTITUENTS OF THE TUMOR MICRO-ENVIRONMENT

The intrinsic pressure driving the metastatic process of tumor cells is the need for additional nurturing factors such as new blood vasculature and increased nutrients for the ever-expanding volume of the primary tumor cell mass. The disseminated tumor cells take advantage of the metastasis-associated proteins already residing in and on the cells of the ECM and interstitial spaces. These metastasis-associated proteins, so crucial for break-away tumor cells, are presented in the discourse listed below and in Table 1.

Cell adherence and cell-to-cell contact family proteins

Cell adherence and contact processes can be attributed to a gene superfamily termed the cadherins which consist of protocadherins, cadherins, desmocollins, desmogleins, contactins, and connexins^[14] [Table 1]. Such proteins function in cell adhesion to other cells, and to ECM constituents, and to formation of adherin junctions between cells. Cadherin family members display calcium (Ca^{2+}) binding repeat domains in their intrinsic polypeptide structure^[15]. Different cadherin subfamily members can act in concert to join cells together in both homotypic and heterotypic types of attachments. Some family members (protocadherin Cad-13) serve to stabilize and maintain cell connections during oxidative stress, neural cell development, neurite outgrowth, cell signaling, invasion, and migration^[16]. Other family members are involved in cell survival, potassium channel transmission, maintaining the microvasculature, KRAS signaling, and transmembrane activities. The PECAM, connexin, and contactin proteins play roles in gap junction maintenance, platelet adherence, and aged white blood cell removal and destruction^[17].

ECM family proteins

The ECM family of proteins include the integrins, zinc matrix metalloproteases (MMPs), A distinguishing and metalloproteinase (ADAM) family, collagenases, gelatinases, and annexins^[18] [Table 1]. The MMPs are synthesized as nonactive precursor proteins which require proteolytic cleavage exposing catalytic hemopexin domains utilized for collagen degradation. The MMPs play key roles in development, metabolic disorders and diseases, immune and autoimmune disorders, and in cancer. In comparison, the ADAM family members function as transmembrane-anchored proteins resembling snake venom disintegrins which are

Figure 1. Peptide disruption of tumor to stroma communication. The peptide disruption of the tumor-to-stromal cell communication network is displayed together with the connective tissue layers, cell components, and signaling pathways. Note that the top half of the diagram displays the communication network connection indicated by the dashed lines (---) between tumor/stromal cells; while the bottom second half demonstrates the blocked linkage (←---X→) due to peptide disruption of tumor-to-stroma communication (see text for references and Ref.[45])

involved in cell mobility, migration, adhesion, platelet aggregation, and cell-to-cell contact; such processes occur during reproduction, neurogenesis, muscle development, and tumorigenesis^[19]. The collagenases and gelatinases are family members involved in tissue remodeling, bone mineralization, reproduction, autoimmune diseases, inflammation, and cancer development^[20]. The integrins are composed of alpha/beta chain proteins that participate in cell adhesion/contact and ECM-to-cell membrane inside-out signaling^[21]. Finally, annexins are Ca^{2+} and phospholipid binding proteins that serve in blood coagulation processes^[22].

The growth factor receptor family proteins

The growth factor receptors associated with the tumor microenvironment and metastatic sites are largely G-coupled seven-transmembrane receptors containing kinase domains required for intracellular signaling and cross-talk between adjacent pathways^[23] [Table 1]. These receptors bind growth factors such as fibroblast

Table 1. Selected metastasis-associated protein constituents of the tumor microenvironment are listed as four major functional groups. Such proteins are involved in cell activities such as adherence, mobility, growth, migration, invasiveness, angiogenesis, signaling, and proteolytic degradation

