IF IHC staining was employed to investigate the expression of components of RAS by the CSC subpopulations within LMCA by co-staining with ESC markers OCT4 and SOX2. PRR [Figure 2A, red] was expressed by the cells within the TNs and the cells within the PTS, regardless of whether they were OCT4⁺ [Figure 2A, green] or OCT4⁻ [Figure 2A]. ACE [Figure 2B, green] was expressed on the luminal surface of the cells within the TNs as well as the endothelium of the microvessels within the PTS, which also expressed SOX2 [Figure 2B, red]. ATIIR1 [Figure 2C, green] was demonstrated in cells within the TNs, the endothelium of the microvessels within the PTS [Figure 2C] and the cells within the PTS [Figure 2C], which also expressed SOX2 [Figure 2C, red]. A similar expression pattern was seen for ATIIR2 [Figure 2D, red] in the cells within the TNs and the cells within of the PTS whether they expressed OCT4 [Figure 2D, green] or not [Figure 2D].

Split images of the stains presented in Figure 2 are shown in [Supplementary Figure 2]. Minimal staining was present on the negative control [Supplementary Figure 2I], confirming the specificity of the primary antibodies used.

NanoString mRNA expression analysis

NanoString mRNA expression analysis of PRR, ACE, ATIIR1, and ATIIR2 on six snap-frozen LMCA tissue samples of the original cohort of 16 patients used for DAB IHC staining, normalized against the

Figure 2. Representative immunofluorescence immunohistochemical-stained sections of liver metastasis from colon adenocarcinoma demonstrating the expression of pro-renin receptor [(A), red] by the cells within the tumor nests (TNs), the cells within the peritumoral stroma (PTS) regardless of whether they were OCT4⁺ [(A), green] or OCT4⁻ (A). Angiotensin converting enzyme [(B), green] was expressed on the endothelium of the microvessels within the PTS, which also expressed SOX2 [(B), green]. Angiotensin II receptor 1 (ATIIR1) [(C), green] was demonstrated on cells within the TNs, the endothelium of the microvessels within the PTS (C) and the cells within the PTS (C), which also expressed SOX2 [(C), red]. A similar expression pattern was seen for ATIIR2 [(D), red] in the cells within the TNs and the cells within of the PTS whether they expressed OCT4 [(D), green] or not (D). All slides were counter-stained with 4',6'-diamino-2-phenylindole [(A-D), blue]. Scale bars: 20 μ m; insert: 400 \times magnification

housekeeping gene GUSB, confirmed the presence of PRR, ACE and ATIIR1 mRNA in all six samples and ATIIR2 in one sample [Figure 3], with ATIIR2 mRNA expression at a significantly lower level in all six samples compared to the other genes ($P < 0.05$).

Western blotting

WB on the three snap-frozen LMCA tissue samples demonstrated the presence of bands at the expected molecular weight for PRR, ATIIR1, ATIIR2 and ACE [Figure 4]. PRR was detected in all three samples at 22 kDa [Figure 4A], with the specificity of the antibody confirmed using a recombinant PRR protein (cat# ab153053, Abcam). ATIIR1 was detected in all three samples at the expected molecular weight of 41 kDa [Figure 4B], and ATIIR2 was detected in two out of three samples at 50kDa [Figure 4C], consistent with ATIIR2 variants from adrenal glands and from ATIIR2 proteins with high glycosylation^[32]. ACE was detected at a low abundance in all three samples at the expected molecular weight of 194 kDa [Figure 4D]. This is supported by detection of ACE using the same antibody in different tissues^[33]. β -actin confirmed approximate equivalent protein loading for all LMCA samples examined [Figure 4E]. The isotype controls are presented in Supplementary Figure 3.

Figure 3. NanoString mRNA expression analysis of pro-renin receptor (PRR), angiotensin converting enzyme (ACE), angiotensin II receptor 1 (ATIIR1), and angiotensin II receptor 2 (ATIIR2) on six snap-frozen samples of liver metastasis from colon adenocarcinoma normalized against the housekeeping gene GUSB, confirmed the presence of PRR, ACE and ATIIR1 mRNA in all six samples and ATIIR2 in one sample, with ATIIR2 mRNA levels at a significantly lower level within all six samples compared to the other genes ($P < 0.05$)

DISCUSSION

The classical RAS is an endocrine system that is crucial in regulating blood pressure and fluid homeostasis through its effects on the kidney, cardiovascular, and central nervous systems^[24]. Physiologically angiotensinogen is cleaved by renin to form ATI. ACE then cleaves ATI to form ATII. ATII is the main effector of the RAS that mediates its effects by binding with its receptors ATIIR1 and ATIIR2^[24]. Recent literature suggests a critical role for the RAS in cancer growth and metastasis^[24]. There is increasing appreciation of the complex interplay between the RAS and other pathways including IGF, VEGF, and potential bypass loops consisting of cathepsins B, D and G^[22,34]. These related pathways are implicated in a number of biological processes such as angiogenesis, cell migration, tumorigenesis and hematopoiesis which may create a conducive environment for carcinogenesis by promoting the proliferation of CSCs^[22].

More specifically to LMCA, a report by Heinzerling *et al.*^[26] shows the use of ACE inhibitors independently predicts less likelihood of patients with stage II CRC to develop distant metastasis. Using a murine model of CRC liver metastasis, Wen *et al.*^[35] show that administration of captopril, an ACE inhibitor, reduces proliferation of the CRC cells. These coupled with a recent review, highlighting the role of ACE inhibitors and ATIIR1 blockers in reducing of the incidence of CRC and the development of distant metastasis from CRC^[25]. Taken together it is exciting to speculate that the expression of components of the RAS by the CSCs in LMCA is crucial in the maintenance and proliferation of these CSCs, although this remains the topic of future investigation.

We have recently demonstrated three subpopulations of CSCs within LMCA, including an OCT4⁺ subpopulation, and an OCT4⁻ subpopulation within the PTS and the TNs, suggesting the presence of a CSC hierarchy^[21]. In this study we have demonstrated the expression components of the RAS: PRR, ACE and ATIIR1 and ATIIR2 by these CSC subpopulations within LMCA. It is interesting that ATIIR2 was detected by DAB IHC staining in all 16 samples, but only two out of the three samples by WB and in only one sample by NanoString mRNA analysis, possibly due to sampling bias.

The novel findings in this study mirror similar findings in OCSCC affecting the oral tongue^[28], buccal mucosa^[27] and lip^[16], and GB^[17]. The expression of ACE on the endothelium of the microvessels within the

Figure 4. Western blot images of total protein extracted from snap-frozen samples of liver metastasis from colon adenocarcinoma (LMCA) from three patients demonstrating the presence of pro-renin receptor (PRR) in all three samples at 22 kDa (A), with the specificity of the antibody confirmed using a recombinant PRR protein. Angiotensin II receptor 1 was detected in all three samples at the expected molecular weight of 41 kDa (B); angiotensin II receptor 2 was detected in two out of three samples at 50 kDa (C); angiotensin converting enzyme was detected at a low abundance in all three samples at the expected molecular weight of 194 kDa (D); and β -actin confirmed approximate equivalent protein loading for all LMCA samples examined (E)

PTS suggests a role in regulating epithelial-to-mesenchymal transition by influencing angiogenesis^[16,24], although this requires further investigation.

It is exciting to speculate that CSCs may be a novel therapeutic target by modulation of the RAS using existing medications such as aliskiren which targets renin, β -blockers which inhibit the production of prorenin and hence decrease renin levels, ACE inhibitors and ATII receptor blockers^[36-38]. A recent meta-analysis on the use of ACE inhibitors and ATIIR1 blockers demonstrate an average 20% improved survival or reduction of recurrence in different types of cancers, including primary CRC^[29], suggesting a crucial role of these drugs in tumorigenesis, potentially through modulation on the RAS, although this requires further investigation.

Cathepsins B, D and G are proteases that constitute bypass loops for the RAS^[22] and have been implicated in tumorigenesis and metastasis in CRC due to their ability to degrade extra-cellular matrix. We have shown the expression of cathepsin B and cathepsin D by the CSC subpopulations within oral tongue squamous cell carcinoma^[27], GB^[39] and more recently LMCA^[34], implying the presence of bypass loops for the RAS.

The novel finding of the expression of the components of RAS and cathepsin B and cathepsin D by the CSC sub-populations within LMCA, provides insights into possible more effective modulation of the RAS in targeting the CSCs. Further studies including a larger sample size and *in vivo* functional experiments are needed to explore the functional role of the RAS.

In conclusion, the novel finding of the expression of PRR, ATIIR1 and ATIIR2 on the CSCs within the TNs and CSCs within the PTS, and the expression of ACE in the endothelium of the microvessels in LMCA suggests the CSCs may be a novel therapeutic target by manipulation of the RAS.

DECLARATIONS

Acknowledgments

We thank Mrs Liz Jones and Mr Nick Bockett at the Gillies and McIndoe Research Institute, for performing the immunohistochemical staining and photographing the DAB IHC slides, respectively.

Authors' contributions

Formulated the study hypothesis: Tan ST, Itinteang T

Designed the study: Wickremesekera SK, Tan ST, Itinteang T

Interpreted the DAB and IF IHC data: Narayanan A, Brasch HD, Tan ST, Itinteang T

Interpreted the NanoString mRNA expression data: Narayanan A, Wickremesekera SK, Tan ST, Itinteang T

Performed the WB analysis and interpreted the results: van Schaijik B

Performed the statistical analysis: Marsh RW

Abstract

Aim: Fibulins and ADAMTSs are two families of extracellular matrix proteins implicated in key functional and pathological processes. The fact that the fibulin-1 and ADAMTS-1 proteins interact raises new questions about the roles of these extracellular matrix proteins in modulating tumor progression. Herein, we described the functional implications of the interaction between fibulin-1 and ADAMTS-1 on the behavior of breast cancer cell lines.

Methods: Fibulin-1 and ADAMTS-1 were exogenously expressed in MCF-7 and MDA-MB-231 cell lines to assay the effect of their interaction in cellular properties.

Results: ADAMTS-1 expression exacerbates tumor effects in terms of proliferation, invasion and mammosphere formation. In contrast, the simultaneous expression of ADAMTS-1 and fibulin-1 impairs these effects. The analysis of the expression of both proteins in human breast cancer tissue arrays provides new insights into the complex roles of fibulin-1 and ADAMTS-1 in this type of tumor.

Conclusion: Our results suggest that the interaction between ADAMTS-1 and fibulin-1 induces a pronounced anti-tumoral effect.

Keywords: ADAMTS-1, fibulin-1, cell migration, cell proliferation, breast cancer, MCF-7, MDA-MB-231

INTRODUCTION

The extracellular environment is a dynamic niche in which multiple molecular interactions occur that govern cell fate. Several families of extracellular proteins function in this molecular dance, influencing cell properties and thus regulating either physiological or pathological processes^[1,2]. In addition, stromal cells are considered especially important in the extracellular environment as they induce extracellular modifications that can promote dysfunction in processes such as in cancer progression^[3].

In general, proteases are considered to be responsible for altering tissues and initiating the extracellular remodeling of tissues. Among proteases, members of the ADAMTS family have been widely implicated in different steps of cancer development. The ADAMTS family consists of 19 members, all of which have several domains, including a metalloprotease, a disintegrin and a variable number of thrombospondin motifs, which allow them to interact with different components of the extracellular matrix (ECM)^[4]. ADAMTS-1 was the first identified member of this family of matrix metalloproteases due to its association with inflammation processes^[5]. Since its discovery, ADAMTS-1 has been described to participate in several other processes, such as organogenesis, vessel formation and ovulation^[6-8]. The participation of ADAMTS-1 in cancer is underlined by its implication in some of the most important features of cancer development and progression^[9]. Thus, ADAMTS-1 has positive effects on cell survival, invasion and migration processes and, in general, does not participate in cell proliferation^[10,11]. Furthermore, ADAMTS-1 promotes angiogenesis in breast xenografts, but it is also able to inhibit angiogenesis in lung and hepatic metastasis as well as in other cell-based angiogenic experiments^[11,12].

Several studies provide conflicting associations of ADAMTS-1 with breast cancer; ADAMTS-1 has been reported to be both a pro- and anti-tumorigenic factor^[10,13-15]. This dual function of ADAMTS-1 depends on the conditions in which the ADAMTS-1 pathway is functioning, i.e., microRNAs such as miR-365 or peroxisome proliferator-activated receptor (PPAR δ)^[16,17]. The tumor promotion or tumor inhibition properties associated with ADAMTS-1 can also depend on the fragmentation of ADAMTS-1 or the interactions of ADAMTS-1 with other components of the ECM^[18]. One of the known partners of ADAMTS-1 in the ECM is fibulin-1; the interaction of these two proteins was described as a result of a yeast two-hybrid screen for potential interactions of ADAMTS-1. As a result of this interaction, the proteolytic activity of ADAMTS-1 towards aggrecan is increased; thus, fibulin-1 is considered a cofactor of ADAMTS-1 aggrecanase activity^[19].

Fibulin-1 was the first identified member of the fibulin family of matrix proteins^[20]. The members of this family each contain a fibulin-like domain at the carboxy terminal of the protein. The fibulin family consists of seven members of different lengths that contain different motifs with varying functions, such as anaphylatoxin domains (fibulin-1 and fibulin-2), epidermal growth factor (EGF)-like modules (fibulin-3 and fibulin-4), thrombospondin-like and von Willebrand factor domains (fibulin-6) or a sushi domain (fibulin-7)^[21]. In particular, fibulin-1 and fibulin-2 are closely related and characterized by the presence of anaphylatoxin and calcium-binding EGF (cbEGF) modules. However, only fibulin-2 contains two additional modules: cysteine (cys)-rich and cys-free domains. In addition, fibulin-1, fibulin-2, fibulin-3, fibulin-4 and fibulin-5 are considered elastogenic fibulins since they are important components of elastic fibers that are particularly abundant in the dermis, lungs and arterial walls^[21,22].

The roles of fibulins in tumor development have been widely discussed, and they show both pro- and anti-tumor activities^[23]. In particular, fibulin-1 has been described to be overexpressed in various human cancers and associated with processes such as invasion, migration, and *in vivo* tumor growth^[24-26]. The role of fibulin-1 in breast cancer depends on multiple factors. For example, four alternative forms of fibulin-1 have been described (fibulin-1A, fibulin-1B, fibulin-1C and fibulin-1D), which differ at the carboxy terminal^[27]. Fibulin-1D acts as a product of a tumor suppressor gene, whereas fibulin-1C (lacks only 21 amino acids of the fibulin-like domain) behaves as an oncogenic protein^[25,28]. Furthermore, the identification of fibulin-1 localization or fibulin-1-expressing cells are also important metrics since fibulin-1 is one of the genes specifically expressed in normal fibroblasts but not in breast cancer-associated fibroblasts^[29]. The epigenetic downregulation of fibulin-1 has also been described in various cancers, such as gastric cancer, colorectal cancer, hepatocellular carcinoma, and bladder cancer, but this downregulation has not been described in breast cancer^[30-33].

Herein, we describe the effects of the ADAMTS-1/fibulin-1 interaction on breast cancer cell properties related to cancer progression and development. We found that cell proliferation, invasion and migration are susceptible to being affected by this interaction as well as the capacity of tumorsphere formation, which reflects the capability of cancer cells to form tumor focus. Finally, we detected very low levels of ADAMTS-1 expression and high levels of fibulin-1 expression in a human tissue array from breast cancer patients, which can be considered a deviation towards a cancerous phenotype.

METHODS

Cells lines and cell culture conditions

Human MDA-MB-231 and murine MCF-7 breast cancer cell lines were kindly provided by Dr. Carlos López-Otín (University of Oviedo, Spain). Cells were routinely maintained in Dulbecco's Modified Eagle's medium (DMEM) containing 10% fetal bovine serum, 50 µg/mL streptomycin and 100 U/mL penicillin (Life Technologies). For transfection experiments, vectors containing the full-length human cDNAs for fibulin-1 (kindly provided by Dr. Tatako Sasaki, Oita University, Japan) and Flag-tagged ADAMTS-1 (Origene) were transfected into cells at 75% confluence using TransIT-X2 (Mirus) as recommended by the manufacturer. Cells transfected with an empty vector were used as a control. Stably expressing transfectants were selected with 500 µg/mL G418 (Sigma-Aldrich) and used for all the experiments.

Western blotting and immunoprecipitation

For western blot analysis, proteins were resolved by 10% polyacrylamide gel electrophoresis, transferred to a nitrocellulose membrane and subsequently probed with the indicated antibodies. Primary antibodies for the detection of ADAMTS-1 were purchased from Sigma-Aldrich (FLAG M2, for immunoprecipitation) and Bioss (bs-1208R-A488, for immunohistochemistry and western blotting), and those used for the detection of fibulin-1 were obtained from Novus (NBP1-84725, for immunohistochemistry) and Santa Cruz Biotechnology (H-190, for western blotting).

The anti-actin antibody used as the load control was purchased from Sigma-Aldrich (AC-15). Immunoreactive proteins were visualized using HRP-peroxidase-labeled anti-rabbit or anti-mouse secondary antibodies and an electrochemiluminescence (ECL) detection system (Pierce). For immunoprecipitation, MCF-7 double-transfected cells (ADAMTS-1 and fibulin-1) were resuspended in lysis buffer (100 mM Tris-HCl at pH 7.4, 150 mmol/L NaCl, 10 mmol/L EDTA, 1% desoxycholic acid, 1% Triton X-100, and 0.1% SDS containing one complete protease inhibitor cocktail (one tablet/50 mL buffer; Roche Molecular Biochemicals) and incubated for 2 h on ice with eventual stirring. Cell debris was removed by centrifugation in a bench-top centrifuge for 15 min at 4 °C. Protein concentration was quantified using the BCA Protein Assay Kit from Pierce Technology. For immunoprecipitation, 1 mg of protein extract was incubated with anti-FLAG M2 affinity gel

(Sigma-Aldrich) for 16 h at 4 °C following the manufacturer's instructions. After three washes in lysis buffer, the immunoprecipitates were resolved by western blotting.

Invasion assays

In vitro invasion potential was evaluated using 24-well Matrigel-coated invasion chambers with an 8- μ m pore size (BD Biosciences). For MCF-7 cells, 5×10^5 cells were allowed to migrate for 96 h using 10% fetal bovine serum as a chemoattractant. Cells that reached the lower surface were stained with crystal violet. At least three independent experiments were performed in triplicate for each condition. Cells were counted in eight randomly selected microscopic fields. In the case of MDA-MB-231 cells, invasion was evaluated after 24 h.

Migration assays

The migratory capacity of cells on the ECM components fibronectin, laminin I, and type-I collagen was examined using the RadiusTM 24-Well Cell Migration Assay kit (Cell Biolabs) following the manufacturer's instructions. Briefly, 5×10^5 cells were seeded per well, and migration was monitored by time-lapse microscopy using a Zeiss Axio Observer Microscopy. Experiments were performed in triplicate, and the covered area was quantified at different times using ImageJ. For MCF-7 cells, the results were obtained after 24 h of migration. In the case of MDA-MB-231 cells, we used a barrier-migration assay over a period of 24 h and the same ECM components^[34].

Cell proliferation determination by Ki-67 staining

Cell proliferation was estimated by the quantification of Ki-67-positive nuclei in MCF-7 and MDA-MB-231 cell cultures, including controls and the different transfectants. Cells were fixed with 4% paraformaldehyde, blocked with 10% fetal bovine serum and incubated overnight with an anti-Ki67 antibody (Santa Cruz Biotechnologies). After three washes in phosphate buffered saline (PBS), the cells were incubated with a secondary Alexa 546-conjugated antibody (Life Technologies) for 1 h. In all samples, DAPI (100 ng/mL) was added to visualize the DNA in the cell nucleus. Images were obtained using a fluorescence microscope (Axiovert). After quantification, the data were plotted as an average of Ki-67-positive nuclei in relation to the total number of nuclei per microscopic field.

Mammosphere cultures

A total of 4×10^4 MCF-7 cells were plated in 6-well ultralow attachment plates (Costar) and grown in MammoCult Basal Medium (Stem Cell Research) supplemented with 10% MammoCult Proliferation Supplement, 4 μ g/mL heparin and 0.5 μ g/mL hydrocortisone. After 7 days, mammospheres were collected and enzymatically dissociated as previously described^[35]. The individual dissociated cells were cultured in 96-well ultralow attachment plates at a density of 20 cells/well. Mammosphere formation was microscopically monitored daily to ensure that the mammospheres were derived from single cells and not from aggregates. The number of mammospheres was determined after 7 days of culture.

Human breast cancer tissue array

A breast cancer tissue array containing samples from different tumor stages was employed to evaluate ADAMTS1 and FBLN1 expression in human breast cancer samples. The tissue array was obtained from the Institute of Oncology of Asturias Tumour Bank. Written informed consent was obtained from all patients prior to sample collection. The study was approved by the appropriate institutional review board according to national and EU guidelines.

Slides were processed for indirect peroxidase immunohistochemistry as follows: sections were deparaffinized, rehydrated and then rinsed in PBS containing 1% Tween-20. For the detection of fibulin-1 and ADAMTS-1, the sections were heated in an Envision FLEX target retrieval solution at high pH and 80 °C for 20 min and then incubated for 20 min at room temperature in the same solution. Endogenous peroxidase activity (3% H₂O₂) and nonspecific binding (33% fetal calf serum) were blocked, and the sections were incubated overnight at 4 °C with primary antibodies diluted 1:100. We used labeled polymer-HRP (ready for use)

antibodies from DAKO as the secondary antibodies. 3-3'-Diaminobenzidine was employed as a chromogen. Selected slides were counterstained with hematoxylin to ascertain structural details. As immunostaining controls, representative sections were processed in the same way as described above using nonimmune rabbit or mouse sera instead of the primary antibodies or by omitting the primary antibodies during the incubation. Furthermore, when available, additional controls were carried out using specifically preabsorbed antisera.

Fibulin-1 immunostaining intensity was semiquantitatively evaluated by two independent observers directly under the microscope using ten randomly selected fields (20x objective and a 20x ocular). The intensity of the immunoreaction was evaluated as strong (+++), moderate (++), weak (+) or negative (-).

Survival analysis

To assess the effect of ADAMTS-1 and fibulin-1 on breast cancer prognosis, survival probability was determined using the data available at www.kmplot.com^[36]. The results are presented as Kaplan-Meier long-rank test survival plots.

Statistical analysis

Statistical analysis was carried out using Microsoft Office software. Data are presented as mean \pm SE. The occurrence of significant differences was determined with the Student-Welch *t* test. *P* values under 0.05 were considered statistically significant (**P* < 0.05, ***P* < 0.01, ****P* < 0.005).

RESULTS

ADAMTS-1 and fibulin-1 interact in breast cancer cell lines

Fibulin-1 has been described as an ADAMTS-1 cofactor because of its proteolytic activity towards aggrecan degradation^[19]. Fibulin-1 is not an ADAMTS-1 substrate; instead, it is an interacting partner that can affect cancer-associated properties such as the migration, invasion and proliferation of breast cancer cell lines. Thus, we used two common human breast cancer cell lines, MCF-7 and MDA-MB-231. First, we quantified the endogenous expression of both proteins in cell extracts obtained from both cell lines [Figure 1]. No detectable levels of fibulin-1 or ADAMTS-1 were visualized by western blotting in either the MCF-7 or the MDA-MB-231 cell extracts [Figure 1A]. Thus, we transfected both cell lines with the corresponding cDNAs (ADAMTS-1, fibulin-1 or both simultaneously) to obtain transfectants expressing one of the proteins or both proteins together. For control purposes, we used an empty vector as a negative control [Figure 1A, control]. Once we obtained all the transfectants, we tried to probe the *in vivo* interaction of ADAMTS-1 and fibulin-1 in MCF-7 extracts by immunoprecipitation. To this end, we took advantage of the Flag epitope present in the exogenously expressed ADAMTS-1 protein. Fibulin-1 western blotting following Flag (ADAMTS-1) immunoprecipitation showed a 100 kDa reactive band only in extracts from the ADAMTS-1/fibulin-1 double-transfected cells [Figure 1B, top], which demonstrated the existence of this interaction in the MCF-7 double transfectants [Figure 1B]. To probe the presence of ADAMTS-1 in the same immunoprecipitate, we carried out a Flag western blot that showed the presence of a 100 kDa reactive band that corresponded to the size of ADAMTS-1 [Figure 2, bottom].

Effect of the fibulin-1/ADAMTS-1 interaction on invasion properties

After we demonstrated the fibulin-1/ADAMTS-1 interaction in breast cancer cells, we decided to explore the functional consequences of this event by first checking the effects of this interaction on the invasion properties of both cell lines. To address invasion properties, we used Matrigel-coated invasion chambers [Figure 2], and we observed that the fibulin-1/ADAMTS-1 interaction resulted in a significant reduction in the invasion capability of both cell lines. Thus, the invasive potential of the double transfectants of both the MDA-MB-231 and the MCF-7 cell lines was decreased compared with that of the control cell lines (MDA-MB-231: average of 112 double transfectants cells/field vs. 240 control cells/field; MCF-7: 65 double

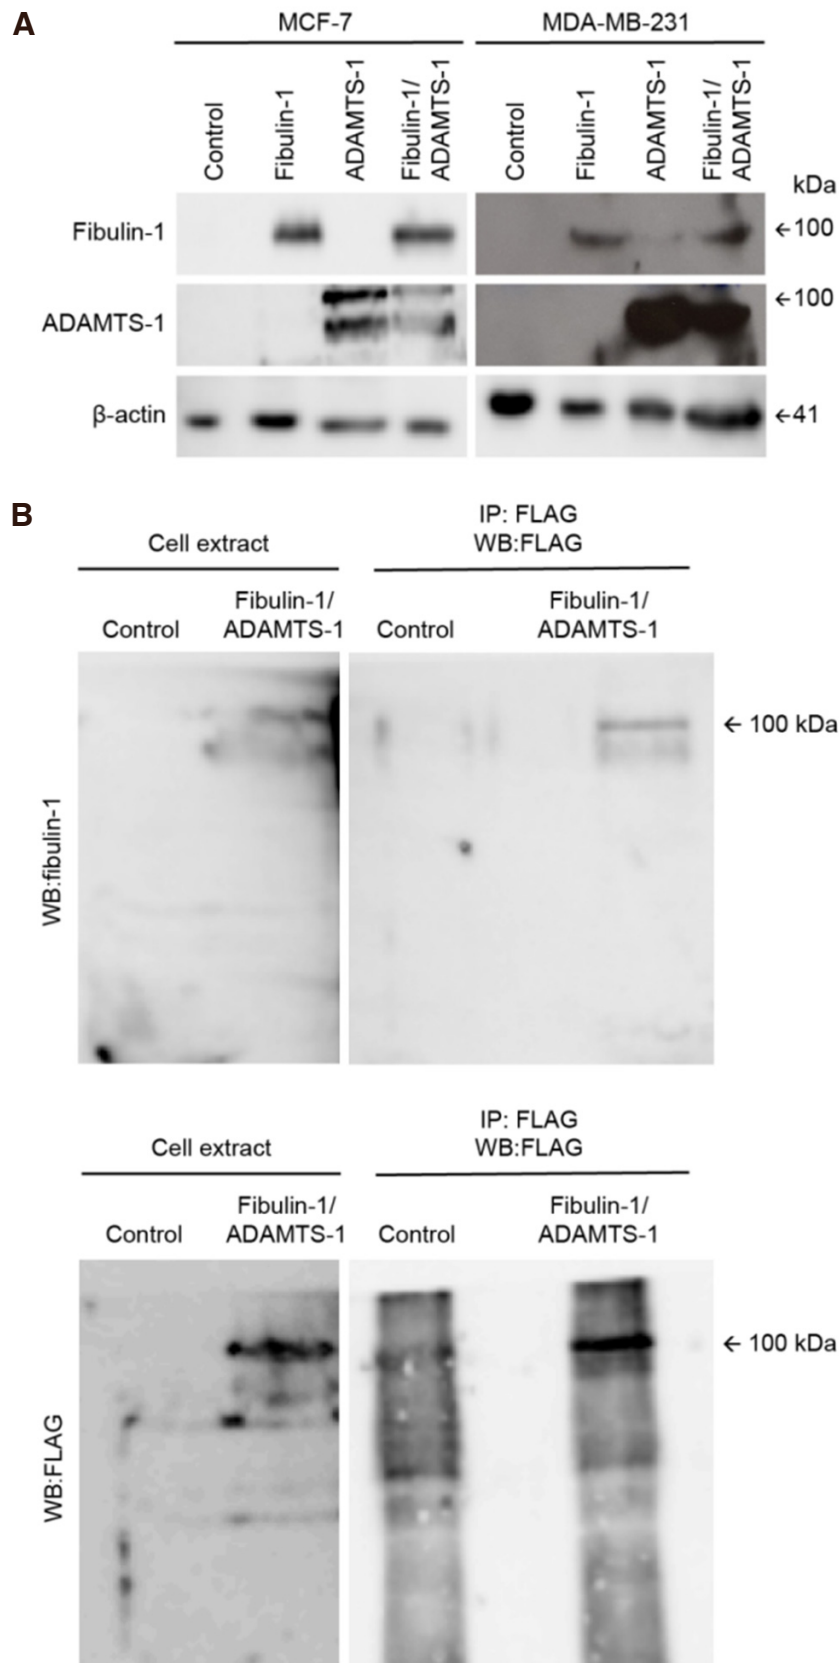

Figure 1. Selection of MCF-7 and MDA-MB-231 stable transfectants and coimmunoprecipitation of fibulin-1 with ADAMTS-1. transfectants cells/field vs. 90 control cells/field). The expression of fibulin-1 alone had the ability to reduce the invasiveness of MDA-MB-231 cells (an average of 175 vs. 240 cells/field) but not the invasiveness of MCF-7 cells. In contrast, and in agreement with the previously described tumor-promoting properties of ADAMTS-1, the invasion capabilities of the ADAMTS-1 transfectants of both cell lines showed an important increase compared with those of the control cell lines (averages of 340 vs. 240 cells/field for the MDA-MB-231 cell line and 275 vs. 90 cells/field in MCF-7 cells).

Effect on the migration properties of the fibulin-1/ADAMTS-1 interaction

Next, we analyzed the migration potential of both cell lines over two components of the extracellular matrix, type-I collagen and fibronectin. After 24 h, we measured the covered area and graphed the results for a better interpretation of the results. In all cases, substrates and cell lines, we observed that the migration properties

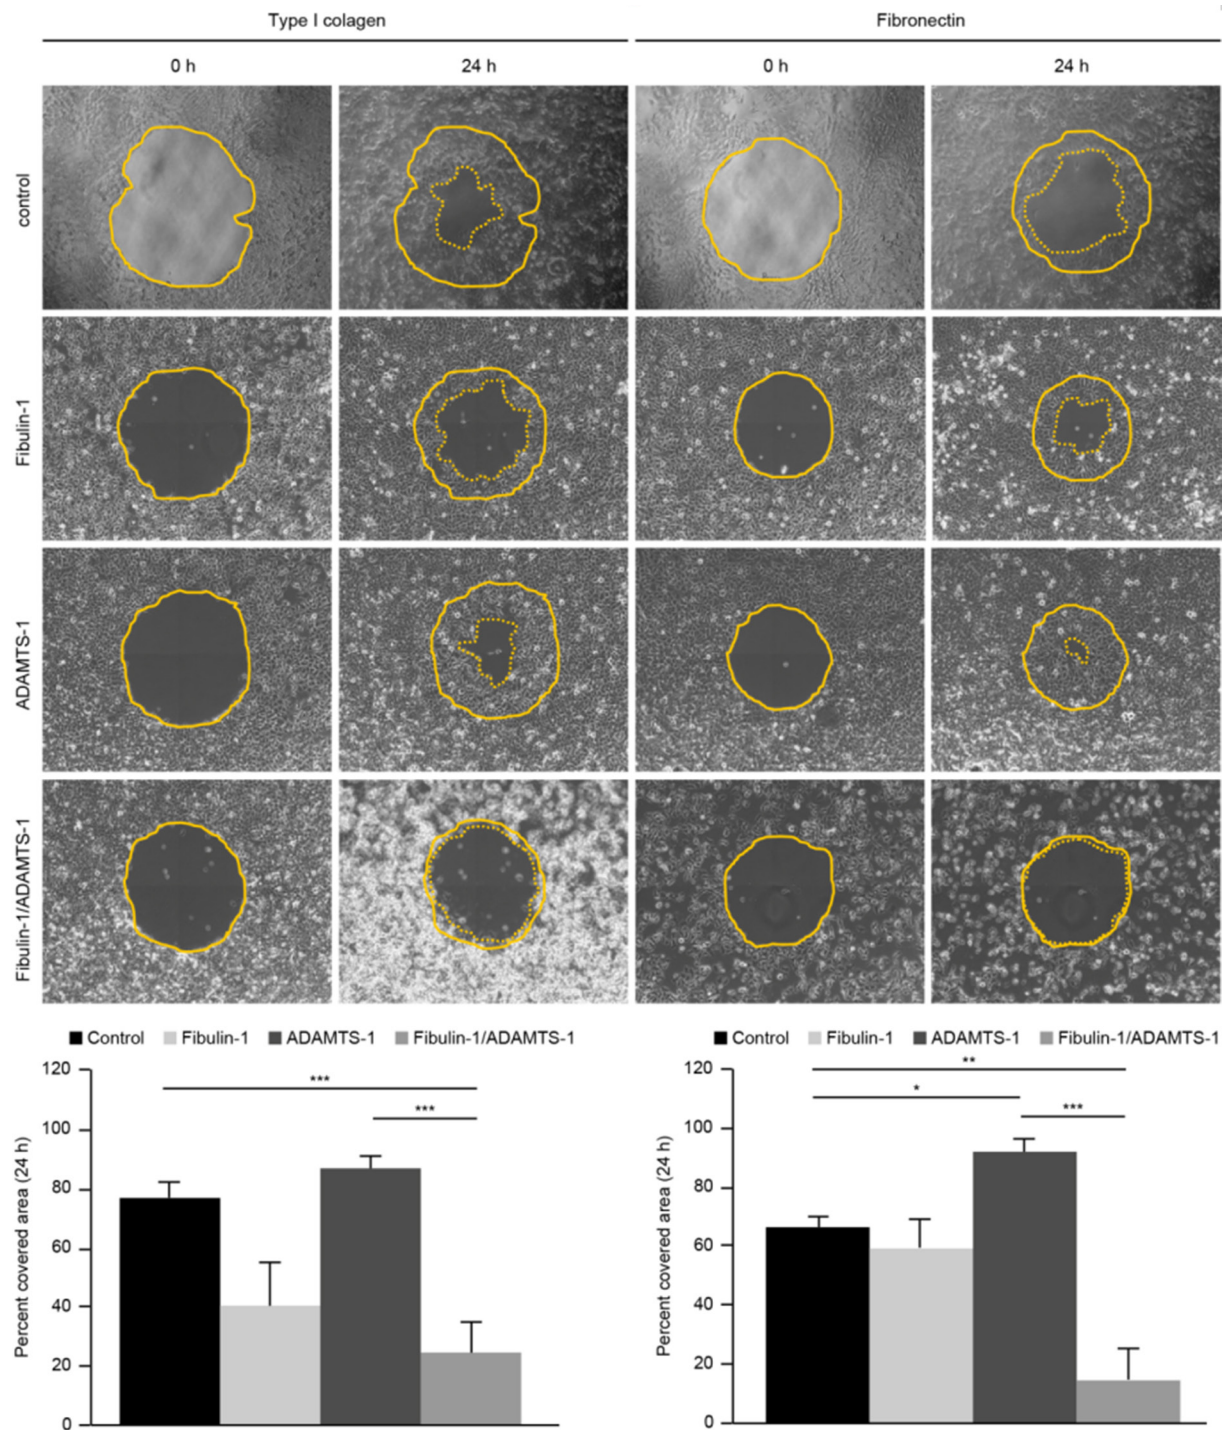

Figure 3. Coexpression of ADAMTS-1 and fibulin-1 reduces the migration properties of the breast cancer cell line MCF-7 over type-I collagen and fibronectin. Top, Representative images of the migration of MCF-7 transfectants on wells coated with type-I collagen and fibronectin using the RadiusTM 24-Well Cell Migration Assay kit (Cell Biolabs). MCF-7 cells transfected with an empty vector were used as a control. Pictures of the initial (t: 0 h) and final (t: 24 h) times are included. The starting point is indicated with a thin dotted line, and the final point is indicated with a thick dotted line. Bottom, graphical representation of percentages of the area covered after 24 h (from three independent experiments)

of the double transfectants (fibulin-1 and ADAMTS-1) were significantly compromised compared with those of their respective controls. We observed that the control MCF-7 cells were able to cover 79% of the area on type-1 collagen-coated dishes, whereas the double transfectants only were able to cover 25% of the area. In

the case of fibronectin, the control cells could cover 65% of the dish area, and the double transfectants could cover 18% of the dish area [Figure 3]. The data for the control and double transfectants cells of the MDA-MB-231 cell line were somewhat similar; the control cells covered 90% of the areas of the type-1 collagen- and fibronectin-coated plates, while the double transfectants covered 35% and 25% of the type-1 collagen- and fibronectin-coated plates, respectively [Supplementary Figure 1]. The expression of ADAMTS-1 alone also showed significant effects on migration only over the fibronectin substrate compared with the control cells and double transfectants of the MCF-7 and MDA-MB-231 cell lines [Figure 3 and Supplementary Figure 1, respectively]. The overexpression of fibulin-1 alone showed significant effects compared with the double-transfected and ADAMTS-1-overexpressing MDA-MB-231 cells over fibronectin and type-1 collagen [Supplementary Figure 1].

Effects of the fibulin-1/ADAMTS-1 interaction on cellular proliferation

Ki-67 nuclear staining is a good marker to measure the proliferative state of any given cell line. In this study, we used Ki-67 nuclear staining to evaluate the proliferative properties of all the transfectants generated. In both cell lines, MDA-MB-231 and MCF-7, ADAMTS-1 overexpression increased cell proliferation, as shown in Figure 4. The number of Ki-67-positive nuclei in the ADAMTS-1-expressing and control cells of the MDA-MB-231 cell line was 63 and 48, respectively, whereas that in the ADAMTS-1-expressing and control cells of the MCF-7 cell line was 82 and 64, respectively. On the other hand, fibulin-1 overexpression was able to significantly reduce proliferation in only the MCF-7 cells; 49 and 64 Ki-67-positive nuclei were detected in the fibulin-overexpressing and control cells, respectively. When ADAMTS-1 and fibulin-1 were transfected together, a reduction in the cell proliferation of both cell lines was observed. Specifically, in MDA-MB-231 cells, 35 and 48 Ki-67-positive nuclei were detected in the double transfectants and control cells, respectively, whereas in MCF-7 cells, 45 and 64 Ki-67-positive nuclei were detected in the double transfectants and control cells, respectively [Figure 4].

Effects of the fibulin-1/ADAMTS-1 interaction on mammosphere formation

One way of mimicking a tissue environment using 3D cell culture *in vitro* is through the formation of mammospheres, allowing the quantification of the size of these structures as well as the self-renewal capacity of the cell. In this context, we were able to examine the influence of fibulin-1 and ADAMTS-1 on the mammosphere formation of breast cancer cells. The fibulin-1/ADAMTS-1 interaction resulted in fewer and smaller mammospheres than did the other three combinations [Figure 5]. Furthermore, significant differences in mammosphere forming units (MFUs) were observed among all possible combinations. It is remarkable that the ability to develop MFUs was almost completely abolished when fibulin-1 and ADAMTS-1 were coexpressed (no MFUs were detected). Compared with the control cells, cells expressing fibulin-1 also exhibited a diminished ability to develop MFUs (11 MFUs vs. 4 MFUs). In contrast, ADAMTS-1 expression slightly increased this capacity. Taken together, our data indicate that fibulin-1 and ADAMTS-1 affect the ability of this cell line to form mammospheres.

Analysis of ADAMTS-1 expression in breast cancer tissue samples

We performed an immunohistochemical analysis of the expression of ADAMTS-1 and fibulin-1 in a tissue array containing 69 breast cancer tissue samples, including 18 ductal carcinomas, 3 poorly differentiated ductal carcinomas, 12 moderately differentiated ductal carcinomas, 1 well-differentiated ductal carcinoma, 20 lobular carcinomas, 6 mucoid carcinomas, 3 colloid carcinomas, 3 apocrine carcinomas, and 3 medullary atypical carcinomas [Supplementary Table 1]. Overall, using serial slides, the results indicated no colocalization of the proteins regardless of the tumor type or stage [Figure 6]. Consistently, ADAMTS-1 immunoreactivity was almost absent or expressed at residual levels in all types of carcinoma samples [Figure 6]. On the other hand, positive immunostaining for fibulin-1 was distributed in both the tumor cells and the stromal spaces with the exception of the colloid carcinoma, in which fibulin-1 expression was restricted to the tumor cells [Figure 6, Top].

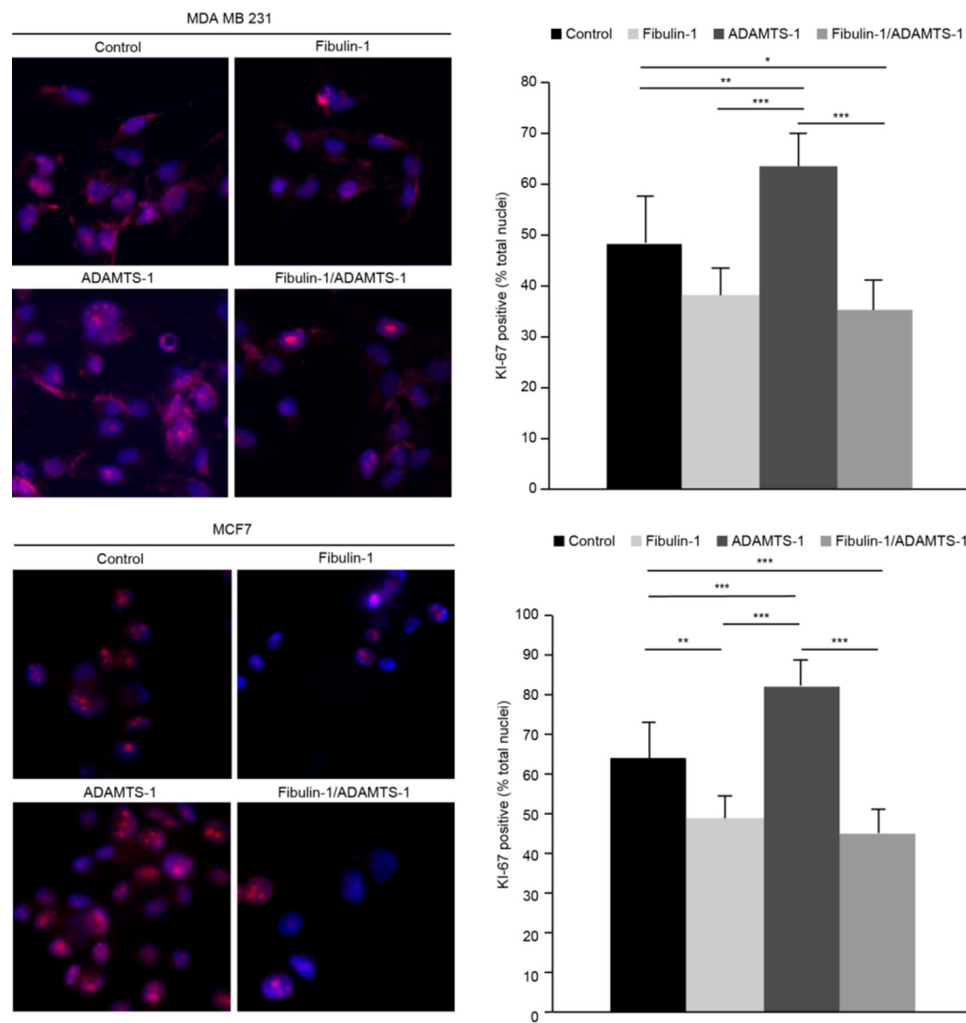

Figure 4. Coexpression of ADAMTS-1 and fibulin-1 reduces the proliferation of the breast cancer cell lines MCF-7 and MDA-MB-231. The proliferative state of breast cancer cell lines was measured by quantifying the proliferative nuclear marker Ki-67 by immunocytochemistry. Top Left: representative images of Ki-67 staining in the indicated MDA-MB-231 transfectants; bar, 10 μ m. Top Right: quantification of Ki-67-positive nuclei (as a percentage of total nuclei labeled by DAPI staining). Bottom Left, representative images of Ki-67 staining in the indicated MCF-7 transfectants; bar, 10 μ m. Bottom Right, quantification of Ki-67-positive nuclei (as a percentage of total nuclei labeled by DAPI staining)

We next assessed the association of ADAMTS1 and FBLN1 expression with clinical outcome using data available at www.kmplot.com. Overall survival Kaplan-Meier analysis revealed that the high expression of FBLN1 and ADAMTS1 correlated with the best prognosis for breast cancer patients (Figure 6, Bottom; measured as a mean of expression of both genes, $P < 0.001$). Similarly, high levels of FBLN1 can be considered a marker for good breast cancer prognosis ($P < 0.005$). On the other hand, this analysis also showed no influence of ADAMTS1 expression level on overall survival rate [Figure 6, Bottom]. We also evaluated progression-free survival and metastasis-free survival and found no significant differences in any of the cases analyzed (each gene alone or both together; data not shown). These data suggest that factors other than these two genes could modulate the pro- or anti-tumor activities of both fibulin-1 and ADAMTS-1.

Taken together, our results suggest that the inhibitory effect on the invasion, migration or mammosphere formation processes exhibited by breast cancer cell models cannot be fully extended to breast cancer tissue samples. Therefore, it cannot be ruled out that other factors can influence tumor cell behavior, such as the presence of protease inhibitors or the generation of bioactive fragments due to proteolytic activities. Additionally, the presence of fibulins other than fibulin-1, such as fibulin-5, can influence context-

Figure 5. Coexpression of ADAMTS-1 and fibulin-1 abolishes mammosphere formation. Left: representative images of the mammospheres derived from MCF-7 transfectants in two consecutive generations. Control, MCF-7 cells transfected with an empty vector. Top row, mammosphere appearance before dissociation. Bottom row, mammosphere appearance 6 days after dissociation. Right: mammospheres were dissociated and passaged at a density of 20 cell/well in 96-well plates, and MFUs were counted and calculated as a percentage of the mammospheres formed from the number of cells seeded. White bar: 100 μ m

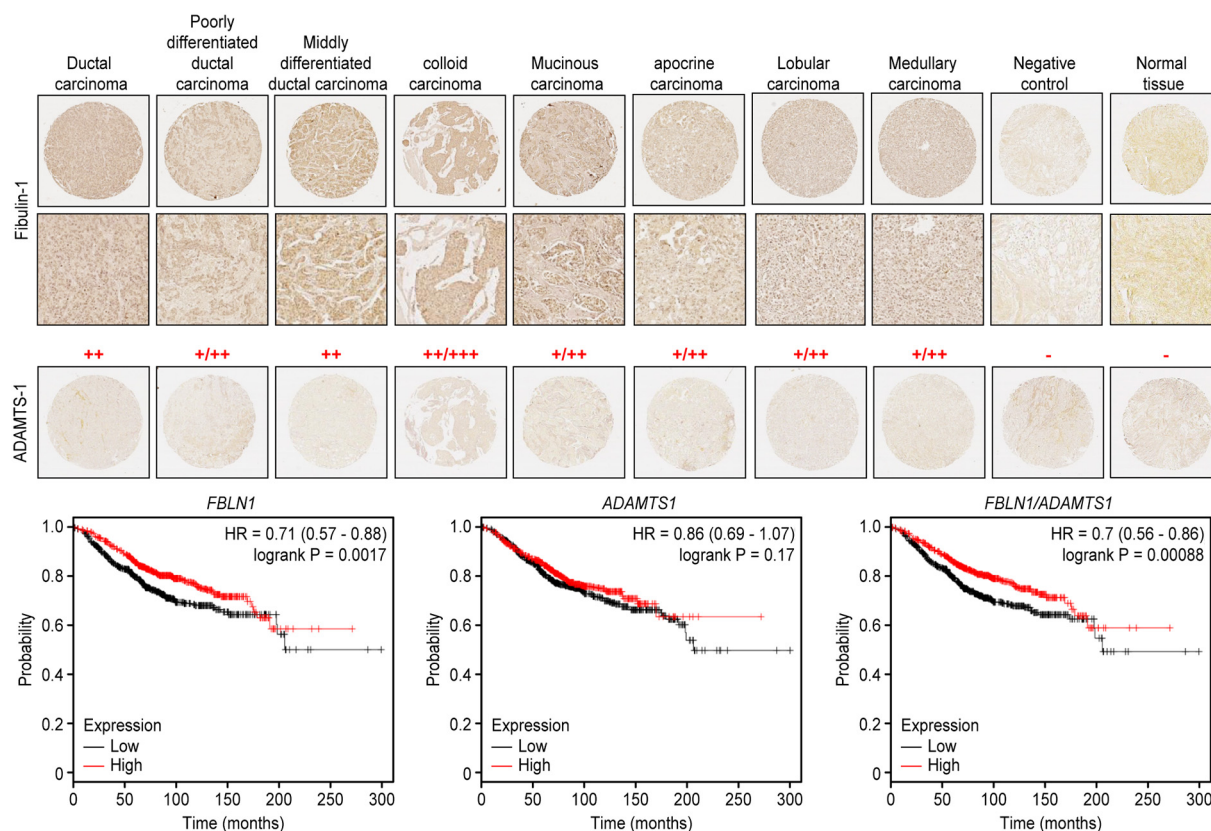

Figure 6. Different patterns of ADAMTS-1 and fibulin-1 expression in a breast cancer tissue array. Top: representative images of tissues used for the detection of ADAMTS-1 and fibulin-1 in different stages of breast carcinoma. Top two lines: fibulin-1 pattern at $\times 4$ and $\times 20$ magnifications. Bottom line: ADAMTS-1 pattern at $\times 4$ magnification. Negative controls were performed by omitting primary antibodies. The intensity of fibulin-1 immunostaining is indicated as strong (+++), moderate (++) or negative (-). specific effects on breast cancer cells^[37]. In this sense, fibulin-5 inhibits these same cellular properties; it was detected in a tissue array analysis of breast cancer samples and was inversely correlated with Ki-67 immunostaining^[38].