Group-I proteins: cell adherence and cell-to-cell contact
1. Protocadherin-Beta-1 (Q9Y5F3)
2. Cadherin-6 (AAH00019)
3. Cadherin-13 (NP_001248)
4. Cadherin-22 (CAB51587)
5. Contactin-3 (N_P387504)
6. Neural Cell Adhesion Molecule (NP_000606)
7. Platelet Endothelial Adhesion Molecule (NP_000433)
8. Connexin GJA5 (AAH13313)
9. Neuratropic tyrosine kinase R-3 (NP_001012338)
Group-II proteins: matrix metalloproteases (MMP) and ADAMS
1. MMP-2 (ABD38929)
2. MMP-9 (CAC10459)
3. MMP-10 (AAH02591)
4. MMP-13 (AAH74808)
5. ADAM-22 (NP_068368)
6. Integrin Alpha-6 (AAH50585)
7. Integrin Alpha-2 (NP_002194)
8. Annexin-A8 (P13928)
9. Collagen IV, Alpha-3 (CAA56335)
Group-III proteins: growth factor receptors - cell surface
1. Fibroblast Growth Factor Receptor (P22455)
2. G-protein Coupled Receptor-54 (QT69F8)
3. Interleukin-8 Receptor (NP_001548)
4. FMS-like Tyrosine Kinase Receptor (AAB23636)
5. Laminin Receptor (AAC50652)
6. TSH-associated Receptor (AAD31568)
7. Somatostatin Receptor-2 (NP_001041)
8. Ephrin Receptor-2B (CA122899)
9. C-Met Hepatocyte Growth Factor Receptor (NP_000236)
Group-IV proteins: growth factors and regulators
1. Transforming Growth Factor B-1 (NP_000651)
2. Vascular Endothelial Growth Factor (CAC19516)
3. Retinoblastoma-Assoc. Protein-1 (NP_000312)
4. p53 Protein Tumor Cell Antigen (NP_000537)
5. Tyrosine Protein Phosphatase Non-Receptor-7 (NP_002823)
6. C-terminal (CTB) Binding Protein (AAD14597)
7. NME-Nucleoside-Disphosphate Kinase (CAG46912)
8. Metastasis Suppressor Protein MTSS-1 (AAF15947)

See Table 3 for Metastasis-associated functional activities, text, and Ref.[14-31]. Parenthesis indicates National Center for Bioinformatics (NCBI) Accession number. ADAM: A disintegrin and metalloproteinase gene family

growth factor, laminin, somatostatin, ephrin, IL-8, and KISSIR^[24]. The receptor-mediated activities encompass angiogenesis, mitogenesis, growth enhancement, differentiation, kinase function, cancer genesis and maintenance. These receptors can further activate, influence, and regulate cell cycle transitions, mitogenesis, cell motility, migration, and metastasis. Some receptors contain tyrosine kinase domains that enhance or influence growth in multiple tissues including the blood vasculature. The somatostatin receptors regulate the release of various hormone and secreted proteins, while the ephrin receptors are involved in tissue formation, cell migration and contact, stem cell differentiation, and cancer growth^[25,26]. Finally, the G-coupled receptor-54 functions as a receptor for the KISS gene product, a cancer metastatic suppressor protein which when mutated, induces chemotaxis and invasion in numerous cancer cells. Thus, the metastasis-associated growth factor receptors are heavily involved in cell-to-ECM adhesion, invasion, migration, cancer growth and metastatic activities.

Growth factor and regulator family members

The microenvironment and metastasis-associated proteins encompass a wide range of growth factors and kinase enzymes that include transforming growth factor, vascular endothelial growth factor, MTSS1, p53 cell

Table 2. Selected examples of naturally occurring protein-derived peptides (small proteins) are displayed together with their amino acid sequence numbers and protein of origin

Name of peptide	Number of amino acids in sequence	Host protein of origin (pre-protein)	Peptide biological activity, function
1. Angiostatin	184	Plasminogen	Blocks blood vessel growth
2. Endostatin	330	Collagen Type XVIII	Angiogenesis inhibitor
3. Vasostatin	180	Calreticulin	Angiogenesis inhibitor
4. Constatin	150	Collagen Type IV	Inhibits endothelial cell growth
5. Tenacin	220	Fibronectin Repeat Domain	Anti-adhesion Function
6. Fragment of GHRH	15	GHRH	Stimulates Lipogenesis
7. Angiotension II	8	Angiotensinogen 22 Globulin	Increases Vasopressin Production
8. Bradykinin	9	Kininogen Precursor	Contracts Smooth Muscle
9. Oxytocin	9	Oxytocin Precursor	Uterine Contracting Hormone
10. Endothelin	21	Pre-Pro-Endothelial	Potent Vasoconstrictor
11. TRH	3	242 Amino Acid Polypeptide Precursor	Governs Release of TSH
12. GIP*	34	Alpha-fetoprotein polypeptide (609 amino acids)	Suppresses growth of hormone and non-hormone dependent growth and proliferation (normal and cancer growth)
GIP Sub-fragments:*			
(1) P149a	12	AFP AA#464-475	Inhibit platelet aggregation and blood factors
(2) P149b	14	AFP AA#476-488	Blocks metastasis-assoc. proteins and cancer growth
(3) P149c	8	AFP AA#489-496	Inhibits estrogen-dependent growth

Note that many peptides are derived from blood and extra-cellular matrix proteins. Naturally-occurring peptides can number in the hundreds of amino acids, while synthetic peptides are limited to 50 amino acids or less. *Synthetic peptides. AA: amino acid; AFP: alpha fetoprotein; GIP: growth inhibitory peptide; P149a: AAs; LSEDKLLACGEG (12 mer); P149b: AAs; AADIIIGHLCIRHE (14 mer); P149c: AAs; EMPVNPNG (also known as AFPep) (8-mer; both linear and cyclic). Data extracted from Ref.[33-38]. GHRH: growth hormone releasing hormone; TRH: thyroid releasing hormone; GIP: growth inhibitory peptide; TSH: thyrotrophin stimulating hormone

tumor antigen (phosphoprotein-53), tyrosine (tyr) protein-phosphate non-receptor type-7 protein, among others^[28,29] [Table 1]. These proteins function in activities such as angiogenesis, tumorigenesis, metastasis, cancer proliferation, signal transduction, and cell cycle progression. Some of these proteins contain kinase enzyme domains which are contained in their polypeptide structure; other proteins act as regulators of cell cycle transition and tumor growth. The p53 cell antigen is a phospho-protein, which in the non-mutated state, normally function as tumor suppressors that protect the genome. The tyr (tyrosine) protein phosphatase non-receptor-7 is a signaling molecule involved in cell transformation, cell cycle transition, growth, and proliferation both in non-cancer and in malignant cells^[30]. This latter protein further interacts with lymphokine-secretory cells and exhibits MAP kinase activity. Another family member of this group can phosphorylate the C-terminal end of the SRC family kinases, while the NDPK protein is involved with cell growth, proliferation, development, signal transduction, and G-protein coupled receptor activities^[16]. Finally, the MTSS1 protein functions, in its non-mutated state, as a metastasis suppressor protein that contains an actin binding (cytoskeletal) segment involved in cell migration^[16].

Naturally-occurring protein-derived fragments

There exists an extensive reserve of natural protein-derived peptide segments encrypted within the polypeptide structure of circulating blood proteins and ECM/interstitial cell-secreted proteins^[31,32]. The proteome of both humans and other mammals contain precursors and preproteins that when cleaved by proteolysis, release peptide fragments with diverse biological activities. Although not widely mentioned, this containment fraction of active peptide fragments are derived from naturally-occurring sources such as blood proteins, growth factors, hormones, clotting factors, ECM proteins, and angiogenic factors. Such peptide fragments constitute segments from precursor derived proproteins or preproteins which are produced following proteolytic enzyme degradation (i.e., trypsin); they can also be produced by cleavage in the laboratory using agents such as cyanogen bromide. Some of nature's most potent anti-angiogenic peptides are derived from abundant plasma proteins, growth factors, and ECM and stromal proteins^[33,36] [Table 2]. Such peptide fragments are garnering attention in the biomedical literature due to their functioning in signal transduction, receptor cross-talk, growth regulation, vasodilation/vasoconstriction, hormone release, blood clotting and inflammation^[16]. Some peptide fragments can be cleaved from the amino-terminal

Table 3. Selected cell adherence and cell-to-cell contact protein superfamily members are listed with their functional activities together with their third domain alpha-fetoprotein binding/interaction sites

Selected Protein Name	Functional Activities	AFP Amino Acid Sequence Numbers	AFP Amino Acid Sequence**

**AFP amino acid sequence (single letter code); *growth inhibitory peptide (GIP) sequences. AFP: alpha-fetoprotein; ADAM: A disintegrin and metalloproteinase protein family; MMP: matrix metalloproteinases; Data extracted from Ref.[16,31,37-39]

or carboxy-terminal ends of various proteins, while others can be exposed following a conformational change in the proteins' tertiary structure. Such a conformational change in a protein can be induced by environmental events such as stress, shock, oxidative state changes, osmotic pressure, pH, and high ligand concentrations^[31,32]. Once identified in nature, single peptide fragments can be synthesized in the laboratory.