DISCUSSION

ECM proteins can be considered as important players in tissue homeostasis as it is considered the cellular component. Interactions among different components of the ECM have crucial roles in normal and pathological processes such as bone remodeling or tumor development^[1,39]. The components of the ECM that contain multiple motifs within the same protein unit are good candidates to establish various interactions and build bridge connections between cells and other components of the ECM. Such is the case for the members of two extracellular families of proteins, the fibulins and ADAMTSs^[4,21]. Members of both families have been associated with cancer development and progression and have been reported on many occasions to interact with other components of the ECM, acting as pro- or anti-tumor agents^[18,23].

Fibulin-1 has been previously described to be an ADAMTS-1 cofactor and to stimulate the proteolytic activity of ADAMTS-1 towards aggrecan and versican^[19,40]. Herein, we have been able to describe the significance of this fibulin-1/ADAMTS-1 interaction in the proliferation, migration and invasion properties of breast cancer cell lines. Overall, our data support the idea that ADAMTS-1 is a pro-tumor agent in breast cancer, whereas fibulin-1 is able to block this effect and acts as an anti-tumor agent. We have been able to show that the presence of both proteins reduces the migration and invasion properties of two breast cancer cell lines, MCF-7 and MDA-MB-231. The participation of ADAMTS-1 in cancer has been associated with mammary tumor growth and progression to metastasis in the MMTV-PyMT model in an *Adamts1*-/- background^[10], whereas it has also been reported to be a tumor suppressor gene through proteolysis of nidogen-1 and nidogen-2 in an HEK293T tumor xenograft assay^[41]. In our study, ADAMTS-1 expression was not detected by tissue array analysis in samples of different stages of breast cancer. Additionally, the Kaplan-Meier plots reflect the absence of an influence of ADAMTS-1 on expected patient overall survival. However, the ectopic expression of ADAMTS-1 in breast cancer cell lines increased the tumorigenic potential of these cell lines in terms of proliferation, migration, invasion and mammosphere formation. Initially, breast cancer profiles showed the downregulation of ADAMTS-1 in malignant tumors compared to normal tissues^[42].

However, other studies indicated the participation of ADAMTS-1 in aiding breast cancer development^[10,11,13,43]. Thus, the participation of ADAMTS-1 in breast cancer development and progression might depend on substrates it is able to act upon, such as versican to facilitate spreading of tumor cells or semaphorin 3C, which is known to promote metastatic potential of breast cancer cells^[10,44]. Interestingly, *ADAMTS1* was the third most overexpressed gene in highly metastatic MDA-MB-231 clones, and the knockdown of ADAMTS-1 in these clones regressed disease spread and reduced secondary tumor burden^[45,46]. The effect of this protein might also be dependent on which cell type produces and secretes ADAMTS-1, similar to the paracrine effect of breast cancer cells over cancer-associated fibroblasts of the vicinity^[15]. Finally, the impact of ADAMTS-1 might also depend on other ECM proteins that interact and bind with ADAMTS-1 and, as result, are able to modulate ADAMTS-1 activity.

The fact that fibulin-1 has been described as an ADAMTS-1 cofactor able to modulate ADAMTS-1 activity further implies the roles of both proteins in tumor development.

Fibulin-1 can interact with various ECM components, including known ADAMTS-1 substrates, such as nidogen-1 and versican^[2,21,27]. Fibulin-1 has also been implicated in cellular transformation and, similar to ADAMTS-1, can behave as both a tumorigenic factor or tumor suppressor depending on the tissue environment^[23]. Our results showed that the ectopic expression of fibulin-1 in breast cancer cell lines was able to block the tumorigenic properties of these cell lines. Furthermore, fibulin-1 expression was able to dramatically block these properties even in the presence of ADAMTS-1. Similar properties have also been described in our laboratory in the interaction of two related components of the ECM, fibulin-2 and ADAMTS-12. In this interaction, the expression of ADAMTS-12 alone exerted pro-tumoral activities, whereas the coexpression of both ADAMTS-12 and fibulin-2 showed an important anti-tumoral effect^[47].

It is noteworthy that fibulin-1 expression was initially associated with improved survival in patients with a lymphoid infiltrate at the tumor site^[48]. Similarly, the Kaplan-Meier analysis showed better prognosis for patients with high levels of fibulin-1 than for those with low fibulin-1 expression. In fact, the low expression of fibulin-1 has been described in various tumor types, such as gastric cancer, bladder cancer, colorectal cancer and hepatocellular carcinoma. In all these cases, low expression correlates with the hypermethylation of the FBLN1 promoter and can be used as a prognosis marker^[30-33,49]. Thus, our data are in accordance with all these studies in which it seems feasible that the presence of fibulin-1 might have a prevalent anti-tumor activity. In our immunohistochemical analysis, we could detect the presence of only fibulin-1; no ADAMTS-1 was observed. From our cellular experiments, it is clear that the presence of both proteins has a pronounced effect on the tumorigenic properties of both cell lines. The downregulation of ADAMTS-1 might be a mechanism of escape towards tumor progression, avoiding binding with fibulin-1 and thus eliminating the anti-tumoral properties of their interaction.

In summary, the interactions between members of both families of ECM proteins, fibulins and ADAMTSs, seem to be important for cancer development, as is the case for ADAMTS-12/fibulin-2 and ADAMTS-1/fibulin-1. Furthermore, we have also been able to demonstrate the cleavage of fibulin-2 by ADAMTS-4 and ADAMTS-5, which increased the tumorigenic potential of breast cancer cell lines^[50]. Therefore, it is tempting to speculate the existence of similar mechanisms that control fibulin-1 participation in breast cancer development and its interaction with other ECM components, a hypothesis that warrant further study.

DECLARATIONS

Acknowledgments

Abstract

Endocrine therapy is essential for the treatment of patients with estrogen receptor positive (ER+) breast cancer, however, resistance and the development of metastatic disease is common. Understanding how ER+ breast cancer metastasizes is critical since the major cause of death in breast cancer is metastasis to distant organs. Results from many studies suggest dysregulation of the estrogen receptor alpha gene (*ESR1*) contributes to therapeutic resistance and metastatic biology. This review covers both pre-clinical and clinical evidence on the spectrum of *ESR1* alterations including amplification, point mutations, and genomic rearrangement events driving treatment resistance and metastatic potential of ER+ breast cancer. Importantly, we describe how these *ESR1* alterations may provide therapeutic opportunities to improve outcomes in patients with lethal, metastatic breast cancer.

Keywords: Endocrine therapy resistance, ESR1 fusions, ESR1 mutations, breast cancer, metastasis

INTRODUCTION

Breast cancer is one of the leading cancer-related causes of death worldwide with more than one million new cases and more than 450,000 deaths per year according to the World Health Organization. About 70% of diagnosed cases express estrogen receptor alpha (ER)^[1], where ER signaling is the defining and driving event contributing to tumor growth and disease progression in these ER+ breast tumors.

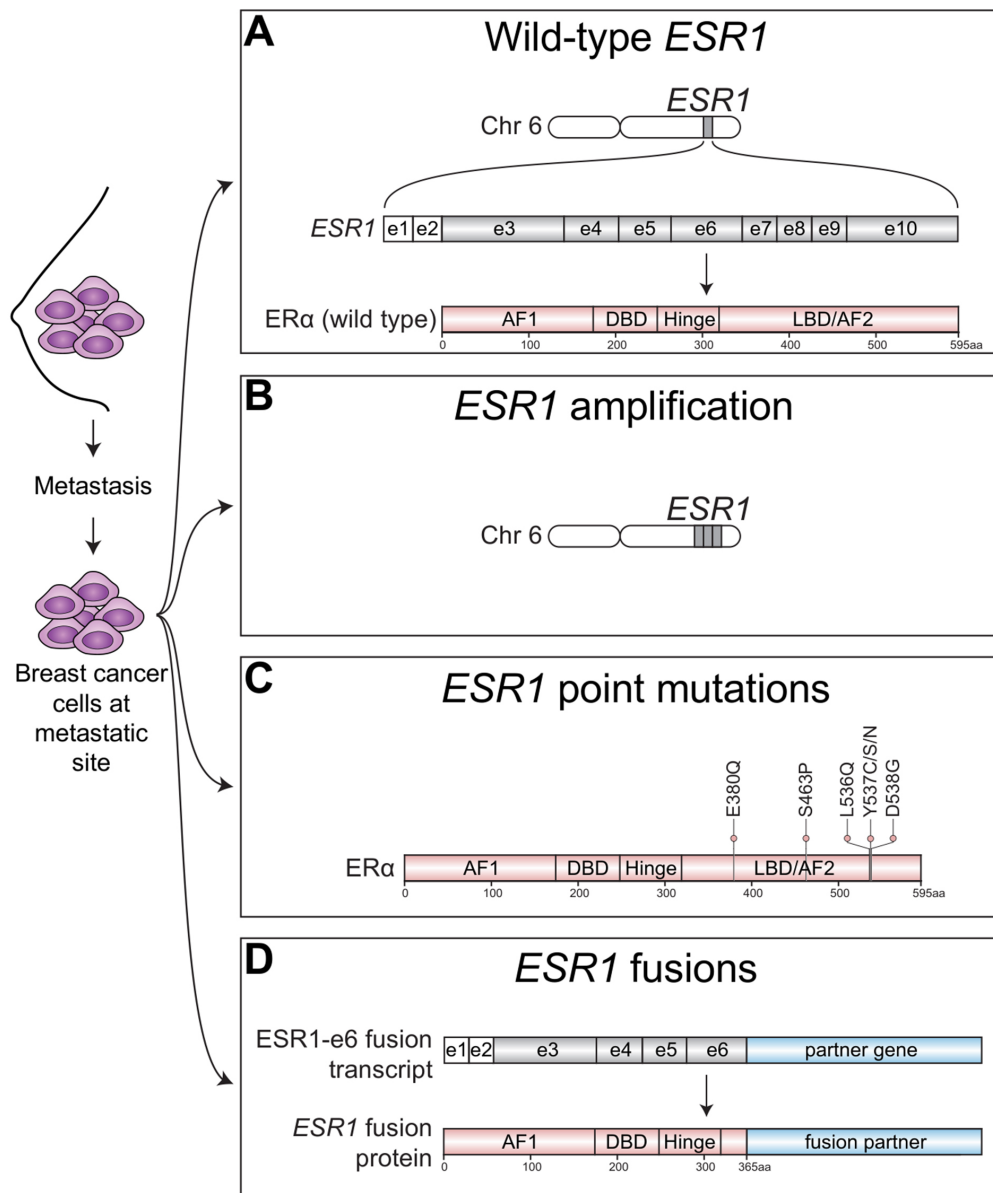

Figure 1. Spectrum of *ESR1* alterations found in metastatic ER+ breast cancer. ER+ breast cancer cells that have spread beyond the breast to metastatic sites have been found to express wild-type *ESR1* or harbor a variety of *ESR1* alterations. A: Metastatic tumors can express wild-type estrogen receptor alpha protein (ERα), which is encoded by the estrogen receptor alpha gene (*ESR1*) located on chromosome (chr) 6. *ESR1* transcripts are generated from 2 non-coding exons (e) depicted by white boxes and 8 coding exons depicted by gray shaded boxes; B: Metastatic ER+ tumors may also harbor amplification of *ESR1* resulting in multiple copies of *ESR1* and increased ER protein expression; C: Point mutations that cluster within the ligand-binding domain (LBD) of *ESR1* that confer constitutive ligand-independent activation of *ESR1* mutants have also been well-described in metastatic ER+ breast tumors, especially those which had been extensively pretreated with AIs; D: Emerging studies have now identified structural rearrangements involving *ESR1* that generate in-frame *ESR1* fusion transcripts. In-frame fusion transcripts that retain the first 6 exons of *ESR1* (*ESR1*-e6) produce stable *ESR1* fusion proteins have been shown to be transcriptionally active and drive endocrine therapy resistance and metastasis in ER+ breast cancer. AF1: activation function 1 domain; DBD: DNA-binding domain; AF2: activation function 2 domain; aa: amino acid

ER is a transcription factor consisting of various functional domains encoded by *ESR1* located on chromosome 6 [Figure 1A]. *ESR1* transcripts are generated by 2 non-coding and 8 exons that specifies protein-coding domains. The N-terminal activation function 1 (AF1) domain functions in a hormone-independent manner and is post-translationally modified by phosphorylation events that increase transcriptional and pathogenic activity^[2-5]. The DNA-binding domain (DBD) contains two zinc finger motifs responsible for binding to estrogen response element (ERE) DNA sequences within the enhancers

and promoters of ER target genes. The C-terminal domains include the ligand-binding domain (LBD) and ligand-dependent activation function 2 (AF2) domain required for dimerization and transactivation. The LBD is required not only for estrogenic ligands but is also the domain that controls responses to anti-estrogen antagonists. The hinge domain contains the nuclear localization sequence and connects the activity from the ligand-independent AF1 and ligand-dependent AF2 together to fully promote activation of ER^[6].

Standard-of-care endocrine therapies that target ER itself include selective estrogen receptor modulators (SERMs), such as tamoxifen, and selective estrogen receptor degraders (SERDs), such as fulvestrant, that bind to the LBD. Aromatase inhibitors (AIs), such as letrozole, anastrozole, and exemestane, block the production of estrogens from androgens resulting in lower levels of circulating estrogen in the body. Despite the success of these agents in reducing relapse rates when given prophylactically after breast surgery and chemotherapy (adjuvant treatment), endocrine therapy resistance and the development of lethal metastatic disease is common and a major clinical problem. A major clinical feature of the disease is the long-term persistence of disseminated tumor cells despite endocrine therapy, with relapse risk continuing for decades after diagnosis^[7]. The etiology of endocrine therapy resistance is complex and tremendous efforts have been made to uncover diverse mechanisms^[8].

Downstream signaling events from aberrantly activated growth factor receptor tyrosine kinases (RTKs) such as epidermal growth factor receptor (EGFR) and HER2 (*ERBB2*) have been shown to phosphorylate and increase ER transcriptional activity in a hormone-independent manner^[9]. ER+ tumors that exhibit *ERBB2* amplification have reduced ER expression, reduced sensitivity to ER targeted therapies, and poor outcomes^[10]. Nonetheless, co-targeting ER+/HER2+ breast cancer has been clinically successful. Experimental models have extended these ideas to other RTKs that are expressed by ER+ breast cancer. Interestingly, these investigations revealed a non-genomic or transcription-independent function of ER in association with EGFR^[11] and insulin-like growth factor receptor (IGF1-R)^[12] at the plasma membrane. However, clinical trials testing the use of EGFR inhibitors in endocrine treatment resistant ER+ breast cancer have produced modest or negative results^[13] suggesting that further insight into underlying mechanisms for RTKs and ER interactions are required for successful translation of this aspect of ER function.

Since *PIK3CA* is the most frequently mutated gene in ER+ breast cancer^[14], targeting components of the PI3K-AKT-mTOR pathway has also been described to treat endocrine refractory disease. Preclinical models demonstrated enhanced activation of the PI3K pathway in long-term estrogen deprived (LTED) ER+ breast cancer cells and a negative feedback system by which PI3K inhibition increases ER activity, potentially explaining the effectiveness of combinatorial mTOR and ER inhibition^[15]. The use of an mTOR inhibitor, everolimus, in combination with endocrine therapy, significantly improves progression-free survival (PFS) for patients failing previous endocrine therapies^[16], although side effects are severe and stratification of patients for this treatment is essential. Treatment with a pan-PI3K inhibitor, buparlisib, in combination with fulvestrant increased PFS with compared to fulvestrant alone in patients with ER+ locally advanced or metastatic breast cancer (BELLE-3 clinical trial)^[17]. Greater benefit was observed in patients treated with buparlisib harboring *PIK3CA* mutations. However, significant toxicities in buparlisib treated patients have stopped further clinical trials of the drug in this setting. In contrast to pan-PI3K inhibitors, alpelisib, an agent that specifically targets the alpha isoform of *PIK3CA*, has been shown to overcome the toxicities associated with pan-PI3K treatment. Apelisib greatly improved PFS in patients when given in combination with fulvestrant to patients with endocrine-refractory, advanced ER+ breast cancer harboring *PIK3CA* mutations^[18]. There was no significant benefit to PFS in patients with non-*PIK3CA* mutant tumors suggesting that *PIK3CA* status is a potential biomarker to predict response to PI3K inhibition. Results from studies also further suggest that targeting specific mutant isoforms of PI3K reduces toxicities leading to increased tolerability and therefore can be given for a longer duration compared to other pan-PI3K agents such as buparlisib.

Dysregulation of cell cycle components is common in ER+ breast cancer, particularly the Cyclin D-CDK4/6-Rb axis in the luminal B subtype^[19]. This includes amplification of Cyclin D1 (*CCND1*), gene copy gain of *CDK4* and loss of negative regulators such as p16 and p18 (*CDKN2A* and *CDKN2C*)^[19]. Together with downstream activity from tyrosine kinase growth factor signaling described earlier, these events promote phosphorylation of Rb and resistance to endocrine therapy^[20]. CDK4/6 inhibitors such as palbociclib and ribociclib, are now FDA approved for use in combination with endocrine therapy to treat advanced stage ER+ disease. Other studies are now examining the use of such inhibitors to treat early stage ER+ disease in both neoadjuvant and adjuvant settings (ClinicalTrials.gov identifiers for PALLET NCT02296801 and PALLAS NCT02513394, respectively). Some trials have already reported promising results in the neoadjuvant setting^[21].

In addition to metastatic breast tumors expressing wild-type ER [Figure 1A], alterations in *ESR1* itself, such as *ESR1* amplifications have been identified in metastatic ER+ disease^[22] [Figure 1B]. Other *ESR1* alterations found in endocrine therapy resistant breast tumors include point mutations in the ligand-binding domain (LBD)^[23] [Figure 1C] that confer constitutive hormone-independent activation of ER and are now a well-described mutational mechanism identified in up to 40% of metastatic breast cancer cases^[24]. These are especially enriched in tumors pretreated with aromatase inhibitors^[25]. Emerging evidence now suggests that chromosomal rearrangement events involving *ESR1* are yet another *ESR1* mutational mechanism driving endocrine therapy resistance and metastatic disease progression [Figure 1D]. Hereon, we focus on the spectrum of *ESR1* aberrations underlying treatment resistance and metastasis in ER+ breast cancer.

ESR1 AMPLIFICATION

The copy number increase of a confined area of a chromosome is defined as gene amplification/gain [Figure 1B] which may result in protein overexpression of the amplified gene therefore driving tumor biology. For example, *ERBB2* amplification^[26] and fibroblast growth factor receptor 1 gene (*FGFR1*) amplification^[27] are drivers of therapeutic resistance and poor prognosis in ER+ breast cancer. The discovery of *ESR1* gene amplifications in 1990^[28] sparked intense interest in investigating the role of this mutational event to be a potential driver of endocrine therapy resistance and recurrent disease in ER+ breast tumors.

Incidence of *ESR1* amplifications in ER+ breast cancer

ESR1 amplification is found in up to 30% of ER+ breast tumors^[22,28-37] depending on the detection method and scoring systems^[38]. A study by Holst *et al.*^[29] that analyzed over 2,000 breast tumors, showed that 20.6% of tumors harbored *ESR1* amplifications and 14% showed *ESR1* copy number gain by using fluorescence in situ hybridization (FISH) method and validated by quantitative PCR^[29]. Nearly all *ESR1* amplified tumors in these samples also expressed high levels of ER protein by immunohistochemistry. Additional analysis from precancerous ductal and lobular carcinoma in situ (DCIS and LCIS) breast tumors showed over one-third of these samples also harbored *ESR1* amplifications suggesting that *ESR1* amplifications present in early-stage breast cancer may drive disease progression. Two other independent studies that also used FISH, both showed that *ESR1* amplification frequency is between 20%-22%^[34-35], consistent with Holst *et al.*^[29]. In contrast, other studies by Brown *et al.*^[30], Horlings *et al.*^[31], Reis-Filho *et al.*^[32], and Vincent-Salomon *et al.*^[33], have shown a much lower frequency of *ESR1* amplifications, in which *ESR1* amplification or gain was less than 5% by using array comparative genomic hybridization (aCGH) and validated by FISH by the majority of these studies. Another study which used a multiplex ligation-dependent probe amplification (MLPA) approach to analyze 104 invasive breast cancers identified 16% of samples harbored *ESR1* amplifications consisting of low level gains^[36]. A variation in the frequency of *ESR1* amplification found among metastatic breast samples has also been reported. A seminal study from Jeselsohn *et al.*^[37] examined *ESR1* amplification in the metastatic setting using next generation sequencing approaches. They reported the frequency of *ESR1* amplification in ER+ tumors at less than 2% in both the primary and metastatic setting^[37]. Using NanoString sequencing approaches, a recent study reported that 13% of ER+ metastatic breast tumors harbored *ESR1* amplifications. Interestingly, the authors found an enrichment of *ESR1* amplifications in bone metastatic

samples, suggesting that *ESR1* amplification may underlie organ-specific metastatic behavior of ER+ breast cancers^[39].

Correlation between *ESR1* amplification, protein expression, and clinical significance

Many studies show positive correlation between *ESR1* amplification and ER protein expression suggesting that amplification may lead to production of elevated levels of oncogenic ER protein^[28,29,34,35]. Interestingly, studies have shown that *ESR1* amplification in a subset of ER+ breast cancers were associated with tamoxifen resistance and poor prognosis^[40,41]. In contrast, contradicting studies have identified *ESR1* amplification as an indicator of longer disease-free survival and increased sensitivity to tamoxifen treatment^[35,42]. These conflicting results suggest that more dedicated studies will be required to fully understand the clinical implications of *ESR1* amplifications. Results from other studies have identified *ESR1* amplification in benign and early-stage breast cancer and is associated with endocrine therapy resistance. Discovery of *ESR1* amplifications in benign papillomas and early-stage breast cancer such as ductal hyperplasias suggests that *ESR1* amplifications may play a role in the tumor initiation process since high expression of ER in benign breast cells is associated with higher breast cancer risk^[29,43,44], but these findings still require further validation. The insignificant difference of *ESR1* amplification between invasive and non-invasive breast cancers suggests that *ESR1* copy number alteration might not be used as a key predictive marker for invasion and metastasis, however its enrichment in recurrent disease, especially after endocrine therapy treatment, suggests that it likely plays a role in intrinsic and/or acquired resistance to endocrine therapy and metastatic disease progression^[45-48].

Although the use of endocrine agents that block estrogen production (AIs) or block ER function (SERM/SERD) are front-line therapies to treat metastatic ER+ breast cancer, the use of high-dose estrogens has also been reported to be effective. This approach was first described over 70 years ago before the discovery of anti-estrogens to treat advanced breast cancer^[49]. More recently, a study reported a breast cancer patient harboring an *ESR1* amplification showed tumor regression in a liver metastasis after receiving estradiol treatment as a primary therapy^[50]. Another study using a patient-derived xenograft (PDX) model harboring an *ESR1* amplification derived from a patient with endocrine-refractory disease demonstrated that tumor growth was suppressed with estradiol treatment^[47]. These results were corroborated in an independent study using a LTED ER+ MCF7 breast cancer cell model system in which such cells acquire *ESR1* amplification during long term estrogen deprivation showed an apoptotic response upon estradiol treatment^[48]. Collectively, these studies suggest a role for *ESR1* amplification in driving endocrine therapy resistance and metastasis and that treating *ESR1* amplified tumors with intermediate doses of estradiol (6 mg daily) is an option for some patients.

The presence of *ESR1* amplification in some breast cancers is undeniable. However, a clear link between the presence of *ESR1* amplifications in breast tumors and endocrine therapy resistance and metastasis remains to be shown. Deeper multi-dimensional characterization of relapsed and/or metastatic breast tumors at the RNA, DNA, and protein levels may aid to better understand its prognostic value. Therefore, more studies will be required to better understand the functional and therapeutic significance of *ESR1* amplifications in driving endocrine therapy resistance and metastasis.

***CYP19A1* amplification**

While *ESR1* amplification has been an intense area of investigation underlying endocrine therapy resistance as described above, a study focusing on genomic aberrations of the drug target of AIs, aromatase (*CYP19A1*), has deepened our understanding of endocrine-refractory ER+ breast tumors. Copy number alterations in the gene encoding aromatase, *CYP19A1*, also has been shown to promote resistance to AIs in patients with metastatic ER+ breast cancer. While *CYP19A1* amplification is very rare in primary untreated ER+ breast cancers, Magnani *et al.*^[51] found that 21.5% of AI-refractory relapsed tumors to harbor *CYP19A1* amplification, suggesting that *CYP19A1* amplification is an acquired endocrine therapy resistance

mechanism^[51]. This study also revealed that both *CYP19A1* and *ESR1* were frequently co-amplified in AI treated patients, further suggesting that these two amplification events may function collaboratively. To better understand the role of *CYP19A1* amplification and endocrine therapy resistance, a LTED MCF7 ER+ breast cancer cell model was used which was found to acquire copy number alterations around the *CYP19A1* locus compared to parental cells MCF7 cells^[51]. Elevated levels of both *CYP19A1* mRNA and CYP19A1 protein were observed in *CYP19A1* amplified LTED cells compared to parental cells. The functional consequences of *CYP19A1* amplification in the LTED cells were increased aromatase activity, enhanced ER recruitment to regulatory regions on DNA of target genes and their transcriptional activation leading to reduced sensitivity to AI treatment^[51]. These results suggest that *CYP19A1* amplification, in addition to *ESR1* amplification, could potentially represent biomarkers of endocrine therapy resistance. More studies are needed to validate these findings in more patient datasets. Furthermore, deeper studies focusing on how these amplification events contribute to the metastatic behavior of endocrine-refractory ER+ breast tumors are needed. These results highlight the possibility that response to standard-of-care endocrine therapies are not only as a consequence of *ESR1* amplification but may also be critically dependent on the status of the target genes of endocrine therapies themselves.

***ESR1* POINT MUTATIONS**

When patients with ER+ breast cancer relapse, up to 15% have lost ER expression and therefore targeting ER in this population is likely to be ineffective, although false negative ER results are a concern if the ER analysis was conducted on bone biopsies exposed to acid formalin, or if the analysis was conducted on samples prone to degradation such as cells detected in pleural fluid. The remaining 85% of patients may initially benefit from first-line endocrine therapy, but metastatic disease progression due to acquired resistance is inevitable. One well-established mechanism explaining this relentless pattern of acquired endocrine therapy resistance is the acquisition of activating point mutations that cluster within the ligand-binding domain (LBD) of *ESR1* [Figure 1C]. Substitution of tyrosine at position 537 to serine (Y537S) in the LBD of *ESR1* was first reported to confer constitutive, ligand-independent activity of ER in experimental breast cancer models^[52]. However, such mutations were not known to occur in human tumors until Fuqua *et al.*^[23] reported that estrogen-independent activation could be driven by another Y537 substitution, Y537N, that was identified in a metastatic sample from a breast cancer patient who experienced disease progression on hormonal therapy. This study also showed that Y537N was able to drive resistance to tamoxifen in experimental models.

Frequent *ESR1* point mutations in endocrine-refractory, metastatic ER+ breast cancer

Advances in sequencing technologies have allowed more sensitive detection and thus insights into the landscape of *ESR1* LBD point mutations in both primary and metastatic ER+ breast tumors. Three *ESR1* mutations, Y537S, Y537N, and D538G were identified by next-generation sequencing in 14 out of 80 patient samples with endocrine-refractory, metastatic ER+ breast cancer^[53]. Notably, all breast tumors from patients that were found to harbor *ESR1* LBD point mutations were treated with AIs. Interestingly, these alterations were not detected in matched primary samples and were also not detected in separate large sets of treatment naïve patients. Analysis of an independent ER negative (ER-) cohort also failed to detect any *ESR1* point mutations in the LBD^[53]. Although *ESR1* mutations were found in 3% of primary samples in this population, alterations in Y537 and D538 residues of *ESR1* were enriched in patients treated extensively with AIs^[53]. These results suggest that these *ESR1* LBD mutations are acquired, or detected, in patients after treatment with endocrine therapy.

In addition to Y537 alterations, frequent amino acid substitution of aspartate 538 to glutamate (D538G) was identified in liver metastases from 5 out of 13 metastatic ER+ breast samples^[54]. Another study which enrolled 11 metastatic ER+ breast cancer patients with exposure to serial endocrine therapies, identified that over half of these patient's metastatic samples harbored *ESR1* mutations localized in the LBD, that included Y537S, Y537C, Y537N, D538G, and L536Q mutations^[55]. Further evidence for the recurrent presence of Y537 and D538 mutations in the LBD of *ESR1* was shown in 9 out of 76 metastatic samples from patients with ER+

disease^[37]. One patient from this study acquired a tyrosine substitution to cysteine mutation (Y537C) at the metastatic site, which was not detected prior to treatment^[37]. Taken together, these studies indicate the most frequent *ESR1* LBD point mutations are those affecting Y537 and D538 residues. Furthermore, the presence of *ESR1* point mutations predominately appear in late-stage breast cancer patients that have been treated with multiple lines of endocrine therapies but rarely in treatment naïve cases. This strongly suggests a role for *ESR1* point mutations in acquired endocrine resistance and metastasis.

Although formalin-fixed paraffin-embedded tumor specimens are widely used for next generation sequencing to capture *ESR1* mutations used by studies as described above^[37,53,54], collection of plasma circulating DNA to detect *ESR1* mutations by droplet digital PCR (ddPCR) have now been implemented in several clinical trials^[56-59]. Such “liquid biopsies” have shown that collecting circulating DNA samples maintains the genomic landscape of the primary tumor suggesting that less invasive detection methods may efficiently identify *ESR1* point mutations once the disease has become resistant to treatment and/or has become metastatic. Interestingly, Y537 and D538 substitutions were identified in 7% of ER+ primary tumors using ddPCR, which may lead us to review the conclusion that *ESR1* point mutations rarely exist in primary tumor, towards the idea that rare *ESR1* mutant sub-clones exist in primary breast tumors that become selected for over time^[60].

Experimental models of *ESR1* point mutations

Several preclinical breast cancer models harboring *ESR1* LBD point mutations have been generated, providing research platforms to characterize the functional, transcriptional, and pharmacological properties of these mutations. ER point mutant proteins have been overexpressed by transfecting^[37,53,54] or transducing lentiviral vectors^[55,61] encoding *ESR1* mutant constructs into various ER+ breast cancer cell line models. The growth promoting properties of *ESR1* mutant expressing cell line models have shown that *ESR1* LBD mutants drive hormone-independent proliferation that is resistant to tamoxifen treatment^[23,37,47,53,54]. Although fulvestrant efficiently inhibited the growth of point mutation bearing cells in a dose-dependent manner, growth was not reversed to levels of wild-type *ESR1* expressing cells^[37,47].

Since the expression of exogenous *ESR1* variant transcripts encoded by expression vectors is often initiated from non-endogenous human promoters that drive very high expression of constructs, it is unlikely to mimic the expression levels in human breast tumors harboring *ESR1* point mutations. To more accurately recapitulate tumor-related *ESR1* mutational events, CRISPR/Cas9 approaches have been utilized to knock in *ESR1* mutated sequences into ER+ breast cancer cells^[62,63]. Both heterozygous and homozygous knock-in models have been shown to mediate resistance to endocrine therapies^[62,63].

Transcriptional properties of *ESR1* mutations in the LBD include their ability to drive constitutive hormone-independent transcriptional activation and enhance cell proliferation^[23,37,47,53-55]. Human embryonic kidney 293T cells transfected with Y537C, Y537N, and D538G mutant constructs strongly activate an ERE-luciferase reporter in a ligand-independent manner compared to wild-type ER. Luciferase activity was unaffected by clinically relevant doses of tamoxifen and fulvestrant, however, high doses of these agents blocked *ESR1* mutant driven ERE-luciferase reporter activity^[37,53-55]. These *ESR1* point mutations have also been shown to drive estrogen-independent activation of ER target genes in ER+ breast cancer cells^[37,53,54]. The recruitment of ESR1-Y537S mutant to ER target genes and their expression driven by the mutant were further validated by ChIP-seq and RNA-seq^[62].

ESR1 mutant-driven estrogen-independent tumor growth was also validated in both ER+ cell xenografts and patient-derived xenograft (PDX) models^[47,53]. A PDX harboring ESR1-Y537S, WHIM20, has been generated from a patient with endocrine-refractory metastatic ER+ breast cancer that retains genomic features of the human counterpart^[47]. This WHIM20 PDX model demonstrated estrogen-independent tumor growth^[47].

Despite such in-depth studies of transcriptional and growth-promoting properties endowed by *ESR1* LBD point mutations, the role of such mutations in driving cell invasion and tumor metastasis is underexplored. A scratch wound assay was performed on Y537S and D538G mutant expressing MCF7 cells to examine cell motility which showed enhanced cell migration under hormone-deprived conditions driven by these *ESR1* mutants^[54,61]. A recent study sheds light on ER mutant-driven metastatic biology, showing a remarkable enrichment of metastasis-associated gene sets in *ESR1* mutant cells^[64]. Consequently, Y537S and D538G mutant expressing MCF7 cells developed metastases after survival surgery to remove primary tumors in xenograft models. The Y537S mutant greatly potentiated both tumor growth and metastasis compared to D538G mutant^[64].

Mechanisms and therapeutic vulnerabilities of breast cancers harboring *ESR1* point mutations

Structural analysis has revealed that the formation of hydrogen bonds between S537 or G538 and D351 located within helix 12 of *ESR1* LBD confers an agonist conformation to *ESR1* mutant proteins^[53]. In wild-type ER, the binding of ligand alters the position of helix 12 into an open pocket, favoring recruitment of transcriptional coactivators such as p160 family members that include SRC-3, and histone acetylases CBP and p300. In contrast, tamoxifen results in disposition of helix 12 that hinders coactivators binding and results in recruitment of corepressors such as N-CoR/SMRT^[65]. The substitution of D538 to glycine mimics the active conformation of wild-type ER bound by estrogen^[54].

To better understand the consequences of coactivator recruitment to mutant ER proteins, a proteomic profiling approach was used and revealed enhanced recruitment of transcriptional coactivators, histone H3 lysine 4 (H3K4) methyltransferase KMT2D/2C complex, as well as steroid receptor coactivators (SRCs), to ERE-bound *ESR1*-Y537S and *ESR1*-D538G mutants compared to ERE-bound wild-type ER^[66]. Genetic inhibition of SRC-3 in HeLa cells expressing *ESR1*-Y537S and *ESR1*-D538G significantly suppressed activity of an ERE-luciferase reporter. Pharmacological inhibition using a pan-SRC inhibitor, SI-1, also suppressed transcriptional activation in *ESR1* mutant expressing HeLa cell lines and blocked cell proliferation in ER+ breast cancer cells stably expressing *ESR1*-Y537S and *ESR1*-D538G. Using a PDX naturally harboring the *ESR1*-Y537S mutation (WHIM20), treatment with an improved pan-SRC inhibitor, SI-2, suppressed growth *in vivo*. Suppression of WHIM20 tumor growth was even greater when SI-2 was administered in combination with an oral SERD, AZD9496, compared to either single agent alone, suggesting that targeting coactivator recruitment in combination with endocrine therapy could be a promising therapeutic strategy for breast tumors harboring *ESR1* LBD mutants such as Y537S and D538G^[66]. Another study identified that the transcription factor TFIIH was also recruited by the *ESR1*-Y537S mutant^[62]. Phosphorylation of Ser118 was found to be mediated by TFIIH kinase, cyclin-dependent kinase (CDK) 7 and subsequent *ESR1*-Y537S driven cell proliferation was suppressed by a CDK7 inhibitor, THZ1^[62]. These results suggest that CDK7 may represent another target that is associated with *ESR1* mutant proteins for therapeutic intervention.

Targeting non-genomic signaling pathways activated by *ESR1* mutants has also been investigated. As discussed above, interactions between ER with RTKs such as EGFR, HER2, and IGF1-R can activate downstream kinases. This results in phosphorylation of multiple transcriptional factors, including ER, and coregulators leading to changes in gene expression in a hormone-independent manner^[67]. A recent study demonstrated that IGF1 signaling was the most activated pathway in *ESR1* mutant MCF7 cells^[61]. IGF1 stimulation lead to increased phosphorylation of both IGF1-R β and insulin receptor substrate-1 (pIRS-1). Treatment with an IGF1-R β inhibitor (GSK183705A) monotherapy was able to block Y537S-driven cell motility and combinatorial treatment with tamoxifen abrogated transcriptional activity and cell growth driven by Y537S, Y537N, and D538G mutants^[61]. These results suggest that targeting non-genomic signaling pathways activated by *ESR1* mutants may be an additional therapeutic strategy to block *ESR1* mutant driven breast tumors.

Fulvestrant is used to treat metastatic ER+ breast cancer patients who have developed resistance to AI and tamoxifen. In preclinical models, transcriptional activity and cell proliferation of *ESR1* LBD mutant cells

are partially sensitive to fulvestrant, requiring higher doses of fulvestrant compared to controls^[37,47,63]. Moreover, fulvestrant did not completely block transcriptional activity nor cell proliferation compared to control cells expressing wild-type *ESR1*. Of note, *ESR1* mutants showed differential responses to fulvestrant. Y537S required the highest dose to completely block transcriptional activity and cell proliferation compared to other mutants, D538G, E380Q and S463P^[63]. Using an MCF7 xenograft model, *ESR1* mutants also showed differential responses to fulvestrant. Tumor growth of E380Q, S463P and D538G expressing tumors were significantly reduced while Y537S tumors showed resistance to treatment^[63]. Given the inconvenience and poor bioavailability of intramuscular fulvestrant injections, second-generation SERDs, such as AZD9496, that can be orally administered have been tested and showed anti-proliferative ability in endocrine resistant experimental models cell xenograft models^[63,68]. AZD9496 which has improved bioavailability compared to fulvestrant, was able to provide greater suppression of tumor growth in the Y537S MCF7 xenograft model and in a D538G PDX model compared to fulvestrant treatment^[63]. A phase I clinical trial with AZD9496 in extensively pretreated advanced ER+ breast cancer patients has recently been completed with promising results, providing disease stabilization to the study cohort^[69]. These results suggest that newer generation SERDs with improved bioavailability could be an attractive therapeutic option to treat endocrine-refractory breast tumors driven by *ESR1* mutations.

Treatment of late-stage ER+ breast cancer patients with CDK4/6 inhibitors in combination with endocrine therapy has been tremendously successful. CDK4/6 inhibitors have also been tested in PDX breast cancer models harboring *ESR1* point mutations. Wardell *et al.*^[70] reported the suppressive effects of a CDK4/6 inhibitor, palbociclib, on endocrine-refractory PDX tumors as long as the downstream target retinoblastoma (Rb) protein was expressed. Used as monotherapy or in combination with a hybrid SERM/SERD, bazedoxifene, palbociclib suppressed tumor growth of a WHIM20 PDX tumor harboring an *ESR1*-Y537S mutant. In contrast, palbociclib was ineffective in inhibiting the growth of WHIM43, a PDX naturally bearing *ESR1*-D538G mutant due to the lack of Rb protein expression, suggesting that Rb is a determinant of CDK4/6 treatment response. CDK4/6 inhibitors also showed favorable therapeutic effects in treatment-resistant ER+ patients harboring *ESR1* point mutations^[59].

Currently, screening of *ESR1* point mutations have not been used as biomarkers to predict response to therapy in the clinic. Wild-type ER, human epidermal growth factor receptor 2 (HER2), and progesterone receptor (PR), are histopathological markers that guide therapeutic selection. In clinical management of metastatic ER+ breast cancer, SERDs, such as fulvestrant is used for patients with resistance to AIs and tamoxifen without regard for *ESR1* mutation status. An analysis of BOLERO-2, a phase III clinical trial that enrolled ER+ breast cancer patients with locally advanced or metastatic disease whom progressed on AI, evaluated the prevalence of the two most frequent *ESR1* point mutations, Y537S and D538G and their effects on patient outcomes in ER+ metastatic patients^[56]. Having either one or two of these mutations was associated with decreased overall survival. In the PALOMA-3 clinical trial which enrolled ER+ breast cancer patients with advanced, endocrine refractory disease, palbociclib combined with fulvestrant led to longer PFS than fulvestrant alone^[59,71]. 69% of patients from the PALOMA-3 were analyzed for *ESR1* mutation status, which showed that 25% of these cases harbored *ESR1* mutations consisting mainly of Y537S, Y537N, D538G, and E380Q mutations^[59]. However, palbociclib was found to provide equal benefit regardless of *ESR1* mutation status. Although these studies indicate that the presence of *ESR1* mutations may predict poor outcomes, they also highlight the need for more analyses of studies investigating the predictive value of *ESR1* mutation status and response to therapy once the disease has become endocrine therapy resistant.

The development of sequencing technologies and the various models to recapitulate *ESR1* mutant bearing tumors allow insightful studies into the landscape and targeted therapies of activating point mutations in the *ESR1* LBD. Further studies are needed to address the use of *ESR1* mutations as predictive biomarkers to stratify patient subsets and predict *ESR1* mutation specific therapeutic vulnerabilities.

***ESR1* structural rearrangements and *ESR1* fusions**

In contrast to well-studied *ESR1* point mutations, structural rearrangements involving *ESR1* are understudied. A variety of *ESR1* gene fusion transcripts have been identified in luminal breast tumors^[72,73]. Analysis of RNA-seq data from 990 primary TCGA breast samples revealed that 21 of these tumors (2.1%), all of the luminal B subtype, contained recurrent fusion transcripts involving the first two non-coding exons of *ESR1* fused to various C-termini sequences from the coiled-coil domain containing 170 gene, *CCDC170* (*ESR1-e2>CCDC170*)^[73]. These fusion transcripts do not provide sufficient coding sequences to generate chimeric ER fusion proteins but instead generate truncated forms of *CCDC170* proteins (Δ *CCDC170*). Exogenous expression of Δ *CCDC170* in ER+ breast cancer cells led to enhanced growth and reduced sensitivity to tamoxifen^[73] suggesting a role for *ESR1-e2>CCDC170* in endocrine therapy resistance. Another independent study that examined early stage and non-metastatic ER+ breast samples also identified two *ESR1-e2>CCDC170* fusion transcripts as well as *ESR1-e2>C6orf211* and another fusion containing the first 6 exons of *ESR1* fused to *AKAP12* (*ESR1-e6>AKAP12*)^[72]. These *ESR1* fusions were identified in 4 out of 62 surgical samples (6.5%) that were resistant to letrozole aromatase inhibitor treatment 10-21 days post treatment as defined by Ki67 labeling^[74], suggesting a higher frequency for these *ESR1* fusions gene events in endocrine-refractory tumors compared to primary, untreated samples. However, detailed functional characterization and evidence demonstrating a causal role for *ESR1* fusions in endocrine therapy resistance has been lacking and the incidence of *ESR1* fusions from late-stage ER+ breast cancer still remains unclear. Furthermore, therapeutic strategies to treat *ESR1* translocated tumors remains poorly understood.

Using a PDX model to better understand endocrine therapy resistance, we previously reported a somatic gain-of-function event in the form of a chromosomal translocation identified in a patient presenting with aggressive endocrine therapy resistant, metastatic ER+ disease. This translocation produced an in-frame fusion gene consisting of exons 1-6 of *ESR1* (*ESR1-e6*) and the C-terminus of the Hippo pathway coactivator gene, *YAP1* (*ESR1-e6>YAP1*), thereby generating a stable *ESR1* fusion protein that was a highly active constitutive transcription factor^[47] [Figure 1D]. Our group more recently discovered another in-frame *ESR1* fusion gene involving the protocadherin 11 X-linked gene, *PCDH11X* (*ESR1-e6>PCDH11X*) provided by inter-chromosomal translocation that also produced stable *ESR1* fusion protein identified in a patient with endocrine-refractory, metastatic ER+ breast cancer^[75]. In both *ESR1-e6>YAP1* and *ESR1-e6>PCDH11X* fusions, the LBD of *ESR1* is replaced with in-frame sequences from another gene, and therefore the drug binding domain that endocrine therapies recognize is absent. These two fusions promoted endocrine therapy resistant cell proliferation and constitutively activated ER target genes. Interestingly, both fusions also upregulated an epithelial-to-mesenchymal transition (EMT)-like transcriptional signature, induced cell motility, and increased lung metastatic frequency^[75]. These results suggest that *ESR1* fusions are able to drive not only endocrine therapy resistance, but also drive metastasis, linking these two lethal processes together.

Importantly, *ESR1* fusion-driven growth could be suppressed by CDK4/6 inhibition. This suggests that targeting downstream kinases of ER could be a potential therapeutic strategy to treat *ESR1* translocated tumors and further suggests that *ESR1* fusion status may be a potential biomarker to stratify patients to CDK4/6 inhibitor therapy. To further explore therapeutic strategies to target *ESR1* fusions, a collaborative study was performed to examine interacting proteins with *ESR1* fusion transcriptional complexes^[66]. Results from that study showed enhanced recruitment of 26S proteasomal subunits to *ESR1-e6>YAP1* driving transcriptional activation and cell proliferation. Subsequent pharmacological inhibition with a broad-spectrum proteasome inhibitor, MG132, blocked *ESR1-e6>YAP1*-mediated activation of an ERE-luciferase reporter. Furthermore, bortezomib, a specific 26S proteasome inhibitor in phase II clinical trial used to treat endocrine-refractory, metastatic ER+ breast cancer in combination with fulvestrant^[76] suppressed growth driven by *ESR1-e6>YAP1*. Taken together, these results suggest that downstream ER kinases such as CDK4/6 as well as transcriptional coregulators such as the 26S proteasome are attractive therapeutic targets to treat *ESR1* fusion positive, metastatic breast tumors.

Additional in-frame *ESR1* translocations with diverse partner genes have now been identified in late-stage, endocrine-refractory, ER+ metastatic cases. These include *ESR1-e6>DAB2*, *ESR1-e6>GYG1*, and *ESR1-e6>SOX9*^[77]. Like the *ESR1-e6>YAP1* and *ESR1-e6>PCDH11X* fusions, the *ESR1-e6>DAB2* and *ESR1-e6>GYG1* fusions produce stable *ESR1* fusion proteins and all three were able to drive hormone-independent activation of a ERE-luciferase reporter^[77]. Remarkably, these *ESR1* fusions all follow a pattern preserving the first six exons of *ESR1*, containing the N-terminal DNA binding domain fused in-frame to C-terminal partner genes, thus excluding the LBD in *ESR1* [Figure 1D]. Therefore, these additional *ESR1* fusion proteins likely drive pan-endocrine therapy resistance like our previously discovered *ESR1-e6>YAP1* and *ESR1-e6>PCDH11X* fusions^[75]. The functional and therapeutic significance of these additional *ESR1* fusions are the focus of ongoing investigation by our group and others.