Examples of protein-derived fragments from the amino- or carboxy- ends of natural large proteins encompass a growing list of candidates. Such fragments include: angiotensin from angiotensinogen; endothelin from pre-pro-endothelin; bradykinin from kininogen, and others [Table 2]. Some examples of internal peptides encrypted within the chain of a protein include: Tenacin-C from fibronectin-III, angiostatin from plasmin, and endostatin from collagen-III [Table 2]. The chemically-synthesized peptides are usually restricted to less than 50 amino acids (AA) due to technical synthesis limitations, while naturally produced peptides can exceed 100 AAs. An example of a conformationally-exposed peptide segment from Table 2 is the growth-inhibitory peptide (GIP) derived from the full-length alpha-fetoprotein (AFP) molecule^[37-40]. The GIP segment is uncovered on the AFP molecule following exposure of the protein to high concentrations of estrogens, fatty acids, and growth factors. The GIP-exposed form of AFP is a transitory (molten globular) form which can refold back to its natural tertiary structure following removal of the high ligand concentrations. The encrypted GIP segment on AFP is normally concealed within a hydrophobic cleft of the tertiary-folded AFP molecule. Moreover, GIP and its sub-fragments have been chemically synthesized, purified, and characterized in multiple assays of biological activities including anti-cancer growth and metastasis inhibition in both *in vitro* and *in vivo* models^[37,38].

In the AFP derived GIP fragment example, a normal growth enhancing AFP molecule is converted to a growth inhibitory full-length protein capable of blocking normal and cancer growth and metastasis. Aside from GIP, other protein-derived peptide sites on the AFP third domain have since been identified and mapped; some such peptide segments have been found to bind and/or interact with other proteins such as metastasis-associated family members of the ECM, interstitial, and stromal proteins of tumor microenvironments^[16].

Third-domain derived AFP peptide-interactions with ECM proteins

As displayed in Table 2, the third domain of AFP provides an example of naturally occurring protein-derived peptides segments with biological activities of significance. The AFP third domain houses multiple peptide segments (8-10 or more amino acids) that have been identified by “in silico” prediction tools and molecular modeling; these were verified by in vitro cell-based assays and the AFP-derived peptides were found to bind various proteins^[16,41,42]. Recent examples of confirmed protein-to-peptide binding interactions between AFP peptides and natural proteins include the scavenger receptor proteins, immune dendritic cells, mucin proteins, retinoic acid receptors, and metastasis-associated proteins in both cancer and non-malignant models^[42]. Logic would dictate that disruption and/or interference of cross-talk and signaling pathways between tumor cells and their surrounding proteins (both free and cell bound) located in the microenvironment might serve to hamper or obstruct this crucial linkage. As discussed above, the tumor microenvironment contains 4 or more protein families of metastasis-associated proteins relate to tumor cell detachment, adhesion, contact, and migration via the ECM. By use of the AFP receptor and protein binding third domain peptides as displayed in Table 3, it can be noted that such peptides might be capable of disabling and/or disrupting communication lines between the tumor primary mass and/or metastasis nesting sites. The identities of these potential protein-to-AFP peptide interaction sites with the metastasis-associated proteins from tumor micro-environments are addressed below.