In contrast to transcriptionally active *ESR1* fusions, we also identified an in-frame *ESR1-e6* fusion, *ESR1-e6>NOP2* in a treatment naïve primary breast tumor that was transcriptionally inactive despite producing stable *ESR1* fusion protein^[75]. *ESR1-e6>NOP2* did not promote endocrine therapy resistant growth and was found to bind relatively few sites in a genome-wide DNA binding assay, potentially explaining the weak functional activity measured by our experimental systems. In addition, out-of-frame *ESR1* fusions identified in primary tumors preserving diverse exons of *ESR1* gene, *ESR1-e3*, *ESR1-e4*, *ESR1-e5*, and *ESR1-e6* did not facilitate estrogen-independent proliferation^[75]. More studies are required to fully understand the contribution of transcriptionally inactive in-frame and out-of-frame *ESR1* fusions in breast cancer.

ESR1 fusion structural studies revealed that driver *ESR1* fusions from metastatic patients follow the same fusion pattern containing the first 6 exons of *ESR1* (*ESR1-e6*) fused to C-termini of diverse gene partners suggesting this pattern is strongly connected to endocrine therapy resistant, metastatic ER+ breast tumors. The observation of a highly consistent and recurrent *ESR1* breakpoint, together with the promiscuity of *ESR1* for a variety of fusion partners is certainly interesting. In prostate cancer, recurrent fusions involving promoter regions of an androgen regulated gene, transmembrane protease serine 2 gene (*TMPRSS2*) fused to coding sequences of erythrovirus E26 gene (*ETS*) family members have been identified in more than 50% of prostate cancer cases^[78]. Androgen receptor (AR) signaling has been shown to bring the androgen regulated gene *TMPRSS2* and the *ERG* gene in close proximity in prostate cancer cell line models^[79]. Androgen signaling also generates DNA damage in the form of double strand breaks (DSBs) at sites of *TMPRSS2-ERG* genomic breakpoints. These DSBs have been shown to be mediated by the class II topoisomerase beta, TOP2B, which is recruited to AR, inducing DSBs^[80]. *TMPRSS2-ERG* gene fusions can then arise from dysfunction of mechanisms to repair DSBs, such as homologous recombination (HR) pathway and the error-prone non-homologous end-joining (NHEJ) pathway. AR-mediated DSBs in prostate cancer may provide clues to the recurrent *ESR1* breakpoints for *ESR1* fusions seen in breast cancer. Recruitment of TOP2B to ER and subsequent DSBs have been shown to occur at regulatory regions of ER target genes as a consequence of ER-mediated transcriptional activation^[81]. Since regulatory regions of *ESR1* itself has also been shown to be bound by ER^[82], transcription-induced DSBs by ER, coupled with dysregulation of DSB repair mechanisms may contribute to the highly recurrent *ESR1* breakpoints. Although none of the fusion partners from endocrine-refractory, metastatic disease observed in our studies are known ER targets, additional studies are needed to better understand the diversity of preferred *ESR1* partner genes.

ESR1 fusions that contain the first six exons of *ESR1* fused in-frame to partner genes are almost exclusively observed in endocrine therapy resistant, metastatic ER+ breast cancer, with the exception of *ESR1-e6>NOP2*, as described above, likely suggesting a role in driving disease pathogenesis. However, very few functionally significant *ESR1* fusions have been studied to date and therefore *ESR1* fusion events remains an understudied form of somatic mutation in breast cancer. The incidence of *ESR1* fusions is also still not well understood, especially in the metastatic setting, but the studies discussed here collectively suggest *ESR1* fusions to be present in at least 1% of metastatic breast cancer cases^[77], with the actual frequency likely to

be higher as more studies on *ESR1* fusions emerge. Additional studies on *ESR1* fusions will further support the causal role *ESR1* fusions and have significant diagnostic and clinical implications since pathogenic *ESR1* fusions could be used as biomarkers to stratify patients for individualized healthcare in ER+ breast cancer. Therapeutic vulnerabilities from *ESR1* translocated tumors could be an alternative to chemotherapy in patients with rapidly progressing, endocrine therapy resistant disease.

CONCLUSION

Endocrine therapy resistance and metastasis in ER+ breast cancer patients remain significant clinical problems. This review has focused on studies describing a spectrum of *ESR1* alterations including amplification, point-mutations, and structural rearrangements in endocrine-refractory, metastatic ER+ breast cancer cases. Results from these studies have provided insights into the underlying mechanisms that contribute to endocrine therapy resistance and metastasis.

Amplification of the *ESR1* locus results in overexpression of oncogenic ER protein in the breast and potentially reducing sensitivity of *ESR1* amplified breast tumors to endocrine therapies and therefore likely leads to disease progression and metastasis. Point mutations in the LBD of *ESR1*, the most common of which are Y537S and D538G, confer an agonist confirmation to such *ESR1* mutant proteins resulting in constitutively active mutant ER transcription factors that lead to activation of ER target genes in a hormone-independent manner while also promoting activation of metastasis-associated genes^[64]. The finding that ER LBD mutant proteins are constitutively active in an estrogen-independent manner suggest that therapeutic strategies which work by blocking estrogen production, such as ovarian ablation and treatment with AIs, are likely to be ineffective in breast tumors harboring *ESR1* point mutations. Indeed, a significant proportion of *ESR1* LBD point mutations were identified in metastatic tumors that were extensively treated with AIs, suggesting that such mutations may be enriched in breast tumors upon AI treatment^[53]. *ESR1*-Y537S and *ESR1*-D538G are partially sensitive to fulvestrant^[37,47,63], and newer oral SERDs that have better bioavailability compared to fulvestrant, such as AZD9496, have shown promising results in treating tumor growth driven by *ESR1* LBD point mutants in experimental models^[66]. Although fulvestrant is used exclusively in the metastatic setting for ER+ disease, treating primary breast tumors upfront with fulvestrant or more potent SERDs like AZD9496 may reduce the incidence of disease driven by *ESR1* LBD point mutations.

Despite the potential effectiveness of fulvestrant in targeting ER proteins with point mutations in the LBD, it is completely ineffective against ER fusion proteins generated from in-frame *ESR1* fusion transcripts arising from *ESR1* translocations^[75]. These *ESR1* fusions transcripts, *ESR1*-e6>YAP1 and *ESR1*-e6>PCDH11X, were identified in patients with metastatic ER+ breast tumors that were pan-endocrine therapy resistant^[75]. Both fusions retain the first 6 exons of *ESR1* fused in-frame to C-terminal sequences of the partner gene but lack exons encoding the LBD, rendering these fusions insensitive to all endocrine therapies that target the LBD, including fulvestrant and most likely AZD9496. These *ESR1* fusions were found to generate hyperactive *ESR1* fusion proteins that not only drive endocrine therapy resistant growth, but also play a role in the metastatic process, reprogramming the ER cistrome to drive EMT and metastasis to lung^[75]. Despite the lack of an *ESR1* LBD, blocking signaling downstream of *ESR1* fusions with a CDK4/6 inhibitor, palbociclib, suppressed *ESR1* fusion-driven growth at primary and metastatic sites in experimental models^[75]. Similar to *ESR1* point mutations, *ESR1* fusion formation is likely a mechanism of acquired endocrine therapy resistance. To date, *ESR1* fusion transcripts that produce stable *ESR1* fusion proteins have only been detected in metastatic breast tumors resistant to multiple lines of endocrine therapies. This suggests that *ESR1* fusions may be enriched in tumors from the selective pressure of endocrine treatment. Since the *ESR1*-e6>YAP1 and *ESR1*-e6>PCDH11X fusions were identified from a small cohort of late-stage ER+ patients, more RNA-seq data from primary and late-stage, treatment-refractory tumors are clearly required, particularly with longer sequencing reads, which increase fusion gene detection sensitivity to better understand the incidence of *ESR1* fusions in both primary and metastatic breast cancer.

The underlying mechanism of how *ESR1* fusions arise remains unclear. However, as mentioned earlier, DSBs mediated by recruitment of TOP2B to ER transcriptional complexes may contribute to formation of *ESR1* fusion genes, and therefore TOP2B could potentially be an attractive therapeutic target to prevent the formation of *ESR1* fusion events. More studies are required to test this hypothesis. Daunorubicin, an FDA-approved chemotherapeutic drug indicated for treating leukemia, targets TOP2B, however, this agent is very toxic. Developing less toxic agents that target TOP2B may represent a therapeutic strategy to prevent *ESR1* translocation events and deserves further study in the context of ER+ breast cancer.

Therapeutic targeting these aberrant forms of ER have shown promise in pre-clinical experimental models with more studies required to translate such findings to the clinic. Collectively, these studies deepen our understanding of how *ESR1* alterations trigger breast cancer to become lethal metastatic disease and will guide development of therapeutic strategies to treat a subset of patients with tumors that contains these *ESR1* alterations.

DECLARATIONS

Abstract

Breast cancer is the most significant cause of cancer-related death in women around the world. The vast majority of breast cancer-associated mortality stems from metastasis, which remains an incurable disease state. Metastasis results from evolution of clones that possess the insidious properties required for dissemination and colonization of distant organs. These clonal populations are descended from breast cancer stem cells (CSCs), which are also responsible for their prolonged maintenance and continued evolution. Telomeres impose a lifespan on cells that can be extended when they are actively elongated, as occurs in CSCs. Thus, changes in telomere structure serve to promote the survival of CSCs and subsequent metastatic evolution. The selection of telomere maintenance mechanism (TMM) has important consequences not only for CSC survival and evolution, but also for their coordination of various signaling pathways that choreograph the metastatic cascade. Targeting the telomere maintenance machinery may therefore provide a boon to the treatment of metastatic breast cancer. Here we review the two major TMMs and the roles they play in the development of stem and metastatic breast cancer cells. We also highlight current and future approaches to targeting these mechanisms in clinical settings to alleviate metastatic breast cancers.

Keywords: Breast cancer, cancer evolution, cancer stem cells, metastasis, telomerase

INTRODUCTION

Breast cancer is the most common malignancy and most frequent cause of cancer-related death in women globally^[1]. The vast majority of breast cancer-related morbidity and mortality can be ascribed to metastasis, which occurs in ~30 percent of cases and underlies ~90 percent of breast cancer deaths^[2,3]. Metastasis is a multistage cascade that commences when cancer cells migrate from their primary tumor of origin and undergo hematogenous dissemination that terminates in the seeding and colonization of distant organs^[4]. This so-called “invasion-metastasis cascade” serves as an evolutionary bottleneck that requires disseminated tumor cells (DTCs) to: (1) activate migratory and invasive programs; (2) survive within the vasculature in an anchorage-independent manner; (3) interact with other circulating cells to facilitate survival and extravasation; and (4) coordinate tissue-specific signaling inputs to persist in unfamiliar microenvironments^[5-7]. Thus, metastasis can be viewed as a process of clonal selection whereby a heterogeneous primary tumor gives rise to subpopulations that are fit to traverse the invasion-metastasis cascade. Following tissue colonization, these disseminated subclones retain growth-permissive features of the original primary tumor and undergo further evolution and clonal expansion within metastatic microenvironments^[8,9].

Metastatic evolution occurs via a number of distinct yet spatiotemporally overlapping mechanisms, including linear and parallel progression of monophyletic or polyphyletic founder clones^[10]. Cancer stem cells (CSCs) are fundamental components of tumors that enable the maintenance of emergent clonal populations yielded by evolutionary forces^[11-13]. CSCs are operationally defined by their self-renewal and tumor-initiating capacities; that is, a single CSC can recapitulate a tumor in its entirety, including a stable CSC pool^[14]. Historically, stochastic clonal evolution was believed to be mutually exclusive with a tumor developmental hierarchy built upon a stem cell population^[15,16]. More recent evidence suggests that there is a relationship between tumor evolution and CSCs that manifests through at least two mechanisms. First, the CSC population itself becomes highly heterogeneous during tumor development, indicating that CSCs are directly subjected to selective pressures^[17,18]. Second, non-stem cancer cells that define unique genetic and epigenetic lineages can be reprogrammed into CSCs^[19,20]. Thus, the plasticity that exists within and between stem and non-stem cancer cells provides a bidirectional route to engender clones that harbor distinctive properties, including the ability to metastasize. Of note, the functional significance of CSC evolution in the development and progression of multiple malignancies has been extensively documented^[21-23].

Numerous pathways that exert control over the metastatic propensity of cancer cells do so by regulating the production or function of CSCs. For instance, Wnt/ β -catenin signaling in both the primary tumor and metastatic microenvironments enhances breast CSC self-renewal and metastatic colonization^[24,25]. Likewise, inhibiting Wnt signaling abrogates metastatic outgrowth by depleting the CSC population^[26,27]. Similarly, vascular endothelial growth factor (VEGF) activates stem programs in breast cancer cells via VEGF receptor (VEGFR)-and neuropilin (NRP)-dependent cascades^[28,29]. VEGF can additionally push breast CSCs to undergo endothelial-like differentiation, thereby promoting tumor vascularization and cancer cell dissemination^[30]. The NF- κ B transcription factor pathway also acts as a critical regulator of breast CSC function^[31]. In particular, microenvironmental stimuli from resident stromal cells, extracellular matrix components, and the local immune milieu activate NF- κ B signaling to sustain CSC development^[25,32,33]. As a result, NF- κ B inhibitors demonstrate potent activity against breast CSCs^[34]. Related to these events, CSC expansion is associated with the epithelial-mesenchymal transition (EMT), a process whereby epithelial cells lose their intrinsic polarity and markers of differentiation and adopt features of mesenchymal cells, including enhanced migration and invasiveness^[35,36]. Key transcription factors that orchestrate EMT in breast cancer, such as Snail, Slug, and Twist1, simultaneously play a role in the acquisition of stem-like traits^[37]. Importantly, both Wnt/ β -catenin and NF- κ B signaling exert direct transcriptional control over these EMT-associated factors^[36,38]. Furthermore, EMT induces upregulation of VEGF, which bolsters the activities of β -catenin and NF- κ B and promotes angiogenesis to support CSC self-renewal and permit dissemination^[39-41]. In short, breast CSC survival and maturation are determined by a confluence of cell-intrinsic and microenvironment-derived signals that are transduced through parallel EMT-dependent and -independent circuits.

CSCs, like embryonic and tissue stem cells, possess replicative immortality^[42], a process achieved in part by activating telomere maintenance mechanisms (TMMs)^[43,44]. As outlined below, TMMs function within a network that unites cellular immortalization with processes, including EMT, that drive the development and outgrowth of metastatic cells. Telomeres, therefore, serve as essential mediators of CSC maintenance and consequent metastatic evolution. In addition, the results detailed below implicate telomere homeostasis as an attractive target for novel therapeutics to treat metastatic breast cancer.

TELOMERES AND TELOMERE DYNAMICS IN CSCS AND METASTATIC CELLS

Telomeres are nucleoprotein complexes located at the ends of linear chromosomes that safeguard against chromosomal instability and the loss of genetic information during cell division^[45]. In humans, the DNA component of telomeres is composed of tandem (TTAGGG)_n repeats with a 3' single-stranded overhang that invades telomeric duplex DNA to form a protective loop^[46]. These DNA regions are coated with proteins that collectively constitute the shelterin complex. Shelterin proteins serve to shield telomeres from illicit activation of DNA damage responses (DDR); they also maintain genome integrity and recruit factors responsible for regulating telomere length^[47,48]. In somatic (i.e., non-immortalized) cells, telomeres shorten during iterative rounds of cell division. To combat this event, stem cells and cancer cells maintain their telomeres using one of two TMMs: telomerase or alternative lengthening of telomeres (ALT). Telomerase is a reverse transcriptase enzyme composed of an RNA moiety (TERC, also known as TR) that provides a template for telomeric DNA synthesis and a protein moiety (TERT) that facilitates telomerase recruitment and carries out its polymerase activity^[49]. In contrast, ALT relies upon homology-directed, recombination-dependent synthesis of nascent telomeric DNA^[50]. ALT requires transient deprotection of telomeres coupled to activation of a DDR that is accompanied by telomere extension in a manner similar to break-induced DNA synthesis^[51,52]. DDR activation occurs in response to alterations in telomeric and subtelomeric chromatin structure that are brought about by loss of the chromatin remodelers ATRX and DAXX^[53,54]. Notably, evidence of each of these mechanisms has been found in breast cancer and can be correlated with specific histologic subtypes or disease stages^[55,56]. These findings support the idea that TMM identity may impact breast cancer progression, including the onset of metastasis.

While TMM acquisition has been identified as a feature of both stem and non-stem cancer cells, these processes play an essential role in preferentially sustaining the CSC population^[42]. By virtue of their replicative immortality, CSCs function as progenitors that exist over a sufficient timescale for evolution to take place. Remarkably, telomere shortening appears to be a primary driving force underlying tumor evolution. Telomere shortening precedes TMM activation^[57], which allows for the formation of critically short telomeres that cannot be adequately capped by shelterin. Cells interpret these short telomeres as free DNA ends, which are temporarily repaired by chromosome end-to-end fusions that ultimately induce breakage-fusion-bridge (BFB) cycles^[58,59]. BFB cycling leads to complex genomic rearrangements including deletions, non-reciprocal translocations, and formation of dicentric or circular chromosomes^[60]. Telomere catastrophe may also yield chromosomal instability that is resolved via chromothripsis or other forms of chromoanagenesis, an event termed telomere crisis^[61,62]. Breast cancer-initiating cells can harbor both short telomeres and telomerase activity^[41], consistent with the model that telomere shortening instigates genomic instability and CSC evolution while telomere elongation maintains emergent CSC subpopulations [Figure 1]. Evidence identifying ALT in breast CSCs has not yet been found. However, ALT has a stem cell origin^[63], while ALT activity has been observed in non-breast CSCs^[44,63,64]. Future studies examining TMMs in breast CSCs and their connection to genome architecture and tumor heterogeneity will be of great value.

Telomere maintenance proteins have been heavily implicated in many of the central signaling pathways in metastasis^[65] [Figure 1]. For instance, TERT is capable of regulating Wnt target genes by forming a transcriptional co-activation complex with β -catenin^[66]. In addition, TERT directly regulates NF- κ B-dependent gene expression by binding to the NF- κ B p65 subunit at the promoters of target genes^[67,68].

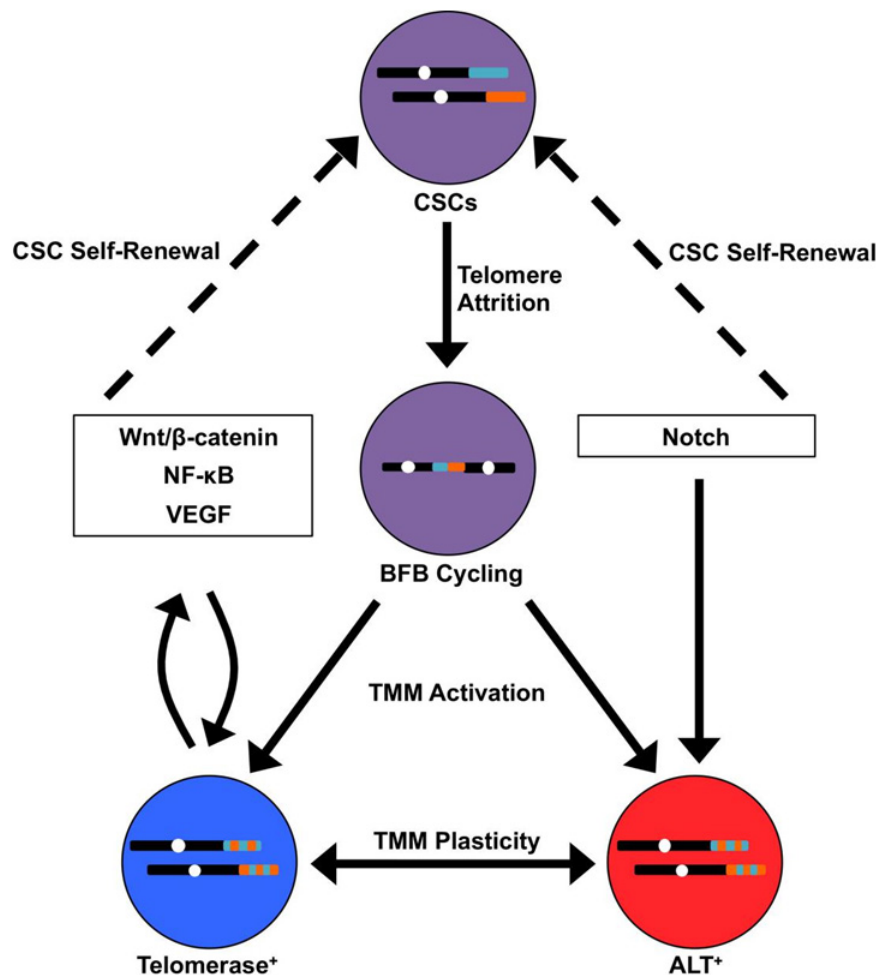

Figure 1. Telomere-centric model of breast cancer stem cell (CSC) biogenesis and metastatic evolution. CSCs (purple) harboring telomeres of a given length (shown for two different chromosomes in teal and orange) undergo telomere attrition as a by-product of self-renewal. This ultimately yields critically short telomeres that are temporarily repaired by chromosome end-to-end fusions, resulting in breakage-fusion-bridge (BFB) cycling (represented by dicentric chromosome). BFB cycling or chromoanagenesis (not shown) cause widespread chromosomal instability (represented by dual-colored telomeres) and the acquisition of new genetic features, including those that are advantageous for metastasis. At the same time, telomere maintenance mechanisms (TMMs) are activated in these new clonal populations, which are defined in part by their reliance on telomerase (blue) or ALT (red). In addition, TMMs exhibit a degree of plasticity, such that TMM identity may interconvert between telomerase and ALT. TMM selection is influenced by signaling pathways that simultaneously promote CSC propagation (dashed arrows). In turn, telomere maintenance proteins directly regulate these signaling pathways, establishing reciprocal feedback loops that coordinate TMM activation and CSC maintenance

Each of these pathways exerts reciprocal control over TERT^[69,70], thereby preserving TMM identity and CSC phenotype. Of note, TERT can also bind to the VEGF promoter to stimulate VEGF expression and neoangiogenesis^[71]. Other transcriptional regulators of TERT, such as c-Myc, further serve to induce EMT and stemness in breast cancer cells^[72-74]. Compared to telomerase, ALT is less well-characterized at a molecular level; therefore, our understanding of its role in EMT and breast cancer metastasis is presently incomplete. Nevertheless, ALT is most often associated with tumors of mesenchymal origin^[75], indicating a possible role for ALT in EMT. Accordingly, carcinoma cells exhibiting telomerase dysfunction were driven to adopt a mesenchymal stem-like phenotype, which was accompanied by activation of ALT and the formation of metastatic tumors^[76,77]. In breast cancer cells, TERT expression is mutually exclusive with the mesenchymal state^[78]. Similarly to TERT, the expression of ALT-associated proteins, such as the Bloom syndrome protein (BLM), is governed by signaling pathways, such as Notch, that are responsible for CSC fate specification and self-renewal^[79,80]. Given these findings, it is paramount that future studies explore the significance of the relationship between stemness and telomere plasticity in breast cancer progression.

TELOMERE-DIRECTED THERAPIES FOR METASTATIC BREAST CANCER: CURRENT AND FUTURE PERSPECTIVES

The functions of telomerase in tumorigenesis have been rigorously interrogated over the last several decades, as has the potential to target telomerase therapeutically^[65,81]. The telomerase inhibitors BIBR1532 and GRN163L (also known as Imetelstat) display high efficacy in depleting the CSC pool and disrupting breast cancer metastasis^[82-85]. Indeed, Imetelstat was assessed in a Phase I clinical trial for recurrent or metastatic breast cancer, although the trial was suspended due to dose-limiting toxicity^[81]. In addition to such toxicity concerns, the success of telomerase inhibitors in clinical trials has thus far been moderated by the inherent complexity of telomere homeostasis. First, telomere shortening-induced senescence can be bypassed in the absence of functional p53 or other components of the DDR machinery^[86]. Second, the critically short telomeres and chromosomal instability associated with telomere crisis are disproportionately associated with metastasis^[87,88]. Thus, the evolution of DTCs that underlie metastatic disease may be enhanced unwittingly by therapies that promote telomere shortening. Despite these challenges, telomerase remains an appealing therapeutic objective in need of innovative targeting approaches in which these evolutionary considerations are taken into account.

Emerging telomerase-targeting strategies include cytotoxic small molecules that act as substrates for telomerase as well as anti-telomerase immunotherapies^[89-92]. Current immunotherapeutic platforms are primarily centered on telomerase peptide or dendritic cell vaccines, which can be engineered to elicit either CD4+ or CD8+ T cell antitumor responses^[93]. These strategies are being assessed in diverse preclinical settings, including breast cancer. Indeed, the telomerase peptide vaccine Vx-001 is progressing through clinical trials for advanced solid tumors^[90]. More recent investigations have examined the feasibility of adoptive transfer of anti-telomerase chimeric antigen receptor (CAR) T cells for treating triple-negative breast cancer^[94]. Future studies into the generalizability of anti-telomerase CAR T cell therapy to other breast cancer subtypes, as well as the efficacy of these diverse immunotherapeutic approaches in clinical settings will be of tremendous value.

Although the functions of specific ALT-associated proteins have been elucidated, their utility as therapeutic targets for ALT-driven cancers has only recently been investigated. For example, the DNA damage-responsive kinase ataxia-telangiectasia and Rad3-related (ATR) is activated secondary to depletion of ATRX, which leads to persistent retention of replication protein A (RPA) at telomeres and generation of a recombinogenic substrate. Inhibition of ATR, in turn, triggers apoptosis of ALT-positive cells^[95]. BLM, a RecQ DNA helicase, unwinds telomeric G-quadruplex structures and coordinates 5'→3' end resection during telomere recombination^[96,97]. Accordingly, a recently-developed small molecule inhibitor of BLM may possess great potential as an anticancer agent against ALT-driven tumors^[98]. Finally, topoisomerase III α (Topo III α) associates with BLM and regulates the topology of telomeric recombination intermediates. Interestingly, genetic inactivation of Topo III α selectively reduces the survival of ALT-positive compared to telomerase-positive cells^[99]. Moreover, telomerase activity is enhanced in the surviving fraction of Topo III α -deficient cells^[100], suggesting that telomerase activation provides a pathway for chemoresistance. Thus, targeting TMMs may best be achieved using a multidrug regimen consisting of multiple anti-TMM agents or an anti-TMM agent in combination with chemotherapy or other targeted agents^[101]. The effectiveness of these therapeutic modalities in eliminating breast CSCs and in treating metastatic breast cancers remain intriguing and important open questions.

CONCLUSION

By overseeing multiple pathways that promote breast cancer stemness, EMT, and metastasis, telomeres function as critical nodes in the nexus between cellular immortalization, tumor evolution, and disease progression. The selection of TMM likely exhibits a high degree of plasticity in different tumor cell types

or across disparate stages of breast cancer development, including metastasis. Indeed, TMM selection may itself be subject to evolutionary dynamic forces. In addition, the plasticity inherent in TMM identity has far-reaching prognostic and therapeutic implications. Tumors driven by distinct TMMs may show sensitivity or resistance to specific treatments, which has substantial impact on patient survival. Moreover, different subpopulations within a single tumor (e.g., stem vs. non-stem cells) may be reliant upon unique TMMs. Such TMM heterogeneity may beget residual, resistant clones that underlie disease recurrence. In the future, gaining a deeper understanding of telomeres and the pathways controlled by the telomere machinery will provide immense insight into the origin, progression, and eradication of one of the world's deadliest cancers.

DECLARATIONS

Acknowledgments

Members of the Schiemann Laboratory are thanked for critical comments and reading of the manuscript.

Authors' contributions

Conception and study design: Robinson NJ, Schiemann WP

Drafted and revised the manuscript: Robinson NJ, Taylor DJ, Schiemann WP

Availability of data and materials

Not applicable.

Financial support and sponsorship

Research support was provided in part by the National Institutes of Health (CA236273) to Schiemann WP, (CA186571) to Taylor DJ; and (T32 GM007250 and F30 CA213892) to Robinson NJ. Additional support was graciously provided by the METAvivor Foundation (Schiemann WP), and by pilot funding from the Case Comprehensive Cancer Center's Research Innovation Fund, which is supported by the Case Council and Friends of the Case Comprehensive Cancer Center (Schiemann WP), and from the Case Clinical & Translational Science Collaborative (Schiemann WP). Finally, Taylor DJ is also supported by the American Cancer Society (RSG-13-211-01-DMC).

Abstract

Hyponatremia is the most frequent electrolyte disorder encountered in hospitalized patients. Several studies have demonstrated that hyponatremia is a negative prognostic factor in different clinical scenarios. Noteworthy, not only severe and acute hyponatremia has been associated with an increased risk of mortality, but also moderate or even mild chronic hyponatremia may increase the risk of death. This has been demonstrated in different categories of patients, including cancer patients. There is growing evidence that both progression free survival and overall survival are significantly reduced in cancer patients with hyponatremia compared to patients with normonatremia. One important, and still open, question is whether the worse outcome associated with hyponatremia in cancer patients is directly attributable to the electrolyte disorder itself or might be a sign of the severity of the underlying disease. With regard to this point, some basic research studies suggested that low sodium concentration stimulates per se cancer cells proliferation and invasiveness. Recent clinical evidence appears to indicate that the correction of hyponatremia is an independent and favourable prognostic factor in cancer patients. Admittedly, robust confirmatory data from clinical practice are needed, in order to validate the hypothesis that cancer patients may die for hyponatremia and not just with hyponatremia.

Keywords: Hyponatremia, cancer, mortality, prognosis, vasopressin

INTRODUCTION

Hyponatremia, which is the most frequent electrolyte disorder in hospitalized patients^[1], frequently occurs also in cancer patients at different stages of disease. For instance, a recent retrospective study, performed

© The Author(s) 2019. **Open Access** This article is licensed under a Creative Commons Attribution 4.0 International License (<https://creativecommons.org/licenses/by/4.0/>), which permits unrestricted use, sharing, adaptation, distribution and reproduction in any medium or format, for any purpose, even commercially, as long as you give appropriate credit to the original author(s) and the source, provide a link to the Creative Commons license, and indicate if changes were made.

at a large University Hospital in Germany in inpatients receiving specialist palliative care, showed that the prevalence of hyponatremia was 38.7% (e.g., 275 out of 710 patients) and that low serum sodium concentration $[\text{Na}^+]$ was associated with symptom severity^[2]. Several studies have demonstrated that hyponatremia is a negative prognostic factor in different clinical scenarios. Noteworthy, not only severe and acute hyponatremia has been associated with an increased risk of mortality, but there is evidence that also moderate or even mild chronic hyponatremia may increase the risk of death. This has been shown for instance in a large cohort study, which included more than 50,000 inpatients at a teaching academic medical center. This study showed that mildly reduced serum $[\text{Na}^+]$ was associated with an increased in-hospital mortality. In addition, each mmol/L reduction of serum $[\text{Na}^+]$ increased the risk of death by 2.3%^[3]. Among different clinical settings, hyponatremia has been associated with an increased risk of death in patients with heart failure^[4-6], acute myocardial infarction^[7,8], pneumonia^[9], cirrhosis^[10,11], renal failure^[12], pulmonary embolism^[13], intracerebral hemorrhage^[14], in the elderly^[15], in intensive care patients^[16], in patients undergoing surgery^[17] or cardiovascular procedures^[18]. An extensive meta-analysis, including more than 850,000 patients, of whom 17.4% with hyponatremia, confirmed an increased mortality rate associated with reduced serum $[\text{Na}^+]$ ^[19].

The literature addressing cancer patients indicated that hyponatremia is a negative prognostic factor also in this subset of patients. This chapter will review the published data, so far, with the exception of patients with lung cancer, which is the specific topic of another chapter.

HYPONATREMIA AS A PROGNOSTIC AND PREDICTIVE FACTOR IN CANCER PATIENTS

Ten years ago Waikar *et al.*^[7] published the results of a prospective cohort study, conducted in two teaching hospitals in Boston, MS, in which the association between serum $[\text{Na}^+]$ and mortality was investigated. The main outcome measures were in-hospital 1-year and 5-year mortality of patients with hyponatremia vs those with normal serum $[\text{Na}^+]$. Patients with hyponatremia had higher in-hospital mortality rates either at 1 year and at 5 years, even when serum $[\text{Na}^+]$ was only slightly reduced (130-134 mmol/L). Among the different clinical subgroups that were analyzed, the risk of in-hospital mortality was significantly higher in hyponatremic patients with metastatic cancer [hazard ratio (HR) 2.05, 95% confidence interval (CI): 1.67-2.53] compared to normonatremic patients.

Shortly after, another study addressed predictors of inpatients mortality in an acute palliative care unit at the M. D. Anderson Cancer Center of the University of Texas. Of the 500 cancer patients admitted, 124 (25%) died^[20]. Hyponatremia was one of the multiple predictors of a negative outcome (HR 3.02, 95%CI: 1.76-5.17, $P < 0.001$), together with younger age, hypernatremia, high blood urea nitrogen, high heart rate, high respiration rate, and supplemental oxygen use.

A retrospective analysis of patients admitted at the same Cancer Center during a three months period in 2006, aiming to correlate hyponatremia with 90-day mortality, was performed^[21]. Serum $[\text{Na}^+]$ was categorized into four groups, e.g., normonatremia (serum $[\text{Na}^+]$ 135-147 mmol/L), mild (130-134 mmol/L), moderate (120-129 mmol/L), and severe (< 120 mmol/L) hyponatremia. In all hyponatremic groups the risk of mortality at 90 days was higher than in normonatremic patients (HR for mild, moderate, and severe hyponatremia: 2.04 (95%CI: 1.42-2.91; $P < 0.01$); 4.74 (95%CI: 3.21-7.01; $P < 0.01$), and 3.46 (95%CI: 1.05-11.44; $P = 0.04$), respectively. Although the authors recognized limitations to the study (observational, retrospective study, inability to adjust for all comorbid conditions), and the fact that it has not been proven that hyponatremia correction can reduce mortality, these data further confirmed the clear relationship between hyponatremia and increased mortality in cancer patients.

An Italian study performed in Ancona analyzed 105 consecutive cancer patients, affected by gastrointestinal, lung, breast, female genital tract, renal, brain tumors, and sarcoma, hospitalized during a 6 month period^[22].

Median overall survival (OS) from the day of hospitalization was 50 days. Hyponatremic patients had a significantly reduced OS ($P = 0.0255$) compared to normonatremic patients. In addition, the authors reported that the presence of metastases was associated with a reduced OS ($P = 0.0418$). Similar results were obtained by Castillo *et al.*^[23], who analyzed a population of patients with lymphoma, breast cancer, colorectal cancer, small cell and non-small cell lung cancer. Hyponatremia was negatively associated with OS in all types of tumor, but the highest HRs were found in lymphoma (HR 4.5, $P < 0.01$) and in breast cancer (HR 3.7, $P < 0.1$).

In a retrospective cohort study, performed in a single center, 204 cancer patients affected by hyponatremia secondary to the syndrome of inappropriate anti-diuresis (SIAD), which is the most common cause of hyponatremia in oncology, were selected. Malignancies included lymphoma, leukemia, colorectal, breast, lung, pancreas, prostate, head and neck, bladder, esophagus, gastric cancer. About 75% of patients had malignancy-associated SIAD, whereas in roughly 25% SIAD was due to other etiologies (e.g., medications, pulmonary infections, pain or nausea). The authors found that patients with malignancy-associated SIAD had a significantly shorter median survival (58 days vs. 910 days, $P < 0.001$). The authors hypothesized that the cause of SIAD in cancer patients might represent a useful prognostic factor^[24].

A correlation between hyponatremia and a negative outcome was found also in patients with terminal cancer. A retrospective observational study conducted in a tertiary hospital palliative care unit in the Republic of Korea reported that, in addition to serum C-reactive protein (HR 1.22; $P < 0.001$) and Palliative Performance Scale (HR 0.69, $P < 0.001$), serum $[\text{Na}^+] \leq 125$ mmol/L was associated with a reduced survival time (HR = 1.91; $P < 0.001$) among 576 terminally ill patients (pancreatic/hepatobiliary, gastric, colorectal, lung cancer)^[25].

In a retrospective study performed at a University Hospital in China, among patients affected by nasopharyngeal carcinoma, glioma or oral cancer, that had been subjected to radiotherapy and developed radiation-induced brain necrosis, the risk of progression (i.e., increase of edema area $\geq 25\%$ on the MRI) was three-fold higher in patients with hyponatremia compared to those with normonatremia. Thus, the authors claimed that hyponatremia may be considered as a potential predictor for the progression of radiation-induced brain necrosis and recommended that hyponatremia is appropriately managed also in these patients^[26].

Other authors addressed their attention to a different subset of cancer patients, i.e., those who develop spontaneous tumor lysis syndrome, that induces acute uric acid nephropathy. This is a rare, yet potentially fatal complication in cancer patients, and it is important to determine the relevance of potential prognostic predictors. Although only 12 patients developed this condition among the 1,073 patients admitted with acute renal failure to a single hospital during a period of four years, hyponatremia and hypoalbuminemia on the first day of admission were the best predictors of poor prognosis^[27].

An interesting retrospective cohort study performed in a primary care setting in Copenhagen, Denmark, examined another issue, i.e., the predictive role of hyponatremia on the subsequent development of cancer. This type of analysis is facilitated in countries, like Denmark, which have a National Patient Registry. The authors showed that there is a level-dependent increased risk to develop cancer in patients with hyponatremia. The cumulative incidence increased in patients with mild (serum $[\text{Na}^+] 130\text{--}135$ mmol/L), moderate (125–129 mmol/L) or severe hyponatremia (< 125 mmol/L) [HR 1.32 (95%CI: 1.26–1.39), 1.31 (95%CI: 1.17–1.47), 1.77 (95%CI: 1.39–2.24), respectively] at 12 months, compared to normonatremic subjects. When different cancers types were analyzed separately, this finding was confirmed in head and neck, pulmonary and gastrointestinal cancer^[28].

Some studies on the role of hyponatremia in cancer have addressed specific cancer types. With regard to renal cell carcinoma (RCC), 212 newly diagnosed patients with localized RCC undergoing nephrectomy were

recruited in a study aiming to examine the prognostic value of hematologic and biochemical parameters, and other tumor-related factors. Multivariate analyses showed that preoperative serum $[\text{Na}^+]$ was an independent predictor of OS and disease-free survival, when considered either as a continuous variable or when patients were grouped based on a cut-off of serum $[\text{Na}^+]$ of 139 mmol/L (median value). The estimates of 5-year OS were 67.6% (95%CI: 54.2-80.9) and 44.3% (95%CI: 32.8-55.8) for patients with serum $[\text{Na}^+]$ above or below 139 mmol/L respectively^[29]. A Danish study addressed patients with metastatic RCC, divided into two independent cohorts of 120 patients/each. In each cohort 20% and 14% of patients had hyponatremia. Patients with hyponatremia at baseline had a median OS of 5.5 and 4.8 months in the two cohorts, whereas patients with normonatremia at baseline had a median OS of 18.6 and 16.9 months, respectively^[30]. In multivariate analysis, hyponatremia proved to be an independent prognostic factor (HR 1.90, 95%CI: 1.1-3.2, $P = 0.014$), together with increased neutrophils (HR 1.75, CI: 1.1-2.8, $P = 0.018$), lactate dehydrogenase > 1.5 ULN (HR 2.09, 95%CI: 1.3-3.3, $P = 0.002$), and number of metastatic sites ($+3$) (HR 1.92, 95%CI: 1.3-2.9, $P = 0.003$). Finally, hyponatremia was significantly associated with lack of response to treatment in both cohorts. A more recent Japanese study confirmed that hyponatremia appears to be a powerful prognostic predictor in patients with metastatic RCC treated with tyrosine-kinase inhibitors following radical nephrectomy^[31]. In this study both progression-free survival (PFS) and OS were significantly lower in hyponatremic patients (median 10.0 and 20.9 months, respectively) than in normonatremic patients (median 28.4 and 38.5 months, respectively).

Reduced serum $[\text{Na}^+]$ was indicated as a negative prognostic marker also in patients with gastric cancer and bone marrow metastases [HR 4.57; 95%CI: 1.99-10.52; $P < 0.001$]^[32] and in patients with hepatocellular carcinoma^[33].

WHY IS HYPONATREMIA ASSOCIATED WITH A WORSE OUTCOME IN CANCER PATIENTS?

Clinical data clearly indicate that hyponatremia may be viewed as a predictor of a negative outcome in cancer patients. Admittedly, one open question is whether the reduced PFS and OS, described by a number of publications, is directly attributable to the electrolyte disorder itself or might be a sign of the severity of the underlying disease. With regard to this point, a Belgian prospective study on hyponatremia in cancer patients, published almost 20 years ago, suggested that the increase mortality rate observed in cancer patients with hyponatremia (19.5% vs 6.3% in normonatremic patients) was not apparently due to reduced serum $[\text{Na}^+]$, thus indicating that hyponatremia was to be considered as a marker of general debility in advanced disease^[34]. A retrospective review (entitled “Mortality and serum sodium: do patients die from or with hyponatremia?”) of the medical records of patients admitted to a teaching hospital in Rochester, NY, for different pathologies and who died after developing hyponatremia, also suggested that the main determinant of the observed deaths was likely the severity of the underlying illness rather than the degree of hyponatremia^[35]. Similarly, a retrospective study that included patients diagnosed with SIAD in a community hospital in Israel showed that long-term survival was determined by SIAD etiology rather than by hyponatremia severity^[36].

Recently, a study performed at two teaching hospitals in Italy and one teaching hospital in England demonstrated that serum $[\text{Na}^+]$ normalization during first-line therapy is an independent prognostic factor for OS and PFS in patients with non-small cell lung cancer^[37]. Similarly, normalization of serum $[\text{Na}^+]$ was associated with a better prognosis in patients with metastatic RCC treated with everolimus^[38]. These findings are in agreement with the results of a meta-analysis that analyzed articles reporting the outcome of patients with different diseases in which hyponatremia had been corrected. The meta-analysis indicated that any improvement of hyponatremia was associated with a reduced risk of overall mortality [HR = 0.57 (0.40-0.81)]^[39].

Anyway, this issue is still a matter of debate and prospective randomized studies in cancer patients with hyponatremia, aiming to evaluate whether correction of hyponatremia can counteract the progression of the disease, are necessary.

Interestingly, some basic research studies have evaluated whether a microenvironment with a low $[Na^+]$ may affect cell proliferation and invasion ability. A study performed in prostate cancer cells *in vitro* demonstrated for instance that the exposure to a slightly hypertonic milieu induced a dormant state. Cell dormancy represents a limiting step of the metastatic process by preventing the proliferation of isolated cells outside the primary tumor. Conversely, the authors demonstrated that in the presence of a hypotonic milieu, obtained for instance by reducing $[Na^+]$ in the culture medium, cell cloning significantly increased^[40]. Another study showed that low $[Na^+]$ reduced neuroblastoma cell adhesion and increased invasion ability^[41]. A micro-array analysis was performed, in order to analyze the gene expression pattern of cells exposed to low $[Na^+]$ compared to normal $[Na^+]$. Among the genes that had different expression levels in the presence of reduced $[Na^+]$, the heme-oxygenase 1 gene (HMOX-1), a marker of oxidative stress, was the gene with the greatest variation. In fact, HMOX-1 gene expression showed a 200-fold increase in cells exposed to low $[Na^+]$. Immunocytochemistry for HMOX-1 protein confirmed these results. It is known that oxidative stress favors carcinogenesis, cancer growth and invasion, angiogenesis, and overall creates a permissive environment for cancer cells^[42]. Accordingly, selective inhibition of HMOX-1 has been proposed as a therapeutic target for cancer treatment^[43]. Although additional studies are needed in order to confirm these data, in view of the above described results from basic research it can be hypothesized that also *in vivo* low $[Na^+]$ might promote cancer cell progression through the same mechanisms. If so, then we might probably say that patients die not only with hyponatremia, but also for hyponatremia.

CONCLUSION

In recent years evidence indicating that hyponatremia is a predictor of a worse outcome in cancer patients has accumulated. There is emerging evidence, mainly from basic research studies at this time, that hyponatremia may by itself increase the risk of mortality of patients, rather than being a simple bystander of the progression of the disease. However, robust confirmatory data from clinical practice are certainly needed in order to definitively validate the hypothesis that cancer patients may die for hyponatremia.

Meanwhile, the author is truly convinced that it is worth to correct hyponatremia in patients, including cancer patients, because of the overall beneficial effect on the quality of life, which includes clinical improvement, such as amelioration of neurocognitive and motor performance, reduced length of stay in the hospital and re-admission probability^[44-46].

Abstract

Although greater than 90% of breast cancer-related mortality can be attributed to metastases, the molecular mechanisms underpinning the dissemination of primary breast tumor cells and their ability to establish malignant lesions in distant tissues remain incompletely understood. Genomic and transcriptomic analyses identified a class of transcripts called long noncoding RNA (lncRNA), which interact both directly and indirectly with key components of gene regulatory networks to alter cell proliferation, invasion, and metastasis. We identified a pro-metastatic lncRNA BMP/OP-Responsive Gene (BORG) whose aberrant expression promotes metastatic relapse by reactivating proliferative programs in dormant disseminated tumor cells (DTCs). BORG expression is broadly and strongly induced by environmental and chemotherapeutic stresses, a transcriptional response that facilitates the survival of DTCs. Transcriptomic reprogramming in response to BORG resulted in robust signaling via survival and viability pathways, as well as decreased activation of cell death pathways. As such, BORG expression acts as a (1) marker capable of predicting which breast cancer patients are predisposed to develop secondary metastatic lesions; and (2) unique therapeutic target to maximize chemosensitivity of DTCs. Here we review the molecular and cellular factors that contribute to the pathophysiological activities of BORG during its regulation of breast cancer metastasis, chemoresistance, and disease recurrence.

INTRODUCTION

With over 250,000 newly diagnosed cases in 2017, breast cancer is the most commonly diagnosed malignancy among U.S. women^[1]. Although recent advances in treatment have produced a moderate decline in the mortality rate associated with breast cancer^[2], this disease nevertheless still plagues women and is the second leading cause of cancer-related death, resulting in over 40,000 deaths each year^[1]. The clinical management of breast cancer is complicated by its manifestation as an exceptionally heterogeneous disease. In fact, the degree of molecular and histopathologic variation demonstrated by breast cancers necessitates its classification not as a single, uniform disease, but rather as one that is composed of a diverse collection of diseases that possess varying clinical prognoses and require distinct treatment strategies. Integral to this heterogeneity are the receptors for the ovarian steroid hormones estrogen (ER) and progesterone (PR), and for the membrane-associated tyrosine kinase HER2/ErbB-2. Moreover, the expression or lack thereof of these receptors dictates therapeutic schemes and disease-free progression^[3,4]. Likewise, the multiple various permutations in the expression patterns of these receptors exemplify the heterogeneity of the disease and necessitate the tailoring of specific treatments to each individual patient. In fact, clinicopathologic detection for the expression of these receptors remains an advantageous trait, as they represent some of the most consistently predictive and actionable molecular targets in all of oncology^[5]. As such, the largest clinical burden associated with breast cancer stems from a subset of patients whose tumors fail to express ER, PR, and HER2, lesions known as triple-negative breast cancer (TNBC). This genetically distinct breast cancer subtype constitutes ~15%-20% of all diagnosed breast cancers^[6] and portends the worst overall survival rates of all breast cancer subtypes, an untoward trait that reflects their extreme propensity to relapse within 5 years of initial diagnosis and treatment^[7]. The molecular features that underlie the development, metastasis, and relapse of TNBCs remain to be fully elucidated. Recently, a novel intergenic lncRNA known as BMP/OP-Responsive Gene (BORG) was identified as being a prominent driver of these tumorigenic activities in TNBCs. Here we highlight the pathophysiology associated with aberrant BORG expression in TNBCs, as well as discuss clinical implications of BORG and its potential for therapeutic targeting to alleviate metastatic disease.

Breast cancer metastasis

Despite immense efforts undertaken to characterize the molecular complexity of primary breast cancers, the lethality associated with all subtypes of breast cancer is attributed primarily to the dissemination and colonization of distant tissues^[8,9], an untoward clinical event that results in dismal median survival rates of ~1 year. Moreover, the finding of metastatic TNBC is essentially a fatal diagnosis regardless of the chemotherapeutic intervention deployed to combat this disease^[10]. Despite decades of intense investigation, a complete understanding of the molecular forces vital to metastasis remains incomplete, a knowledge gap that continues to hinder the development of therapeutics capable of specifically targeting and alleviating metastatic lesions. Nonetheless, fundamental steps taken by malignant cells to facilitate their dissemination from the primary tumor site to distant tissues for colonization have been identified and are called the metastatic cascade^[11]. The events that comprise this multi-step process include: (1) local invasion and migration of malignant cells into the stroma surrounding the primary lesion; (2) intravasation into the vasculature or lymphatic system to permit transit through these circulatory routes; (3) vascular stasis and subsequent extravasation into parenchymal tissues at distant sites of colonization; (4) survival and micrometastasis formation; and (5) overt growth and metastasis formation^[12]. Interestingly, the earliest phases of metastatic progression (i.e., dissociation and emigration from site of origin via the vasculature) represent the barriers that are most easily surmounted by primary lesions, as evidenced by the fact that tumors readily liberate thousands upon thousands of cells into the circulation each day^[13,14]. However,

despite the relative abundance of tumor cells traversing the vascular systems of some patients, the process of metastasis remains a supreme inefficient event. Indeed, animal modeling studies estimate that only ~0.01% of circulating tumor cells are capable of initiating some form of metastatic outgrowth^[15], and as such, it is the late stages of metastatic progression that ultimately dictate the competency of disseminated cells in establishing overt metastases within the metastatic niche^[12].

Dormancy: a metastatic bottleneck

The acquisition of metastatic phenotypes was originally believed to be an evolutionary consequence of advanced, late-stage disease. However, recent findings indicate that carcinoma cells comprising primary breast tumors do in fact enter the circulation months-to-years prior to the point at which the primary tumor becomes symptomatic and diagnosable^[16]. As such, a large proportion of breast cancer patients already harbor disseminated tumor cells (DTCs) at their time of diagnosis^[11,17,18]. Indeed, DTCs are readily detected in the bone marrow of 30%-40% of patients diagnosed with early-stage breast cancer, an event that portends a significantly worse prognosis as compared to patients whose bone marrow is free from DTCs at the time of diagnosis^[19]. Interestingly, a large fraction of these DTCs initially remain clinically asymptomatic due in part to their acquisition of dormancy-associated phenotypes upon arrival to the micrometastatic niche^[12].

Although diverse genetic and epigenetic analyses have begun to reveal the molecular landscape that characterizes metastatic breast cancers, only recently have these investigations been directed at and tailored for DTCs and their reactivation of proliferative programs during metastatic relapse. As such, a unified definition of dormancy remains elusive. At a cellular level, current models suggest that metastatic cells often undergo proliferative arrest upon arriving to a micrometastatic niche, a phenomenon believed to reflect the initial maladaptation of DTCs to foreign stromal environments^[20]. Indeed, the stromal characteristics that impact DTC dormancy are multifactorial and encompass a diverse array of immunomodulatory and vascular endothelial cell signals (e.g., cytokine milieu, rigidity of the microenvironment, presence of active immunosurveillance^[17,21,22]) that converge on niche-localized DTCs. In doing so, these unique microenvironment signals may prove to be inhospitable to DTCs, thereby provoking cellular stress and the initiation of apoptosis as these cells struggle to cope and respond to foreign junctional and adhesive signaling networks^[23-25]. Consequently, newly established micrometastatic lesions fail to propagate and expand due to: (1) deficiencies to initiate and progress through the cell cycle; and (2) propensity to undergo apoptosis at a pace that equals or exceeds the proliferative rate of DTCs. Despite these barriers, a subset of DTCs remain viable and poised to reactivate proliferative programs that result in metastatic relapse years-to-decades after implementation of initial treatments, such as chemotherapy and radical primary tumor resection^[26,27]. Clinically, extended periods of metastatic dormancy is evidenced by growth modeling studies performed on over 1,000 breast cancer patients. In doing so, two discrete peaks that define the probability of metastatic recurrence were identified: (1) one correlating with a model of continuous, slow growth of metastatic cells; and (2) one corroborating the principle that the majority of delayed relapses are indeed the result of a temporary period of dormancy prior to reactivation of proliferation programs^[28]. Indeed, it is this second peak that poses the greatest threat to breast cancer patients, with ~62% of breast cancer deaths occurring 5-20 years after initial diagnosis^[27]. Taken together, these findings reveal that dormant DTCs play a pivotal role in the majority of breast cancer-associated mortality, a feature that cements them as one of the most clinically relevant targets in all of oncology.

MODELS OF METASTATIC DORMANCY IN BREAST CANCER

In vitro and *in vivo* models of dormancy represent critical tools for investigating the molecular mediators that impact dormant states. However, the establishment of such models pose significant challenges, as the growth and propagation of dormant cell lines is, by definition, inherently impractical. Likewise, the size and sparsity of dormant micrometastases makes their identification highly burdensome. Nonetheless, accepted models of breast cancer dormancy do in fact exist. One particularly powerful model of metastatic dormancy

is the murine D2.HAN series, which consists of two cell lines that display distinct metastatic properties, namely the dormant D2.OR cell line and the highly metastatic D2.A1 cell line^[29]. These cell lines were derived from a premalignant murine hyperplastic alveolar nodule implanted into the cleared mammary fat pad of *BALB/c* mice, resulting in spontaneous tumors that were subsequently classified by alternations in their surface glycoprotein composition as determined by retention to the lectin, peanut agglutinin^[29].

Accordingly, dormant D2.OR cells exhibit high affinity for peanut agglutinin and produce slow growing tumors that are incapable of forming disseminated tumors in either spontaneous or experimental metastasis models. In stark contrast, metastatic D2.A1 cells exhibit low affinity for peanut agglutinin and produce fast growing tumors that metastasize aggressively^[30]. Importantly, *in vivo* videomicroscopy reveals that these D2.HAN derivatives show no differences in the mechanism, timing, and proportion of cells capable of extravasating into the lungs of mice, indicating that post-extravasation events underlie their vastly disparate abilities to undergo metastatic outgrowth^[31]. Despite their inability to form secondary tumors, a large proportion of disseminated D2.OR cells readily survive the process of extravasation (i.e., ~80% at 3 weeks and ~50% at 11 weeks) and remain viable despite their non-proliferative phenotype (i.e., Ki-67-negative)^[32]. Collectively, these cellular and functional features form the crux of the dormancy-associated phenotypes exhibited by D2.OR cells *in vivo*, thus establishing them as a valuable model for studying the molecular mechanisms underlying metastatic dormancy^[33-35].

lncRNAs in breast cancer

Elucidating the molecular determinants of breast cancer metastasis, especially those associated with DTC acquisition of and eventual emergence from dormancy, remains a critical undertaking that is essential to the future development of therapies capable of targeting DTCs. Recently, a surprising class of molecules called long noncoding RNAs (lncRNAs) have been identified and function as potent contributors to the malignant properties of breast cancer cells. Broadly, these transcripts are defined as RNA molecules that are > 200 nucleotides in length and lack an open reading frame capable of producing a functional protein^[36]. lncRNAs were originally believed to possess negligible function and exist primarily as “transcriptional noise” originating from illegitimate regulatory DNA elements. However, it is now clear that lncRNA expression patterns transpire in a highly specific cell- and tissue-dependent manner^[37,38]. Importantly, noncoding RNA molecules do not require protein-coding capacity to act as powerful determinants of cell fate. Indeed, lncRNAs harbor immense intrinsic functionality within the course of cellular homeostasis and disease formation. For instance, the developmental complexity of organisms correlates more closely with the extent and diversity of the noncoding genome rather than with the collective composition of protein-coding genes^[39-41].

In light of the dynamic and diverse functions attributed to lncRNAs, it is unsurprising that malignant cells, including those arising from the breast, have hijacked lncRNAs to directly and indirectly alter their proliferative, invasive, and metastatic ability^[42-44]. As such, several lncRNAs have been shown to modify critical breast cancer-associated molecular pathways in a manner that transcends hormone receptor status, frequently driving the development and progression of TNBCs^[45]. Similarly, ER-associated signaling pathways also regulate the expression of lncRNAs^[46], including HOTAIR, whose promoter contains several estrogen response elements^[47].

Moreover, induction of HOTAIR promotes the growth and metastasis of breast cancers via widespread epigenetic reprogramming^[48].

BORG

Although numerous lncRNAs have been linked to breast cancer tumorigenesis and metastasis^[49], the intergenic lncRNA BORG has recently emerged as a unique and formidable regulator of the metastatic competence and survival of breast cancer cells. Originally discovered in murine C2C12 myoblast cells treated with BMP2 or BMP7, BORG is a spliced and polyadenylated ~2.8 kb transcript that shows no

evidence of an open reading frame and carries multiple conserved repeat sequence elements of unclear significance^[50]. Collectively, these features implicate BORG as a lncRNA, whose primary sequence has been subject to several functional analyses. For instance, BORG houses several novel pentamer motifs that are essential in facilitating its strict residence in the nucleus, representing the first demonstration of sequence-based determinants operant in dictating the subcellular localization of lncRNAs^[51]. Indeed, the nuclear localization of lncRNAs directly impacts their ability to elicit widespread alterations in transcriptional networks by: (1) localizing transcription factors to specific genomic loci^[52-54]; and (2) exerting gross changes in the nuclear architecture of cells^[55]. Likewise, BORG oversees a host of cellular functions that are readily harnessed by breast cancer cells to enhance their tumorigenic behaviors. As will be discussed in the succeeding sections, these BORG-dependent events play an essential role in promoting breast cancer cell proliferation, chemoresistance, and survival.

Control of proliferation

In undertaking a combination of *in silico* and cell biological analyses, we recently determined that the expression of BORG directly correlates with aggressive breast cancer phenotypes, and with their metastatic competence and recurrence. Specifically, BORG liberates D2.OR cells from a state of dormancy in 3D-organotypic cultures by conferring a proliferative shift in the cell cycle from G0/G1 to G2/S^[56]. Importantly, this proliferative stimulus is sufficient to enable BORG-expressing D2.OR cells to form overt metastases in the lungs of BALB/c mice^[56]. Interestingly, the mitogenic properties of BORG are highly context-dependent, as they only emerge in D2.OR cells propagated in microenvironments that mimic primary and/or metastatic tumor sites (e.g., 3D-cultures). Such context-dependent activities of BORG imply that this lncRNA confers malleable phenotypes to DTCs, thus compelling them to activate adaptive signaling programs that enable their survival and outgrowth within diverse metastatic niches.

BORG as a manipulator of protein function

In searching for mechanistic insights into how BORG induces DTCs to escape from dormancy, we performed mass spectrometry analyses on proteins captured by the pulldown of biotinylated, anti-sense BORG transcripts. These analyses identified the E3 SUMO ligase TRIM28 (KAP1) as a strong binding partner of BORG^[57]. TRIM28 functions as a transcriptional co-repressor and scaffolding protein for histone and DNA modifying enzymes that enhance breast cancer cell proliferation, doing so in part by suppressing the transcription of senescence promoting genes, especially *p21* and *Gadd45a*^[58-61]. Interestingly, elevating BORG expression in D2.OR cells to levels that approximate those detected in their metastatic D2.A1 counterparts dramatically downregulated the expression *p21* and *Gadd45a*, indicating that BORG may rely upon TRIM28 to confer proliferative states to dormant DTCs. Indeed, CRISPR/Cas9-mediated knockout of TRIM28 restores a dormant phenotype in BORG-expressing D2.OR cells, as does expression of mutant BORG transcripts that can no longer bind TRIM28^[57]. Thus, the oncogenic activities of BORG depend upon its physical interaction with TRIM28, an event that serves as a proliferative stimulus to dormant DTCs.

The diverse range of functions elicited by lncRNAs is thought to be promoted by their unique structural diversity. Their inherent length and nucleic acid structure allow the formation of flexible, complex secondary and higher order structures that facilitate their interactions with macromolecular complexes^[40]. Indeed, lncRNAs can acquire behaviors analogous to ligands, as their binding to proteins can trigger conformational changes and/or modify protein: protein interactions that dramatically impact protein activation states^[62]. Accordingly, BORG enhances the function of TRIM28 to inhibit transcription by regulating the pause and release of RNA Polymerase II (Pol II)^[63,64]. For instance, heterologous expression of mutant BORG transcripts that retain their capacity to bind TRIM28 remain competent to elicit Pol II promoter pausing at the *p21* and *Gadd45a* loci, whereas those BORG mutants incapable of binding TRIM28 fail to impact the pausing index of Pol II at these loci^[57]. Furthermore, widespread evidence indicates that lncRNAs can function as molecular scaffolds for proteins, thereby: (1) tethering cooperative proteins together to enhance their functions; or (2) localizing RNA-protein complexes to specific genomic regions through base-pair and

tertiary structure interactions with DNA^[41,65]. Along these lines, chromatin immunoprecipitation assays reveal that BORG enhances the binding of TRIM28 to specific genomic loci^[57]. Thus, BORG promotes the metastatic outgrowth of dormant DTCs in part through its ability to promote the localization and transcriptional repressive activity of TRIM28. Although BORG directly modifies the ability of TRIM28 to suppress the expression of *p21* and *gadd45a* in dormant DTCs, it should be noted that TRIM28 also exerts widespread alterations in the transcriptomes of a multitude of cell types^[63,64,66]. To gain additional insight into the repertoire of transcriptional events coupled to TRIM28 in DTCs, we performed RNA-seq and microarray-based transcriptomic analyses on parental and BORG-expressing D2.OR organoids propagated in 3D-cultures. To assess the specific impact of TRIM28 on these dormancy-associated phenotypes (i.e., parental dormancy *vs.* BORG-mediated outgrowth), we also rendered these cells deficient in TRIM28 expression. Unsurprisingly, BORG-expressing D2.OR cells harbored a transcriptional signature that deviated significantly from its parental and TRIM28-deficient counterparts. Moreover, cellular network analyses revealed specific BORG- and TRIM28-dependent transcriptional patterns that were significantly enriched for proliferative and pro-metastatic signatures^[57]. Collectively, these findings establish BORG as the only known lncRNA that functions in modifying the activity and cellular localization of a transcriptional regulator (i.e., TRIM28) to confer genome-wide transcriptomic alterations that compel the reactivation of proliferative programs in dormant DTCs.

Chemoresistance

The development of therapeutic resistances continues to hamper the prolonged efficacy of standard-of-care treatment regimens. Moreover, these clinical challenges are compounded by the fact that the underlying mechanisms responsible for targeted and chemotherapeutic resistance are immensely diverse. Nonetheless, malignant breast cancer cells regularly rely on the malleable intrinsic state of cancer cells, which enables their adaptation to cytotoxic cellular stresses in order to maintain viability^[67] in a manner that most closely follows the paradigm of acquired resistance^[68]. Indeed, the plasticity underlying the appearance of chemoresistance is naturally permissive and reflects alterations in the epigenome. Moreover, these events are bolstered by defects in the ability of DTCs to maintain genome integrity that arise in response to aberrant cell cycle checkpoints and DNA repair mechanisms, and to increased rates of proliferation. Additionally, interactions between DTCs and the tumor microenvironment induce unique *de novo* mechanisms of therapeutic resistance, as cell adhesion networks (e.g., integrins) activate a specialized survival program known as “cell adhesion-mediated” drug resistance that elicit DTC insensitivity to numerous treatment regimens^[69,70]. As such, the stromal composition of the metastatic microenvironment creates a natural sanctuary for DTCs to survive therapeutic insults.

Interestingly, dormant DTCs have long been recognized for their inherent resistance to commonly used chemotherapeutic drugs^[11]. These resistant traits naturally stem from the quiescent phenotype of dormant cells, which effectively abolishes the clinical utility of chemotherapeutics and cytotoxic agents that target metabolically active and dividing cells^[71]. Moreover, dormant cells preferentially upregulate signaling pathways associated with cell survival, a trait stemming from their allocation of metabolic resources away from cell cycle progression as a means to remain viable in the face of environmental stressors (i.e., chemotherapy)^[72]. Accordingly, chemotherapeutic treatment can select for a subset of dormant cells that are enriched for pro-survival pathways and multidrug resistance, implying that cytotoxic insults can select for a population of cells that are exceedingly equipped to instigate post-therapy relapse^[73,74]. Importantly, we recently determined that BORG plays a central role in driving the development of chemoresistance in TNBCs (see below).

BORG: a novel inducer of chemoresistance

In addition to possessing enhanced proliferative abilities, BORG-expressing D2.OR cells also exhibit: (1) extensive upregulation of pro-survival and viability pathways; and (2) widespread downregulation of cell

Table 1. BORG-associated signaling pathways

*Indicate a downregulation in protein expression; [#]represent proteins hypothesized to mediate BMP/OP-Responsive Gene (BORG) action based on findings published in the literature. BORG plays essential functions in regulating breast cancer proliferation, metastasis, and chemoresistance. The specific effectors of BORG that activate cells proliferation and survival systems are annotated above, as are the BORG:effector complexes operant in mediating these events

death pathways^[56]. Moreover, BORG expression is highly responsive to metabolic stresses such as hypoxia and nutrient deprivation, as well as to treatment with a wide panel of chemotherapeutic drugs, including doxorubicin, hydroxyurea, docetaxel, 5-fluorouracil, and 6-thioguanine^[56]. These cellular attributes of BORG are consistent with its ability to enhance metastatic outgrowth and disease recurrence. Indeed, comet assays demonstrate that heterologous expression of BORG dramatically mitigates the extent of double-stranded DNA breaks experienced by D2.OR cells in response to doxorubicin exposure. Moreover, these genoprotective features of BORG rely upon its binding to the single-strand DNA-binding protein, RPA1, which functions as an essential molecule in the repair of DNA damage^[75,76]. Interestingly, the capacity of BORG to induce resistance to doxorubicin appears to supersede its ability to enhance cell cycle progression, an event that could potentially render BORG-expressing cells more sensitive to the cytotoxic activities of doxorubicin^[77,78]. As such, the genoprotective effects of BORG are essential in establishing the foundation operant in mediating deadly relapse in patients with metastatic breast cancers. Moreover, as lncRNAs typically function as molecular scaffolds that facilitate the formation of protein complexes, particularly in the nucleus^[79], it is tempting to speculate that BORG promotes the interaction of RPA1 with proteins critical to its repair of DNA, including additional subunits RPA2 and RPA3^[80], as well as other DNA-repair associated proteins, such as BRCA2, XPA, and p53^[81-83] [Table 1].

BORG and NF- κ B: a feed-forward loop to chemoresistance

Cellular network analyses of parental and BORG-expressing D2.OR derivatives demonstrate significant enrichment of a hallmark gene signature that correlates with the induction of NF- κ B activity^[56]. Accordingly, NF- κ B reporter assays show enhanced activation of NF- κ B signaling in BORG-expressing D2.OR cells as compared to their parental counterparts. In light of the longstanding association between NF- κ B activation and the initiation of pro-survival and cellular stress responses^[84,85], we further explored the connections between NF- κ B and BORG in eliciting DTC resistance to chemotherapy. In doing so, we inactivated the NF- κ B pathway via several complementary strategies, including: (1) stable expression of a dominant-negative form of I κ B α ; (2) CRISPR/Cas9-mediated knockout of the BORG-responsive gene NEMO/IKK γ ; or (3) administration of small molecule inhibitors to IKK β . In all cases, inhibiting NF- κ B signaling in BORG-expressing D2.OR cells restored their sensitivity to doxorubicin both *in vitro* and *in vivo*, and to apoptosis induced by hypoxia- and nutrient deprivation^[56]. It should be noted that while BORG requires ample expression of RPA1 to protect against doxorubicin-induced DNA damage and subsequent apoptosis, this event appears to be dissociated from the ability of BORG to activate NF- κ B signaling. Indeed, CRISPR/Cas9-mediated disruption of RPA1 expression had no effect on the ability of BORG to activate NF- κ B signaling^[56]. Thus, the chemoresistant phenotypes afforded by BORG-RPA1 interactions act independently of the NF- κ B signaling axis.

Interestingly, the promoter region of the BORG locus contains multiple stretches of nucleotides that exhibit sequence homology to the consensus DNA-binding sequence for NF- κ B. Accordingly, NF- κ B readily bound to the BORG promoter in BORG-expressing cells, thereby identifying a novel feed-forward loop whereby the activation of NF- κ B (i.e., through chemotherapeutic and environmental stressors^[86-89]) leads to enhanced BORG expression, which further promotes the induction NF- κ B responsive genes. Along these lines, expression of a dominant-negative I κ B α in TNBCs prevented their expression of BORG following exposure to doxorubicin, and to environmental stresses, such as hypoxia and nutrient deprivation^[56]. Collectively, these findings implicate BORG as a unique lncRNA that is capable of promoting a NF- κ B feed-forward signaling loop that effectively links metastasis-associated cellular stresses to a coordinated signaling program that engenders the survival of disseminated TNBCs.

BORG and breast cancer stem cells

Breast cancer stem cells (BCSCs) are malignant cells capable of tumor initiation, self-renewal, and differentiation into a heterogeneous group of cancer cells that reflect those present in the original primary breast tumor; they are also associated with the acquisition of metastatic and chemoresistant phenotypes^[90-93], particularly upon their colonization of foreign tissue microenvironments^[94]. BCSCs typically divide asymmetrically to create: (1) a single progenitor cell capable of differentiating into a variety of functionally diverse cancer cell types; and (2) a single BCSC that can expand and undergo continual self-renew. Attempts to characterize BCSCs has been hampered by a relative lack of universal markers for BCSCs^[95,96]. Indeed, BCSCs have been linked to the expression of several cell surface proteins, such as CD133 and CD44⁺/CD24⁻, and to the intracellular protein, ALDH1^[97-99]. Recent findings have associated the expression of lncRNAs with the generation and expansion of BCSCs. For instance, the lncRNAs ROR, HOTAIR, and Hh all induce the expression of transcription factors that regulate “stemness”, such as SOX2 and OCT4; they also impact the initiation of EMT programs^[100-103], which elicit the selection, expansion, and self-renewal of BCSCs^[104]. The role of BCSCs in regulating metastasis, chemoresistance, and survival signaling are reminiscent of the features attributed to aberrant BORG expression, suggesting that BORG may also regulate the behaviors of BCSCs. Accordingly, BORG expression is elevated significantly in BCSCs as compared to non-BCSCs populations; it also enhances the mammosphere forming activity of human and murine breast cancer cells (Gooding *et al.*^[56,57], unpublished observation). Thus, future studies need to determine precisely how BORG impacts the transcriptomic and epigenetic landscapes of breast cancer cells to impart BCSC characteristics coupled to metastatic progression and disease recurrence.

DISCUSSION AND CLINICAL IMPLICATIONS OF BORG

Metastasis is an exceedingly complicated process, whereby tumor cells must undergo coordinated efforts to successfully disperse from primary tumors, emigrate to distant tissues, and survive and colonize foreign microenvironments. Even for highly transformed cells, traversing the metastatic cascade is immensely challenging, with the vast majority of disseminated cells unable to form overt metastases^[15]. The inefficiencies characterizing metastasis are predominantly attributed to the cellular stresses associated with unfamiliar metastatic microenvironments, forces that obstruct both the survival and outgrowth of DTCs. Accordingly, BORG has emerged as a potent and unique lncRNA that is poised to enhance breast cancer metastasis by altering both sides of this equation, i.e., providing both proliferative and pro-survival stimuli to DTCs.

From a potential clinical perspective, aberrant BORG expression is most frequently associated with TNBC/basal-like breast cancers, as determined by scrutinizing several publicly available RNA-seq datasets. Moreover, we detected significant elevations of BORG in metastatic human patient-derived xenograft tissue samples, and in CNS metastases and their matched primary tumors from which these metastatic foci derived. In all cases, malignant tissues clearly express increased levels of BORG as compared to normal human mammary epithelial cells^[56,57]. Thus, these findings support the hypothesis that primary

malignancies that house high levels of BORG will disperse aggressive breast cancer cells that are predisposed to establishing clinically-relevant, chemoresistant secondary lesions. Indeed, TNBC patients who succumbed to metastatic relapse within 5 years of initial diagnosis and treatment possessed primary tumors that contained significantly higher levels of BORG compared to primary tumors derived from TNBC patients who remained disease-free for at least 5 years post-treatment^[57]. Taken together, these intriguing findings suggest that quantifying BORG expression in primary tumors could offer important insights into predicting the natural and clinical course of breast disease within TNBC patients.

The correlative finding that BORG expression largely aligns with the overall malignant propensity of breast cancer cells fails to address the mechanisms and signaling systems ultimately coupled to its upregulation in developing mammary tumors. Indeed, it has been proposed that lncRNAs evolved as a means to assist in maintaining cellular homeostasis in response to a wide variety of pathophysiologic conditions^[105]. Accordingly, we show that BORG expression is similarly influenced by a number of cellular stressors, including chemotherapeutic insult, nutrient deprivation, and hypoxia^[56], as well as in response to heat shock (Gooding *et al.*^[56] and Valadkhan *et al.*^[105], unpublished observation). Moreover, NF- κ B is critical in linking the responsiveness of BORG to these environmental stressors^[56], as NF- κ B activation has long been tied to the survival of cells confronted with a host of intrinsic and extrinsic stressors^[84,85,106]. It therefore stands to reason that increased flux through the NF- κ B pathway stemming from exposure to noxious stimuli may serve as the initial impetus in triggering the aforementioned NF- κ B feed-forward loop, wherein NF- κ B-induced upregulation of BORG propagates expression of NF- κ B-responsive gene expression patterns^[56].

Tumor progression and metastatic competence are thought to rely heavily upon the intrinsic plasticity of malignant cells, which facilitates their adaptation to harsh foreign microenvironments in order to maintain viability^[67,107]. Because BORG is largely regulated by extracellular paracrine factors (e.g., TGF- β , BMP-2, and BMP-7^[50,56]) and the environmental cues, we surmise that BORG acts as a context-dependent, transcriptional rheostat for disseminated breast cancer cells, thereby dictating their engagement of proliferative and pro-survival pathways. Indeed, when faced with environmental or therapeutic stresses, the induction of BORG in malignant cells orchestrates a transcriptional signature that provokes aggressive tumorigenic states that ensures for their survival. As such, preventing BORG expression or impeding the activation of its downstream targets represents an innovative and potentially impactful strategy to target metastatic breast cancers and drive them into an apoptosis-prone state.

Current mechanistic insights into the regulation of BORG and its downstream effectors reveal that this lncRNA is uniquely poised to promote the metastasis of breast cancer cells. Indeed, BORG clearly exerts a pro-metastatic effect at both the primary and metastatic sites of tumor growth. For example, a subset of breast cancer patients may harbor primary tumor cells that have gained the expression of BORG (BORG^{hi}) as a result of environmental stresses associated with a growing primary tumor (i.e., hypoxia and nutrient deprivation; Figure 1). Such tumors are prone to shedding BORG^{hi} cells into the circulation that disseminate to distant tissues, wherein they exploit the proliferative and pro-survival effects of BORG to overcome the hostile metastatic microenvironment and form overt metastases [Figure 1]. Accordingly, and as noted above, TNBC patients who succumbed to metastatic relapse within 5 years of initial diagnosis and treatment possessed primary tumors that contained significantly higher levels of BORG compared to primary tumors derived from TNBC patients who remained disease-free for at least 5 years post-treatment. Furthermore, breast cancer cells can emigrate from the primary tumor at very early stages of tumor development^[18]. As such, these early disseminated breast cancer cells are likely to originate from a lesion experiencing little hypoxic or metabolic stress and are therefore more prone to harboring low levels of BORG (BORG^{lo}). Although still capable of disseminating to distant tissues, these BORG^{lo} cells are predicted to struggle within their foreign microenvironments, resulting in their undergoing cell death or retreating into a state of metastatic dormancy. Nonetheless, stromal paracrine signals (e.g., TGF- β , BMP2, or BMP7), as well as the

Figure 1. BORG is a potent facilitator of breast cancer metastasis. Breast cancer cells can disseminate at very early stages of development. Due to the benign microenvironment associated with these lesions, these cells are likely to harbor low levels of BORG (BORG^{lo}) expression and are prone to establishing dormant lesions in metastatic tissues. Nonetheless, stromal factors and environmental stressors in the metastatic microenvironment can induce BORG expression, thereby compelling these dormant cells to reinstate proliferative programs. The progression of primary tumors is associated with a hypoxic environment and stark competition for nutrients. Such stresses can enhance BORG expression in a subset of cells (BORG^{hi}). These BORG^{hi} cells can disseminate to distant tissues where they exploit the proliferative and survival advantages afforded by BORG to produce overt metastases. Cytotoxic chemotherapeutic treatment is effective against BORG^{lo} cells, but BORG^{hi} cells show resistance to such therapies and are the foundation for chemoresistant, residual disease that can eventually metastasize to distant tissues. BORG: BMP/OP-Responsive Gene

hypoxic and metabolic stresses associated with the metastatic microenvironment, can lead to the induction of BORG expression within these dormant DTCs, thereby activating proliferative programs and survival signaling to promote their metastatic outgrowth [Figure 1].

Finally, neoadjuvant or adjuvant treatment of primary breast cancers with chemotherapeutic agents (e.g., doxorubicin) will selectively kill BORG^{lo} cells that are not inherently resistant to the cytotoxic effects of these agents. The residual, chemoresistant BORG^{hi} cells can subsequently contribute to the recurrence of metastatic or primary lesions that are insensitive to standard-of-care therapies [Figure 1]. These diverse cellular outcomes downstream of BORG establish this lncRNA as an essential driver of breast cancer metastasis and highlight the potential utility derived from therapeutically targeting BORG or its effectors as a novel means to alleviate the metastatic outgrowth and recurrence of disseminated TNBCs.

DECLARATIONS

Acknowledgments

Members of the Schiemann Laboratory are thanked for critical comments and reading of the manuscript.

Abstract

Aim: Volumetric modulated arc therapy (VMAT) has been utilized to plan and treat multiple cranial metastases using a single isocenter due to its ability to provide steep dose gradients around targets as well as low doses to critical structures. VMAT treatment is delivered in a much shorter time compared to using a single isocenter for the treatment of each lesion. However, there is a need to develop methods to reduce the treatment planning time for these cases while also standardizing the plan quality. In this work we demonstrate the use of RapidPlan, which is knowledge-based treatment (KBP) planning software to plan multiple cranial SRS cases.

Methods: The 66 patient plans with 125 lesions (range 1-4, median 1) were used to train a model. In addition, the model was validated using 10 cases that were previously treated and chosen randomly. The clinical plans were compared to plans generated by RapidPlan for target coverage and critical organ dose.

Results: Coverage to the target volume, gradient index, conformity index and minimum dose to the target showed no significant difference between the original clinical plan vs. the plan generated by KBP. A comparison of doses to the critical organs namely the brainstem, brain, chiasm, eyes, optic nerves and lenses showed no significant difference. Target dose homogeneity was slightly better with the clinical plan, however this difference was also statistically insignificant.

Conclusion: This work demonstrates that KBP can be trained and efficiently utilized to help not only speed up the planning process but also help standardize the treatment plan quality.

Keywords: Brain metastases, radiotherapy, volumetric modulated arc therapy, knowledge-based planning, stereotactic, radiosurgery

INTRODUCTION

Volumetric modulated arc therapy (VMAT) is a radiation treatment planning and delivery technique that has been investigated and clinically applied for all disease sites including malignancies of the head and neck, thorax, abdomen and pelvis, and compared to static field intensity modulated radiation therapy (IMRT), VMAT has been shown to reduce treatment time and monitor units (MU), making it an attractive radiotherapy delivery technique^[1]. Recent reports have established VMAT as a treatment technique for delivering cranial stereotactic radiosurgery (SRS)^[2-4] providing optimal dose distributions while improving the efficiency of treatment delivery. Conventionally, SRS uses one isocenter per lesion and requires multiple isocenters for multiple lesions. This not only prolongs the delivery time reducing patient throughput but is also uncomfortable for the patient. The use of a single isocenter to treat multiple cranial metastases has been accomplished using VMAT producing highly conformal dose distributions while reducing treatment times. Target coverage and dose gradients produced by this technique have been shown to be comparable to Gamma Knife-based SRS^[5,6]. After the initial feasibility studies, reports have been presented outlining further refinement of the procedure, dosimetric indices as well as plan quality parameters for single isocenter VMAT in radiotherapy treatment of multiple cranial metastases^[7,8]. Depending on the complexity of the case however, planning for these cases can be very time consuming and reports have expressed the need to shorten the planning time, thereby aiming to improve the efficiency.

Knowledge-based planning (KBP) is a new paradigm in treatment planning and is a shift towards the direction of automating the planning process^[9,10]. KBP utilizes the dose distributions of prior plans to build a model that can predict the same for new patients. KBP has been effectively utilized to generate high quality treatment plans with consistency utilizing IMRT or VMAT for malignancies at various sites including prostate, lung, liver, head and neck as well as intracranial stereotactic radiotherapy^[11-15]. Although comprehensive studies describing prediction methodologies that make precise estimations of SRS plan quality metrics have been made using in-house systems^[15], clinical application of a commercial KBP system for treatment planning of multiple intracranial lesions with VMAT using a single isocenter has yet to be performed. Recently RapidPlan (TM), which is commercial KBP software from Varian Medical Systems, Palo Alto CA has become available for clinical use. In this study we train a knowledge-based model using RapidPlan for multiple cranial lesions treated at our institution with VMAT. We then retrospectively apply this model to compare the results of previously planned and treated cases.

METHODS

Treatment planning

VMAT plans were generated for 91 patients with a total of 139 lesions (range 1-4, median 1) in Eclipse V13.6 (Varian Medical Systems, Palo Alto, CA USA) from June 2017 to November 2018. Each case was planned with a single isocenter using 3 to 6 arcs. The location of the isocenter was based on the geometric center of the lesions to be treated. The arcs used were non-coplanar. Their distribution in terms of full arcs vs. partial arcs, couch angles, collimator angles were such that they best covered the group of lesions to be treated within that single isocenter. The arcs were chosen to avoid situations where there were two targets in the same leaf track in order to avoid excess dose to the brain. The algorithm used for optimization with VMAT was the progressive resolution optimizer and dose calculation was performed with analytical anisotropic

algorithm using a 1 mm dose calculation grid size. X-ray energy used was 6 flattening filter free (FFF) and dose rate for planning was 1400 MU/min. Contouring of the gross tumor volume (GTV) and the critical structures such as the brain, brainstem, chiasm, optic nerves and tracts, eyes and lenses closely followed previously published guidelines^[7,8]. At our institution, no margin is used to convert GTV to planning target volume (PTV). The range of the PTV was from 0.1-7 cm³. The gradient index (GI) was defined as the ratio of volume covered by the 50% isodose line to that covered by the 100% isodose^[16]. The conformity index (CI) and the homogeneity index (HI) were chosen for plan evaluation. The CI was defined as the ratio of the volume covered by the 100% isodose to the volume covered by the PTV. The HI was taken as the maximum PTV dose to the prescription dose. Dose prescribed in a single fraction was 20 Gy, 18 Gy or 16 Gy and was decided based on the size and volume of the lesion and its proximity to critical organs. The constraints and strategy for optimization was similar to that previously published^[7,8,18,19]. The dose constraints used for planning are shown in [Table 1](#).

KBP with RapidPlan

RapidPlan is a treatment planning application developed by Varian medicalsystems that utilizes a knowledge-based approach. Previously accepted clinical plans are taken from which data are extracted which include the volumes of the OARs and PTVs, percentage of the overlap volume for each OAR with the target, percentage of the OAR volume that is out of the field for each OAR, prescription dose, structure dose-volume histogram (DVH) and geometry based expected DVH for each OAR. The geometry based expected dose is a measure of dose received by a portion of an OAR if only the patient anatomy and desired target dose are to be considered. Principle component analysis is conducted on this extracted data and the principle components are used to build a DVH estimation model^[17]. When a treatment plan is to be generated for a new patient, the RapidPlan model will create DVH estimates for the OARs based on the anatomy for that particular case. These DVH estimates will then be used as part of the objectives for optimization to achieve the dosimetric goals for that patient.

Model training

To create the RapidPlan DVH estimation model, we selected 66 patients with 125 lesions (range 1-4, median 1). The model was trained for multiple target dose levels, namely high risk, intermediate risk and a low risk PTV. These levels of risk for the PTVs were matched accordingly in both the training and validation. For all single lesion cases, the plan had only 1 target, which was matched to high dose level. If the plan had 2 targets that were prescribed to the same dose level, then they both were matched to the highest dose level. However, if they went to different dose levels, the target receiving higher prescription was matched to the higher dose level and the one receiving the next dose level was matched to the intermediate dose. Similarly if a plan had 3 targets, each prescribed to different dose levels, the targets were matched correspondingly, i.e., high to high, intermediate to intermediate and low to low. However if they went to 2 different dose levels, the target(s) with the highest prescription dose would be matched to high and the target(s) with the next dose level would be matched to intermediate dose level. Similarly if all the 3 went to the same dose level, all of them would be matched to high dose. This methodology of matching is recommended by the training software. The OARs included for training were brain, brainstem, chiasm, optic nerves, eyes and lenses. The training process consisted of identifying the geometric outliers and the dosimetric outliers. The geometric outliers are typically cases where the PTV and/or OAR volumes, shapes and overlaps differ substantially from the majority of the training set. Dosimetric outliers are cases where the clinical DVH differs substantially from the estimated DVH. Geometric outliers can be identified using regression plots, which illustrate the correlation between the best prediction of the DVH and the most likely geometric parameter that would be responsible for that DVH such as the volume of the structure or the overlap with the target or a combination of both. Geometric outliers are points that are typically identified as points that fall far away from the regression line or that are substantially isolated from it. Similarly, dosimetric outliers can be identified using something called residual plots that correlate the best estimation of the DVH to the actual clinical DVH for

Table 1. Table summarizing dosimetric criteria

Structure	Parameter	Objective
PTV	D_{max} (%)	$\leq 125\%^*$
	D_{min} (%)	$\geq 90\%^*$
	V_{100} (%)	$\geq 98\%^*$
Brainstem	D_{max} (Gy)	$\leq 13\text{ Gy}^*$
Brain	$V_{7\text{Gy}}$ (%)	$\leq 5\%^*$
	$V_{12\text{Gy}}$ (cm ³)	$\leq 8\text{ cm}^3^*$
	$V_{10\text{Gy}}$ (cm ³)	$\leq 10\text{ cm}^3^*$
Optics	D_{max} (Gy)	$\leq 8\text{ Gy}^*$
Lens	D_{max} (Gy)	$\leq 8\text{ Gy}^*$

*Signifies used as limiting constraints, while the others are used as guidelines. D_{max} (%) is the maximum dose to the structure in %, D_{min} (%) is the minimum dose to the structure in %, V_{100} (%) is the volume of the structure in % that receives 100% of the prescription dose. D_{max} (Gy) is the maximum dose to the structure in Gy and $V_{x\text{Gy}}$ (%) is the % volume of the structure receiving X Gy, and $V_{y\text{Gy}}$ (cm³) is the absolute volume of the structure receiving Y Gy. At our institution, the maximum dose constraint to the brainstem is used only if target overlaps with the brainstem. PTV: planning target volume

the training case. A case is considered to be a dosimetric outlier when the clinical DVH differs substantially from the DVH estimated by the model. By removing the geometric and dosimetric outliers, and re-training the model, the ability of the model to estimate the DVHs is measured. A minimum of 20 patients/cases are required to successfully train the model.

Optimization objectives

Once the model has been trained and reviewed, optimization objectives are added to the model. It is critical to mention at this point that these estimation models can predict achievable OAR DVHs for individual patient anatomy; however optimization objectives are required to achieve these dosimetric goals. These dose-volume objectives and the priorities are estimated by the model for the selected structure and are automatically loaded when the model is selected to create a plan for a new patient.

Model validation

Ten patients were chosen for validation. Among the 10 patients, 6 had 1 lesion each, 2 had 2 lesions each, 1 had 3 lesions and 1 had 4 lesions. The validation process consists of comparing the clinical DVH to that obtained from the plan using the model and then evaluating the plan for clinical acceptability. The dosimetric parameters extracted with respect to target coverage were maximum dose to the PTV, minimum dose to the PTV, volume of the PTV covered by 100% of the prescription dose, i.e., PTV V_{100} , GI, CI and HI, all of which have been defined earlier. With respect to the critical organs, the dosimetric parameters noted were the maximum dose to the brainstem, brain, chiasm, optic nerve, eyes and lenses. The $V_7\text{ Gy}$, $V_{12}\text{ Gy}$ and $V_{10}\text{ Gy}$ to the brain were also noted. Significance testing between the dosimetric results of the clinical plan vs. the plan generated by the model, i.e., the validation plan was performed by using the Wilcoxon sign rank test, which is a non-parametric test for matched pairs of data.

RESULTS

Although 91 patients with a total of 139 lesions were planned, we could only use 66 of them with a total of 125 lesions due to limitations in Eclipse V 13.6 as some of the target volumes were too small to be extracted. Comparison of dosimetric parameters for target coverage between the original clinical plan and the corresponding knowledge-based validation plan using RapidPlan are shown in Table 2. Similarly in Table 3, is the comparison of the dosimetric parameters for OAR sparing between the original clinical plan and the validation plan. In Table 4, for the validation cases, the diameter and volume of each lesion treated in a single radiotherapy session is indicated. For multiple lesion cases, i.e., 2.3 and 4 lesions, the total volume of all lesions treated as well as the maximum diameter is indicated. In Table 5, is shown the distribution of the lesions to the various risk levels. Each validation plan was generated within 30 minutes without human

Table 2. Comparison of dosimetric parameters for target coverage between the original clinical plan and the corresponding knowledge based plan, i.e., Rapidplan. Wilcoxon sign-rank test shows that the dosimetric results with respect to target coverage show no statistically significant difference between the two planning techniques

Structure	Parameter	Clinical plan	KBP	P value

Figure 2. Comparison of dose distribution in the axial, coronal and sagittal views for a clinical plan vs. a RapidPlan for a 2 lesion case

Figure 3. A: Comparison of dose distribution in the axial, coronal and sagittal views for a clinical plan vs. a RapidPlan for a 4 lesion case (first 3 lesions seen in this figure); B: comparison of dose distribution in the axial, coronal and sagittal views for a clinical plan vs. a RapidPlan for a 4 lesion case (4th lesion seen in this figure)

PTV and the critical organs for the clinical plan vs. the RapidPlan for one of the single lesion cases is shown in [Figure 4](#).

PTV coverage

The PTV coverage in terms of PTV V100, the minimum dose to the PTV showed no statistically significant difference between the clinical plan vs. the RapidPlan. Both the clinical and the RapidPlan showed no statistically significant difference in the CI. The GI was slightly higher with the RapidPlan compared to the clinical plan. The maximum dose to the PTV was higher by 2% using KBP. However these hotspots were retained within the target volume.

OAR sparing

Dose constraints for the brainstem, brain, chiasm, optic nerves, eyes and lenses were all achieved as per [Table 1](#) for both the clinical plan as well as the KBP. No statistically significant differences were seen in the dosimetric parameters to the majority of these critical structures.

Monitor units (MU) and calculated treatment time

The total MU for the original clinical plan on average were $5,215 \pm 924$, while with RapidPlan were 5503 ± 1208 . This difference was not found to be statistically significant ($P = 0.5$).

DISCUSSION

Studies have shown that LINAC based radiosurgery plans using VMAT can produce target coverage and dose fall-off in the high dose area similar to Gamma-Knife plans^[5,6]. Single isocenter cranial VMAT radiosurgery technique can produce with the major advantage being improvement in clinical efficiency. The use of FFF beams with a high dose rate of delivery at 1400 MU/min has further contributed towards to this goal. As the single isocenter VMAT technique replaces the use of multiple isocenter techniques for multiple targets, there is also a need to improve the efficiency of clinical treatment planning for these cases. Although the concept of knowledge-based planning with in-house systems has been applied to predict plan quality metrics in intracranial SRS^[12], our study has demonstrated the use of RapidPlan, which is a commercial system for automated planning of intracranial SRS. Our results indicate that both the clinical as well as the validation plan (RapidPlan) showed no significant difference with respect to target coverage, conformity index, gradient index, homogeneity as well as critical organ sparing.

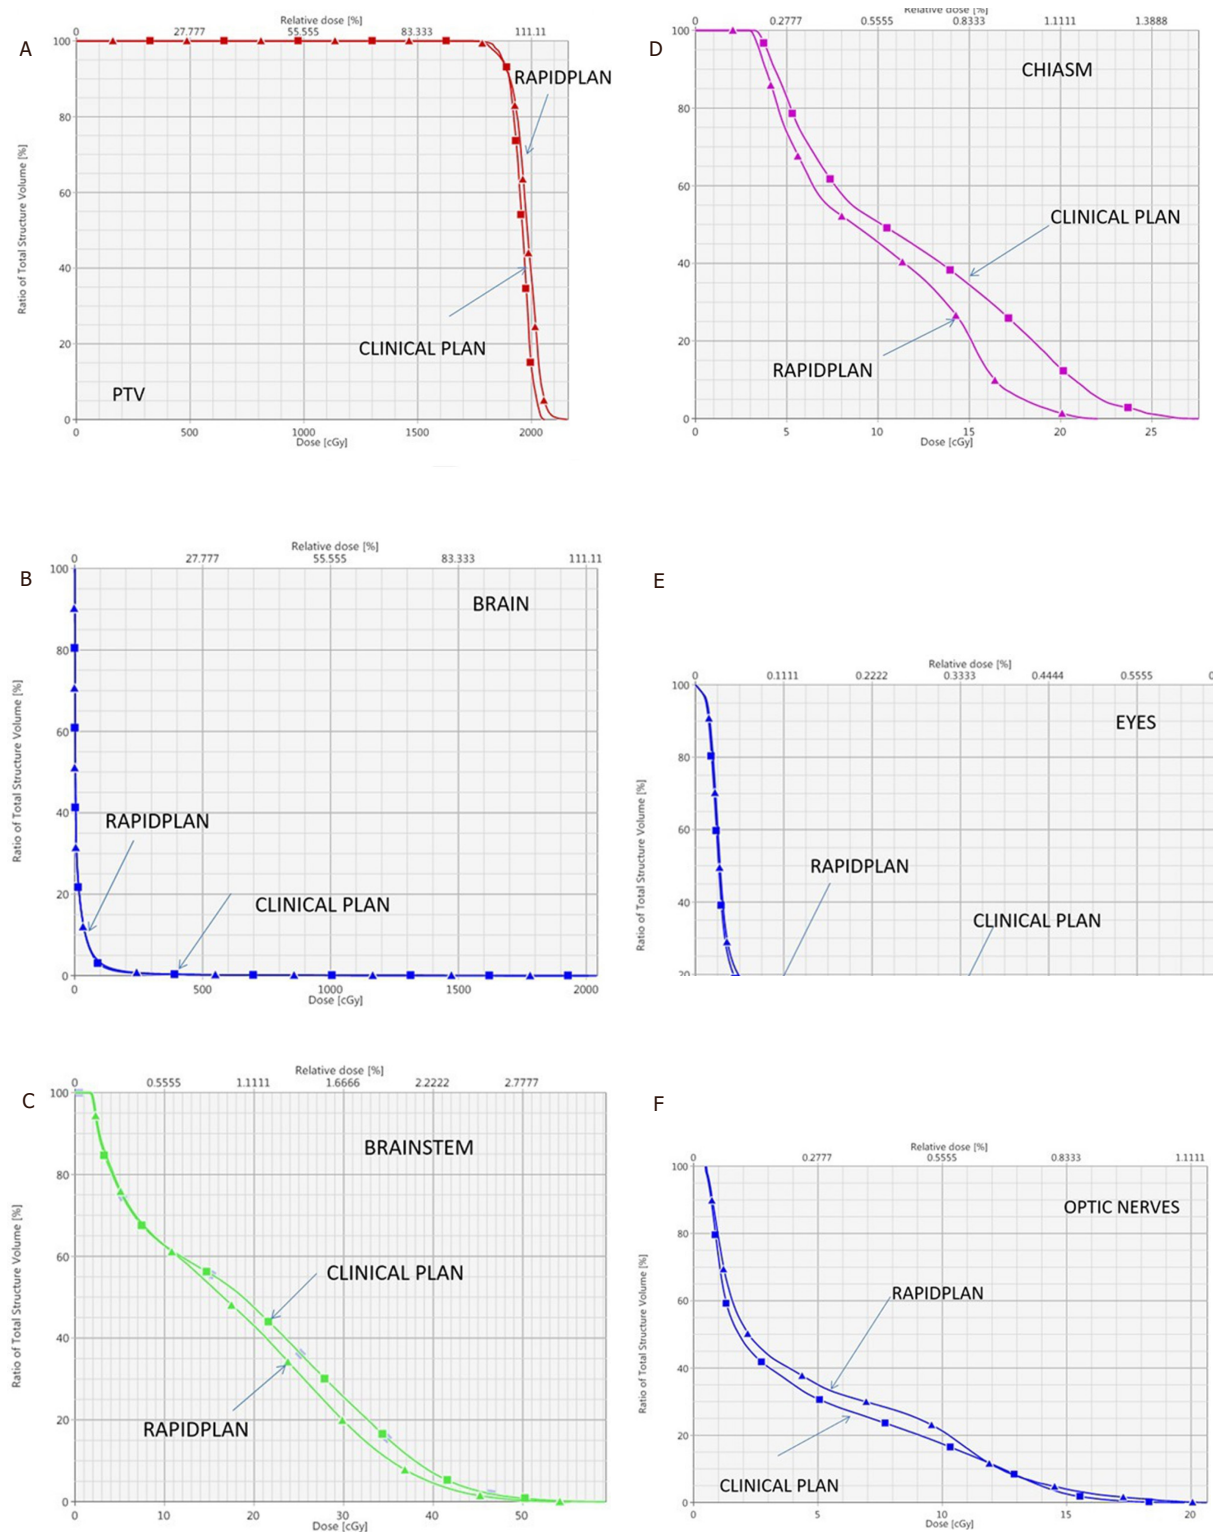

Figure 4. A: DVH comparison of target coverage for clinical plan vs. RapidPlan for the single lesion case shown in Figure 1; B: DVH comparison for the brain between the clinical plan vs. RapidPlan for the single lesion case of Figure 1; C: DVH comparison for the brainstem between the clinical plan vs. RapidPlan for the single lesion case of Figure 1; D: DVH comparison for the chiasm between the clinical plan vs. RapidPlan for the single lesion case of Figure 1; E: DVH comparison for the eyes between the clinical plan vs. RapidPlan for the single lesion case of Figure 1; F: DVH comparison for the optic nerves between the clinical plan vs. RapidPlan for the single lesion case of Figure 1. DVH: dose-volume histogram

All the cases for training and validation were chosen without any pre-selection criteria. The limitation of this study is that it was trained and tested only with a maximum of 4 lesions per case. This was because in the cohort of patients that were treated, there were only 3 cases that had > 4 lesions, which essentially is not enough to train a model. As we treat and acquire data on more patients that have > 4 lesions, these can be incorporated into the model. Another limitation of this study is that the cases used for training were of smaller volume and were typically peripheral and far away from critical organs as well as from each other. This model therefore cannot be used for lesions that are overlapping with critical organs or for lesions in close proximity of each other.