Interaction of metastasis-associated proteins with AFP-derived peptides

It has previously reported that metastasis-associated proteins are capable of binding and/or interacting with AFP-derived peptides of the third domain^[16,42]. In that report, members of the cell adhesion/contact protein family, such as cadherins, contactins and connexins were identified “in silico” to interact with AFP derived peptide sites on the amino-terminal half of domain-3, AA#401-500. The same was true for the ECM-associated proteins of the MMP and ADAM family proteins being clustered from AA# 409-480; moreover, these results showed interaction sites with AFP AA# 504-558 in the carboxy end of domain-3. The third group of interacting proteins, the growth factor receptors, demonstrated two cluster interaction sites on AFP-3D; the first group at AA#s 433-477 and the second grouping at AA# 512-550. Finally, the last class of AFP interacting proteins, the growth factors and regulators, consisted of two distinct interaction regions; the first extending from AA# 413-487, while the second encompassed sites at AFP AA#s 508-522. It can be concluded from these data that metastasis-related proteins are potentially capable of interaction with various AFP peptide segments on both the 1st and 2nd halves of the AFP domain-3^[16].

CONCLUSION

It can be concluded from the above discourse that both naturally occurring protein-derived and synthetic peptides, ranging from 8-50 AA or larger, might be candidates capable of disabling tumor-to-microenvironment communications. Such network connections are essential for supplying blood vascular and nutrient supplies from the ECM to the tumor, critical locations required for tumor survival and subsequent metastasis. The microenvironmental compartments surrounding tumors are required for successful cell detachment from the primary mass and taking advantage of migration and adhesion factors already present in the extracellular and stromal cell areas.

The present study further highlighted the many natural protein-derived peptides in human beings, whose activities involved cell adhesion, mobility, contact, angiogenesis, blood clotting, and tumorigenesis. In

some instances, the derived peptide displayed an opposite action from its host protein such as angiogenic inhibition versus enhancement of new blood vessel growth. In another type of protein-derived peptide, the amino acid segment is not cleaved from the preproprotein, but rather exposed following a conformational change of the tertiary folded polypeptide. As an example, metabolic stresses of excessive ligand concentrations can temporarily convert the growth enhancing AFP molecule into a growth inhibitory protein. The transitory AFP molecule then refolds back to its tertiary form, and full length AFP once again displays the property of growth enhancement.

In the future, it might be feasible to administer short peptides to metastatic patients by injection, infusion, and osmotic pumps, or via sublingual routes to patients in early and/or late metastatic disease. Such peptides are also capable of down-regulating the expression of metastasis-associated proteins as previously described for GIP^[44]. Peptides are short half-life molecules with good targeting properties, and adequate target binding (loading/off-loading) affinities^[43]. Natural or synthesized peptides might potentially serve as treatment adducts in combination with next generation therapeutic cancer drugs. Peptide binding, occupation, down-regulation, and saturation of ECM proteins in the interstitium may possibly serve to disable and sever the primary tumor and/or metastatic nesting sites from their ECM communication networks.

Abstract

Aim: We have recently identified a cancer stem cell (CSC) subpopulations within the tumor nests (TNs) and another within the peritumoral stroma (PTS) in liver metastasis from colon adenocarcinoma (LMCA). This study investigated the expression of components of the renin-angiotensin (RAS): pro-renin receptor (PRR), angiotensin converting enzyme (ACE), and angiotensin II receptor 1 (AT1R) and angiotensin II receptor 2 (AT2R) in LMCA.

Methods: 3,3-Diaminobenzidine (DAB) immunohistochemical (IHC) staining was performed on 16 LMCA samples for PRR, ACE, AT1R and AT2R. Immunofluorescence (IF) IHC staining was performed to investigate co-expression of these components of the RAS with SOX2 or OCT4. NanoString analysis ($n = 6$) and Western blotting (WB, $n = 3$) were performed on snap-frozen LMCA samples to confirm mRNA and protein expression, respectively.

Results: DAB IHC staining showed the expression of PRR, ACE, AT1R and AT2R within all LMCA samples. NanoString analysis and WB confirmed gene and protein expression of these components of the RAS. IF IHC staining demonstrated expression of PRR, AT1R and AT2R by the SOX2⁺ CSCs within the TNs and the OCT4⁺ CSCs within the PTS. ACE was expressed on the endothelium of the microvessels within the PTS.

Conclusion: These finding suggests the CSCs within LMCA maybe a novel therapeutic target by manipulation of the RAS.

INTRODUCTION

Colorectal cancer (CRC) accounts for 9.7% of all cancers with approximately 1.5 million cases worldwide in 2015^[1], including 3158 cases in New Zealand^[2]. It is the second most common cause of cancer death in the United Kingdom^[3] and New Zealand^[2].