The plans were slightly more inhomogeneous compared to the original clinical plans. This could be due to the fact that we used a line objective for the DVH in addition to the maximum point dose objective for the critical organ. Although the DVH for the PTV shows a longer tail, the dose inhomogeneity is contained within the target. We anticipate that with more training cases, the dosimetric results will improve. The GI was also slightly higher with the KBP plans than the recommended value of < 4. However the plans were dosimetrically very similar. Moreover, when a typical clinical plan would take at least 2 to 3 h to complete, the RapidPlan gave a clinically acceptable result in under 30 min.

The quality of the treatment plan generated by RapidPlan can only be as good as that of the treatment plans used to generate the DVH estimation model. Other technologies such as Hyperarc® are available from Varian Medical Systems that can automate SRS planning, however, they are currently unavailable with RapidPlan. This study demonstrates the feasibility of using RapidPlan as it pertains to a limited number of lesions (≤ 4). Going forward, we plan on expanding its training and application to > 4 lesions. In the future we plan to expand this to > 4 lesions and perform a comparison with plans generated using Hyperarc.

In conclusion, we have developed an efficient method for treatment planning of multiple cranial SRS lesions using VMAT and a single isocenter. This is a step not only towards a reducing the treatment planning time but also providing the planner a guide on the achievable dose distribution for the given case, thereby helping to standardize the quality of the treatment plans.

DECLARATIONS

Authors' contributions

Built the model, studied design, performed the dosimetric and statistical analysis: Dumane VA

Planned the clinical cases that were used for training and testing while building the model: Tseng TC

Designed the database used for obtaining patient treated with SRS using VMAT on Eclipse planning system: Sheu RD

Provided input towards study design and performed statistical analysis: Lo YC

Contributed towards writing the manuscript: Dumane VA, Tseng TC, Sheu RD, Lo YC, Gupta V, Saitta A, Rosenzweig KE, Green S

Participated in the study design, contouring of all the target volumes and critical organs, reviewing plans: Green S

Abstract

Breast cancer is the second leading cause of cancer-associated death in women in the United States, with more than 90% of those deaths attributed to metastasis. Breast cancer metastasis is incurable and possesses few treatment options and a poor overall prognosis due in part to confounding metastatic attributes, particularly the acquisition of dormancy-associated phenotypes. Dormant disseminated tumor cells can persist for years-to-decades before recurring as highly aggressive, secondary lesions. Dormancy-associated phenotypes are exhibited by breast cancer stem cells (BCSCs), which undergo tumor initiation and unlimited self-renewal. In addition to their specialized abilities to circumvent chemotherapeutic insults, BCSCs also upregulate autophagy during metastatic dormancy as a means to survive in nutrient poor conditions and environmental stress. As such, therapeutic targeting of autophagy is actively being pursued as an attractive strategy to alleviate metastatic disease and the recurrence of dormant BCSCs. Here we review the molecular and cellular features of autophagy, as well as its paradoxical role in both suppressing and promoting mammary tumor development and metastatic progression. Finally, we highlight the clinical challenges associated with therapeutic targeting of autophagy in metastatic breast cancers.

Keywords: Autophagy, breast cancer, cancer stem cells, metastatic dormancy, metastatic relapse

INTRODUCTION

Breast cancer is the second deadliest malignancy in women, accounting for nearly 41,000 deaths in the United States in 2018^[1]. More than 90% of the deaths attributed to breast cancer are caused by metastasis, a disease state associated with poor prognosis and little-to-no effective treatment options^[2]. Indeed, while initial treatment of breast cancers can be effective and achieve remission, an estimated 30% of lymph

node-negative and 70% of lymph node-positive breast cancer patients will eventually relapse 5-20 years following initial diagnosis^[3,4]. The period of time between clinical remission and relapse can be attributed to dormancy, a process whereby disseminated tumor cells (DTCs) enter a non-proliferative state coupled with the activation of cellular stress programs^[5]. Even in the earliest stages of mammary tumor development, breast cancer cells are actively shed from the growing tumor and traverse the metastatic cascade before colonizing distant metastatic sites^[6,7]. These solitary micrometastases can persist in distant organs for years or even decades before emerging as recurrent metastatic tumors. Indeed, experimental evidence and *in silico* modeling indicate that dormant DTCs exist in a quiescent state as opposed to one that reflects a balance between cell proliferation and apoptosis^[8-12]. Dormant cells upregulate pro-survival factors and are inherently chemoresistant given their non-proliferative state. As such, treatment with currently available therapeutics does little to limit the population of dormant cells in breast cancer patients. In fact, ~62% of breast cancer-associated deaths occur 5 years following diagnosis^[13]. As such, the clinical detection and treatment of these recurrent metastases remains challenging due to: (1) difficulties in detecting growing lesions years or decades following remission; (2) limited treatment options that are effective against metastatic disease^[14,15]. Despite the fact that systemic relapse following a period metastatic dormancy remains a large unmet clinical burden, the precise mechanism(s) that enable dormant metastatic lesions to reactivate proliferative programs and recur remains incomplete^[3]. Here we highlight the importance of breast cancer stem cells (BCSCs) and their reliance upon autophagy to govern the activation and eventual emergence from metastatic dormancy, as well as clinical implications of targeting autophagy therapeutically as a means to alleviate metastatic disease.

BCSCS AND METASTATIC DORMANCY: A ROUTE TO EVADE DETECTION AND THERAPEUTIC ELIMINATION

Recent evidence suggests that DTCs endowed with the ability to survive metastatic dormancy and initiate recurrent metastatic lesions are BCSCs^[16-18], which undergo unlimited self-renewal and contribute to tumor initiation^[19]. Likewise, genomic analyses of primary and relapsed metastatic breast cancers reveal numerous common driver mutations shared between primary and metastatic tumor lesions in a given patient. As such, these common mutational landscapes implicate the presence of a common malignant cell of origin and support the notion that disseminated BCSCs initiate recurrent metastatic lesions years or decades following clinical remission^[20-23]. This process reflects the ability of BCSCs to adopt dormancy-associated phenotypes through several malleable events, including modulation of E-cadherin and lncRNA expression^[24,25]. Equally important facets of metastatic relapse are the capacity of BCSCs to evade immune surveillance and resist therapeutic interventions aimed at eradicating residual disease. Amongst the pro-survival strategies activated by BCSCs are: (1) upregulated expression of ATP-binding cassette transporters that mediate cellular efflux of chemotherapeutic agents^[26-28]; (2) increased production of Interleukin-4 (IL-4) to suppress apoptosis^[29]; (3) enhanced generation of reactive oxygen species in response to radiation^[30]; (4) elevated activation of autophagy^[16-18,31] [Figure 1]. As such, dormant BCSCs are inherently resistant to traditional chemotherapeutic agents and radiation that target rapidly dividing tumor cells. In the succeeding sections, we highlight the role of autophagy in regulating mammary tumorigenesis and dormancy-associated phenotypes during metastatic progression and relapse.

CONTEXT-DEPENDENT ROLE OF AUTOPHAGY IN TUMOR PROGRESSION

Macroautophagy (hereafter referred to as autophagy) is a highly conserved process that maintains cellular homeostasis through the lysosomal degradation of proteins and organelles, a phenomenon that is tightly controlled by autophagy-related genes (ATGs)^[32]. The autophagosome cargo protein, p62/sequestosome 1 (SQSTM1), binds to degradation targets and facilitates selective autophagy^[33]. Indeed, during the activation of autophagy, ATGs mediate the recycling of p62/SQSTM1-tagged cargo through the formation of double-membrane vesicles, termed autophagosomes, which fuse with lysosomes to form autophagolysosomes. Lysosomal fusion facilitates the degradation of nonfunctional cellular components and also functions

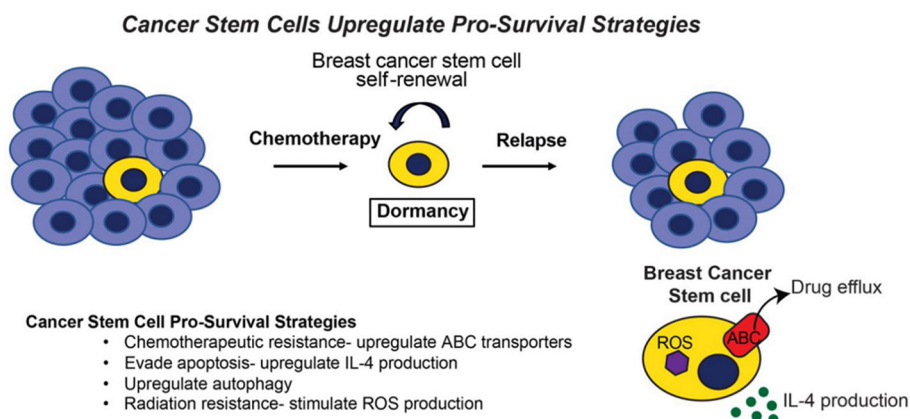

Figure 1. Cancer stem cells upregulate pro-survival strategies. Early in mammary tumor development, breast cancer cells are shed and disseminated from the growing lesion, ultimately colonizing distant metastatic sites before clinical detection of a primary breast tumor. Upon breast cancer diagnosis, neoadjuvant chemotherapy in conjunction with surgical resection, or more traditionally, surgery followed by adjuvant chemotherapy are both effective in eliminating the bulk the primary tumor cells. In contrast to bulk tumor cells, breast cancer stem cells manage to survive chemotherapeutic treatment by upregulating a number of pro-survival strategies, thereby contributing to metastatic relapse following a period of remission and dormancy. In doing so, cancer stem cells can (1) upregulate ABC transporter expression, which evades the cytotoxic activities of chemotherapies; (2) enhance IL-4 production, which inhibits apoptosis; (3) activate autophagy; (4) induce ROS production, which confers resistance to radiation. In addition, breast cancer stem cells also evade apoptosis by lying dormant for years or even decades, a pathophysiological state that further protects these cells from the cytotoxic activities of chemotherapy and radiation, and from the apoptotic activities engendered by metabolic, hypoxic, and environmental stressors

to meet the energy demands of a cell in periods of environmental stress^[32,34] [Figure 2]. Recent basic and clinical research findings have highlighted the context-dependent role of autophagy in regulating tumorigenesis. Indeed, in the earliest stages of tumor growth and development, autophagy functions as a tumor suppressor, thereby limiting tumor growth. However, once primary tumors or their metastases are established, autophagy can promote tumorigenesis by subverting stress responses, and consequently, facilitating tumor cell survival and disease progression^[35] [Figure 3]. At present, a thorough understanding of the molecular mechanisms that enable autophagy to both suppresses or promote mammary tumorigenesis is lacking, as are cell- and context-specific signals that underlie the paradoxical functions of autophagy in breast cancers. Future studies need to address these important questions as a means to uncover novel therapeutic strategies aimed at modulating autophagy in patients with metastatic breast cancer.

AUTOPHAGY AND TUMOR SUPPRESSION

Anecdotal evidence indicates that autophagy can act as a barrier to prevent tumor initiation in a number of solid tumors, including those of the breast. For instance, autophagy is readily induced by the tumor suppressors PTEN and p53, while their inactivation in developing neoplasms inhibits autophagy, as does oncogenic activation of PI3K/AKT and BCL2^[36]. Likewise, monoallelic deletion of the autophagy regulator, beclin-1, is observed in 40%-75% of breast and ovarian human tumors^[37], suggesting that autophagy functions to suppress tumor initiation. Accordingly, genetic inactivation of beclin-1 in mice predisposes their development of a variety of tumors, findings consistent with the notion that autophagy regulates cellular homeostasis and prevents tumor initiation^[37-39]. Furthermore, activation of the transcription factor NRF2 elicits deregulation of autophagy due in part to aberrant accumulation of p62/SQSTM1 that can promote tumor formation^[40-42]. Indeed, under tonic conditions, NRF2 interacts with Keap1, which targets NRF2 for ubiquitin-mediated degradation. The interaction between Keap1 and NRF2 can be prevented by the accumulation of p62/SQSTM1, thereby: (1) inhibiting the activation of autophagy; (2) stabilizing NRF2 expression, leading to its transcriptional activation^[40-43]. Finally, emerging evidence suggests a role for autophagy in maintaining genomic integrity, as metabolic stress induced by loss of autophagy can promote DNA damage and chromosomal instability^[44]. Indeed, when confronted with DNA damage, autophagy-

Autophagy: A Pro-Survival Strategy Employed by Breast Cancer Stem Cells

Figure 2. Autophagy: a pro-survival strategy employed by breast cancer stem cells. One of the pro-survival strategies employed by breast cancer stem cells during their acquisition of dormant states is autophagy, which facilitates the recycling of damaged or unnecessary organelles and/or proteins as a means to provide energy during periods of metabolic stress. Upon initiation of autophagy, the phagophore encircles those cellular contents targeted for autophagic degradation. LC3 is recruited to the phagophore and subsequently binds to the cargo adaptor protein, p62/SQSTM1. Upon doing so, a double membrane structure called the autophagosome forms and encircles cellular candidates for autophagic degradation. Subsequently, the autophagosome binds to the highly acidic lysosome to form the autophagolysosome, wherein p62/SQSTM1 bound cellular contents are degraded

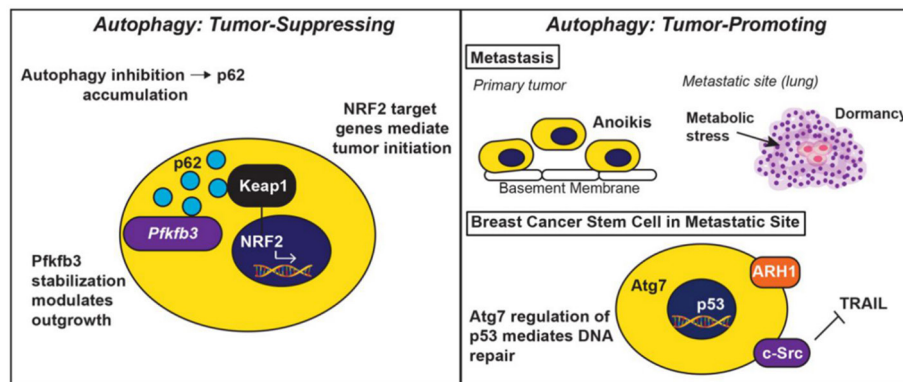

Figure 3. The tumor-suppressing and tumor-promoting activities elicited by autophagy. Autophagy functions to suppress tumor initiation (left panel), as well as to promote tumor development and progression (right panel). In early stages of tumor formation or during periods of metastatic dormancy, autophagy is tumor suppressive. Upon autophagy inhibition, p62/SQSTM1 accumulates and stabilizes Pfkfb3, leading dormant breast cancer stem cells to initiate metastatic relapse. Additionally, p62/SQSTM1 also inhibits the interaction between Keap1 and NRF2, thereby preventing NRF2-mediated expression of genes operant in tumor initiation (left panel). In stark contrast, autophagy provides established tumors with pro-survival phenotypes, including protection from anoikis and intrinsic cellular stressors encountered during metastatic dormancy. Likewise, autophagy protects breast cancer stem cells by ensuring for their resistance to the apoptotic stimuli housed within the metastatic microenvironment (e.g., Src-mediated TRAIL resistance), and to chemotherapeutic insults (e.g., Atg7-mediated p53 regulation of DNA repair). Finally, dormant cells can upregulate ARH1 to induce autophagy and promote the activation of pro-survival signaling systems that ensure for their survival

deficient cells exhibit diminished homologous recombination (HR) repair of damaged DNA that arises due to proteasomal degradation of checkpoint kinase 1 (Chk1)^[45,46]. While non-homologous end joining (NHEJ) appears to be largely unaffected by autophagy inhibition, the diminished HR proficiency in these cells can render them more sensitive to DNA damage, especially if NHEJ is subsequently impaired^[45,46]. Collectively, these findings identify important mechanisms whereby autophagy functions to suppress malignant transformation and tumor development.

AUTOPHAGY AND TUMOR PROMOTION

In contrast to its tumor suppressing functions, autophagy can also serve as a tumor promoting process, particularly by: (1) enhancing the ability of DTCs to traverse the metastatic cascade; (2) inhibiting

immunosurveillance by tumor infiltrating immune cells. During metastasis, cells shed from the primary tumor must invade through the extracellular matrix, intravasate into blood vessels, survive the turbid flow of the vasculature, extravasate, and finally colonize a distant metastatic site^[47]. Not surprisingly, cells traversing the metastatic cascade experience a variety of cellular stressors and vastly different tissue microenvironments, including changes in the (1) composition of the extracellular matrix composition; (2) availability of nutrients due to alterations in vascular and lymphatic networks; (3) biomechanical properties of metastatic sites; (4) tumor immunosurveillance programs^[48-50]. Importantly, autophagy activation protects DTCs during periods of metabolic stress encountered by anoikis and entry into foreign microenvironments^[51-53], and by bouts of dormancy at distant metastatic sites^[54,55].

AUTOPHAGY INHIBITS TUMOR IMMUNOSURVEILLANCE

Tumor immunosurveillance is a critical physiological process that inhibits the development and progression of mammary tumors. Accumulating data in the literature indicate that tumor immunosurveillance programs are an all-encompassing system that involves not only the adaptive immune system and cytotoxic effector pathways, but also the release of a complex set of cytokines and chemokines that coalesce to prevent tumor development^[50]. Although the molecular mechanisms used by tumor cells to escape immunosurveillance are varied, recent evidence has implicated a role for autophagy in mediating this phenomenon. Indeed, autophagy activation has been shown to inhibit immune cell killing of tumor cells as a means to promote escape from immunosurveillance and DTC outgrowth^[50]. In doing so, autophagy activation can target the activation of Signal Transducer and Activator of Transcription 3 (STAT3), a gene commonly dysregulated in breast cancer that also plays a prominent role in regulating the immune system^[56]. For instance, the activation of autophagy can induce the phosphorylation and stimulation of STAT3 in tumors, an event that initiates cellular cross-talk between tumor and immune cells that ultimately suppresses Cytotoxic T Lymphocyte (CTL)-mediated lysis of tumor cells^[56,57]. Likewise, autophagy can inhibit natural killer cell (NK)-mediated tumor cell killing by degrading granzyme B, a serum protease that is released by NK cells during NK-mediated cell killing^[58,59]. Finally, breast cancer development and metastatic progression is critically dependent upon Epithelial-Mesenchymal Transition (EMT) programs^[60]. Interestingly, autophagy is activated as carcinoma cells traverse the EMT program, with the resulting post-EMT mesenchymal-like cells exhibiting elevated levels of autophagy relative to their pre-EMT epithelial-like counterparts. Importantly, EMT-mediated activation of autophagy inhibits CTL-mediated antitumor immunosurveillance in a beclin-1-dependent manner^[50,61-63]. Collectively, these studies highlight the tumor intrinsic and extrinsic functions of autophagy, with the latter function, fulfilling an essential role in governing the fidelity of tumor immunosurveillance mechanisms.

DORMANT BCSCS AND AUTOPHAGY ACTIVATION

BCSCs can lie dormant for decades before recurring as metastatic lesions in breast cancer patients. During this time, disseminated BCSCs must survive nonpermissive tumor environments, while simultaneously maintaining their viability and the capacity for tumor initiation^[5,64]. Emerging evidence implicates autophagy as an essential feature in maintaining the phenotypes associated with BCSCs, particularly their resistance to chemotherapies and hypoxic microenvironments^[16,18,54,55,65-67]. The mechanisms whereby autophagy promotes BCSC survival at metastatic sites are varied and include the ability to confer resistance to apoptotic stimuli (e.g., Src-mediated TRAIL resistance in bone metastases^[68]), to chemotherapeutic insults (e.g., DNA repair via Atg7 and p53 by Atg7^[69]), and to cellular stressors^[70]. Similarly, aberrant expression of ARHI (aplasia Ras homolog member 1) can elicit autophagy activation and modulate the survival of dormant cells in preclinical models of ovarian cancer, further implicating autophagy as an essential mediator of dormant cell survival^[71]. Finally, tumor cells that possess defects in autophagy readily accumulate p62/SQSTM1, an event that alters p62/SQSTM1 function and contributes to tumorigenesis^[17]. The aforementioned studies highlight the oncogenic and pro-survival activities of autophagy that contribute to tumor progression, as well as the

acquisition and eventual emergence from metastatic dormancy. In the succeeding sections, we discuss the implications of targeting the dichotomous roles of autophagy in clinical settings.

CLINICAL TARGETING AND MODULATION OF AUTOPHAGY

Numerous clinical trials have aimed with varying degrees of success to inhibit or stimulate autophagy as a potential cancer therapeutic^[35]. Despite significant investments in preclinical and clinical investigations, no FDA-approved drugs designed to modulate autophagy have been approved for the treatment of primary or metastatic breast cancers. This clinical deficit reflects the challenges associated with the dichotomous roles played by autophagy during mammary tumor development and metastatic progression, and with the inability of science and medicine to fully appreciate the downstream consequences of autophagy modulation in metastatic disease settings.

INHIBITORS OF AUTOPHAGY

At present, nearly 32 human clinical trials have been undertaken to assess the efficacy of autophagy modulating agents [Table 1], either administered alone or in combination with standard-of-care chemotherapeutics (www.clinicaltrials.gov). Pharmacological inhibition of autophagy in clinical settings is primarily accomplished using chloroquine, or a closely related molecule, hydroxychloroquine. Chloroquine functions to block autophagosome-lysosome fusion by preventing the acidification of the lysosome, thus inhibiting autophagy^[72,73]. While the vast majority of studies include either chloroquine or hydroxychloroquine in combination with standard-of-care regimens, one recent study utilized a novel proteasome inhibitor, MLN9708, as a means to assess the impact of autophagy in conferring breast cancer resistance to the cytotoxic activities of doxorubicin^[74]. Interestingly, administration of MLN9708 to breast cancer cells resulted in autophagy activation in a manner paralleling previous connections between proteasomal inhibitor and autophagy^[75,76]. Moreover, MLN9708 enhanced the sensitivity of breast cancer cells to doxorubicin in a manner that was inversely correlated with the extent of autophagy activation^[74]. As such, future studies need to assess the effectiveness of combining proteasomal and autophagy inhibitors with cytotoxic chemotherapies (e.g., doxorubicin).

Additional translational insights into how autophagy inhibition impacts cancer cell survival has been accomplished using a combination of pharmacologic (e.g., chloroquine and/or hydroxychloroquine) and genetic (e.g., knockdown of autophagy associated genes) approaches. In general, these studies support the concept that inactivation of autophagy limits the development and spread of human cancers. Interestingly, recent evidence indicates that the molecular mechanisms underlying the cytotoxic activities of chloroquine and hydroxychloroquine are distinct from those employed to inhibit autophagy. Indeed, induction of lysosomal membrane permeabilization was insufficient to elicit apoptosis in cells treated with chloroquine. Rather, the cytotoxic activities of chloroquine were found to manifest subsequent to mitochondrial membrane permeabilization^[77], and to reduced expression and activity of JAK3 and DNMT1^[78]. Precisely how these alternative targets and activities attributed to chloroquine contribute to its clinical successes and failures remains an important line of research in the field of autophagy modulation.

STIMULATORS OF AUTOPHAGY

In light of the dichotomous activities autophagy plays during tumorigenesis, clinical investigation has also evaluated the impact of stimulating autophagy as a means to limit the growth and spread of cancers. Indeed, mTOR (mammalian target of rapamycin) is the primary pathway targeted pharmacologically as a means to induce autophagy in human breast cancers. For instance, several studies have investigated the importance of rapamycin^[79], Everolimus^[80,81], and Temsirolimus^[80,82] as potential inducers of autophagy in clinical settings. In general, autophagy activation elicited in response to mTORC1 inactivation is a byproduct of the intended

Table 1. Cancer clinical trials evaluating autophagy modulation

Clinical trial title	Status	Conditions	Interventions
Autophagy Bladder Cancer	Not yet recruiting	Bladder Cancer	
Sorafenib Induced Autophagy Using Hydroxychloroquine in Hepatocellular Cancer	Recruiting	Hepatocellular Cancer	Drug: Sorafenib (SOR) Drug: Hydroxychloroquine (HCQ)
A Phase I/II/Pharmacodynamic Study of Hydroxychloroquine in Combination With Gemcitabine/Abraxane to Inhibit Autophagy in Pancreatic Cancer	Active, not recruiting	Advanced Adenocarcinoma Metastatic Adenocarcinoma	Drug: Hydroxychloroquine (HCQ) Drug: Gemcitabine
Hydroxychloroquine, Palbociclib, and Letrozole Before Surgery in Treating Participants With Estrogen Receptor Positive, HER2 Negative Breast Cancer	Recruiting	Anatomic Stage I Breast Cancer AJCC v8 Anatomic Stage IA Breast Cancer AJCC v8 Anatomic Stage IB Breast Cancer AJCC v8 Anatomic Stage II Breast Cancer AJCC v8 Anatomic Stage IIA Breast Cancer AJCC v8 Anatomic Stage IIB Breast Cancer AJCC v8 Anatomic Stage III Breast Cancer AJCC v8 Anatomic Stage IIIA Breast Cancer AJCC v8 Anatomic Stage IIIB Breast Cancer AJCC v8 Anatomic Stage IIIC Breast Cancer AJCC v8 Anatomic Stage IV Breast Cancer AJCC v8 Estrogen Receptor Positive HER2/Neu Negative MKI67 Positive Postmenopausal Prognostic Stage I Breast Cancer AJCC v8 Prognostic Stage IA Breast Cancer AJCC v8 Prognostic Stage IB Breast Cancer AJCC v8 Prognostic Stage IIA Breast Cancer AJCC v8 Prognostic Stage IIB Breast Cancer AJCC v8 Prognostic Stage III Breast Cancer AJCC v8 Prognostic Stage IIIA Breast Cancer AJCC v8 Prognostic Stage IIIB Breast Cancer AJCC v8 Prognostic Stage IIIC Breast Cancer AJCC v8 Prognostic Stage IV Breast Cancer AJCC v8	Drug: Hydroxychloroquine Drug: Letrozole Drug: Palbociclib
Imaging Tumor Hypoxia With 18F-EF5 PET in Recurrent or Metastatic Clear Cell Ovarian Cancer	Active, not recruiting	Ovarian Cancer Ovarian Neoplasms	Drug: 18F-EF5 PET/CT scan Procedure: Optional biopsy
Enzalutamide and Metformin Hydrochloride in Treating Patients With Hormone-Resistant Prostate Cancer	Active, not recruiting	Prostate Cancer	Drug: Enzalutamide Drug: Metformin Hydrochloride
Vorinostat Plus Hydroxychloroquine Versus Regorafenib in Colorectal Cancer	Recruiting	Colorectal Cancer	Drug: Vorinostat Drug: Hydroxychloroquine Drug: Regorafenib
Sirolimus or Vorinostat and Hydroxychloroquine in Advanced Cancer	Active, not recruiting	Advanced Cancers	Drug: Hydroxychloroquine Drug: Sirolimus Drug: Vorinostat
MLN9708 and Vorinostat in Patients With Advanced p53 Mutant Malignancies	Active, not recruiting	Advanced Cancers	Drug: MLN9708 Drug: Vorinostat
Akt Inhibitor MK2206 and Hydroxychloroquine in Treating Patients With Advanced Solid Tumors, Melanoma, Prostate or Kidney Cancer	Active, not recruiting	Adult Solid Neoplasm Hormone-Resistant Prostate Carcinoma Recurrent Melanoma Recurrent Prostate Carcinoma Recurrent Renal Cell Carcinoma Stage IIIA Cutaneous Melanoma AJCC v7 Stage IIIB Cutaneous Melanoma AJCC v7 Stage IIIC Cutaneous Melanoma AJCC v7 Stage IV Cutaneous Melanoma AJCC v6 and v7 Stage IV Prostate Cancer AJCC v7 Stage IV Renal Cell Cancer AJCC v7	Drug: Akt Inhibitor MK2206 Drug: Hydroxychloroquine Other: Laboratory Biomarker Analysis Other: Pharmacological Study
Hydroxychloroquine + Vorinostat in Advanced Solid Tumors	Active, not recruiting	Malignant Solid Tumour	Drug: Hydroxychloroquine Drug: Vorinostat
Novel Molecular Targets for Ductal Carcinoma In Situ (DCIS)	Active, not recruiting	Breast Cancer	Other: Biomarkers
Observational Study of Biomarker During Liver Surgery	Recruiting	Liver Cancer Hepatobiliary Tract Adenomas and Carcinomas	Procedure: Hepatocellular carcinoma
Pantoprazole and Docetaxel for Men With Metastatic Castration-Resistant Prostate Cancer	Active, not recruiting	Prostate Cancer	Drug: Pantoprazole

A Randomized, 2x2 Factorial Design Biomarker Prevention Trial of Low-dose Aspirin and Metformin in Stage I-III Colorectal Cancer Patients.	Recruiting	Tertiary Prevention in Colon Cancer	Drug: Aspirin (ASA) + Metformin (MET) Drug: ASA Drug: MET Drug: Placebos
Randomized Phase II Trial of Pre-Operative Gemcitabine and Nab Paclitaxel With or Without Hydroxychloroquine	Active, not recruiting	Pancreatic Cancer	Drug: gemcitabine Drug: abraxane Drug: hydroxychloroquine
The Treatment of Advanced Lung Cancer With Dribbles Antigen by Targeting Activation of Tcells	Not yet recruiting	Carcinoma, Non-Small-Cell Lung	Biological: Dribble vaccine
Pre-Operative Trial (PGHA vs. PGH) for Resectable Pancreatic Cancer	Recruiting	Pancreatic Cancer Resectable	Drug: Gemcitabine, Nab-Paclitaxel, hydroxychloroquine and Avelumab Drug: Gemcitabine, Nab-Paclitaxel, and hydroxychloroquine
Sunitinib Malate and Hydroxychloroquine in Treating Patients With Advanced Solid Tumors That Have Not Responded to Chemotherapy	Active, not recruiting	Adult Solid Neoplasm	Drug: Hydroxychloroquine Other: Laboratory Biomarker Analysis Other: Pharmacological Study Drug: Sunitinib Malate
The Role of Fibroblast Activation in Uterine Fibroid	Not yet recruiting	Uterine Fibroid	Genetic: Measurement of protein expression in tissue and/or blood samples.
International Cooperative Phase III Trial of the HIT-HGG Study Group (HIT-HGG-2013)	Recruiting	Glioblastoma WHO Grade IV Diffuse Midline Glioma Histone 3 K27M WHO Grade IV Anaplastic Astrocytoma WHO Grade III Diffuse Intrinsic Pontine Glioma Gliomatosis Cerebri	Drug: Temozolomide + Valproic Acid Drug: Temozolomide + Chloroquine
Short Course Radiation Therapy With Proton or Photon Beam Capecitabine and Hydroxychloroquine for Resectable Pancreatic Cancer	Active, not recruiting	Pancreatic Cancer	Drug: Capecitabine Drug: Hydroxychloroquine Radiation: Proton or Photon Radiation Therapy
Androgen Deprivation Therapy Muscle Protein Metabolism and Blood Glucose	Recruiting	Prostate Cancer Resistance	Drug: Zoladex
Autophagy Inhibition to Augment mTOR Inhibition: A Phase I/II Trial of RAD001 and Hydroxychloroquine in Patients With Previously Treated Renal Cell Carcinoma	Active, not recruiting	Metastatic Clear Cell Renal Cell Carcinoma	Drug: Hydroxychloroquine Drug: RAD001
Dabrafenib/Trametinib/Hydroxychloroquine for Advanced Pretreated BRAF V600 Mutant Melanoma	Recruiting	Melanoma	Drug: Dabrafenib Drug: Trametinib Drug: Hydroxychloroquine
The Addition of Chloroquine to Chemoradiation for Glioblastoma,	Not yet recruiting	Glioblastoma Astrocytoma, Grade IV	Drug: Chloroquine
The Addition of Chloroquine to Chemoradiation for Glioblastoma	Recruiting	Glioblastoma Multiforme	Drug: Chloroquine Radiation: Radiotherapy Drug: Temozolomide
Gemcitabine, Docetaxel, and Hydroxychloroquine in Treating Participants With Recurrent or Refractory Osteosarcoma	Recruiting	Recurrent Osteosarcoma Refractory Osteosarcoma	Drug: Docetaxel Drug: Gemcitabine Drug: Hydroxychloroquine
The BAMM Trial: BRAF, Autophagy and MEK Inhibition in Metastatic Melanoma: A Phase I/2 Trial of Dabrafenib, Trametinib and Hydroxychloroquine in Patients With Advanced BRAF Mutant Melanoma	Recruiting	Advanced BRAF Mutant Melanoma	Drug: Trametinib 2 mg daily Drug: hydroxychloroquine (HCQ)
Characterization of the Mechanisms of Resistance to Azacitidine	Recruiting	Myelodysplastic Syndromes or Acute Myeloid Leukemia With Multilineage Dysplasia	
TN-TC11G (THC+CBD) Combination With Temozolomide and Radiotherapy in Patients With Newly-diagnosed Glioblastoma	Not yet recruiting	Glioblastoma	Drug: TN-TC11G Drug: Temozolomide Oral Product Radiation: Radiotherapy
Hepatocellular Carcinoma in Patients With a Cirrhosis Due to an Alcoholic or a Non Alcoholic Fatty Liver Disease	Recruiting	Hepatocellular Carcinoma	Other: blood collection

List of clinical trials (www.clinicaltrials.gov) that are currently active, recruiting, or not yet recruiting patients for clinical trials to study how autophagy modulation, primarily through chloroquine or hydroxychloroquine treatment, influences tumor growth and progression

drug target, thereby producing synergistic cell killing in the form of autosis (i.e., autophagic cell death^[83]). Along these lines, several clinical trials associated with mTOR modulation have sought to overcome endocrine resistance associated with hormone receptor positive breast cancer treatments. Unfortunately, single agent modification of autophagy by administration of mTOR pathway inhibitors has proven to be

highly ineffective at restoring endocrine sensitivity to estrogen receptor-positive breast cancers. Likewise, combining autophagy modulators with anti-estrogens has also failed to significantly improve the clinical course of these patients, with severe toxicities being associated with Everolimus^[80]. Thus, similar to the strategy of autophagy inhibition, the clinical utility of autophagy activation to eliminate metastatic breast cancers awaits additional mechanistic and translational investigation.

CONCLUSION

Metastatic dormancy is mediated by BCSCs and responsible for the majority of breast cancer-associated deaths. An inherent property of BCSCs reflects their ability to activate a variety of pro-survival strategies to circumvent metabolic stress within the metastatic niche, and to overcome therapeutic insults mediated by chemotherapies and radiation. The activation of autophagy has proven to be a critical component of the pro-survival strategies employed by BCSCs, especially when confronted with nutrient deprivation, with inhospitable tissue microenvironments, with cytotoxic agents, and with dormancy-associated phenotypes. Indeed, preclinical evidence implicates important roles for autophagy modulation in the treatment of breast cancer. However, the paradoxical functions of autophagy to both suppress and promote tumorigenesis has clearly hampered the development and implementation of effective autophagy modulators for the treatment of metastatic breast cancer. Accordingly, several important avenues of basic and clinical investigation need to be achieved in order to generate effective autophagic agents. First, studies need to determine the extent to which chemotherapeutic drugs rely upon autophagy modulation when inducing their cytotoxic activities in target cells. Indeed, these so-called “off-target” effects on autophagy may underscore either directly or indirectly the extent to which a therapeutic regimen is effective, or alternatively, is rendered insensitive. Second, additional efforts need to be directed at identifying improved autophagy modulating drugs, particularly those that are effective against metastatic disease. Third, enhancing our understanding of how the tumor microenvironment impacts the targeting of autophagy-directed drugs is also warranted^[84-86]. Finally, efforts directed at developing biomarkers capable of identifying patients most likely to benefit from autophagy modulation needs to be undertaken to minimize potential untoward side effects (e.g., disease progression, emergence from dormancy, and metastatic relapse) of this course of treatment. Ultimately, addressing these research avenues will provide new inroads for strategies aimed at targeting autophagy vulnerability in BCSCs, and consequently, at eliminating metastatic relapse.

DECLARATIONS

Acknowledgments

Members of the Schiemann Laboratory are thanked for critical comments and reading of the manuscript.

Abstract

Breast cancer remains the main cause of cancer-related mortality for women world-wide. Main cause of death is the development of therapy-resistant metastases. Relapses occur with a bimodal temporal distribution, with a first peak at 1-2 years after initial therapy and a second peak 2-3 years later. This discontinuous growth kinetics is consistent with the notion that disseminated cancer cells can remain dormant over a prolonged period of time before resuming growth. How cancer cells enter, sustain and exit dormancy, are unanswered questions with relevance to cancer biology, monitoring and therapy. Investigating mechanisms of breast cancer dormancy remains challenging, as in patients the condition is elusive and experimentally there are only a few models that recapitulate the clinical condition. Thus, developing new models to identify clinically relevant mechanisms and candidate therapeutic targets may open new avenues for novel therapies to induce and prolong dormancy. We have observed that cells surviving chemotherapy can enter a state of immunological dormancy. Using this model, we identified IRF-7/Interferon type I/IFNRA as signaling axis essential for this effect. Here we will review concepts and recent developments in cancer metastasis and dormancy with emphasis on breast cancer, and elaborate strategies to exploit them therapeutically.

Keywords: Breast cancer, chemotherapy, resistance, dormancy, T lymphocytes, interferon

INTRODUCTION

With a few exceptions, as in the case of brain or liver cancer, the main cause of cancer-related death is not the primary tumor itself but rather the formation of secondary tumors, so called metastases, in vital organs,

in particular lung, liver, bone or brain, leading to organ destruction and failure, resistance to therapy and cachexia^[1,2]. Metastasis formation is believed to be a highly inefficient process^[3]. The main rate limiting step in the metastatic process appears to be the ability of tumor cells to adapt to the new environment^[4,5]. During this adaptation step at the metastatic site, cells have to establish bidirectional paracrine communication with a new tissue different from the primary site, acquire novel survival capacities and escape immune destruction. While cell autonomous processes, such as genetic evolution and epigenetic modifications, altered gene expression and metabolic adaptation, are essential to the metastatic process, the microenvironments of the primary tumor and of the metastatic site are equally critical determinants of metastasis formation^[5-8]. Tumor angiogenesis, the remodeling of the extracellular matrix, the activation of local resident cells and the recruitment of inflammatory cells provide essential contributions to the metastatic process, including in breast cancer^[9-11]. At diagnosis, only a minority of cancers have already formed clinically overt metastases (i.e., stage IV)^[12]. Those that progress to metastatic disease can do with strikingly different kinetic. For example, lung and colorectal cancers mostly relapse within 1-3 years after diagnosis and the 5-year survival rates for these cancers are about 20% and 60%, respectively^[13,14]. Conversely, in prostate cancer relapses occur late, with over 90% of the patients still alive 15 years after initial diagnosis^[15]. In breast cancer, relapses occur with a peculiar bimodal distribution: a first peak appears generally 1-2 years and a second peak 4-5 years after surgery, followed by a tailed extension up to 15 years^[16,17].

BREAST CANCER SUBTYPES AND ADJUVANT THERAPIES

Breast cancer is the most common cancer diagnosed among women. In spite of improved management over the past 30 years, it remains the leading cause of cancer-related mortality for women world-wide^[18]. Therapy and prognosis are largely determined by the biological and molecular characteristics of the primary tumor and its size and spreading at time of diagnosis^[19,20]. There are three main clinically relevant biological subtypes: Oestrogen/Progesterone receptor positive breast cancer (ER⁺/PR⁺), HER2 amplified (HER2⁺) breast cancer and Triple Negative Breast Cancer (TNBC; i.e., ER⁻, PR⁻, HER2⁻)^[21-23]. Based on gene expression signatures four main molecular subtypes have been reported: Luminal A and B, HER2⁺, and basal-like, which overlap largely, but not fully with the ER⁺/PR⁺, HER2⁺ and TNBC biological subtypes, respectively^[24,25]. Both biological and molecular classifications have prognostic and predictive (therapeutic) relevance^[19,20,24,25]. ER⁺ tumors are treated with adjuvant anti-estrogen therapies (e.g., tamoxifen) while HER2⁺ tumors are treated with HER2 inhibitors (e.g., trastuzumab), in addition to radiotherapy and chemotherapy, if necessary^[19,26]. TNBC, has no molecular target useful for targeted therapy yet and adjuvant radio- and chemotherapies are still the standards of care^[22,27]. The rationale for administering adjuvant therapy after surgery is to eradicate disseminated tumor cells (DTC) or micro-metastases to decrease the risk of relapse. A large body of evidence from adjuvant studies suggest that ER⁺ breast cancer benefits less from chemotherapy compared to ER⁻ breast cancer^[28]. This is particularly true for the luminal A molecular subtype of ER⁺ breast cancer, which has a low rate of proliferation. Luminal A tumors have lower rates of pathologic complete response to chemotherapy compared to the highly proliferative ER⁺ luminal B breast cancer subset, as demonstrated with neo-adjuvant anthracycline/taxane-based chemotherapy^[29,30]. For HER2⁺ breast cancer the introduction of HER2 inhibitors as adjuvant therapy, in combination with taxane-based chemotherapy, has vastly decreased the risk of metastatic progression and greatly improved survival in this cancer subtype^[23,31]. TNBC is highly proliferative and respond better to chemotherapy compared to ER⁺ cancers^[22,32]. Today no established targeted therapy exists for TNBC^[33]. Interestingly, a fraction of TNBC are rich in tumor infiltrating lymphocytes and this infiltration has been associated with improved disease-free survival and overall survival OS, suggesting that immune cells may contribute to therapy success and implying the possibility of applying check-point inhibitors-based immunotherapies for these patients^[10,22].

In spite of an approx 30%-35% decrease in mortality over the past 35 years due to combined systematic early detection and improved adjuvant therapies, there are still about 20%-25% of breast cancer patients, all stages combined, that will eventually succumb to their disease due to formation of therapy resistant metastases.

This corresponds to about 95,000 and 40,000 women in Europe^[1] (EU 28) and the United States^[2], dying every year, respectively^[18,19,34]. As of today, there are no effective, curative therapies for metastatic disease. Therapy-resistance and therapy-related toxicity limit therapeutic options^[35].

METASTATIC DISSEMINATION

Cancer metastases is a multistage process. Cancer cells have to first escape from the primary tumor, survive in the circulation as circulating tumor cells (CTC), seed at distant sites as DTC and grow to colonize the new tissue and form secondary tumors^[36-38]. Growing evidence indicates that metastases are formed by a subset of tumor cells with “stem cell-like” features^[39-41] that also associated with resistance to treatments and dormancy^[42-44]. Accordingly, molecules controlling stem cell maintenance and differentiation^[10,22,45] have been implicated in metastasis, including Wnts, BMPs, TGF β family members, Notch, CD44 and integrins^[46,47]. Cancer stem cells (CSCs), in contrast to normal adult stem cells, seem able to revert the hierarchy so that a differentiated cancer cell can revert and recover the stem-like features, while normal, differentiated somatic cells are not able to do so. Thus, CSCs may be rather defined by function than lineage and may represent a form of adaptation of cancer cells to cellular or microenvironmental stress^[48-50]. This plasticity may be one reason why by eliminating CSCs as proposed as a new therapeutic approach to eradicate cancer, may actually not be as effective as anticipated^[51-54]. Acquisition of CSCs traits has been associated with Epithelial-to-Mesenchymal Transition (EMT), a condition endowing cancer cells with increased migratory, invasive, metastatic and therapy resistance capacities^[53,55,56]. For example, breast cancer cells undergoing EMT acquire a cell surface phenotype (i.e., CD44^{high}/CD24^{low}) associated with CSCs properties^[57]. Accordingly, EMT is a reversible process, as cells that disseminated through EMT and lost epithelial features, can revert back to their epithelial phenotype through an opposite process called Mesenchymal-to-Epithelial Transition (MET)^[8]. Both CSCs and EMT are features that are heavily influenced by the microenvironment such as the vascular niches or inflammation (See below).

The genetic and epigenetic basis of metastasis is still not fully elucidated^[58]. A current paradigm relies on the notion that the accumulation and selection of genetic mutations and epigenetic alterations is the basis of clonal evolution at the primary site and metastatic dissemination is its ultimate expression^[59]. This notion is supported by the clinical observation that primary tumor size is a main risk factor for metastasis. This suggests that metastasis formation occurs rather in late disease stage as the end product of an evolutionary processes in the primary tumor (linear model of metastasis)^[8,37,60,61]. According to this model many driver mutations found in the primary tumor are present at the metastatic site, and only a few additional mutations accumulate between primary tumor and metastases^[62-64], including in breast cancer^[65-68]. In the other hand, comparative genomic hybridization analysis in breast and other cancers revealed that DTCs display significantly more genetic aberration than in the primary tumors^[69-72]. These observations imply that metastatic cells disseminate early during tumor development and then progress independently from the primary tumor through multiple steps of genetic mutations. Therefore, the parallel progression model of metastasis has been proposed^[60]. Importantly, the two models are not mutually exclusive: a first vague of cancer cells may disseminate early during tumor formation, for example at the time of oncogene activation or EMT induction^[73-75], followed by the late dissemination of cells that acquired metastatic properties through local evolution^[64,76]. Recently, evidence for the parallel progression model in breast cancer was reported by using experimental models. By studying metastasis in a HER2-driven murine model of breast cancer, Harper *et al.*^[77] showed that cancer cells migrate away from early lesions shortly after HER2 activation. In this model over 80% of the metastases were derived from early disseminated cancer cells. Using the MMTV-HER2 breast tumor model, Harper *et al.*^[77] identified a subpopulation of ERBB2⁺/p-p38^{low}/p-ATF^{low}/TWIST1^{high}/E-CAD^{low} early cancer cells that are invasive and can spread to distant organs (early disseminated cancer cells - eDCC). By using intra-vital imaging they showed that ErbB2⁺ eDCC precursors invaded locally, intravasated and lodged in target organs through a WNT-dependent EMT-like dissemination program. Strikingly, although the majority of eDCCs were TWIST1^{high}/E-CAD^{low} and

dormant, they eventually formed metastasis. This experimental observation supports the notion that DTC/DCC can remain dormant for prolonged periods before resuming growth to form macroscopic metastases. As current adjuvant treatment in breast cancer seems to have reached a plateau in term of survival benefits, understanding how DTC and micro-metastases adapt to the distant environment, survive and eventually resume growth to form macroscopic metastases may identify new therapeutic opportunities^[1,8,78].