The pathogenesis of CRC relates to a complex interaction between genetic predisposition and lifestyle factors^[1]. There are hereditary and non-hereditary CRC sub-types, although the majority are sporadic and result from somatic mutation in response to environmental factors^[1]. A key molecular pathway in the development of about 80% of CRC cases is the adenocarcinoma sequence, in which an accumulation of genetic mutations, particularly in the adenomatous polyposis coli pathway leads to carcinogenesis^[4]. Diets high in animal fat and red meat, physical inactivity and excess body weight, heavy alcohol consumption and smoking are known modifiable risk factors for CRC^[5].

The liver is commonly the first metastatic site for CRC, and may be the only site of spread in up to 30%-40% of patients with advanced disease^[6]. 20%-25% of CRC patients have detectable synchronous liver metastases at the time of diagnosis, and another 40%-50% of patients will subsequently develop metachronous liver metastasis within three years of resection of the primary tumor^[7].

The current concept of CRC proposes that the primary mode of tumor spread is via the portal system, and hence resection of isolated liver metastasis from CRC adenocarcinoma may be curative^[6]. However, the observation of circulating CRC cancer stem cells (CSCs)^[8] infers that the assumption of the liver being the most suitable site for metastasis remains to be determined. The median survival of liver metastasis from CRC adenocarcinoma without treatment is less than 12 months from presentation, with improved prognosis for patients with isolated liver metastasis^[9]. Approximately 20%-30% of patients with liver metastasis from CRC adenocarcinoma have disease confined to the liver and is therefore potentially operable^[10] with a five-year survival of 25%-44%^[7,11]. There has been recent focus on pre-operative neo-adjuvant chemotherapy to improve disease-free and overall survival by downsizing metastatic liver disease to increase operability and treat systemic disease^[12].

The CSC concept of cancer proposes that a subpopulation of cells within a cancer that possesses the properties of embryonic stem cells (ESCs) are the driving force for carcinogenesis due to their innate ability to promote angiogenesis, local invasion, distant metastasis, and resistance to apoptosis^[13]. Although the origin of CSCs remains to be elucidated, they are distinguishable from the cancer cell population by their expression of ESC markers, well researched in many cancer types including oral cavity squamous cell carcinoma (OCSCC) affecting different sub-sites^[14-16] and glioblastoma (GB)^[17]. Increased expression of ESC markers has been associated with increased tumor size, local invasion and metastasis^[18], worsening prognosis, treatment resistance^[19] and risk of local recurrence or metastasis^[20].

We have recently demonstrated the presence of three CSC subpopulations within liver metastasis from colon adenocarcinoma (LMCA): a SOX2⁺/NANOG⁺/KLF4⁺/c-MYC⁺/OCT⁻ subpopulation within the tumor nests (TNs), and a SOX2⁺/NANOG⁺/KLF4⁺/c-MYC⁺/OCT4⁻ CSC subpopulation and a SOX2⁺/NANOG⁺/KLF4⁺/c-MYC⁺/OCT⁺ CSC subpopulation within the peri-tumoral stroma (PTS)^[21].

The renin-angiotensin system (RAS) is a hormonal system that is classically known for regulation of cardiovascular homeostasis and blood pressure^[22]. A key component of the RAS is angiotensinogen which

is physiologically released from the liver into the circulation and is converted to angiotensin I (ATI) by renin - the active form of the proenzyme, pro-renin. The receptor for both renin and pro-renin is pro-renin receptor (PRR)^[23]. ATI is then converted to angiotensin II (ATII) by angiotensin converting enzyme (ACE). The effects of ATII are mediated through its receptors, angiotensin II receptor 1 (ATIR1) and angiotensin II receptor 2 (ATIR2)^[24].

Recent studies show that the RAS promotes tumor growth at a local tissue level by modulating angiogenesis, tumor cell proliferation, immune responses and extracellular matrix formation^[24]. Patients who are administered RAS modulators have a reduced incidence of CRC as well as lower rate of developing distant metastasis from CRC^[25,26].