In both the linear and parallel tumor progression models, the genomic instability of tumor cells is the basis of the evolutive process. The variability emerging among tumor cells within the same tumor tissue is referred to as intratumoral heterogeneity and is also found within metastases^[79]. This heterogeneity may also be responsible to the presence of tumor cells with low and high tumorigenic potentials, the latter being CSCs or cancer initiating cells (CICs)^[80]. Moreover, it is believed that heterogeneity also exists inside the CSC population itself. In such a scenario, metastasis progression and resistance to anti-tumor treatment are thought to be due to clonal evolution and selection much alike Darwinian evolution^[59]. Intratumoral heterogeneity may also contribute to tumor dormancy or escape from it. Marusyk *et al.*^[81] have used the MDA-MB-468 tumor cell model *in vivo* to show that a IL-11 expressing tumor population is able to drive non-cell-autonomous tumor growth from dormant tumor cells. This indicates that re-establishment of certain heterogeneity is necessary for tumor growth after seeding or treatment. In line with this observation, Aceto *et al.*^[82] have reported that, CTC clusters have higher ability to seed metastasis compared to single CTC, involving at least in part altered DNA methylation^[83]. Furthermore, Kmiecik *et al.*^[84] showed that the heterogeneity of breast cancer cells in the levels of IFN- γ receptor α expression could determine a selective dormancy. Tumor cells expressing high levels of IFN- γ receptor α are eliminated by CD8⁺ T cells, while tumor cells with low expression levels do not die and remain dormant in the presence of IFN- γ producing CD8⁺ T cells. Thus, tumor heterogeneity contributes to tumor dormancy by providing cells with different genetic and biological features.

METASTATIC BREAST CANCER DORMANCY

As mentioned before, breast cancer metastasis occurs with a bimodal distribution with two peaks: a first one 1-2 years and a second one at 4-5 years after surgery, followed by a tailed extension up to 15 years^[17,85,86]. These observations are inconsistent with a model of continuous growth kinetics and rather suggestive of discontinuous growth, thereby implying a period of dormancy^[16,17,85-87]. Clinical observations also revealed that timing of appearance of metastasis has a similar profile for the different breast cancer subtypes, suggesting that after primary tumor removal, DTC from distinct subsets evolve following similar patterns but with different dominances (i.e., TNBC and HER2⁺ cancers tend to relapse at the early peak, compared to ER⁺/PR⁺ cancer which tend to relapse at the second peak or later^[85,86,88,89]). These observations also suggest that relapses occurring at peaks may follow inducible and reproducible patterns based on defined mechanisms, for example tumor surgery^[90], while relapses occurring in between or in the tailed extension may be due to unpredictable or random events, such as genetic mutations, epigenetic modifications or unrelated inflammatory events^[65,67,68,91,92]. Accordingly, these clinical observations were modelled mathematically by considering known basic hazard rates and unknown variables^[93,94]. Dormant disseminated cancer cells and micrometastases have been reported in breast cancer patients^[95] and in experimental animal models^[77,96-98]. Although dormancy is a common phenomenon in breast cancer, the underlying biological mechanisms remain ill characterized. Dormancy might be functionally considered as a transitional, metastable step of cell adaptation to a novel external stress, in particular a “foreign” soil. DTC lacking survival capabilities would rapidly die, while those that have acquired the latter would immediately grow to form macroscopic metastases without latency [Figure 1]. Mechanistically, three forms of cancer dormancy have been described and many genes and molecules involved identified^[99-102]: cellular dormancy, microenvironmental (angiogenic) dormancy and immunological dormancy. These three forms of dormancy are not mutually exclusive and it is likely that clinical dormancy is owed by their combination and interrelation.

Figure 1. Dormancy in cancer progression. Tumor cells can leave the primary tumor site and enter the systemic circulation as circulating tumor cells (CTCs). Once surviving CTCs have reached a target organ, they seed into a new tissue as disseminated tumor cells (DTCs). Their fate is diverse depending on their cell autonomous capacities and complementary cues provided by the local environment. DTCs can rapidly die if they fail to adapt to the new condition or are killed by the immune system. They can immediately resume proliferation if they have acquired full autonomy for cell survival and proliferation or the local microenvironment provide missing complementary cues. In addition, proliferating cells have to evade the immune system. Alternatively, DTC or small tumor cell clusters, can enter a state of dormancy if cell autonomous or microenvironmental signals are sufficient to maintain survival but do not effectively support growth or the immune system keeps them in check by preventing their expansion. Dormant tumor cells can eventually die by exhaustion, be killed by the immune system or resume proliferation and generate clinically relevant metastases at later time points

CELLULAR DORMANCY: SURVIVAL OF NON-PROLIFERATING SOLITARY CELLS

Dormant DTC cells have developed mechanisms of survival in a foreign environment, but not yet those allowing unrestricted growth. They enter a state of cell cycle arrest (i.e., G₀-G₁) and survive as non-proliferating solitary cells or as small cell clusters. Accordingly, solitary dormant cancer cells should be negative for the proliferation marker Ki67 as well as for apoptosis markers such as the terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL). Entry into dormancy and subsequent reactivation seem to be regulated by intrinsic programs and by contextual cues, similar to those involved in the physiological regulation of adult tissue stem cells^[103]. Lack of signaling from the matrix seems to play a role in this form of dormancy, as loss of $\alpha 5 \beta 1$ integrin expression or function and inhibition of uPAR induce dormancy through the inhibition of the RAS-RAF-ERK signaling pathway, activation of p38/JNK signaling, and induction of p53/Rb-dependent cell-cycle arrest^[103-105]. By studying DTC in an experimental model of head and neck squamous cell carcinoma, Sosa *et al.*^[106] have shown that epigenetic upregulation of orphan nuclear receptor NR2F1 (COUP-TF1) plays a critical role in maintaining DTCs in a dormant state. This finding has been further extended by a study in breast cancer patients, in which NR2F1 was tested as a dormancy marker. Breast cancer patients with < 1% NR2F1^{high} DTC in bone marrow aspirate had all systemic relapse within 12 months, while only half of the patients with > 50% NR2F1^{high} remained metastasis-free^[107].

Alterations in cell signaling have been found associated with tumor dormancy. High levels of ERK1/2 activity lean toward a higher proliferation, so the ratio of ERK1/2 to p38 MAPK regulates the cell cycle suggesting that the cross talk between mitogenic and stress signals may be relevant to induce cellular dormancy^[108]. Impinging on the PI3K signaling cascade was shown to lead to quiescence and the activation of autophagy^[109]. Dormant tumor cells express high levels of ARHI, an inhibitor of the PI3K-AKT cascade, and ARHI silencing awakens dormant cells of several tumor types, and promotes their proliferation^[110,111]. Consistently, very low or absent AKT signaling in DTC from breast cancer patient has been shown to correlate with the state of dormancy^[112]. Strikingly, however, mTOR, a known target of AKT, is found to be

activated in quiescent cancer cells. This activation is independent of AKT and is maintained by the small GTPase RHEB with anti-apoptotic activity and itself under control of the stress-regulated transcription factor ATF6 α and high p38 kinase activity. Thus, mTOR seems to be a critical node integrating diverse signaling pathways regulating dormancy^[111,113,114]. Recently Malladi *et al.*^[115] have shown that human breast and lung carcinoma cells express stem-cell like SOX transcription factors, which induces autocrine expression of DKK1, a WNT inhibitor, resulting in a state of metastatic latency and immune evasion consistent with dormancy.

Interaction with the extracellular matrix is also implicated in controlling dormancy^[116], paralleling the role of cell-matrix interaction in physiological CSC niches^[117]. For example, the uPAR interaction with $\alpha 5 \beta 1$ integrin increases ERK activity and integrin binding to fibronectin fibrils suppresses p38 activity, increases ERK activity and promotes cell proliferation. Accordingly, low uPAR-expressing cells that are growth arrested (dormant) *in vivo*, have a high p38/ERK activity ratio and fail to assemble fibronectin fibrils and ligate $\alpha 5 \beta 1$ integrin^[104]. Integrin $\alpha 5 \beta 1$ was shown to promote survival of growth-arrested breast cancer cells reminiscent of breast cancer dormancy in bone marrow^[118]. Collagen-rich matrix (fibrosis) at the metastatic site is also a critical determinant of DTC transition from dormancy to metastatic growth^[116]. For instance, hepatocellular carcinoma cells that colonize rigid matrix resume growth and proliferation through TGF- $\beta 1$ signaling, while cells colonizing a softer matrix remain dormant^[116]. The proliferative switch of dormant DTCs in response to fibrosis in a mouse model of breast cancer was shown to be also mediated by $\beta 1$ integrin^[116]. 3D-in vitro models and further *in vivo* studies demonstrated the critical role of type I collagen in the proliferative fate of DTCs^[119-121]. Another matrix protein, periostin, produced by TGF- $\beta 1$ -stimulated stromal fibroblasts and angiogenic blood vessels^[47,122], can drive DTCs escape from dormancy through WNT signaling in breast carcinoma^[123]. Interfering with extracellular matrix-integrin interaction, in particular $\beta 1$ integrins, has been proposed as therapeutic approach to promote dormancy, including in breast cancer^[124,125].

Autophagy appears to promote DTCs survival and dormancy by maintaining DTCs viable under conditions of microenvironmental stress^[126]. Autophagy also promotes survival of DTC against chemotherapy-induced cell stress^[126]. On the other side, in breast cancer the lack of autophagy is associated with early tumor recurrence and escape from dormancy^[127]. It is important to note, that cellular dormancy is not just a feature of cancer cells but it also occurs in normal cells. For example, hair follicle (bulge) stem cells, muscle stem cells (satellite cells), hematopoietic and liver stem cells are rather quiescent under homeostatic conditions and can be rapidly activated during tissue regeneration and repair^[128-130]. These observations raised the idea that cancer cells may hijack the signaling cascade used physiologically by these cells to enter, maintain and exit dormancy during homeostatic and regenerative conditions^[103,131].

SENESCENCE, A SPECIAL FORM OF CELLULAR DORMANCY?

The term senescence was originally introduced to describe primary human fibroblasts in culture, that after reaching a maximal number of passages (cell divisions) entered a state of permanent growth arrest^[132,133]. Senescent cells remain metabolically and synthetically active but show significant alterations in morphology^[132-134]. Following these original observations, scientists discovered that replicative senescence is driven by telomere shortening^[135]. Telomerase, an enzyme reconstituting telomers, is expressed in germ line cells, early embryonic cells, but not in normal cells, and is re-expressed in most cancer cells^[134]. Besides telomere shortening, other stimuli have been found to induce the senescence^[136] including DNA damage^[137], chemotherapy^[138] and oncogene activation^[139]. Despite the nature of the stimulus initiating the senescence cascade, the signals ultimately converge to the p53/p21 and/or p16^{INK4a}/pRB pathways^[136]. The tumor suppressor proteins DEC1 (Deleted in Esophageal Cancer) and Decoy Receptor 2 are also used as senescence markers in some cell types^[140]. Importantly, when oncogenic HRAS (HRAS^{G12V}) was used to transform immortalized embryo fibroblasts into tumorigenic cells^[141], unexpectedly, it induced senescence in normal cells associated with the accumulation of p53 and p16^{INK4a}^[142]. Thus, senescence may act as a

tumor-suppressor mechanism in response to oncogene activation^[133]. Generally, overexpression or sustained activation of one of the tumor suppressors p53, p21, p16^{INK4a}, or pRB is sufficient to induce senescence^[136,143-145]. Importantly, growth arrest caused by senescence is considered as irreversible as senescent cell could not be stimulated to resume proliferation by exposure to growth factors^[136,141,143]. However, the genetic or epigenetic alternations which cause the shift of the senescence maintaining mechanisms, such as the inactivation of tumor suppressor genes p53 and/or p16^{INK4a}, could potentially push the cells to re-enter the cell cycle^[136,143].

It is not clear whether senescence is one of the mechanisms that drives tumor dormancy and late relapse, but there are some potential links suggesting so. Senescence-associated secretory phenotype (SASP) defines the spectrum of factors secreted by senescent cells. It consists of a mixture of chemokines, cytokines, growth factors and proteases, many of which are pro-inflammatory^[136]. The cytokine GM-CSF (granulocyte-macrophage colony-stimulating factor, also known as CSF2), one of the components from SASP, induces differentiation of myeloid dendritic cells, which present tumor-associated antigens (TAAs), resulting in the activation of the immune system, enhanced immunosurveillance and improved tumor control^[146,147]. Furthermore, Braumüller *et al.*^[148] showed that adaptive TH1 cell are capable, via the combined secretion of IFN- γ and TNFR to induce tumor cells senescence. In conclusion, while senescence is a mechanism capable of negatively controlling tumor growth, its relevance in dormancy is not fully demonstrated.

MICROENVIRONMENTAL DORMANCY: DEFICIENT SUPPORT FROM THE MICROENVIRONMENT

In this form of dormancy, the fate of the DTCs is mainly controlled by the immediate, and possibly distant, host environment^[126,149]: cancer cells proliferate but fail to grow as a tumor mass because proliferation is balanced by cell death^[99]. This situation has been described first when disseminated cancer cells fail to induce blood vessels^[150]. During the early stage of tumor spreading, DTCs associate to preexisting (coopted) blood vessels where oxygen and nutrient levels are highest^[151]. Importantly, quiescent mature blood vessels keep DTCs in a state of dormancy through angiocrine communication^[122]. With the growing tumor mass, however, the increasing metabolic demand call for the formation of novel blood vessels through an angiogenic switch^[152]. Several molecules, including hypoxia-inducible factor 1, vascular endothelial growth factor (VEGF), placental growth factor and angiopoietin-1, are induced upon metabolic stress or hypoxia and initiate endothelial cell sprouting from preexisting vessels^[153]. Angiogenic endothelial sprouts secrete periostin and TGF- β 1 to create a microenvironment that promotes DTCs exit from dormancy and accelerates proliferation^[122]. Thus, the failure of initiating the angiogenic switch will keep the tumor mass small, a condition called angiogenic dormancy^[154]. Conversely, a short-term angiogenic burst may awaken dormant tumor cells^[155]. For example, in the mouse model of Lewis lung carcinoma, dormant micrometastatic cells can be induced to grow by the expression of VEGF and the recruitment of bone-marrow-derived endothelial progenitor cells^[156].

Importantly, inflammatory cells recruited to the tumor microenvironment are critical inducer of the angiogenic switch and lack of recruitment may therefore contribute to angiogenic dormancy^[11,157]. In particular the polarization of tumor associated macrophages toward the M2 phenotype results in the formation of a metastatic niche favoring tumor cell outgrowth^[158]. In addition, the angiogenic endothelium triggers a T helper 2-mediated inflammatory response, which can accelerate metastatic outgrowth in tumor models^[159]. The hemopoietic stem cell niche also supports quiescence and survival through the CXCL12/CXCR4 pathway and Src pathway^[47,160] as well as the TGF- β 2-rich bone marrow microenvironment^[161]. On the other hand, expression of VCAM1 on DTCs promotes escape from dormancy. This is due to the recruitment of osteoclast progenitors via α 4 β 1 integrin binding to VECAM1 causing the breakdown of the bone matrix and stimulation of DTC to grow and form metastases^[162,163]. Likewise, metastatic outgrowth following skeletal traumas was associated with bone remodeling in the reactivation of DTCs via TNF α , IL1 β , IL6 and prostaglandin E2 production^[163]. Thus, the cellular tumor microenvironment, in particular

inflammatory cells, endothelial cells and osteoclasts should be considered as critical regulators of tumor dormancy.

IMMUNOLOGICAL DORMANCY: ACTIVE CONTROL BY THE IMMUNE SYSTEM

The immune system can specifically recognize tumor cells through TAAs and initiate an anti-tumor immune response through a multi-step process called immunoediting^[164,165]: initially, the immune response can effectively eliminate cancer cells and no metastases are formed (elimination phase). If a balance between the tumor suppressive immune response and tumor evasion is achieved (equilibrium phase), the tumor mass remains constant resulting in a state of immunological dormancy^[166]. Tumor cells may eventually succeed in evading the immune system through a combination of genetic evolution and exhaustion of the immune system, and resuming growth to form macroscopic metastases (escape phase). Evasion involves multiple mechanisms, including the down-regulation of TAAs or MHC molecules, secretion of immunosuppressive cytokines, (e.g., IL-10 or TGF- β), recruitment of regulatory T cells (Treg), myeloid derived suppressor cells (MDSC) or alternatively (M2) - polarized macrophages or by expressing immunosuppressive molecules on the cell surface, such as PDL1 or B7^[167-169], in multiple cancer types, including breast cancer^[170]. The occurrence and relevance of immunological dormancy in human cancer is difficult to grasp, as the absence of biomarkers of dormancy makes it hard to investigate in patients. Also, there is paucity of clinically relevant *in vivo* model for experimental studies^[100]. Pommier *et al.*^[171] have recently reported that patients and mice with pancreatic ductal adenocarcinoma contained single quiescent DTCs lacking MHC-I expression, which enabled them to escape immunity and establish latent metastases. Four cases of breast cancer transmission to immunosuppressed transplant recipients from a single, clinically healthy donor have been recently described^[172]. The latency time to metastasis formation ranged from 16 months to 6 years, and transmissions did not occur in a patient that discontinued immunosuppression. This unintentional situation suggested that donor tissues harbored DTCs, which persisted in a latent state because of immune control, while the immunosuppression of the recipient allowed the DTCs to resume growth^[172]. Once cells have escaped immunosurveillance it is unlikely that they can re-enter a second state of immunological dormancy, because the mechanisms that eluded immunosurveillance are generally part of the genetic or epigenetic tumor clonal evolution and therefore irreversible^[59,91].

The recent observation that immunosuppressive immune cells promote angiogenesis^[157], and that some angiogenic factors, including VEGF, are immunosuppressive, established an important cross-talk between these two systems^[173-175]. They implicate that suppression of angiogenesis may stimulate the immune system and that reversal of immunosuppression may inhibit angiogenesis in a bi-directional cross-talk. In support of this notion, several trials have been performed to improve the anti-tumor immune response with anti-angiogenic drugs^[176]. Combination of anti-angiogenic agents with immunotherapy is currently being considered as strategy to improve the response rates and duration of immunotherapy^[177]. For example, VEGF has been shown to suppress the immune-response by impinging on maturation of dendritic cells^[178,179]. Thus, inhibition of VEGF abrogates its immunosuppressive effect and improves the antitumor effect of adoptive cellular immunotherapy^[180]. Combining anti-VEGF therapies with check-point inhibitors (e.g., anti-PD-L1) has shown synergy and positive outcomes in phases I to III studies, particularly in patients with high VEGF levels^[177]. Using the 4T1 experimental model of TNBC we have demonstrated that inhibition of tumor angiogenesis with the anti-VEGFR-2 antibody DC101, attenuated the inhibitory effect of MDSC on T cell proliferation and decreased the frequency of Tregs in primary tumors and lung metastases^[181]. Combined angiopoietin-2 and VEGF inhibition was shown to promote superior vascular regression, tumor necrosis, and enhanced the perivascular recruitment of cytotoxic T lymphocytes, as compared to the single agents in multiple cancer models. Addition of a PD-1 blocker unleashed the cytotoxic activity resulting in improved tumor control^[182,183]. These findings support the rationale for combining anti-angiogenic therapy with immune checkpoints inhibitors in cancer therapy, including in breast cancer. In addition to immunosuppressive angiogenic molecules, endothelial cells themselves also play a direct role in modulating

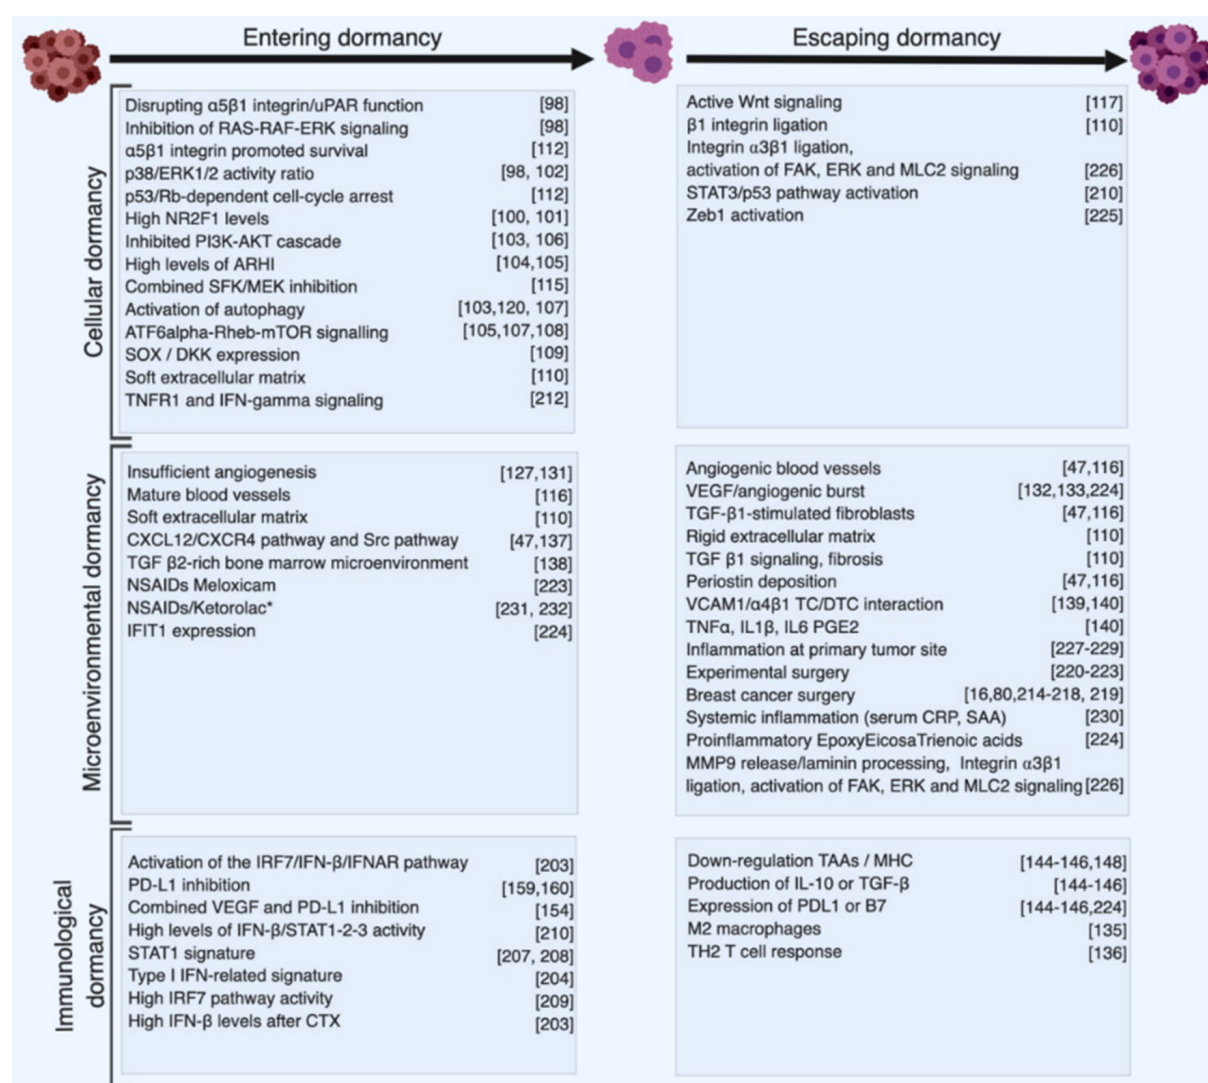

Figure 2. Synthetic summary of cellular and molecular events and interventions associated with dormancy. Cellular and molecular events promoting entering into dormancy or escape from dormancy are listed based on their implication in the three forms of dormancy. Classification is based on the main mechanisms and does not consider potential cross talk between different types of dormancy

cellular dormancy. Quiescent endothelial-derived thrombospondin-1 induces sustained quiescence of DTC in breast cancer, while sprouting vessels wake dormant DTC and promote their outgrowth^[122,184,185] [Figure 2].

DORMANT CANCER CELLS ARE RESISTANT TO THE CYTOTOXIC EFFECTS OF CHEMOTHERAPY

Adjuvant chemotherapy significantly improves breast cancer patient survival, in particular for TNBC, by decreasing the hazard of relapse after surgical removal of the primary tumor^[26,32,186-188]. Relapses and metastases however still occur in a fraction of patients and are likely due to tumor cells that had already invaded the surrounding tissue, lymphatic vessels and lymph nodes, or disseminated through the blood stream to the bone marrow and distant sites prior to surgery and resume grow at a later time point^[60,77,189]. As it is generally assumed that adjuvant chemotherapy acts by killing tumor cells, a corollary of this assumption is that relapses are due to DTC resuming growth at a later time point after surviving chemotherapy. Dormant, poorly proliferative DTC may not be affected by chemotherapy and may persist upon treatment since chemotherapeutic drugs mainly target highly proliferating cells. This has been shown for instance in

acute lymphoblastic leukemia, colorectal, lung, liver and breast cancers^[190-196]. In addition, chemotherapy pre-exposed DTC may develop mechanisms of chemoresistance and become less responsive to subsequent chemotherapies, as is often observed at relapse in patients. CSCs have been shown to be chemo-resistant and to be responsible for post-therapy relapses^[197]. Chemotherapy causes enrichment of CSCs thereby facilitating recurrences and resistance to further chemotherapies in multiple cancers including glioma, ovarian, liver, colon, breast cancers^[197]. Resistance involves multiple mechanisms, such as activation of signaling pathways prominent in stem cells (e.g., WNT, NOTCH, HEDGEHOG)^[198-200], but also pathways that are frequently mutated and activated in cancer, in particular the EGFR-HER2/PI3K/PTEN/Akt/mTORC pathway^[198,200,201]. CSC are often enriched at sites of chronic hypoxia leading to the activation of the HIF pathway^[200,202]. Interestingly, HIF activation leads to the initiation of protective pathways, including WNT and NOTCH, and genes of the ATP-binding cassette (ABC) drug transporter family members, such as MDR1, MRP1 and ABCG2 which are responsible for the efflux of cytotoxic drugs from the cells^[203-208]. Additional, HIF-independent mechanisms have been reported^[209]. In short, the mechanisms behind the long-term beneficial effects of adjuvant chemotherapy remain in part elusive and cannot be fully explained by the direct cytotoxic activity of chemotherapy as dormant/CSC that are mostly responsible for late relapses that are highly resistant to chemotherapy.

IMMUNE RESPONSE AND CHEMOTHERAPY IN BREAST CANCER

Cumulating evidence indicates that tumor infiltrating lymphocytes (TILs) play an active role in controlling progression and clinical outcome in breast cancer, particularly in highly proliferative TNBC and HER2⁺ cancers^[210-212], and in conjunction with chemotherapy^[213,214]. This is particularly relevant to TNBC, as these cancers present the richest presence of TILs, most notably CD8⁺ T lymphocytes, and tertiary lymphoid structures^[211,215,216]. Increased numbers of infiltrating TIL in TNBC, are associated with an improved pathological complete response to chemotherapy^[217], decreased rates of recurrences and improved survival^[210,216,218]. Evaluation of TILs in breast cancer has been recommended as an immunological biomarker with prognostic and potentially predictive values, mainly in TNBC and HER2-amplified breast cancers^[219]. In TNBC, expression of antigen presenting MHC class II pathway molecules is associated with a better outcome, consistent with the hypothesis that a functional antigen presentation pathway may trigger a protective antitumor immune response in response to chemotherapy^[220]. Ladoire *et al.*^[221] demonstrated that pathological complete response to neoadjuvant chemotherapy of breast carcinoma resulted in the disappearance of tumor-infiltrating FOXP3⁺ regulatory T cells and the increase in tumor infiltrating cytotoxic T_H1⁺ and granzyme B⁺ T cells, consistent with the induction of an antitumor immune response by chemotherapy. While the association between lymphocytic infiltrates, and improved outcome after chemotherapy appears to be strongest in TNBC and HER2⁺ breast cancer subtypes, the association with luminal tumors is less clear, and may be limited by the reduced immune infiltration or by the greater tumor heterogeneity of these tumors^[222]. Several recent experimental studies have shown that chemotherapy can induce a therapeutic anti-tumor immune response. For example, Ma *et al.*^[223,224], reported that anthracycline-based chemotherapy induces the release of ATP by dying breast cancer cells, which promotes the recruitment and differentiation of CD11c⁺CD11b⁺Ly6C^{high} antigen presenting cells. Depletion or preventing tumor infiltration by these cells abolished the anti-tumor immune responses elicited by anthracyclines^[223,224].

Besides these desired immunological effects, chemotherapy can also induce unwanted, immune-mediated tumor-promoting effects. For example, increased expression of TNF α in the breast tumor microenvironment due to chemotherapy, induces CXCL1/2 expression via NF- κ B activation in breast cancer cells and initiates a paracrine loop involving myeloid cell-derived S100A8/9 to enhance cancer cell survival and chemo-resistance. Inhibition of CXCR2 blunt this TNF α -induced response and augments the efficacy of chemotherapy, particularly against breast cancer metastasis^[225].

Taken together, there is growing evidence to support the notion that chemotherapy, in particular those based on anthracyclines, can elicit an effective anti-tumor immune response in breast cancer, mainly in the TNBC and HER2⁺ subtypes.

CHEMOTHERAPY-INDUCED IMMUNOLOGICAL BREAST CANCER DORMANCY

One important question emerging from these studies is whether the cytotoxic activity of chemotherapy and the elicited immune response, dominated by CD8⁺ T lymphocytes, may be sufficient to effectively kill cancer cells or whether additional mechanisms may be involved. This is particularly relevant to dormant DTC as these cells are naturally less responsive to chemotherapy due to the fact that they are not or low proliferative. We were interested in the possibility of whether a short chemotherapy treatment, induce a long-lasting immune response leading to immunological dormancy. We recently addressed this question experimentally^[226]. To this end, we treated the TNBC-like 4T1 cells with high dose Methotrexate and Doxorubicin *in vitro* and characterized the *in vitro* and *in vivo* behavior of the surviving cells (MR20 and DR500 derived from Methotrexate and Doxorubicin treatment, respectively). The hallmark of the surviving cell lines was the dormant phenotype at the primary (MR20 in the mammary gland) or at the metastatic (MR20 and DR500 in the lung) site. MR20 cells grew significantly slower *in vitro* compared to parental 4T1 cells and this was due to increased cell death, while there was no significant alteration in the cell cycle. When injected orthotopically in the mammary fat pad of immunocompetent BALB/c mice, only about half of the MR20-injected mice developed tumors with a longer latency (between 6 week and 4 months) compared to parental 4T1 cells (between 2 and 4 weeks). These tumor cells grew with nearly the same rate as parental 4T1 tumors and were highly metastatic. DR500 cells formed primary tumors but no lung metastases. Both conditions were consistent with dormancy. In BALB/c mice MR20 and DR500 cells twisted the immune response from CD11b⁺ Gr1⁺ MDSC-dominated to CD4/8 T cell, B cell and DC dominated response. When injected *in vivo* in immunodeficient NSG mice, however, treated cells formed tumors without latency. We then performed a genome wide gene expression analysis of parental 4T1, MR20 and DR500 cells and the dominant trait observed was a type I IFN gene expression signature and the sustained activation of the IRF7/IFN-β/IFNAR pathway. Upregulated IRF7 expression in treated cancer cells was responsible for suppressed mobilization of CD11b⁺ Gr1⁺ MDSCs, increased expansion of DCs, T and B lymphocytes and chemo resistance. Silencing IRF7 or blocking IFNAR1 resulted in escape from dormancy *in vivo*. Elevated levels of IFN-β were present in the blood of mice injected with dormant cells, while MR20 cells escaping dormancy and forming late tumors no longer expressed IFN-β. Interestingly, the dormant D2.0R murine breast cancer cells that are generally considered as a model of cellular dormancy, also induced a T-cell twisted immune response and had a constitutive active IRF7/IFN-β/IFNAR pathway [Figure 3]. To collect evidence that the activation of the type I IFN pathway was associated with a better response to chemotherapy in patients, we monitored IFN-β levels in serum samples of ER⁻ breast cancer patients treated with neoadjuvant chemotherapy (TOP trial NCT00162812). Patients with detectable IFN-β during neoadjuvant therapy had significantly longer distant metastasis free survival (DMFS) compared to patients with undetectable levels^[226].

TYPE I IFN RESPONSE TO CHEMOTHERAPY MEDIATES IMMUNOLOGICAL DORMANCY IN BREAST CANCER

Taken together our results demonstrate that sustained activation of the IFN-β/IFNAR/IRF7 signaling axis in chemotherapy-treated TNBC-like murine breast cancer cells instigates immunological dormancy. Elevated levels of IFN-β in the serum of TNBC patients during adjuvant therapy correlates with a shorter DMFS. Acute exposure of breast cancer cells to chemotherapy induced IFN-β expression^[226]. Thus IFN-β may be considered as a potential therapeutic tool to improve chemotherapy efficacy and clinical outcome as well as a potential predictive biomarker to identify responding vs. non-responding patients. While the implication of type I IFN in dormancy is novel, previous reports have implicated it in acute anti-tumor

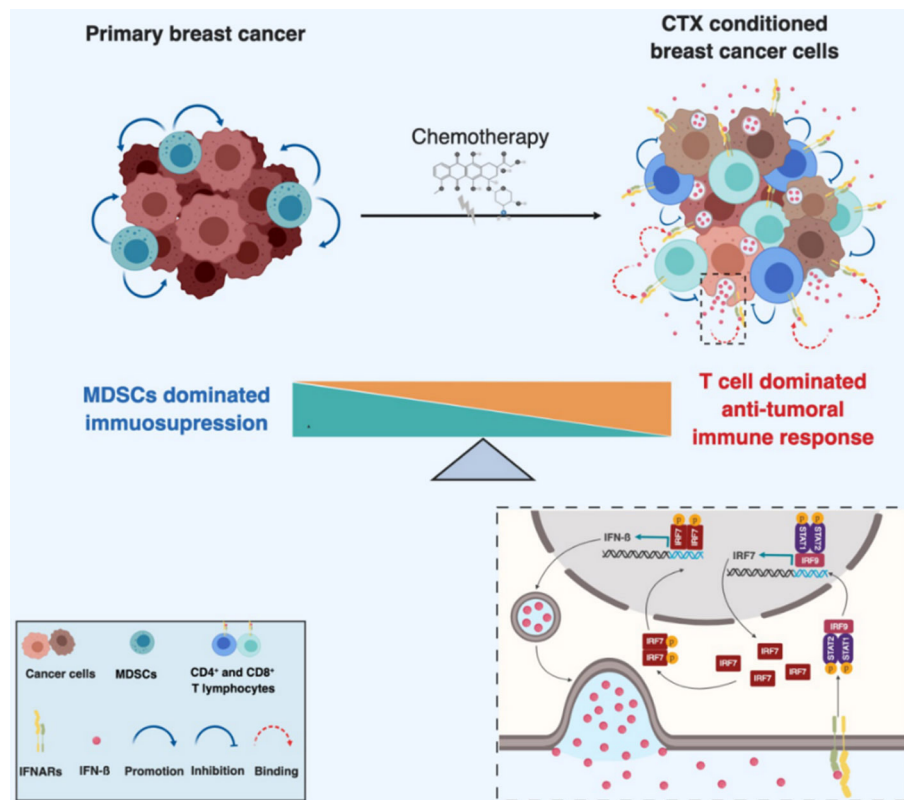

Figure 3. Schematic model of chemotherapy-induced immunological dormancy. Primary breast cancer cells escape immune elimination by inducing the expansion of myeloid derived suppressive cells (MDSC) which also promote tumor growth. Chemotherapy induces a type I IFN response in treated tumor cells, resulting in an autocrine and self-sustained increase of IRF7 expression and activation, which in turn induces expression and secretion of IFN- β . Secreted IFN- β binds to IFNAR and induces signaling in both immune cells and tumor cells. IFNARs signaling in tumor cells activates STAT1/STAT2/IRF9 complex which further induces the expression of IFN- β responsive genes including IRF7 resulting in a sustained autocrine IFN- β expression and secretion. Paracrine activation of IFNARs on immune cells stimulates the expansion of tumor suppressive lymphocytes (e.g., CD4 $^{+}$ and CD8 $^{+}$ T cells) and prevents the mobilization of MDSCs, resulting in the switch of the immune response from immunosuppressive to anti-tumoral

response to chemotherapy. Sistigu *et al.*^[227] reported that anthracycline-based chemotherapy rapidly induced the production of type I IFN in cancer cells via TLR3 activation resulting in CXCL10 secretion promoting an anti-tumor immune response mimicking those induced by viruses. Moreover, a type I IFN-related signature predicted clinical responses to anthracycline-based chemotherapy in breast cancer patients. Using a panel of ER $^{+}$ breast cancer PDXs before and after chemotherapy, Legrier *et al.*^[228] demonstrated activation of the IFN/STAT1 pathway and expression of IFN-inducible genes, early after chemotherapy treatment. IFN- α deficient DC were shown to accumulate in aggressive breast cancers favoring the expansion of Tregs implicating that IFN- α deficiency may contribute to tumor immune tolerance and poor clinical outcome^[229]. Previous studies based on tumor-derived IFN signatures have shown that IFN-regulated genes may correlate with favorable outcomes. A STAT1 signature before therapy was associated with a better response to neoadjuvant chemotherapy^[230] and better prognosis in TNBC and HER2 $^{+}$ breast cancers^[231]. High IRF7 pathway activity in human breast cancer predicted bone relapse-free survival and, and protected mice against bone metastasis^[232]. In the same study, treatment with IFN- α improved bone metastasis-free survival^[232]. High level of IFN- β activates STAT1, STAT2 and STAT3 to facilitate cell autonomous cellular dormancy of melanoma repopulating cells^[233]. Taken together, our recent data extend the role of type I IFN in immunoediting in cancer^[234] to a putative role in inducing immunological dormancy after chemotherapy in TNBC. An important outstanding question raised by our study, concerns the effector mechanism of T cell mediated dormancy. While it is likely that direct CD8 $^{+}$ T cell mediated killing and immune control is involved, particularly since CD4 $^{+}$ Th1 T cells produce IFN- γ which upregulates MHC expression on

tumor cells thereby facilitating killing by CD8⁺ T cells^[235], it is plausible that additional mechanisms may be involved. One possibility is suppression of tumor angiogenesis by the secretion of anti-angiogenic factors, such as CXCL9 and CXCL10 by CD4⁺ T cells^[235]. Another putative mechanism is induction of senescence. CD4⁺ Th1 T cells also produce TNF- α , which in combination with IFN- γ induces an irreversible state of cellular senescence keeping DTC dormant^[235,236]. Ongoing projects in our lab are aimed at unraveling the effectors steps.

BREAKING DORMANCY: IMPACT OF INFLAMMATION

Clinical and experimental observations indicate that dormant tumor cells can resume proliferation and generate macroscopic metastases at various times after primary tumor treatment^[17,85]. Escape from dormancy could be initiated by cell autonomous events, such as oncogenic mutation or inactivation of tumor suppressor genes. Alternatively, alterations in the host micro- or macro-environment may promote escape from dormancy. Metastatic growth following surgical removal of the primary tumor itself is often observed in clinical settings with predictable patterns, including in breast cancer^[16,86,237-241]. Reconstructive surgery after mastectomy for breast cancer significantly accelerates relapse rates proportionally to the extent of surgery, when compared to primary surgery. However, no worsening in long-term survival was reported, consistent with an effect on breaking dormancy and accelerating progression but not altering the overall outcome^[242]. Enhancement of metastatic growth induced by experimental surgery has been long observed in animal models, suggesting that surgical wounding itself may be directly involved in breaking dormancy^[243-245]. Recently Krall *et al.*^[246] described an experimental model that links the wound-healing response after surgery to the outgrowth of DTC at distant sites. The link is mediated by the systemic inflammatory response induced after surgery suppressing a tumor-specific T cell response, thereby resulting in tumor growth. Consistent with these findings, perioperative anti-inflammatory treatment significantly reduced tumor outgrowth. Epoxyeicosatrienoic acids, a family of pro-inflammatory molecules, stimulated escape from dormancy in several tumor models independently of the primary tumor and was associated with increased production of VEGF by endothelial cells^[247]. Recently, it was reported that lung inflammation promotes escape from tumor latency by inducing ZEB1 expression, a regulator of the EMT^[248]. Another recent study reported that neutrophil extracellular traps (NET) produced by neutrophils during repeated acute inflammation awaken dormant cancer cells in a mouse model of breast cancer^[249]. The releasing of neutrophil elastase and MMP9 from NET then remodel laminin in the extracellular matrix rendering it accessible to $\alpha 3 \beta 1$ integrin. Ligated $\alpha 3 \beta 1$ integrin leads to the activation of FAK, ERK and MLC2 signaling resulting in the awakening of the dormant cancer cells^[249].

Clinical and experimental evidence suggests that sustained inflammation may also promote relapses^[91]. Correlations between inflammation at primary tumor site and risk or recurrences were reported for several cancers including oral^[250], endometrial^[251] and breast cancers^[250,252]. Elevated levels of circulating C-reactive protein and serum amyloid A, two proteins of the inflammatory response, are associated with reduced overall survival in breast cancer, independently of body mass index, age and tumor type and stage, consistent with inflammation being involved in breaking dormancy^[253]. Interestingly, perioperative administration of the analgesic nonsteroidal anti-inflammatory drug (NSAID) ketorolac was reported to suppress early breast cancer relapse particularly in TNBC patients^[254] and to reduce distant recurrences in patients with increased BMI^[255]. Taken together, there is compelling clinical and experimental evidence indicating that inflammation promotes breast (and other) cancer relapses by breaking dormancy.

OUTLOOK AND PERSPECTIVES

Tumor dormancy is widely accepted as one discrete step during multistage tumor progression and bears considerable therapeutic potential^[256]. The rapid translation of this innovative concept to the patient is limited by the paucity of therapeutic tools currently available in the clinic. Treatments directly aimed at DTC

Figure 4. Strategies to improve chemotherapy-induced immunological dormancy. Based on work by others and us, we propose four clinically feasible approaches to induce or maintain breast cancer dormancy, primarily in TNBC. Firstly, we propose neo-adjuvant chemotherapy (nCTX) to promote chemotherapy-induced immune response. Chemotherapy may be pursued as adjuvant therapy (aCTX) if necessary. Secondly, during and following surgery we propose the administration of NSAIDs (in particular Ketorolac) to prevent surgery-associated inflammation that may potentially promote relapses. Thirdly, the cytotoxic immune response could be stimulated by providing type I IFN, or inducers of an interferon response such as TLR4 ligands, in particularly in low IFN-producing patients. Fourthly, addition of checkpoint inhibitors, such as anti-PD1/PDL-1 antibodies, may be applied to maintain the immune response active

by critical cell survival and proliferation pathways (e.g., PI3K-AKT or MAPK pathways), stem cell pathways (e.g., WNT, NOTCH) or cell adhesion molecules (e.g., β_1 integrin) would be virtually excluded for such an approach given their expected long-term systemic toxicities. We are proposing here selected strategies based on limiting the host (unwanted) inflammatory response and stimulating the (wanted) anti-tumoral-immune response that may be rapidly tested in clinical-translation studies in breast cancer [Figure 4].

NSAIDs

There is growing clinical and experimental evidence that inflammation can trigger cancer relapse, in particular in breast cancer, and that NSAIDs treatment can prolong dormancy and delay or reduce relapses^[246,248,249,252,254,255,257]. The overall positive safety profile of aspirin and other NSAIDs would make them realistic candidate drugs for such long-term therapies^[258]. Even more interesting, as a short perioperative treatment with ketorolac has been shown to significantly decrease the risk of breast cancer relapses particularly in obese patients^[255], a short term NSAID treatment at time of surgery may have long-lasting effects through suppression of surgery-associated inflammation.

Neoadjuvant chemotherapy

A second approach to consider, is to exploit the ability of chemotherapy to elicit an effective immune response in breast cancer, particularly in lymphocyte-infiltrated TNBC or HER2⁺ tumors^[211,212,222,224,226,227,259].

Our and other's results indicate that chemotherapy induces an effective anti-tumor immune response upon tumor cell treatment^[214,226,227]. Clinically this implies that neo-adjuvant/pre-operative chemotherapies may be more effective in inducing a long-lasting, protective immune response compared to classical adjuvant/post-operative therapies, due to the larger targeted tumor mass^[224,260]. Indeed, neoadjuvant chemotherapy is already used in highly proliferative breast cancers (i.e., Luminal B, HER2⁺ and TNBC) with high frequencies of pathological complete responses (pCR). Interestingly, paclitaxel, in combination with trastuzumab, induced a high rate of pCR in HER2⁺ patients, likely due to the synergy between the immunomodulating properties of these drugs^[260]. Ladoire *et al.*^[221] reported that pCR to breast cancer neoadjuvant chemotherapy was associated with the disappearance of tumor-infiltrating FOXP3⁺ Tregs and recruitment of CD8⁺ T cells, consistent with the induction of an antitumor immune response by chemotherapy.

Type I IFN

In our experimental model we have shown that Type I IFN response is essential to elicit a state of immunological breast cancer dormancy^[226]. Others have shown that exogenous addition of type I IFN boosted an insufficient response to chemotherapy in an experimental model of breast cancer and that a type I IFN-related signature predicted clinical responses to anthracycline-based chemotherapy in breast cancer patients^[227]. We demonstrated that patients with high levels of serum IFN- β during neoadjuvant therapy have a better outcome compared to patients with low levels^[226]. This suggests that administration of type I IFN during neo-adjuvant therapy may be effective in mounting a long-lasting immune response in particular in those patients with low endogenous type I IFN levels. Type I IFN, in particular IFN- α has been already tested as immunostimulatory anti-cancer agent, especially in melanoma and kidney cancers, albeit with mild results, in part also due to the need of repeated administrations and its intrinsic toxicity^[261-263]. Alternatively, less toxic inducers of Type I IFN response, such as TLR-ligands of STING stimulators may be considered^[227,264].

Check point inhibitors

A complementary strategy to IFN administration could be the use of check point inhibitors, in particular anti-PD-1/PD-L1 antibodies to relieve tumor-induced immunosuppression^[265]. In breast cancer, immunotherapy is being explored, in particular in patients with tumors expressing PD-L1 and infiltrated with lymphocytes^[266]. Potential response to PD-1 or PD-L1 inhibitors was demonstrated in metastatic TNBC^[267] and HER2⁺ breast cancers^[268]. However, because the number of potential neoantigens available for immune response in most breast cancers, responses are modest compared with other cancers such as lung and melanoma, the use of check-point inhibitors may require combination with other therapies^[269]. Therefore, combination with neo-adjuvant chemotherapy (causing the release of tumor antigens), anti-angiogenesis therapies (suppressing inhibitory cues)^[182] or Type I IFN (acting immunostimulating)^[270] may be more effective and should be explored.

Biomarkers of dormancy

There are currently no specific non-invasive biomarkers to monitor breast cancer dormancy of clinical utility^[271]. Such markers would allow personalized follow up and accelerate therapeutic decisions in case of evidence of disease progression. CD44⁺/CD24⁻ CTC subsets along with combinatorial expression of uPAR and b1 integrin, as well as proliferation and apoptosis markers in CTC of early breast cancer patients, have been explored for potential use as biomarker of dormancy or aggressiveness^[272,273]. Genomic analysis (i.e., SNP/CNV) of circulating ctDNA was shown to potentially identify breast cancer patients with dormant/minimal residual disease^[274]. Also, serum inflammatory markers might serve as biomarkers of relapse in disease-free patients, as inflammation is associated with escape from dormancy but will likely be unspecific and of limited sensitivity^[275]. Serum IFN- β levels were associated with longer DMFS (as a surrogate of dormancy) in our model of chemotherapy-induced dormancy and during neoadjuvant therapy in patients with favorable outcome^[226]. Also, we observed a shift in peripheral blood leucocyte populations in our

experimental model, from a Gr1⁺CD11b⁺ cell dominated response in mice with progressive tumors toward a CD4⁺/CD8⁺-, B cell and CD11c⁺ cell-dominated response in mice with dormant tumors^[226]. Thus, Serum IFN- β levels and immunophenotyping should be explored for their potential use as biomarkers of breast cancer dormancy.