CSCs in a number of cancer types, including OCS^[16,27,28] and GB^[17] have been shown to express components of the RAS. Hence CSCs may be a novel therapeutic target by modulation of the RAS. A recent meta-analysis reports an average 20% reduced risk of metastasis and improved survival from cancer including CRC, in patients who are administered RAS modulators^[29].

Currently there are few publications showing the presence of the components of the RAS in LMCA. This study aimed to investigate the expression of the components of the RAS: PRR, ACE, ATIR1, and ATIR2 within LMCA, in relation to the three CSC subpopulations we have recently identified^[21], using 3,3-diaminobenzidine (DAB) and immunofluorescence (IF) immunohistochemical (IHC) staining, Western blotting (WB), and NanoString mRNA expression analysis.

METHODS

Tissue samples

LMCA tissue samples from 16 male patients aged 50-80 (mean 65) years including those in our previous study^[21] were sourced from the Gillies McIndoe Research Institute Tissue Bank and used for this study which was approved by the Central Health and Disabilities Ethics Committee. Informed written consent was obtained from all participants.

Histochemical and immunohistochemical staining

Hematoxylin and eosin (H&E) staining was carried out on 4 µm-thick formalin-fixed paraffin-embedded sections of 16 LMCA tissue samples to confirm the presence of the tumor on the slides by an anatomical pathologist (HDB). DAB IHC staining was then performed on these sections using the Leica Bond Rx auto-stainer (Leica, Nussloch, Germany) with primary antibodies for PRR (1:2000; cat# AB40790, Abcam, Cambridge, MA, USA), ACE (1:100; cat# MAB4399, AbD Serotec, Oxford, UK), ATIR1 (1:300; cat# AB9391, Abcam), and ATIR2 (1:2000; cat# NBP1-77368, Novus Biologicals, Littleton, CO, USA), OCT4 (1:30; cat# MRQ-10, Cell Marque), SOX2 (1:200; cat# PA1-094, Thermo Fisher Scientific, Rockford, IL, USA). Antibodies were diluted in Bond primary antibody diluent (Leica). All DAB IHC-stained slides were mounted in Surgipath Micromount (Leica, Nussloch, Germany). To confirm co-expression of two proteins, two representative samples of LMCA from the original cohort of 16 patients used for DAB IHC staining, underwent IF IHC staining. Vectafluor Excel anti-mouse 488 (ready-to-use; cat# VEDK2488, Vector Laboratories, Burlingame, CA, USA) and Alexa Fluor anti-rabbit 594 (1:500; cat# A21207, Life Technologies, Carlsbad, CA, USA) were used to detect the combinations. All IF IHC-stained slides were mounted in Vecta Shield Hardset mounting medium with 4, 6-diamino-2-phenylindone (Vector Laboratories). All antibodies were diluted in Bond primary diluent (Leica). All DAB and IF IHC staining was performed using the Leica Bond Rx auto-stainer (Leica), as previously described^[16,28,30].

Image analysis

The DAB IHC-stained slides were viewed and the images were captured using an Olympus BX53 light microscope fitted with an Olympus DP21 digital camera (Olympus, Tokyo, Japan). An Olympus FV1200

confocal laser-scanning microscope (Olympus) was used for IF IHC-stained slides and the images were processed with CellSens Dimension 1.11 software using the 2D deconvolution algorithm (Olympus).

NanoString mRNA expression analysis

Six snap-frozen LMCA tissue samples from the original cohort of 16 patients included for DAB IHC staining were used to isolate total RNA. RNA was extracted using the MagJET RNA Kit and KingFisher Duo (ThermoFisher Scientific) protocol and quantitated by the NanoDrop 2000 Spectrophotometer (Thermo Scientific) and Qubit (Thermo Scientific). mRNA was assayed by New Zealand Genomics Ltd (Dunedin, NZ), using the NanoString nCounter Gene Expression Assay (NanoString Technologies, Seattle, WA, USA). Probes for the genes were designed and synthesized by NanoString Technologies and are PRR (ATP6AP2, NM_005765.2), ACE (CD143, NM_000789.2), ATIIR1 (AGTR1, NM_000685.3), and ATIIR2 (AGTR2, NM_000686.3). Raw data were analyzed by nSolver software (NanoString Technologies) using standard settings and were normalized against the housekeeping gene glyceraldehyde 3-phosphate dehydrogenase (GAPDH), as routinely performed in our laboratory^[16,28].

Western blotting

Total protein was extracted from three snap-frozen LMCA tissue samples from the original cohort of 16 patients used for DAB IHC staining, resolved by SDS-PAGE, and transferred to a PVDF membrane as previously described^[31], and probed using the following antibodies: PRR (1:500; cat# ab40790, Abcam), ATIIR1 (1:500; cat# sc-1173, Santa Cruz, CA, USA), ATIIR2 (1:1000; cat# ab92445, Abcam), ACE (1:200; cat# sc-12184, Santa Cruz), and β -actin (1:500; cat# ab8229, Abcam). Secondary and tertiary antibodies were goat anti-rabbit HRP (1:2000; cat# ab6721, Abcam) for PRR and ATIIR1, rabbit anti-goat SuperclonalTM biotin conjugate (1:5000; cat# A27013, Thermo Fisher) and goat anti-rabbit SuperclonalTM biotin conjugate (1:5000; cat# A27035, Thermo Fisher) followed by PierceTM Streptavidin Poly-HRP (1:5000, cat# 21140, Thermo Fisher) for ACE and ATIIR2, respectively, and chicken anti-goat Alexa Fluor 647 (1:2000; cat# A21244, Life Technologies) for β -actin. Clarity Western ECL (cat# 1705061, Bio-Rad) was used as the substrate for HRP bands and the Chemi Doc MP Imaging System (Bio-Rad) and ImageLab 5.0 software (Bio-Rad) were used for detection and analysis, as previously used^[16,28]. Positive controls were snap-frozen human placenta tissue for PRR and ATIIR1, snap-frozen mouse lung tissue for ACE, and a recombinant ATIIR2 protein (cat# H00000186-P01, Novus Biologicals) for ATIIR2. Matched mouse (1:500; cat# ab18443, Abcam) and rabbit (1:500; cat# ab171870, Abcam) isotype controls were used as appropriate negative controls.

Statistical analysis

Statistical analysis of the NanoString mRNA data was performed using *t* test (SPSS v 24).

RESULTS

Histology and DAB IHC staining

H&E staining confirmed the presence of LMCA on the slides for each of the 16 tissue samples. DAB IHC staining demonstrated the expression of PRR [Figure 1A, brown] which was localized to cells within the TNs, cells within the PTS and the endothelium of the microvessels within the PTS. ACE [Figure 1B, brown] was expressed on the luminal surface of the TNs and weakly on the endothelium of the microvessels within the PTS. Strong cytoplasmic expression of ATIIR1 [Figure 1C, brown] was present on the cells within the TNs, the cells within the PTS and the endothelium of the microvessels within the PTS. ATIIR2 [Figure 1D, brown] was also expressed by the cells within the TNs, and weakly on the endothelium of the microvessels within the PTS.

The expected expression patterns of positive controls for PRR [Supplementary Figure 1A, brown], ACE [Supplementary Figure 1B, brown], ATIIR1 [Supplementary Figure 1C, brown], and ATIIR2 [Supplementary Figure 1D, brown] were demonstrated in human placenta, kidney, liver and kidney,

Figure 1. 3,3-Diaminobenzidine immunohistochemical-stained sections of liver metastases from colon adenocarcinoma demonstrating the expression of pro-renin receptor [(A), brown] localized to cells within the tumor nests (TNs), the cells within the peritumoral stroma (PTS) and the endothelium of the microvessels within the PTS. Angiotensin converting enzyme [(B), brown] was expressed on the luminal surface of the TNs and weakly on the endothelium of the microvessels within the PTS. Angiotensin II receptor 1 (ATIIR1) [(C), brown] demonstrated strong cytoplasmic expression on cells within the TNs, the endothelium of the microvessels and the cells within the PTS. ATIIR2 [(D), brown] was also expressed on the cells within the TNs and weakly on the endothelium of the microvessels within the PTS. Nuclei were counter-stained with hematoxylin [(A-D), blue]. Original magnification: 400×

respectively. The negative controls on LMCA tissue samples, stained using an IgG isotype [Supplementary Figure 1E], demonstrated the specificity of the primary antibodies used.

IF IHC staining