CONCLUSION

Advances in the understanding of the mechanisms of breast cancer dormancy have raised the hope to therapeutically exploit dormancy to prevent relapses and overt metastatic disease. To date many potential therapeutic targets and strategies have been considered and proposed for clinical testing^[100,185]. However, many of these approaches would be difficult to apply to patients due to lack of suitable drugs, potential long-term toxicity and over all complexity in the in their clinical translation. Recent reports implicating a T cell based immune response in the therapeutic effects of chemotherapy including dormancy, have opened novel perspectives for a feasible clinical translation. Administration of chemotherapy before tumor removal (i.e., neoadjuvant chemotherapy) may be explored for improved effects on immunological dormancy compared to conventional, post-surgery, adjuvant chemotherapy. Drugs with potential beneficial effects on promoting or prolonging dormancy, such as NSAIDs to suppress inflammation, type I interferons, check-point inhibitors or anti-angiogenic drugs to stimulate the immune response, are available for clinical use and could be tested in combination with chemotherapy. Thus, the observation that chemotherapy can induce a state of immunological dormancy adds a new therapeutic effect to the older class of anti-cancer drugs and opens unanticipated therapeutic opportunities for clinical translation in breast cancer (and possibly other cancers).

DECLARATIONS

Acknowledgments

We apologize for not being able to cite all published work relevant to this topic due to space limitation and selective focus of the article.

Authors' contributions

Conceiving the paper: Peyvandi S, Lan Q, Lorusso G, Rüegg C

Writing the paper: Peyvandi S, Lan Q, Lorusso G, Rüegg C

Performed the work of immunological dormancy in the laboratory: Peyvandi S, Lan Q, Lorusso G, Rüegg C

Abstract

With more than one million new diseases per year breast cancer is the most common malignancy in women. Metastatic breast cancer remains an incurable disease and the spinal column is most likely affected by metastases. A significantly prolonged patient survival is the consequence of modern oncologic treatment options in the last decade. Surgical treatment of vertebral metastases has become an increasing focus for spine surgeons. With the turn of the millennium it was possible to classify breast cancer into four intrinsic phenotypes with various survival rates. Well known scoring systems help surgeons to evaluate the patient's prognosis and to choose adequate treatment options. However, tumor entities are differentiated without regard to the molecular subtypes. In this article we describe surgical treatment options in metastatic lesions to the spine with regard to molecular phenotypes of breast cancer malignancy. It is crucial to correctly estimate the expected survival time to plan invasiveness of therapy regarding metastatic spine surgery.

Keywords: Spine, metastases, breast cancer, phenotypes, subtypes, molecular level, prognosis

INTRODUCTION

Breast cancer is one of the most common cancer diseases metastasizing to the spine and the second leading cause of deaths in woman related to cancer^[1]. Modern treatment and diagnostic concepts including bisphosphonates go along with considerable longer survival times and a reduced rate of skeletal

complications^[2-4]. Until 2015 mean survival times of 27 months were described, actual studies report mean survival times of 55 months with a 85% incidence of spinal metastases^[2-15]. An increased need for surgical treatment of complications related to spinal metastases is the consequence. Due to mortality and morbidity rates related to metastatic breast cancer every surgical treatment should be considered carefully. Well evaluated scoring systems (revised Tokuhashi-or Tomita score, revised Bauer score, Van-der-Linden-score, Karnofsky index) help surgeons to individually chose optimal treatment methods and to predict life expectancies in cancer patients. But these scores only differentiate between tumor entities whereas respective tumor phenotypes are not taken into account^[16-21]. With the turn of the millennium five different intrinsic subtypes of breast cancer were reported by means of gene expression profiles^[14-22]. Four phenotypes are decisive in daily clinical routine: luminal A, luminal B, HER2-enriched and basal like/triple-negative. With an accordance of 70%-80%^[23] these phenotypes are assessed with immunohistochemical pathologic markers (e.g., ER, PgR, HER2, KI-67/grading) as standardized gene expression profiling is available with partial coverage^[24]. In this article we describe the molecular parameters of metastatic breast cancer to predict survival time more precisely and to adequately calculate surgical therapies.

ASSESSMENT OF PROGNOSIS

The development of oncologic treatment options in primary breast cancer (in particular medical therapy) led to considerable improved survival rates in the last decade^[2-9,12-15,25-27]. Immunohistochemical diagnostic tools provide a sufficient molecular phenotyping in breast cancer [Table 1].

Visceral, skeletal or cervical spine metastases, surgical complications and advanced patient's age are reported with different data in literature and therefore are not recommended as negative predictors^[13]. In contrast, unimodal postoperative therapies, a disease-free interval less than 24 months, a high number of axillary lymph node metastases and progress after first-line therapy mark assured predictors of shorter survival^[4,10,13]. Furthermore, patients' wishes and preferences, symptoms, biological age, intrinsic breast cancer subtype, tumor burden (number of metastasized organs) and prior therapies have to be taken into account^[4].

MOLECULAR PREDICTORS

Around the turn of the millennium, Sørlie und Perou^[14,22] published fundamental studies to classify breast cancer at the molecular level with relevance to clinical course of disease. As tumor-biological classifications increasingly become more complex, modern oncologic diagnostic and therapy options interact with highly specialized regulatory mechanisms of cells and cell cycles^[8,28]. The actual breast cancer classification [Table 1] is based on histopathological examinations of a biopsy from the breast. Classifying breast cancer^[1-3,5-9,12-15] by estrogen receptor (ER), progesterone receptor (PgR), human epidermal growth factor 2 (HER-2) and a proliferation marker (KI-67) is global standard^[23,24,28-33]. With these molecular genetic parameters breast cancer is differentiated into the four intrinsic phenotypes, which are clinically relevant [Table 1]. Hormone receptor status comprises the combination of ER and PgR status^[3,8,12]. Furthermore, endocrine responsive subtypes (Luminal A and-B), triple negative and HER-2 over expressing immunophenotypes are differentiated^[2,3,8,13,14,23]. Luminal-A and Luminal-B phenotypes are clinically distinguished by proliferation rate (e.g., KI-67), grading or a multigen signature^[2,3,5-9,15,24,30].

The common classification is based on the ubiquitous availability of these diagnostic methods, which enable comparable studies and therapy concepts. With regard to metastatic breast cancer mean survival times of 60 months are reported in the current literature^[4,10,34] in case of endocrine responsive phenotypes (Luminal-A and-B) compared to 26 months until the year 2015^[2,3,35]. Compared to PGR positive (PgR+) status, patients with PgR negative (PgR-) status have a 59% higher mortality risk^[3]. In patients with hormone receptor negative (HR-) status the mean survival time is reduced by 11 months and mortality risk is 52%

Table 1. Molecular phenotypes of metastatic breast cancer with related survival times^[26]

Molecular Phenotype	Luminal A	Luminal B	HER2-enriched	Triple-negative-status
	ER and PR positive Low Proliferation Rate (Ki-67)	ER and/or PR positive High Proliferation Rate (Ki-67)	HER2-positive	ER and PR and HER2-negative (Basal-like)
Mean survival time	60 months	60 months	56.5 months	15-19 months

Table 2. Karnowsky Performance Scale from 1949^[34]

Score	Parameter
100	Normal; no complaints; no evidence of disease
90	Able to carry on normal activity; minor signs or symptoms of disease
80	Normal activity with effort; some signs or symptoms of disease
70	Cares for self; unable to carry on normal activity or to do active work
60	Requires occasional assistance, but is able to care for most of their personal needs
50	Requires considerable assistance and frequent medical care
40	Disabled; requires special care and assistance
30	Severely disabled; hospital admission is indicated although death not imminent
20	Very sick; hospital admission necessary; active supportive treatment necessary
10	Moribund; fatal processes progressing rapidly
0	Dead

higher compared to hormone receptor positive (HR+) status^[6]. Biggest progress regarding survival times and therapy options was achieved in HER-2 enriched phenotypes in the last decade. Until some years a HER-2 positive status was associated as a negative predictor with a mean survival time of 5-9 months. After the introduction of new Anti-Her-2 therapeutics (Trastuzumab, Pertuzumab, T-DMI) the mean survival time is reported with 56.5 months^[2-4,10,34,36].

Whereas triple negative phenotypes (ER-, PgR-, HER-2-) were reported with a mean survival time of 6-9 months until the year 2015, actual data show a prolonged survival time of 15-19 months^[2-6,9,10,13-15,26-28,34,35,37,38].

SCORE SYSTEMS

Life expectancy in metastasized tumor diseases is estimated with well known and evaluated score systems. The Karnofsky-Index [Table 2] dating from 1948 describes patients' general condition and physical resilience^[17,21,39]. Furthermore, the Karnofsky-Index is part of different score systems (Tokuhashi and revised Tokuhashi score, Oswestry Disability Index, Van-der-Linden-Score)^[18,20,21,39,40]. Patients describe pain with the numeric or visual analogue scale (NAS/VAS)^[41]. Vertebral stability is estimated by the Spinal Instability Neoplastic Score (SINS) [Tables 3 and 4]^[21,42], Harrington Score^[21,43] or Taneichi score^[44]. The revised Tokuhashi score [Tables 5 and 6]^[18,34] and Tomita score [Tables 7 and 8]^[19] are worldwide accepted to determine individual life expectancy in malignancy and to plan optimal treatment options. The modified Bauer score^[16], Van-der-Linden score^[20] and Oswestry-risk index^[39] are named for the sake of completeness.

The revised Tokuhashi^[18] and Tomita score^[19] merely discern tumor entities (breast, prostate, lung, thyroid) and in both scores breast cancer is assessed with a favorable prognosis. The four different phenotypes of breast cancer are not included. A life expectancy limited to 5 to 9 months was published until 2015 concerning HER-2 enriched and triple negative phenotypes^[2-6,9,10,13-15,26-28,34,35,37,38,45]. Therefore, modifications in the revised Tokuhashi^[18] and Tomita score^[19] were suggested^[2,3] and highly invasive anterior-posterior spine surgery should be evaluated critically. Based on present-day knowledge we can no longer emphasize these recommendations. Due to better oncologic treatment options actual studies estimate mean survival times of 15-19 months with regard to the triple negative and 56.5 months concerning HER-2 enriched phenotypes^[4,6,7,10,15,26]. A mean survival time of 15-19 months implies that several patients live longer and

Table 3. Spinal Instability Neoplastic Score for the determination of vertebral body stability from 2010^[23]

SINS parameter	Description	Score
Location	Junctional (C0-2, C7-T2, T11-L1, L5-S1)	3
	Mobile spine (C3-6, L2-4)	2
	Semirigid segments (T3-10)	1
	Rigid segments (S2-5)	0
Mechanical pain	Yes	3
	Sometimes	1
	No	0
Bone lesion	Lytic	2
	Lytic/blastic (mixed)	1
	Blastic	0
Spinal alignment	Subluxation/translation present	4
	<i>De-novo</i> -deformity (Kyphosis/Scoliosis)	2
	Normal alignment	0
Vertebral body collapse	> 50% collapse	3
	< 50% collapse	2
	No collapse with > 50% body involved	1
	None of the above	0
Posterolateral involvement	Bilateral	3
	Unilateral	1
	None of the above	0

Table 4. Interpretation of Spinal Instability Neoplastic Score^[23]

Score	Stability
0-6	Stable
7-12	Potentially unstable
13-18	Unstable

Table 5. Revised Tokuhashi-Score parameter^[48]

Score	0	1	2	3	4	5
Karnofsky-score (%)	10-40	50-70	80-100			
Extraspinal bone metastases	3 or more	1-2	0			
Spinal metastases	3 or more	2	1			
Frankel	Frankel A/B	Frankel C/D	Frankel E			
Visceral metastases	Unremovable	Removable	None			
Primary site of cancer	Lung Stomach Bladder Esophagus Pancreas Osteosarcoma	Liver, Gall Bladder Unidentified	Others	Kidney Uterus	Rectum	Breast Thyroid Prostata Carzinoid

Table 6. Interpretation of the revised Tokuhashi-Score^[48]

Score	Prognosis of survival	Recommendation
0-8	85% of patients survive up to 6 months	Conservative therapy or palliative surgery
9-11	73% of patients survive > 6 months; 30% > 12 Monate	Palliative surgery or in exceptions tumor excision
12-15	95% of patients survive > 12 Monate	Tumor excision

these patients have to be filtered out. According to Tomita *et al.*^[19] and Tokuhashi *et al.*^[18] anterior spine surgery is indicated with a life expectancy of 12 months or more. If the patient is in good general condition and asks for surgery, we therefore recommend anterior-posterior techniques after critical evaluation. Furthermore, in 2012 Majeed^[45] evaluated 55 patients according to the revised Tokuhashi^[18] and Tomita score^[19] and reported continuously longer survival times than initially estimated. Majeed^[45] concluded, that prognosis of survival times is not reliable with the current scoring systems.

Table 7. Tomita-Score^[50]

Prognostic factor	Score
Tumor growth	
Slow (Breast, Prostate, Thyroid)	1
Moderate (Kidney, Uterus)	2
Rapid (Lung, Liver, Stomach, Colon, CUP)	3
Visceral metastases	
None	0
Treatable	2
Not treatable	4
Bone metastases	
Solitary	1
Multiple	2

Table 8. Interpretation of the Tomita-Score^[50]

Score	Mean survival time (months)	Treatment goal	Recommendation
2-3	50	Local long-term monitoring	Wide or marginal excision
4-5	23.5	Local mid-term monitoring	Tumor bordering or intralesional excision
6-7	15	Local short-term monitoring	Palliative surgery
8-10	6	Terminal supply phase	Limited palliative surgery or no operative intervention

THERAPEUTIC OPTIONS REGARDING SPINAL METASTASES

With an incidence of 85% breast cancer metastases to the spine may lead to instability with pain, pathologic fractures and neurologic deficits in up to 10%^[21,29,46]. Furthermore, there are severe socioeconomic aspects with 50% of woman have to change the working environment and 37% of woman involved can temporarily or permanently work no longer^[4]. The primary therapy of painful metastases to the spine without relevant loss of stability is radiation and spine surgeons are not necessarily involved. Potentially unstable and painful lesions with a SIN Score > 7^[42] (+/-neurological deficits) are demonstrated to the consulting spine surgeons. Mandatory in every patient is a critical individual evaluation of prognosis to choose correct therapy options^[4,8,11,14,21,29,35,38,45-48]. Improving or maintaining the quality of life is the decisive therapeutic target in an incurable palliative situation. Wishes and priorities of these patients beside the status of metastases, previous therapy lines and general condition mainly influence the appropriate treatment^[4].

Beside local radiation orthotic devices are the main conservative treatment tools to stabilize the spinal column and reduce pain. Concomitantly as systemic osteoprotective therapy a bisphosphonate in combination with calcium and Vitamin D or Denosumab (monoclonal antibody) mark the standard additive medication in advanced breast cancer with bone metastases. With the best response in diverse tumor entities up to 62% of recalcification post radiatio is described in breast cancer spinal metastases^[4,8,21,47,49,50].

Various surgical treatment options can reduce pain and stabilize the spine. Bilateral, percutaneous balloon kyphoplasty as a minimal invasive treatment tool^[13,36,46,47,49,51-54] may not restore vertebral height but correlates with pain reduction. Thermal ablation of vertebral metastases with radio frequency ablation (RFA)^[50,53,55-57] may be combined with kyphoplasty to reduce the likelihood of tumor recurrence. Posterior instrumentation with a screw and rod system is the gold standard in spine surgery to stabilize unstable tumor lesions. In case of spinal stenosis due to tumor the decompression of neural structures is reached via laminectomy and tumor debulking^[13,29,43,46,47,50,52-55]. According to Tomita *et al*^[19] palliative anterior surgery with vertebral body replacement (VBR) [Figures 1-3] can be recommended in patients with a life expectancy > 12 months^[46,47,58,59]. Highly invasive surgical options like *en-bloc* spondylectomy in Tomita technique or vertebral column resection with a mandatory 360 reconstruction [Figure 4] mark curative treatment options in case of solitary spinal metastases^[46,47,58,59].

Figure 1. 73-year-old female patient with multiple metastatic breast cancer ER: 95%; PgR: 0%; HER2-Score 1+; Ki-67: 20%. Sagittal and axial section of a total spine CT scan: unstable metastatic destruction of L3

The various techniques mentioned above can be combined as required. Additional measures like (partial-) resection of soft tissue, thoracic wall or pelvis with potential correction or reconstruction of deformity complete the portfolio^[47]. Modern adjuvant oncologic concepts comprise radio-, chemo- or hormone therapy^[8,47,50].

Due to the wide range of therapy options mentioned above it is impossible for a sole attending physician to determine the individual therapeutical regimes. Such complex decision making demands an interdisciplinary setting like a tumor conference or board^[4]. The spine surgeon determines the individual therapy of

Figure 2. Sagittal section (T2-weighted) of a total spine MRI with contrast agent: metastatic destruction of L3 and multiple metastases

spinal metastases in breast cancer patients. An improved quality of life results of preserved mobility and autonomy with less pain. If possible, pathologic fractures and neurologic deficits up to paraplegia should be avoided^[2,3,8,18,19,29,42,43,47,50].

SPECIAL CASE: SOLITARY METASTASIS

Prognostic statements are especially important in case of a solitary, locally curable metastasis (principle of limited metastasis^[4]) and a treatable primary tumor in a curative way. For us the question was, if solitary metastasis with any phenotype is always to be treated the same way [Figure 5].

Either a Ct-controlled or an open biopsy finally ensures the histopathological phenotype. Until the year 2015 the curative therapeutic approach with *en-bloc* spondylectomy according to Tokuhashi *et al*^[18] and Tomita *et al*^[19] was only recommended in hormone positive receptor status (luminal A and B) with a median survival time of 26 months^[2,13]. In triple-negative or Her-2 enriched phenotypes with an estimated survival time of 5-9 months, a limited posterior instrumentation (screw and rod system) and decompression of neural structures was indicated^[2,13]. Modern oncologic treatment concepts provide clearly longer survival times and therefore, according to Tokuhashi *et al*^[18], curative treatment options (mean survival time > 12 months) can principally be applied to all phenotypes in breast cancer with solitary metastasis. In the worst case (triple-negative phenotype) the mean survival time is actually reported with 15-19 months^[2-4,10,34,35].

Indicating *en-bloc* spondylectomy will never be an automatism and controversial discussions in tumor boards can be expected. Critically evaluation of the individual wish, priorities, general condition,

Figure 3. Postoperative sagittal total spine radiograph: posterior instrumentation L1-L5 with a screw and rod system, decompression via laminectomy, anterior stabilization with an insitu distractable vertebral body replacement of L3

comorbidities, previous lines of treatment and the biological age must influence the decision^[4]. In tumor conferences a (neo-)adjuvant systemic therapy (endocrine therapy, Anti-HER-2 therapy, chemotherapy, osteoprotective therapy) is determined according to tumor load (TNM system) and biology. An adjuvant loco regional radiation therapy is mandatory in case of short edges of the resected areas in preparation slides^[4].

Figure 4. Two plane full spine radiographs of a 65 year old female patient with metastatic breast cancer(A, B). En-bloc spondylectomy in Tomita technique at the Th9 and L1 level with a time interval of 10 years. Anterior in situ distractible cage at the Th9 level and Harms cage at the L1 level, posterior 4-rod instrumentation Th6-L3

CONCLUSION

Evaluating prognosis by means of molecular tumor typing, previous course of disease and actual status of metastases is mandatory prior to elective surgery of breast cancer spine metastases.

Mean survival times of 60 months in endocrine responsive (Luminal A and B) phenotypes, 50 months in HER-2 enriched phenotypes and 15-19 months in triple negative phenotypes are described in actual literature.

The patients's general condition, biological age, intrinsic breast cancer subtype, comorbidities, tumor burden (number of metastases to organs) and previous therapies influence decision making.

Regardless of molecular phenotype solitary spinal metastases may be treated with a curative therapeutic approach.

Close cooperation of all experts participating interdisciplinary tumor boards are essential to determine adequate therapy strategies.

Abstract

Aim: Lactate can signal through the endogenous lactate receptor, GPR81, which is expressed in some cancers. Lactate metabolism is altered by the metastasis-promoting process of epithelial-mesenchymal transition (EMT). This study examined the expression and function of GPR81 in breast cancer samples, and in receptor-positive epithelial vs. triple-negative post-EMT mesenchymal breast cancer cells.

Methods: GPR81 mRNA expression was examined by breast cancer microarray, and by a Kaplan-Meier survival curve. Using 3-dimensional culture conditions, GPR81 mRNA expression in epithelial and mesenchymal breast cancer cell lines was measured by qRT-PCR. GPR81 siRNA was used to assess the role of GPR81, alone or in conjunction with tamoxifen, in the regulation of MCT1 and MCT4 lactate transporters, intracellular lactate, and cell proliferation and survival.

Results: GPR81 mRNA levels were elevated in receptor-positive breast cancer, relative to non-tumor and triple-negative samples, and correlated with increased survival. GPR81 expression was elevated in the two epithelial breast cancer cell lines vs. the corresponding post-EMT mesenchymal cell lines. GPR81 knock-down in epithelial MCF7 cells caused: 1, selectively lower mRNA and protein expression of the MCT1 transporter, but not MCT2 or MCT4

transporters; 2, lower levels of intracellular lactate; and 3, decreased proliferation and survival in lactate only-containing conditions. GPR81 siRNA plus tamoxifen displayed additive suppressive effects on MCT1 expression and cell viability.

Conclusion: GPR81 promotes the ability of epithelial breast cancer cells to import lactate for energy use. As such, GPR81 represents a potential target for treatment of hormone-positive breast cancer cells, and may be prognostic for higher grade breast cancer.

Keywords: GPR81, lactate metabolism, MCT transporters, MCT1, tamoxifen

INTRODUCTION

Invasive breast cancer (IBC) is the most predominant form of cancer among women worldwide and the second leading cause of cancer-related deaths in women in the United States^[1,2]. Moreover, breast cancer is a complex and heterogeneous disease, which includes a range of pathological subtypes associated with different clinical behavior, treatment options and outcomes. The most common subtype of IBC, termed Luminal A, is characterized by an adhesive epithelial phenotype and defined by the overexpression of the estrogen receptor α (ER α) that underlies the endocrine-based treatment of this subtype^[3]. Although Luminal A IBC is a relatively non-aggressive type with a good response to adjuvant endocrine therapy and a high survival rate, failure of early detection is associated with metastatic disease, which in turn is responsible for the majority of deaths in breast cancer patients.

The metastatic dissemination of epithelial IBC cells is initiated by the reprogramming of cellular regulatory pathways that induce a coordinated downregulation of cell-cell adhesion and the acquisition of motility and invasiveness in a subpopulation of cancer cells. Epithelial-mesenchymal transition (EMT) has been proposed as a key regulatory program that drives these early metastasis-related changes^[4]. The process of EMT can be induced by exposure of cancer cells to an altered microenvironment (e.g., hypoxia, pro-inflammatory cytokines), often in conjunction with somatic mutations^[5,6].

We previously reported that prolonged mammosphere culture induced EMT in two distinct epithelial breast cancer cell lines, MCF-7 and BT-474 cells, and generated stable populations of mesenchymal cancer cells, MCF-7M and BT-474M^[7,8]. EMT promoted a more glycolytic phenotype compared to the parental epithelial breast cancer cells that primarily use oxidative phosphorylation to produce ATP (submitted manuscript). The altered metabolic phenotype induced by EMT involved enhanced aerobic glycolysis (i.e., the Warburg effect) along with higher rates of lactate production and extracellular acidification.

As a result of the glycolytic shift induced by EMT, mesenchymal cells co-export higher amounts of lactate and protons to the extracellular microenvironment, thereby creating an acidic microenvironment that has been associated with tumor progression^[9]. Elevated levels of lactate within the tumor microenvironment have been associated with metastasis and poor prognosis of cancer patients^[10-12]. Once exported, lactate can act both as a carbon source for other cells and as a signaling molecule. For example, lactate produced by highly glycolytic cancer cells can be utilized by neighboring oxidative cancer cells for ATP production, a phenomenon known as “metabolic symbiosis”^[13,14]. As a “signaling molecule”, lactate can regulate migration, angiogenesis, immune escape and metastasis^[15-17].

Intracellular and extracellular lactate levels are determined, in part, by different isoforms of the lactate/H⁺ symporter, termed monocarboxylate transporters (MCTs)^[18,19]. MCT isoforms are lactate/proton co-transporters, and thus contribute to the acidification and lactate accumulation and signaling in the tumor microenvironment^[20].

However, different isoforms have different affinities for lactate and pyruvate, which influences whether they act predominantly as cellular exporters or importers of lactate and H⁺. MCT1 is a ubiquitous lactate/H⁺ symporter that is involved in both import and export of lactate, whereas MCT4 is primarily involved in lactate/H⁺ export. Both MCT1 and MCT4 are differentially expressed in several cancers, including breast cancer^[21]. Additional important players in lactate shuttling between cancer cells are the lactate dehydrogenases A and B (LDHA and LDHB) that catalyze the reversible conversion of pyruvate to lactate, alter the NAD⁺/NADH ratio and thus glycolytic flux, and have also been implicated in EMT and metastasis^[22].

Previous studies have identified the cell-surface G-protein-coupled receptor, GPR81, as an endogenous lactate receptor. GPR81 family of receptors consists of three highly homologous members, GPR109a, GPR109b and GPR81, which are regulated by the specific agonists, 3-hydroxybutyrate, 3-hydroxyoctanoate, and lactate, respectively^[23]. GPR81 has been mainly studied in adipocytes, in which the receptor is coupled to Gi/q. GPR81 activation by lactate decreases cAMP production, which ultimately reduces lipolysis^[24]. Recently GPR81 has been shown to be upregulated in several cancers (pancreas, colon, liver, breast, cervix) and its expression levels associated with tumor growth and metastasis^[25-29]. In this current study, we examined GPR81 expression in the context of EMT in breast cancer. We provide evidence that GPR81 promotes lactate transport by MCT1 in hormone-positive breast cancer cells and its expression is crucial for their cell proliferation and survival.

METHODS

Cell culture

BT-474 and MCF-7 cell lines were obtained from the American Type Culture Collection (Manassas, VA). EMT in MCF-7 and BT-474 cells was induced using prolonged mammosphere culture method as reported previously^[7,8]. BT-474 and MCF-7 and their corresponding EMT-derived BT-474-M and MCF-7-M cells were grown in DMEM/F-12 containing 10% heat inactivated FBS (Gibco, Grand Island, NY) and 1 × MycoZapTM Plus-CL antibiotic (Lonza, Walkersville, MD). BT-474 and MCF-7 cells were additionally supplemented with 1 × Insulin-Transferrin-Selenium solution (Gibco, Grand Island, NY). All cells were incubated at 5% CO₂ and at 37 °C.

3-dimensional culture

CorningTM MatrigelTM GFR (Fisher Scientific) or MatrigelTM (Corning) was used as culture matrix following a modified version of the previously described protocol for 3-dimensional on-top assay^[30]. Twenty-four-well plates were coated with 200 μL of the mix of 1:1 MatrigelTM/Physiological modified medium supplemented with 17 μmol/L Insulin-Transferrin-Selenium solution (Gibco, Grand Island, NY) and kept at 37 °C for 30 min to allow the MatrigelTM to solidify. All cell lines were suspended in physiological modified medium supplemented with 1× insulin and seeded into the coated twenty-four-plates. Epithelial and mesenchymal cells were seeded in 250 μL at 100,000 cells/well and 20,000 cells/well, respectively, and incubated at 37 °C for 30 min to allow cell attachment to the Matrigel. All wells were overlaid with 250 μL of physiological modified medium containing 4% MatrigelTM. Culture medium was replaced with fresh medium daily and cells were used for each assay after seven days, unless otherwise indicated.

Physiological modified medium and drugs

RPMI 1640 Medium Modified without L-glutamine, amino acids and glucose (powder, R9010-02; US Biological, Swampscott, MA) was supplemented with the following: from Sigma (St. Louis, MO) - 1X MEM amino acid mixture (minus glutamine) (M5550), 1× Lipid Mixture 1 (L0288), 14.3 mmol/L sodium bicarbonate powder (S5761); from ThermoFisher/Gibco, (Waltham, MA) -1× non-essential amino acid mixture (11140), 10% heat-inactivated FBS (16000069) and 15 mmol/L HEPES (15630-106); from (Lonza, Walkersville, MD) - 1× MycoZapTM Plus-CL antibiotic.

Unless otherwise noted, this medium was also supplemented with physiological levels of: glucose (5 mmol/L; Gibco A24940), sodium pyruvate (0.1 mmol/L; Gibco 11360-070), Na-lactate (1 mmol/L; Sigma L7022) and L-glutamine (0.5 mmol/L; Sigma G7513. This same medium, but without phenol red (powder, R9010-01; US Biological, Swampscott, MA, was used in assays where cells were treated with β -Estradiol or Tamoxifen.

MCT1 inhibitor SR 13800, β -Estradiol and Tamoxifen (Tocris Bioscience, Bristol, UK) solutions were used at concentrations of 100 nmol/L, 10 nmol/L and 1 μ mol/L, respectively.

Imaging of 3-dimensional structures

Cells were cultured in 3-dimensional Matrigel and glass bottom 24-well plate (MatTek Corporation, MA) for seven days. Phase contrast images of the 3-dimensional structures of epithelial and mesenchymal cells were imaged using a Zeiss Axio Observer inverted microscope (Carl Zeiss MicroImaging Inc., Thornwood, NY) equipped a QImaging Retiga EXi CCD digital camera (QImaging, Surrey, BC). For immunofluorescence images cell lines grown in 3-dimensional Matrigel at the seventh day were fixed in 2% formaldehyde in 1 \times PBS for 20 min. Cells were washed with 1 \times PBS and then treated with 0.1% Triton-X 100 for 10 min. Cell were washed with 1 \times PBS and blocked with 1% bovine serum albumin (BSA) for 20 min. After blocking, cells were incubated with F-actin-staining solution for 20 min at room temperature. F-actin-staining solution was prepared with 5 μ L Alexa-488 Phallotoxin (Invitrogen, Carlsbad, CA) stock in 200 μ L 1 \times PBS for each well to be stained. SYTOXTM orange dye (Invitrogen, Carlsbad, CA) was used to stain nuclei. Images were captured using a Zeiss Pascal confocal system with a 40 \times 1.2 NA objective (Carl Zeiss Microscopy, Narashige, MN).

Transient transfection of siRNA

MCF-7 cells were seeded in 250 μ L at a density of 150,000 cells/well in twenty-four-well plates coated with 200 μ L of the mix of 1:1 MatrigelTM/Physiological modified medium supplemented with 17 μ mol/L Insulin-Transferrin-Selenium solution (Gibco, Grand Island, NY) and transiently transfected with Trilencer-27 human siRNA (siNT and siGATA3 "A") at a final concentration of 10 nmol/L (Origene, Rockville, MD) with LipofectamineTM RNAiMAX transfection reagent (Thermo Scientific, Rockford, IL). After 8 h of transfection cells were overlaid with 250 μ L of physiological modified medium containing 4% MatrigelTM. Culture medium was replaced with fresh medium every day and cells were used for each assay after 72 or 96 h after transfection.

Growth and viability assays

MCF-7 cells were seeded at a density of 150,000 cells/well and recovered from Matrigel by incubating them with 5 mM EDTA (Gibco, Grand Island, NY) in ice cold 1 \times PBS for 30 minutes at 4 $^{\circ}$ C and centrifuged for 5 min at 1000 rpm. Recovered cells were digested with 0.25% trypsin for 4 min and resuspended in DMEM with 10% FBS. The cell number was calculated on hemocytometer at specific time point. Viability assays were performed three times for each cell group.

Real-time qPCR and primers

Total RNA was isolated from cell lines using TRIzol Reagent (Ambion RNA, Carlsbad, CA), following the manufacturer's instruction. cDNA was synthesized 1 μ g of total RNA using iSCRIPT cDNA synthesis kit (Bio-Rad, Hercules, CA). SYBR green based SsoFast EvaGreen Supermix (Bio-Rad, Hercules, CA) was utilized to perform real-time PCR from 50 ng of cDNA. Gene expression was normalized to TATA-box binding protein using $2^{-\Delta C_t}$ method. Specificity of the primer sets was confirmed by melting curve analysis.

cDNA arrays

Real-time qPCR was performed in two TissueScanTM breast cancer and normal tissue cDNA arrays I and II (Origene, Rockville, MD). Gene expression was normalized to normal tissue using $2^{-\Delta C_t}$ method.

Glucose uptake and lactate production

Cells were cultured and transfected in 3-dimensional MatrigelTM with physiological modified medium for 72 or 96 h and medium was changed daily. Glucose and lactate concentrations in the culture medium were determined by fluorometric based Glucose Assay Kit and Lactate Assay Kit (BioVision, Inc., Milpitas, CA) according to the vendor's instructions using Synergy 2 Multi-Mode Microplate Reader (BioTek, Winooski, VT). The amount consumed or produced by cells was determined by comparing the concentration in the medium incubated without cells and then normalized to cell number. These assays were performed three times with two experimental replicates for each cell type.

Western blot and antibodies

Cells were collected from 3-dimensional MatrigelTM culture (as described previously) and lysed with RIPA buffer (TEKnova, Hollister, CA) containing Halt Protease and Phosphatase Inhibitor Cocktail (Thermo Scientific, Rockford, IL). The lysates were clarified by centrifugation at 4 °C for 10 min at 12,000 ×g. The concentration of protein in the supernatants was measured using BCA assay (Thermo Scientific Pierce, Rockford, IL). Total proteins (20 µg/lane) were separated on a 10% SDS-PAGE and were transferred to nitrocellulose membrane. The membranes were blocked with 5% BSA in 1× TBST (β-actin) or with 5% non-fat milk (MCT1, MCT4 and Cleaved PARP) and subsequently incubated with primary and secondary antibodies according to the vendor's instructions. Blots were visualized by using Amersham ECL prime (GE Healthcare Life Sciences, Buckinghamshire, UK) and imaged using G:box imaging system (SynGene, Cambridge, UK). Primary antibodies to Cleaved PARP (1:1000) was given by Dr. Claffey from Cell Signaling Technology (Danvers, MA); β-actin (1:2500) and MCT1 (1:1000) were purchased from Abcam (Cambridge, MA). MCT4 (1:1000) was purchased from Millipore (Billerica, MA). All images were imported to Image J for pixel grayscale intensity analysis. Western blot analysis was performed three times using two independent protein samples for each cell group.

Nuclear magnetic resonance spectroscopy and data analysis

Cells were collected from 3-dimensional MatrigelTM culture (as described previously) and lysed with 1:1:1 methanol/chloroform/water in sequence with 5 s of gyration between additions. In order to optimize chemical extraction, non-trypsin-based methods were employed as follows^[31]. A 10 µL sample was then removed for cell counting. Resulting lysed solution was then allowed to separate overnight at 4 °C to form resultant aqueous and organic layers. Aqueous layer containing metabolites of concern were then manually extracted and resulting solution was subjected to addition of Chelex (approximate 3 mg/mL) for removal of divalent ions, which was then removed through vacuum filtration using Buchner filter. Solution was then lyophilized overnight to form solid components. 800 µL of D₂O with 10 mmol/L EDTA and 1 mmol/L 4, 4-dimethyl-4-silapentane-1-sulfonic acid (DSS) was added and solution was centrifuged at 3000 rpm for 5 min prior to placement in standard 5 mm nuclear magnetic resonance (NMR) tube for ¹H NMR.

¹H NMR experiments were performed on 500 MHz Agilent spectrometer with HCN cold probe and a VNMRs console. Default pre-saturation pulse sequences were utilized with the following parameters: pulse-width = 7.2 µs, sweep-width = 8389.26 Hz, 2460 complex points, D₁ = 1.5 s, SATPWR = 6 dB on H₂O signal, and 64 transients. Resulting ¹H NMR underwent Fourier Transformation and data was further analyzed in MestReNova NMR software, version 9.0.0. Processing template for all spectra had the following time domain corrections: drift correction to tail points of 5% and apodization through an exponential of 1.5 Hz. The frequency domain had global phase correction and a baseline correction using Bernstein polynomial of $n = 3$. Reference signal was set as the singlet produced off of DSS at 0 ppm. Lactate and Pyruvate were identified on the spectra through prior titration analyses and the absolute area under the curve was used for their methyl groups with respect to methyl groups found off of DSS with the usage of Line-Shape analysis. These areas were used to calculate concentrations by a ratio of the absolute area to the number of protons

Figure 1. GPR81 expression of epithelial MCF-7 and BT-474 cells and mesenchymal MCF-7M and BT-474M in 3-dimensional Matrigel culture. A: fluorescence microscopy images of 3-dimensional structures of proliferating epithelial (E) and mesenchymal (M) cells in 3-dimensional Matrigel with physiological modified medium for 7 days. Green, Phalloidin staining of F-actin; red/orange, nuclei counterstained with SYTOXTM orange nucleic acid (red); B: real-time qPCR analysis of GPR81 in epithelial (E) and mesenchymal (M) cells. Results are presented as mean \pm S.E.M. * $P < 0.05$; ** $P < 0.01$; *** $P < 0.001$; **** $P < 0.0001$ (ordinary one-way ANOVA)

in the signal used. Resulting concentrations in millimolar were then exported into an Excel spread sheet containing cellular counts to determine a normalized concentration per number of cells.

Statistical analysis

Ordinary one-way ANOVA followed by Sidak's multiple comparison post-test or two-way ANOVA was performed to determine statistical significance. $P < 0.05$ was considered to be significant. Statistical analysis was performed using GraphPad Prism software (La Jolla, CA).

RESULTS

Endogenous lactate receptor GPR81 is upregulated in epithelial breast cancer cells

Epithelial (E) MCF-7 and BT-474 cell lines and the corresponding post-EMT mesenchymal (M) MCF-7M and BT-474M were cultured in a more physiologically relevant system using 3-dimensional Matrigel and physiological modified medium (referred as MPM culture). Under these conditions epithelial breast cancer cells grew as tightly adherent spheroids for 1 week [Figure 1A; "E" boxes]. The two mesenchymal cell lines also formed tight spheroids initially, but after 2 days began invading the Matrigel [Figure 1A; "M" boxes]. After 1 week of MPM culture, cells were examined for the expression of the endogenous lactate receptor GPR81. Epithelial spheroids expressed relatively high levels of GPR81, whereas mesenchymal cells showed no or very low expression [Figure 1B].

GPR81 is highly expressed in human hormone-receptor-positive breast cancer tissues

To determine whether GPR81 was present in human breast cancer tumors, we analyzed mRNA gene expression profiles from 74 human breast cancer samples and 12 non-tumorigenic (NT) breast tissues [Figure 2A]. We grouped these samples in non-tumorigenic (NT), estrogen receptor positive (ER⁺), amplification of the human epidermal receptor growth factor 2 (HER2⁺) and triple negative breast cancer (TNBC) according to their clinical information provided by the supplier. Higher levels of GPR81 mRNA were noted in hormone-

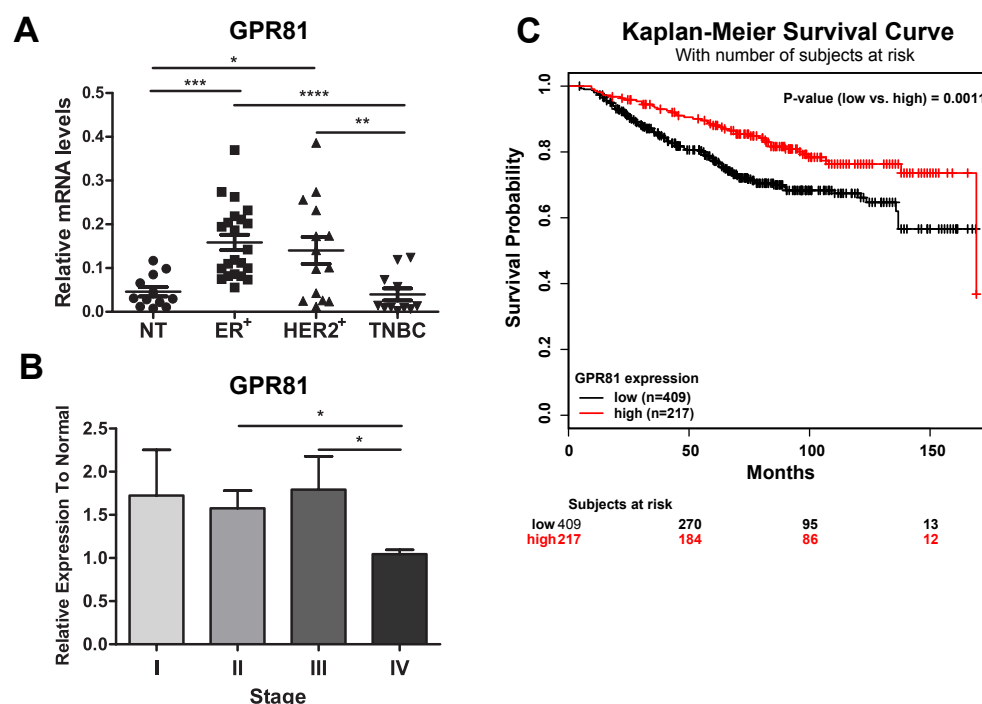

Figure 2. GPR81 is highly expressed in human hormone-receptor-positive breast cancer tissues. A: relative mRNA expression of GPR81 in ER⁺ ($n = 32$), HER2⁺ ($n = 17$) and TNBC ($n = 12$) breast cancer tissues to normal tissue ($n = 12$); B: relative mRNA expression of GPR81 in stage I ($n = 21$), II ($n = 32$), III ($n = 25$) and IV ($n = 4$) of breast cancer; C: Kaplan-Meier plot of estimated overall survival in breast cancer patients ($n = 626$) with low expression of GPR81, below the median (black line) or high expression of GPR81, above the median (red line). Log-rank test P -value = 0.0011. Results are presented as mean \pm S.E.M. * $P < 0.05$; ** $P < 0.01$; *** $P < 0.001$ (two-way ANOVA)

positive breast cancer samples (ER⁺ and HER2⁺) and significantly lower levels were found in the NT and TNBC samples [Figure 2A]. We also analyzed the relative gene expression of GPR81 by the stage of human breast cancer. Breast cancer stage II-III had significantly higher GPR81 expression than stage IV [Figure 2B]. Additionally, the Kaplan-Meier survival plot showed that high expression levels GPR81 was strongly associated with better prognosis and overall survival in breast cancer patients [Figure 2C] ($P = 0.0011$) ($n = 626$)^[32]. We also tested GPR81 expression in other breast cancer cell lines. Hormone-receptor positive HC1500 cells had higher expression of the lactate receptor and lactate importer compared to the TNBC, MDA-MB231 cells [Supplementary Figure 1A-C]. These results demonstrate that GPR81 is mainly expressed in hormone positive and less aggressive types of human breast cancer.

GPR81 regulates expression of the gene involved in lactate import in MCF-7 epithelial breast cancer cell line

A previous study reported that GPR81 regulates the expression of lactate transport related genes MCT1 and MCT4 in pancreatic cancer cells through an as yet unknown mechanism^[26]. To determine the role of the endogenous lactate receptor GPR81 in the lactate metabolism of estrogen positive breast cancer cells, we silenced GPR81 (~60%) in MCF-7 cancer cells using siRNA (siGPR81) up to four days in MPM culture [Figure 3A]. GPR81 knockdown in MCF-7 cells led to a 2-fold reduction mRNA and protein expression of the lactate importer, MCT1, but had no effect on the lactate exporter, MCT4 [Figure 3B and C]. In addition, GPR81 did not significantly alter the expression of other lactate metabolism-related genes (LDHA, LDHB, MCT2) [Supplementary Figure 2].

GPR81 regulates lactate uptake in MCF-7 epithelial breast cancer cell line

We found that the two epithelial breast cancer cell lines had higher steady state levels of intracellular lactate and pyruvate than the corresponding post-EMT mesenchymal cell lines^[33]. Given that MCT1 is primarily a

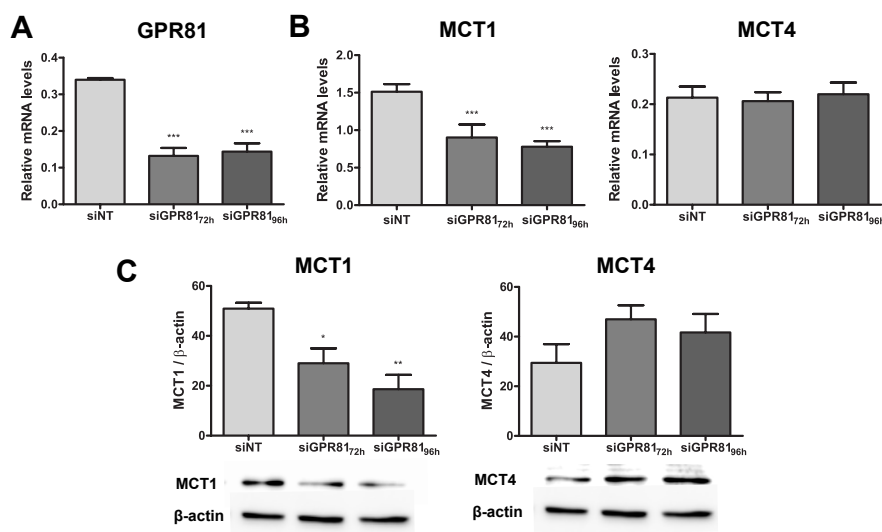

Figure 3. GPR81 regulates expression of the gene involved in lactate import in MCF-7 epithelial breast cancer cell line. A: real-time qPCR analysis of GPR81; B: MCT1 and MCT4 mRNA levels in MCF-7-siNT (control) and MCF-7-siGPR81 cultured in 3-dimensional Matrigel with physiological modified medium at 72 and 96 h after transfection; C: Western blot analysis of cell lysates from MCF-7-siNT and MCF-7-siGPR81 cells used to detect protein expression levels of MCT1 and MCT4. β -actin was used as a loading control. Figure 4. GPR81 regulates lactate uptake in MCF-7 epithelial breast cancer cell lines. A: intracellular lactate of MCF-7-siNT (control) and MCF-7-siGPR81 measured using NMR analysis after 72 h of transfection; B: lactate concentration in the medium of MCF-7-siNT 10 nmol/L and MCF-7-siGPR81 10 nmol/L were measured after 96 h of transfection; C: glucose consumption rate of MCF-7-siNT and MCF-7-siGPR81 were measured after 96 h of transfection. MCF-7-siNT and MCF-7-siGPR81 cells were cultured and transfected in 3-dimensional Matrigel with physiological modified medium and measurements were taken after 24 h of culture in fresh medium. The bars represent the mean \pm S.E.M of three independent experiments; * P < 0.05; ** P < 0.01; (ordinary one-way ANOVA)

lactate importer, we hypothesized that the reduction of MCT1 expression may affect the lactate uptake of the epithelial MCF-7 breast cancer cells. To test this hypothesis, we measured the intracellular lactate of non-targeted control MCF-7-siNT and MCF-7-siGPR81 in MPM culture using NMR analysis. MCF-7-siGPR81 cells had significant lower intracellular lactate compared to MCF-7-siNT cells [Figure 4A], indicating reduced lactate uptake of MCF-7-siGPR81 cells. Additionally, GPR81 knockdown resulted in higher levels of lactate

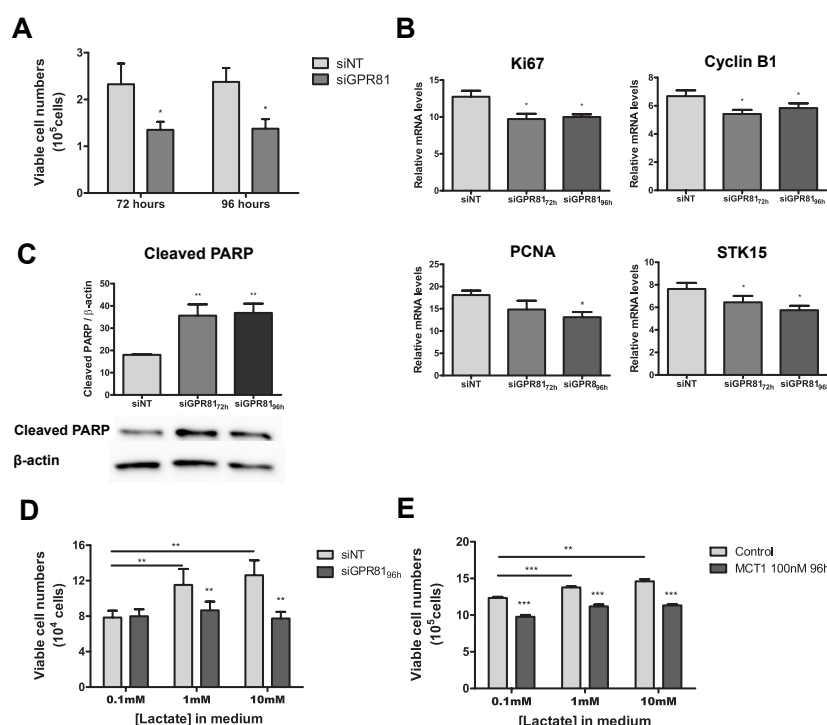

Figure 5. GPR81 is required for cancer cell proliferation and cancer cell survival when lactate is the primary fuel source. A: viable cell counts of MCF-7-siNT (control) and MCF-7-siGPR81 after 72 and 96 h of transfection and subtracting the initial cell number; B: real-time qPCR analysis of proliferation markers: Ki67, Cyclin B1, PCNA and STK15; C: Western blot analysis of cell lysates from MCF-7-siNT and MCF-7-siGPR81 cells after 72 and 96 h of transfection used to detect protein expression levels of the apoptotic marker cleaved-PARP. β -actin was used as a loading control; D: MCF-7-siNT and MCF-7-siGPR81 breast cancer cells were cultured in 3-dimensional Matrigel with physiological modified medium containing only lactate at 0.1 mmol/L, 1 mmol/L and 10 mmol/L concentration for 96 h; E: MCF-7 breast cancer cells were cultured in 3-dimensional Matrigel with physiological modified medium containing only lactate at 0.1 mmol/L, 1 mmol/L and 10 mmol/L concentration and treated with or without MCT1 inhibitor SR 13800 for 96 h. Viable cell counts after treatment. Results are presented as mean \pm S.E.M. of three independent experiments; * P < 0.05; ** P < 0.01; *** P < 0.001 (ordinary one-way ANOVA)

in the culture medium but not control MCF-7-siNT cells [Figure 4B]. We did not detect significant change in glucose consumption [Figure 4C]. Taken together, these data suggest the role for GPR81 in the regulation of the lactate uptake of the epithelial MCF-7 breast cancer cells.

GPR81 is required for cancer cell proliferation and cancer cell survival when lactate is the primary fuel source

Lactate has been previously suggested as an alternative energy source for aerobic breast cancer cells^[13,14,34]. To determine whether GPR81 plays a role in breast cancer cell proliferation, we studied the increase in viable cell numbers and the expression of cell proliferation makers (taken from the OncotypeDx recurrence score assay) in control MCF-7-siNT and MCF-7-siGPR81 cells. Silencing of GPR81 led to about 40% reduction in cell proliferation of MCF-7-siGPR81 [Figure 5A] and decreased relative gene expression of proliferation makers; Ki67, Cyclin B1, PCNA and STK15 [Figure 5B]. Furthermore, the expression of the cell apoptosis marker, cleaved PARP, was significantly increased by 2-fold in MCF-7-siGPR81 cells when compared to control MCF-7-siNT cells [Figure 5C].

To determine whether GPR81 expression is required for cell growth and survival, we cultured control MCF-siNT and MCF-7-siGPR81 cells in 3-dimensional Matrigel with physiological medium lacking glucose, glutamine and pyruvate and with 0.1 mmol/L, 1 mmol/L or 10 mmol/L lactate as the main available nutrient source. Despite of the significant increase in cell number of the MCF-7-siNT cells when cultured in medium containing only 1 mmol/L and 10 mmol/L lactate, GPR81 silencing prevented cell growth under these nutrient-limited

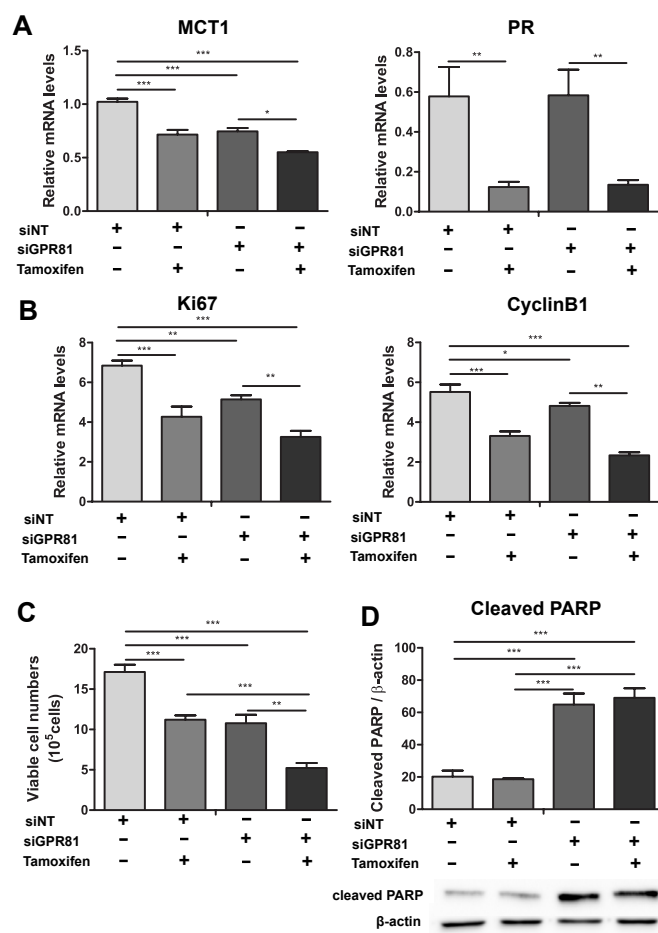

Figure 6. Additive effect of GPR81 knockdown and Tamoxifen treatment in reducing the cell proliferation and increasing cell apoptosis in epithelial MCF-7 breast cancer cells. MCF-7-siNT (control) and MCF-7-siGPR81 cancer cells were treated with or without 1 μ mol/L Tamoxifen for 96 h in 3-dimensional Matrigel with physiological modified medium. A: real-time qPCR analysis of lactate importer MCT1; and progesterone receptor PR; B: relative mRNA expression of proliferation markers: Ki67 and Cyclin B1; C: viable cell counts of epithelial MCF-7-siNT and MCF-7-siGPR81; D: Western blot analysis of cell lysates from MCF-7-siNT and MCF-7-siGPR81 used to detect protein expression levels of the apoptotic marker cleaved-PARP. β -actin was used as a loading control. Results are presented as mean \pm S.E.M. of three independent experiments * P < 0.05; ** P < 0.01; *** P < 0.001; **** P < 0.0001 (ordinary one-way ANOVA)

conditions [Figure 5D]. Similarly, we found that treatment with the MCT1 inhibitor also prevented cell growth when in MCF-7 cells were culture in nutrient-limited conditions [Figure 5E]. Taken together, these data support the physiological role for GPR81 in the regulation of lactate uptake, cell proliferation and survival of the epithelial MCF-7 breast cancer cells under nutrient-limited conditions.

Tamoxifen treatment in reducing cell proliferation and increasing cell apoptosis has additive effect on GPR81 knockdown

We observed here that 1 μ mol/L Tamoxifen further reduced MCT1 gene expression in GPR81-silenced MCF-7 cells treated for 4 days [Figure 6A]. The effect of Tamoxifen was confirmed by the reduced expression of the progesterone receptor^[35]. We next evaluated the effects of Tamoxifen and GPR81 silencing in cell proliferation and apoptosis in ER+ MCF-7 breast cancer cells. GPR81 knockdown and Tamoxifen treatment had an additive effect on the reduction of cell proliferation markers; Ki67 and Cyclin B1 [Figure 6B], as well as viable cell numbers of MCF-7 cells in MPM culture [Figure 6C]. Additionally, cell apoptosis was significantly increased only in MCF-7-siGPR81 cells independently of Tamoxifen treatment, showed by the increased expression of the apoptotic marker cleaved PARP [Figure 6E]. These data suggest GPR81 regulates cell proliferation and apoptosis.

DISCUSSION

The metabolic changes that cancer cells undergo in order to support macromolecule biosynthesis, growth and survival, are collectively referred to as “metabolic reprogramming”, now considered a hallmark of cancer cell biology^[36,37]. Increasing evidence has linked metabolic reprogramming to metastatic transformation. For example, it has been shown that the EMT-transcription factor SNAIL mediates the suppression of mitochondrial respiration and enhances glycolysis in breast cancer^[38,39]. In the accompanying report in this issue, we demonstrated that EMT induced a metabolic shift to a less oxidative and more glycolytic metabolism in two epithelial cell lines MCF-7 and BT-474, as evidenced by increased glucose uptake and lactate production along with increased expression of enzymes and transporters. These studies suggest that metastatic transformation or EMT facilitates the metabolic shift toward glycolysis in some forms of breast cancer.

We also observed that metabolic reprogramming induced by EMT was associated with a striking switch in the expression of the lactate transporters MCT1 and MCT4. The two epithelial breast cancer cell lines expressed high levels of MCT1 and imported lactate as an alternative energy source. In contrast, the mesenchymal cells showed a marked decreased expression of MCT1 and upregulation of the lactate exporter MCT4. Our findings are consistent with those of Hussein and Brooks^[40], who reported MCT1 was expressed in MCF7 cells, but not in mesenchymal, triple-negative MDA-MB-231 cells, that were maintained in 2-dimensional culture containing high glucose medium. Similarly, MCT4 expression was lower in MCF7 cells as compared to the MDA-MB-231 cells. Using 2-dimensional culture and DMEM/F12 media with high glucose levels, Baenke *et al.*^[41] examined MCT4 expression and function in 17 breast cancer cell lines. Although their findings differed from ours in that MCT4 expression was highest in HER2-positive cell lines, these authors reported that MCT4 suppression increased mitochondrial oxidation, linking MCT4 to a more glycolytic phenotype. This is consistent with MCT4 promoting a glycolytic phenotype, and also raises the prospect that breast cancer cells can adapt to targeted therapies in part through metabolic reprogramming. In contrast to our finding of reciprocal expression between MCT1 and MCT4, Pinheiro *et al.*^[42] used immunohistochemistry to analyze primary breast carcinomas for MCT1 and MCT4, and found MCT1 expression occurring most frequently in the Basal-like subtype and in higher grades of breast cancer. It is also important to note that expression of MCTs does not always correlate to lactate/H⁺ transport. For example, hypoxia-induced carbonic anhydrase IX enhanced the activity of MCT1 to export lactate and H⁺ in MCF7 cells in 2-dimensional culture with physiological (5 mmol/L) glucose levels. MCT4 upregulation was previously reported in triple negative breast cancer and high levels of this lactate exporter were associated with poor prognosis and survival^[41,43].

Lactate has been identified as the ligand for the endogenous cell-surface G-protein-coupled receptor 81 (GPR81). GPR81 was first discovered and mostly studied in adipocytes, in which lactate activates GPR81 to decrease the cAMP production to ultimately reduce lipolysis^[24]. GPR81 is highly expressed in neurons^[44], and when activated, it is able to modify electrical activity of primary neuronal cells^[45]. Also, the activation of GPR81 by lactate has been identified as the initial step for an anti-inflammatory response in pancreas, liver and uterus^[46-48].

More recently, GPR81 expression has been found to be upregulated in several types of cancer, including pancreatic, colon, liver, breast, lung and cervical cancers, and in several cases high GPR81 expression was associated with tumor growth, chemoresistance and metastasis^[25-28]. It should also be noted that previous studies indicate that lactate activates GPR81 in the millimolar range (1-5 mmol/L), and in human breast cancer tissues lactate was found to be at concentrations as high as 8 mmol/L^[14], suggesting that GPR81 and downstream signaling pathways could be constantly activated by lactate in the breast tumor microenvironment. Our study provides the first examination of GPR81 expression in the context of EMT, and indicates that GPR81 expression is dependent on the type of breast cancer cell. We showed that hormone-positive epithelial breast cancer cells highly expressed GPR81. In contrast, EMT induction and

transformation of epithelial breast cancer cells into triple negative mesenchymal cancer cells was associated with significantly reduced expression of GPR81. Lee *et al.*^[25] reported that GPR81 expression is significantly increased in breast cancer patients compared to normal mammary tissues. We also observed a significant association between GPR81 overexpression with ER α -positive and human epidermal growth HER2 positive human breast cancer tissues as opposed to triple negative breast cancer. This is consistent with previous observations that ER α -positive breast cancer tissues overexpressed GPR81^[25]. In addition, GPR81 was expressed at higher levels in the first three stages of breast cancer (Stage I, II and III) as compared to Stage IV, and GPR81 expression correlated with better overall survival of breast cancer patients. These findings suggest that GPR81 may be an important regulator in hormone-positive breast cancer and could be used as a prognostic marker in the progression of breast cancer.

GPR81 was reported to regulate the expression of genes involved in lactate metabolism, including lactate transporters, MCT1 and MCT4, in pancreatic cancer cells^[26]. In partial agreement, our study revealed that GPR81 specifically regulates the lactate importer MCT1, but not lactate exporter MCT4, in epithelial breast cancer cells. Oxidative breast tumor cells with high expression of the lactate importer, MCT1, have been reported to import and oxidize extracellular lactate, a mechanism that is essential for cell viability under glucose deprivation^[14,34,49]. In fact, Lee *et al.*^[25] showed that epithelial breast cancer cells imported and utilized ¹⁴C-lactate for mitochondrial respiration. We previously showed that inhibition of MCT1 reduced cell proliferation in epithelial but not mesenchymal cancer cells when lactate was used as the primary extracellular fuel source. Here we report that GPR81 silencing caused downregulation of MCT1 and reduced cell growth in epithelial breast cancer cells grown in complete MPM medium. We reported that the two epithelial breast cancer cell lines contained significantly higher intracellular lactate and pyruvate than the two corresponding post-EMT mesenchymal cell lines (submitted manuscript). In the present study, we observed that silencing of GPR81 in MCF7 cells led to lower intracellular lactate and higher levels of lactate in the culture media, indicating reduction in lactate uptake. Furthermore, we found a protective effect of GPR81 against apoptosis, which was previously described in epithelial MCF-7 breast cancer cells, in which GPR81 activation triggered the PI3K/Akt signaling pathway to inhibit apoptosis^[25]. Together these results suggest a specific regulation of GPR81 on lactate importer MCT1, which affects cell proliferation, apoptosis and survival of hormone-positive epithelial breast cancer cells.

In adipocytes, GPR81 is coupled to Gi/q which inhibits adenylate cyclase activity and decreases the production of cAMP. However, a previous study did not find a significant change in cAMP levels when GPR81 was silenced in epithelial MCF-7 breast cancer cells^[25], suggesting that GPR81 regulates MCT1 expression by another signaling pathway in this cells. Alternate GPR81-associated signaling that is independent of the PKA/cAMP pathway, but involves the GPR81-binding protein β -arrestin, has been reported in monocyte/macrophage^[48]. Further studies are needed to examine whether the β -arrestin pathway or other pathways are linked to GPR81 signaling in epithelial breast cancer, as these pathways may provide targets for future development of adjuvant therapies for Luminal A breast cancer.

DECLARATIONS

Acknowledgments

We thank Dr. Kevin Claffey, Department of Cell Biology, University of Connecticut for providing us the Cleaved PARP antibody and the cell line HC1500. This work supported by the Fund for Biology from the Cell Biology Department at the University of Connecticut Health Center.

Authors' contributions

Made substantial contributions to conception and design of the study and performed data analysis and interpretation: Tafur D, White B

Performed NMR studies, data acquisition, analysis and interpretation: Svrcek P

Abstract

As a field we have made tremendous strides in treating breast cancer, with a decline in the past 30 years of overall breast cancer mortality. However, this progress is met with little affect once the disease spreads beyond the primary site. With a 5-year survival rate of 22%, 10-year of 13%, for those patients with metastatic breast cancer (mBC), our ability to effectively treat wide spread disease is minimal. A major contributing factor to this ineffectiveness is the complex make-up, or heterogeneity, of the primary site. Within a primary tumor, secreted factors, malignant and pre-malignant epithelial cells, immune cells, stromal fibroblasts and many others all reside alongside each other creating a dynamic environment contributing to metastasis. Furthermore, heterogeneity contributes to our lack of understanding regarding the cells' remarkable ability to undergo epithelial/non-cancer stem cell (CSC) to mesenchymal/CSC (E-M/CSC) plasticity. The enhanced invasion & motility, tumor-initiating potential, and acquired therapeutic resistance which accompanies E-M/CSC plasticity implicates a significant role in metastasis. While most work trying to understand E-M/CSC plasticity has been done on malignant cells, recent evidence is emerging concerning the ability for pre-malignant cells to undergo E-M/CSC plasticity and contribute to the metastatic process. Here we will discuss the importance of E-M/CSC plasticity within malignant and pre-malignant populations of the tumor. Moreover, we will discuss how one may potentially target these populations, ultimately disrupting the metastatic cascade and increasing patient survival for those with mBC.

Keywords: Cell plasticity, pre-malignant plasticity, breast cancer, epithelial-mesenchymal transition/cancer stem cell, metastasis

INTRODUCTION: THE MORTALITY OF METASTATIC BREAST CANCER

Breast cancer (BC) is the most commonly diagnosed cancer among women, and the second leading cause of cancer related deaths in women^[1]. The statistics highlight the importance of metastasis in BC mortality: in patients with distant metastasis, 5-year survival rates are only 22% (13% at 10 years), compared to 90% for patients with local disease^[2]. Furthermore, for those patients with metastatic BC (mBC), there are currently no effective treatment options. Understanding how BC cells escape the primary tumor, spread to distant organs, initiate outgrowth at a distant site, and then developing therapies to target those metastatic processes remains a significant clinical challenge. Our understanding of the metastatic cascade has increased in recent years: cells must degrade the extracellular matrix (ECM) surrounding them, extravasate into the circulatory or lymphatic system and circulate throughout the body, intravasate into the new organ tissue, and regain their proliferative capacity^[3-5]. Yet, the molecular mechanisms driving each of these processes, all of which are important for a successful metastatic event, remain unresolved.

A complicating factor to our understanding of BC metastasis is the heterogeneous milieu of the primary tumor site, or tumor micro-environment (TME), which is comprised of epithelial, endothelial, immune, and stromal cells. It is important to note that the epithelial populations can be subdivided into two distinct groups, malignant and pre-malignant. The malignant population has completed the transformation process through loss of tumor suppressive mechanisms and a gain of oncogenic signaling, via genetic mutation or sustained growth factor or cytokine signaling. Conversely, pre-malignant refers to a spectrum of points on the path towards transformation. Pre-malignant cells drift further from normalcy as they acquire mutations and engage aberrant signaling. If intact, a tumor suppressive response may be engaged to halt the transformation process, however if lost, the cell may progress to a fully transformed endpoint. The complex cellular composition within the TME results in a network of secreted factors and ECM proteins, which also profoundly influence metastatic potential^[6-9]. Numerous TME factors can drive epithelial cells to undergo epithelial-mesenchymal transition (EMT) and acquire cancer stem cell (CSC) properties, which we refer to as epithelial-mesenchymal (E-M)/CSC plasticity^[10-14]. Seminal work has defined E-M/CSC plasticity as an important step in metastasis and is often investigated from the perspective of a malignant population. However, malignant cells are not the only populations capable of undergoing E-M/CSC reprogramming. Recent evidence has demonstrated a remarkable ability of pre-malignant epithelial cells to take on a more invasive phenotype able to intravasate and disseminate to secondary sites following signaling cues from the TME^[15,16]. Here, we discuss the challenges of targeting various cell populations and the signaling pathways that contribute to the cellular plasticity driving mBC. Importantly, we will explore the impact of pre-malignant cells escaping senescence by undergoing E-M/CSC reprogramming to gain invasive, metastatic, and tumor-initiating properties. Identifying determinants of metastasis, such as E-M/CSC plasticity, and advancing our ability to target the drivers of plasticity will have a significant impact on survival for those with mBC.

SETTING THE STAGE: HETEROGENEITY WITHIN THE PRIMARY SITE

A major challenge in dealing with BC is the heterogeneity that accompanies it. With three distinct clinical subtypes, estrogen and progesterone receptor positive (ER+/PR+), human epidermal growth factor receptor 2 positive (HER2+), and triple negative breast cancer (TNBC; negative for ER, PR, HER2 expression), finding the proper treatment options can be difficult^[17-19]. Therapies targeting ER/PR hormone signaling via selective estrogen receptor modulators (SERMs) or aromatase inhibitors (i.e., Tamoxifen and Arimidex) have significantly improved patient survival and have made this subtype more manageable. Likewise, HER2+

tumors can be treated with antibodies or kinase inhibitors targeting HER2 signaling (i.e., Trastuzumab and Lapatinib) and are often met with success provided the disease is caught early; the efficacy of these therapies drastically decreases with late stage, metastatic HER2+ BC^[20-23]. Conversely, TNBC currently lacks a targeted therapy tailored to a specific driver oncogene and is most often treated with cytotoxic chemotherapies. Patients with TNBC exhibit an increased risk of metastatic dissemination resulting in higher clinical stage at diagnosis and lower disease-free survival compared to patients with non-TNBC cancers^[24]. Much like metastatic HER2+ BC, metastatic TNBC is not effectively treated, highlighting the need for better therapies targeting those cells which progress beyond the primary site and are ultimately responsible for patient mortality and morbidity. Further challenges in treating BC involve the heterogeneous nature of the tumor cells themselves, a phenomenon often referred to as intra-tumoral heterogeneity (ITH)^[25]. Evidence suggests that across a panel of human cancers, including breast, increased ITH correlates with decreased overall survival, and therapy resistance^[26,27]. Furthermore, high ITH inversely correlates with low tumor infiltrating lymphocytes, which are often associated with increased patient survival^[28-36].

The path to ITH is complex and involves a series of genetic and epigenetic events throughout the transformation process which permit normal human mammary epithelial cells (HMEC) to develop into fully malignant cancer cells^[37-44]. Progress in RNA and DNA sequencing technologies have helped shape the evolutionary picture of HMEC; losing tumor suppressor function (TP53 mutations or RB loss) and acquiring oncogenic drivers (MYC, HER2, or CCND1 amplification or PIK3CA mutations)^[45-49]. Genetic alterations lead to the expansion of a pre-malignant population which progressively acquires additional genetic and epigenetic changes until one or more cells become fully transformed^[50,51]. These additional mutations are numerous, and genomic profiling has found a wide variety of changes in copy number, chromatin alterations, chromosomal rearrangements, and point mutations throughout the genome from single cell sequencing of bulk tumor tissue in TNBC^[36,52,53]. Not only does this dynamic process of transformation alter the cancer cell itself, but transforming cells have a substantial impact on the surrounding environment. Evidence suggests that the accumulation of mutations within epithelial cells can lead to a dysregulated secretory network, including a number of inflammatory cytokines linked to poor prognosis, therapy failure, and disease recurrence (IL-6, IL-8, TGF- β , CCL2, TNF- α , IL-17 and others)^[54-59]. This dysregulated secretory network in turn, changes the cellular composition of the TME, leading to a reciprocal cross-talk between non-cancerous stromal cells and the transforming epithelial cells. Overall, this demonstrates the immense complexity of the tumor, as the heterogeneity described above culminates in a highly diverse TME, with an array of cell types, secreted factors, and structural make up.

Importantly, not all epithelial cells that begin the transformation process reach full malignancy. As a cell senses aberrant activation of signaling pathways/gene induction, it may enact intact tumor suppressive mechanisms, resulting in senescence^[60-66]. Senescence is a major growth-inhibiting and tumor-suppressive barrier that must be bypassed *in vivo* during transformation en-route to tumor development^[63,67-73]. Large senescent cell populations can be found at various stages of tumor development, further contributing to tumor heterogeneity. Remarkably, an investigation by Cotarelo *et al.*^[74] was able to identify the presence of senescent cells in approximately 83.7% of the human invasive breast carcinomas examined, suggesting their involvement throughout the transformation process and as tumors evolve and progress. Since the 129 tumors surveyed in this study were from untreated patients, the origin of senescence within these invasive BC is an *in vivo* physiological response.

Long thought inert, bystanders within the tumor, senescent cells have gained considerable interest for their potential impact on the tumor as a whole. Despite being growth-arrested, senescent cells remain viable, metabolically active, and play an important role in the developing TME^[75-77]. A hallmark of senescent cells is the secretion of a wide variety of growth factors, pro-inflammatory cytokines, chemokines, and proteinases, a characteristic termed the senescence-associated secretory phenotype (SASP) [Figure 1]^[78,79]. Under normal

Figure 1. The Heterogeneity of Breast Cancer. Breast cancer is a heterogeneous disease with a highly dynamic tumor micro-environment (TME). Within the primary site, one can observe the presence of epithelial cells that have undergone E-M/CSC plasticity, malignant epithelial cells, pre-malignant cells, senescent epithelial cells, stromal fibroblasts, infiltrating immune cells, and endothelial cells. The presence of all of these diverse cell types results in a distinct and complex milieu of secreted factors within the TME that influence, tumor progression, disease recurrence, and cell plasticity

conditions, the SASP-factors act in an autocrine manner to maintain the senescence program and recruit immune cells into the local environment^[80-83]. However, paracrine signaling by SASP components can also influence the behavior of adjacent cells, engaging signaling programs that contribute to tumor progression and therapy failure^[64,84-89]. A collection of recent studies has demonstrated the ability of senescent cells and SASP components in the TME to drive cellular E-M plasticity and the expansion of a CSC-like cell population^[90,91]. In fact, the SASP program can promote stemness within both senescent cells and neighboring cells, both *in vitro* and *in vivo*, through secretion of potent inflammatory cytokines associated with disease recurrence, and overall poor prognosis^[92,93]. More specifically, less aggressive luminal MCF-7 cells were treated with conditioned medium harvested from senescent populations experiencing SASP. Exposure to conditioned media led to a more CD24LO/CD44HI invasive/stem like population similar to already aggressive MDA-MB-231 cells, which was dependent upon IL6 and IL8, two well defined SASP-factors, secretion^[94]. Furthermore, sustained hyper-activation of signal transducer and activator of transcription 3 (STAT3) by SASP components plays a critical role in induction of an invasive and stem-like program^[95]. Taken together, the presence of malignant, pre-malignant, and senescent epithelial cells creates a diverse TME suitable to drive E-M/CSC plasticity within the tumor and contribute to metastatic, therapy-resistant, and tumor-initiating phenotypes. Below we will discuss how E-M/CSC plasticity contributes to these deadly phenotypes responsible for patient mortality.

AN IDENTITY CRISIS: MESENCHYMAL VS. EPITHELIAL

Each step along the metastatic cascade presents a new environmental context and challenge that a potentially metastatic cell must adapt to in order to thrive. This adaptation involves changes in a cell's state. Cellular plasticity is defined as the ability of a cell to acquire new biological properties due to intrinsic and extrinsic cues. It is important to recognize that plasticity is most often a highly dynamic and reversible process that can be used to describe multiple cellular changes (i.e., differentiation, metabolism, response to immune cells, motility, and cell fate). Throughout this review, we will refer to cellular plasticity as the ability for cells to undergo E-M/CSC plasticity, that is, cells shifting between epithelial/non-CSC and mesenchymal/CSC states. E-M/CSC plasticity is important in imparting invasive and motile phenotypes as well as cells acquiring tumor-initiating potential and reduced sensitivities to therapy.

The switch from epithelial to mesenchymal state facilitates dissolution of cell-cell junctions (due to the repression of cell adhesion proteins E-Cadherin, EPCAM, and CD24) and increased ability to remodel the surrounding ECM [due to matrix-metalloprotease proteins (MMP), adamalysins (ADAMs), and differential integrin expression]^[3,96-101]. The corresponding cytoskeletal and ECM remodeling imparts a migratory and invasive phenotype important for metastasis. Lineage tracing experiments confirm that epithelial-to-mesenchymal transition (EMT) occurs *in vivo*, and that it precedes metastasis in murine BC models^[102-104]. Through intravital imaging, Beerling and colleagues showed that mesenchymal tumor cells have a unique and specific migratory behavior that results in greater circulating tumor cells (CTC), increased tumor cells within the lungs, and metastasis; in contrast, the more abundant epithelial cell population remained non-motile and less metastatic^[104]. It should be noted that others, Zheng *et al.*^[105] and Fischer *et al.*^[106] have employed *in vivo* lineage tracing models and reported that EMT is not required for metastasis. As Beerling and colleagues discuss, many of these reports rely on fixed gene manipulation (for example, gene silencing or protein overexpression) to experimentally test an EMT-underlies-metastasis hypothesis. It is possible that such artificial manipulation is not able to recapitulate physiologic events and, in this way, contributes to discrepancies in findings. Other small, but crucial, details could play a further role in some discrepancies: (1) EMT may be indispensable to metastasis for select cancer subtypes, but dispensable for others; (2) reliance on activation of a single gene reporter (e.g., Fsp1) to capture and "tag" an EMT event restricts the sensitivity of the model system; (3) criteria for how the EMT program is identified, such as the panoply of specific "epithelial" or "mesenchymal" proteins that are induced or suppressed, may also lead to false-negatives if these identifying protein sets are incongruent across cancers and cancer subtypes. Regarding the latter point, Zheng *et al.*^[105] and Fischer *et al.*^[106] reported on Vimentin and E-cadherin status, but each represents just one exemplar for mesenchymal or epithelial cell state and ultimately, these may not be the most relevant. Finally, evidence that metastases occur in the absence of EMT does not preclude a potential for EMT to enhance cancer cell metastasis.

The gain of migratory and invasive properties which accompany E-M plasticity occurs concomitantly with changes in global signaling programs and gene expression. Several key transcription factors (TF) have been identified as master regulators of EMT: SNAI1 (Snail), SNAI2 (Slug), ZEB1, ZEB2, TWIST1, and TWIST2^[107-112]. These TF are typically kept silenced in adult cells when plasticity is unnecessary but become aberrantly activated by TME factors to induce EMT^[113,114]. EMT-TF expression strongly correlates to regions of the tumor with mesenchymal marker positivity, notably, the invasive front of the tumor where mesenchymal cells act as 'trailblazers' that initiate and guide local metastasis^[108,115-118].

Tissue-invasive cells that encounter vessels may intravasate into vascular or lymph networks and be disseminated throughout the body as CTC. CTC are not only present in measurable quantities in patients with BC, but their abundance is predictive of overall survival and directly correlates with the likelihood of relapse following treatment^[119-123]. Moreover, CTC display a wide range of markers associated with cells that have or are undergoing E-M/CSC reprogramming. CTC often exhibit a decrease in epithelial markers CD24, E-Cadherin (CDH1), EPCAM and an increase in well-known mesenchymal and CSC markers (ZEB1, Snail, CD44, Vimentin)^[116,124-127]. Critically, CTC are capable of tumor initiation at a secondary site, and more importantly demonstrate remarkable plasticity by engaging specific molecular programs that dictate the organ-specificity of metastases^[128-133]. Overall, mesenchymal cells are simply more well-suited to the task of escaping the primary site and reaching distant organs.

However, escaping the primary site and circulating throughout the lymph or cardiovascular system is not sufficient for metastases to develop. Once a mesenchymal cell has reached a secondary organ, it must embed itself in the new tissue and flourish in order to establish a metastatic outgrowth; not all cells have this capability^[3,134]. CSC have been deemed the "roots" of primary and secondary site outgrowth due to their tumor-initiating capacity and their ability to differentiate into multiple lineages, recreating the heterogeneity

seen in the primary site^[135-137]. Since Al-Hajj *et al.*^[138]'s initial isolation of CSC from BC models, marked by CD44HI/CD24LO cell surface expression profile, the field has made significant insight into the CSC paradigm^[138]. Shortly after, Ginestier *et al.*^[139] demonstrated an increase in aldehyde dehydrogenase 1 (ALDH1) activity strongly correlated with both normal and malignant stem/progenitor cells within BC. CSC have been isolated from nearly every human cancer through identification of surface marker expression of nearly 40 different markers which vary from cancer to cancer (CD133, CD44, CXCR4, CD90, *etc.*)^[140]. Further complicating matters, our understanding of the dynamics of breast cancer stem cell (BCSC) populations is poorly understood. For instance, Liu *et al.*^[141] identified ALDH1 activity to inversely correlate with CD44 expression in BC models, suggesting a complex make up of phenotypes contributing to tumor initiation, which further work is required to better understand. Regardless of differences in marker expression, isolated CSC populations all exhibit similar characteristics in terms of their ability to initiate tumor formation in limiting dilution, produce multiple cell lineages, maintain tumor-initiating potential through periods of metastatic latency, and survive cytotoxic therapies due to a wide range of resistance mechanisms^[142,143]. Seminal papers from the Weinberg and Puisieux groups provided the first evidence of a link between shifting from epithelial to mesenchymal identity and the acquisition of CSC properties in BC^[144,145]. Prior to this, the existence of CSC and the occurrence of EMT in malignant neoplasms had each been garnering significant attention, but an association between the two phenotypes had yet to be demonstrated. Specifically, induction of EMT led to a shift in surface marker profiles from CD24HI/CD44LO to CD24LO/CD44HI, resulting in (1) the ability to generate tumorspheres and tumors (self-renewal potential); and (2) the ability to give rise to differentiated daughter cells^[144-148].

One implication of this finding is that breast CSC may not solely arise through malignant transformation of a pre-existing 'normal' mammary stem cell. More recent work, including ours, has described the ability for transformed epithelial/non-CSC populations to acquire mesenchymal/CSC properties in response to autocrine or paracrine signaling initiated from secreted factors within the TME. Importantly, the ability to fluidly move between epithelial/non-CSC and mesenchymal/CSC states has been shown to facilitate metastatic outgrowth [Figure 2A], as cells are believed to reactivate a proliferative program and reacquire epithelial cell phenotypes at the site of metastasis^[12-14,137,141,149-163].

THE QUIET NEIGHBOR: PRE-MALIGNANT CELLS AND PLASTICITY

E-M/CSC plasticity is a major contributor to tumor heterogeneity, progression towards metastasis, and therapy failure. Yet, cellular plasticity also plays a crucial role in normal physiology, such as embryonic development, wound healing, and tissue remodeling^[164,165]. For instance, differentiated epithelial cells can de-differentiate or trans-differentiate, wherein a differentiated cell may change state into an alternate lineage. These forms of plasticity are seen routinely in skin cells, hepatocytes, colon epithelium, pancreatic acinar cells, and others as they undergo a phenotypic transition in order to repair and sustain the homeostatic nature of the tissue^[166-170]. In fact, cellular plasticity of mammary epithelial cells has been suggested to be a driver of the heterogeneity seen in BC^[171-173].

Similarly, normal mammary gland organogenesis and homeostasis requires the presence of mammary stem cells (MaSCs) in the mammary gland epithelium that differentiate into both progenitor cells and differentiated cells^[174]. Remarkably, many of the markers used to distinguish normal MaSCs overlap with those used to identify breast CSC including mRNA expression profiles^[174]. Interestingly E-M plasticity is also essential for normal mammary gland development and maintenance. For example, E-M plasticity is crucial for MaSC migration as well as the expansion and invasion of terminal end buds (TEB) during mammary gland development^[174]. Much like the mechanisms that guide stemness in MaSC, the upregulation of multiple EMT-TFs, such as Snail and Twist, was uncovered in the microenvironment of the TEB by genomic transcriptional analysis^[175]. E-M plasticity in non-MaSC cells that comprise the normal mammary gland guides cell polarity and the organization of mammary cells into their well-defined glandular structures^[176].

Figure 2. Malignant and Senescent Epithelial Cells Contribute to Metastasis. A: malignant cells respond to TME cytokines or intrinsic genetic alterations in order to drive E-M/CSC plasticity, resulting in greater metastasis, enhanced disease recurrence, and therapeutic resistance; B: pre-malignant cells undergo senescence in response to aberrant oncogene or cytokine signaling. However, in some instances a small population of senescent cells may undergo E-M/CSC plasticity, and thus escape the tumor suppressive barrier of senescence and further contribute to the metastatic phenotype

Given its importance in tissue remodeling and homeostasis, the normal processes governing cellular plasticity are strictly regulated^[177-179].

As discussed above, senescence serves as an important tumor suppressive barrier to prevent transformation and the outgrowth of a dysregulated and uncontrolled population. Interestingly, the induction of senescence in normal cells often results in the simultaneous emergence of mesenchymal/stem-cell markers in conjunction with senescence markers, and loss of proliferative capacity. For example, senescence leads to the induction of CD44 expression, a cell surface marker regularly used to distinguish breast CSC from non-CSC, and often expressed as malignant cells acquire MES/CSC properties and undergo plasticity^[138,180-183]. As small subsets of senescent cells dismantle the senescence program, the emergent population of proliferating cells can harbor a mesenchymal/stem-cell phenotype that can persist throughout the remainder of the transformation process, ultimately yielding a more invasive and aggressive cancer cell^[184-187]. Li *et al.*^[15] demonstrated that many of the transcriptional changes observed in BC are also initiated in normal HMEC as they escape senescence. In their study, HMEC were shown to have a “pre-transformation” transcriptome and exhibited a partial EMT following their senescence escape^[15]. Similarly, normal HMEC that have spontaneously escaped replicative senescence exhibit a greater mesenchymal and CD24LO/CD44HI CSC-phenotype^[16,188]. Further studies have suggested cell cycle regulator Cyclin A1 and tumor suppressors p53 and p16 can act as “gatekeepers” to maintain cells in an epithelial state. Dysregulation of these proteins in epithelial cells can result in the initiation of the mesenchymal/stem-cell program, which interestingly corresponds with the escape from senescence^[189,190]. Moreover, induction of EMT (via Snail, Twist, and ZEB1 expression) prior to a cell’s engagement of oncogene-induced senescence, prevents senescence altogether and results in the induction of a CSC program and tumor initiation^[191-196].

In addition to pre-malignant cells, cytotoxic therapies can drive cancer cells into a therapy-induced senescence (TIS). Again, cells that escape TIS have acquired a senescence-associated stemness^[197-199]. Milanovic *et al.*^[200] have shown that cells undergoing TIS express a variety of stem-cell associated markers, and that TIS in B-cell lymphomas exhibit a gene signature which mirrors that of adult tissue stem cells, conferring a highly aggressive phenotype responsible for tumor relapse. The emergence of a stem-like population following the

engagement of senescence may be an inherent phenomenon that also occurs during other stress-induced senescence responses (i.e., oncogenes, replication stress, γ -irradiation) among different cell types^[200-202]. Altogether, these findings suggest that, the mesenchymal/stem-cell program engaged during senescence may have significant negative consequences if those cells can overcome the signals maintaining senescence, resulting in cells with greater ability metastasize and survive therapy [Figure 2B]. Thus, we suggest that therapies that target senescent cells would limit the reservoir of aggressive cells harboring a senescence-associated stemness responsible for therapy failure and relapse. In the following section we will discuss the potential of targeting E-M/CSC plasticity within malignant, pre-malignant, and senescent populations.

HALTING METASTASIS: TARGETING PRE- AND POST-MALIGNANT CELL PLASTICITY

Liquid biopsies from patients with early-stage BC receiving neoadjuvant therapy can be used to identify subjects at high risk of recurrence by quantifying the number of CTC. Furthermore, expression of mesenchymal markers in the CTC correlates with poor prognosis and response to therapy^[138,203-206]. With the advent of single cell analysis techniques, our understanding of the evolution and diversity of tumor cells that are responsible for invasion, metastasis, and therapy failure is expanding. For example, single-cell qPCR has identified mesenchymal/CSC gene expression patterns in early-stage breast cancer micro-metastases^[137]. In contrast, later-stage metastases (from the same PDX tissue) are more heterogeneous, more proliferative, express differentiation markers, and display greater similarity to the primary tumors. The findings are consistent with the idea that mesenchymal/CSC initiate metastatic outgrowth at a secondary site, followed later by increased proliferation and differentiation. More recent single cell RNA-sequencing (scRNA-seq) studies have confirmed that EMT in primary tumors proceeds through distinct, hybrid states, ranging from completely epithelial to completely mesenchymal^[207]. These E-M hybrids, which harbor the greatest level of plasticity, are more efficient at intravasating, extravasating to the lungs, and forming metastases^[208]. Underlying this biology, E-M hybrids have distinct chromatin landscapes and transcriptional profiles. *In situ* analysis identified increasing vascularization and immune cell infiltration (particularly macrophages) nearest the E-M hybrids and fully mesenchymal cells^[208]. A separate scRNA-seq study determined that, in response to chemotherapy, emerging chemo-resistant cells undergo transcriptional changes consistent with EMT. In most patients, this chemo-resistant transcriptional program was not evident before treatment but acquired via transcriptional reprogramming following treatment^[209]. These studies and others make a strong case that epithelial tumor cells can be induced into a drug-tolerant, E-M hybrid cell state by chemotherapy^[141,209-214].

Identifying and targeting the pathways responsible for this chemo-resistant reprogramming would help improve the efficacy of chemotherapy. In a recent example, SRC kinase inhibition prevented the *de novo* generation of chemo-resistant cells^[209]. Importantly, this chemo-sensitization was temporally dependent, and only effective if SRC inhibition occurred after chemotherapy, when the signaling responsible for generating the chemo-resistance phenotype had become activated. More recently, Cazet *et al.*^[215] identified cross-talk between TNBC models and cancer-associated fibroblasts (CAF), which promoted stemness and drug resistance in the cancer cells via paracrine Hedgehog (Hh) signaling. A key developmental pathway, Hh signaling requires receptor mediated binding of Hh to Patched (PTCH), resulting in Smoothened (SMO)-mediated nuclear translocation of Gli1. Gli1 then acts as a transcription factor, mediating Hh pathway transcriptional changes^[216]. Hh signaling is often reactivated in a subset of BC, and specifically in the context of TNBC, a paracrine manner^[217]. After targeting paracrine Hh signaling *in vivo*, via two clinically available smoothened inhibitors (SMOi) Vismodegib and Sonidegib, Cazet *et al.*^[215] observed a suppression of cancer cell plasticity and increased sensitivity to docetaxel. Most importantly, in a phase I clinical trial, 3 of 12 patients with metastatic TNBC observed clinical benefit from combinatorial therapy of SMOi and docetaxel (one with complete response), similar to treatment paradigms we suggest above. SMOi have been beneficial for basal cell carcinomas and medulloblastomas where tumors rely on cell-autonomous hedgehog signaling, however the work here suggests the ability to target the TME in order to dampen cancer cell plasticity, and

achieve a greater therapeutic response^[216,218,219]. Below we will address additional potential therapeutic avenues one may use to dismantle E-M/CSC plasticity in order to prevent metastatic dissemination, secondary site outgrowth, or re-sensitize cancer cells to standard of care therapies.

TARGETING MALIGNANT POPULATIONS

STAT3

STAT3 is persistently activated in cancer cells, as it is a downstream effector of several receptor tyrosine kinases (RTKs) commonly activated by growth factors and cytokines^[220-222]. We, as well as others have demonstrated that, persistent STAT3 activation in cancer cells induces mesenchymal and CSC properties, inhibits apoptosis, and maintains a more un-differentiated phenotype^[12,14]. Therefore, STAT3 is a promising therapeutic target. A number of small-molecule inhibitors of STAT3 (KI16; BP-5-087; WP1066) are currently in development and combination therapies, with BCR-ABL1 or BRAF inhibitors, have shown positive results in the treatment of several cancer types^[223-225]. In the context of TNBC, a recent phase Ib/II study combining the cancer stemness inhibitor Napubacasin (BB608), which prevents STAT3 activation, with weekly administrations of paclitaxel showed improvement in metastatic patients whose cancer had progressed while on a taxane-based regimen (NCT01325441).

PI3K, Akt and mTOR

The PI3K/Akt/mTOR pathway is involved in several cell processes, including proliferation, metabolism and motility, therefore it is not surprising that its dysregulation corresponds to uncontrolled proliferation and propagation in a wide spectrum of cancers. The role of the PI3K/Akt/mTOR pathway in maintaining cell plasticity in cancer has been documented in several publications^[226-228]. In the context of breast cancer, *PIK3CA* mutations have been observed in each of the different subtypes, but mostly in hormone receptor-positive tumors where it's associated with disease progression and resistance to endocrine therapy. Each *PIK3CA* mutation results in an abnormal activation of the alpha subunit of PI3K, that with the beta subunit is the most common in breast tissue^[229]. *PIK3CA* mutations appear to hold prognostic and predictive value in hormone receptor-positive, HER2-negative advanced or metastatic breast cancer. Several studies show how targeting tumors carrying a *PIK3CA* mutation with *PIK3CA* inhibitors increased the PFS of patients^[230]. In January 2019, results from the phase III SANDPIPER clinical trial (NCT02340221) were posted. This international, multicenter, randomized, double-blinded, placebo-controlled study was designed to test the efficacy of a combo of the *PIK3CA* SMI taselisib and the synthetic estrogen receptor antagonist fulvestran versus placebo and fulvestran in the treatment of ER-positive, HER-2-negative locally advanced or metastatic breast cancer harboring a *PIK3CA* mutation in patients with disease recurrence after or during treatment with aromatase inhibitor (AI). SANDPIPER is the first placebo-controlled trial testing the efficacy of a mutant-specific PI3K inhibitor^[231]. Taselisib is specifically directed against the alpha isoform of *PIK3CA*, however it can inhibit the gamma and delta isoforms as well, thus causing an increase in toxicity mostly involving the gastro-intestinal tract. Another phase III clinical trial, BELLE-2 (NCT01610284) is analyzing the effects of the pan-PI3K inhibitor buparlisib in combination with fulvestran compared to fulvestran and placebo combo. Unfortunately, also buparlisib showed important side effects, particularly hyperglycemia^[229]. Several other PI3K inhibitors are currently under investigation in clinical trials, including apelisib (NCT02437318 - SOLAR-1), which showed encouraging clinical benefits in the majority of patients enrolled^[232]. In the future, research efforts should be more focused at inhibiting exclusively the alpha subunit of *PIK3CA*, thus reducing the risk of toxicity and side effects. Interestingly, GDC-0077 from Genentech appears to be extremely more specific towards the alpha subunit of PIK3A over other subunits, thus representing a potentially less toxic alternative to other inhibitors and is currently investigated in a phase I clinical trial alone or in combination with other agents, such as palbociclib, letrozole and fulvestran (NCT03006172).

While the role of mTOR signaling in promoting a CSC phenotype is still controversial, its activation in BC appears to be essential for colony formation *in vitro* and tumorigenicity^[233]. Furthermore, mTOR signaling

increases aldehyde dehydrogenase 1 (ALDH1) activity^[234,235]. IGF-1R activation signaling through PI3K/Akt/mTOR represents a promising target in BC as an abnormal activation of PI3K can also lead to an increased activation of STAT3 through enhanced expression of the chemokine (C-X-C motif) receptor 4 (CXCR4)^[236,237]. IGF-1R is activated in the 50% of breast cancer patients. Several phase III clinical trials targeting IGF-1R with small molecule inhibitors have so far failed due to side effects such as hyperglycemia and metabolic syndrome caused by the homology of IGF-1R and insulin receptor (IR) and IGF elevation in response to disruption of glucose homeostasis. On the other hand, monoclonal antibodies specifically targeting IGF-1R or its ligand have shown a higher specificity by sparing the insulin metabolism from any inhibitory effect in preclinical models^[238]. Early phase trials have been setup to determine the efficacy of an antibody-based inhibition of IGF-1R signaling by targeting either the receptor or the ligand in combination with aromatase inhibitors or mTOR inhibitors but with small success^[239]. A more complex therapeutic protocol combining inhibitors of PI3K or other downstream effectors of IGF-1R would probably be more beneficial.

Several drugs targeting the PI3K/mTOR pathway have shown a selective effect on CSCs, inhibiting their growth and sensitizing them to traditional chemotherapy. Since 2007, when the Food and Drug Administration (FDA) approved the mTOR inhibitor temsirolimus for the treatment of advanced renal carcinoma, new generations of compounds have been developed. Everolimus, is a dual PI3K/mTOR inhibitor, which blocks all PI3K class I isoforms as well as mTORC1 and 2, thus preventing the development of CSCs when combined with letrozole^[240,241]. Interestingly, mTOR is also inhibited by metformin (1,1-dimethylbiguanide hydrochloride), usually prescribed for the treatment of type 2 diabetes. Metformin preferentially kills CSCs over non-CSCs and reduces tumorsphere formation and CSC marker expression (CD133, CD44 and ALDH1)^[242]. Similar effects have been achieved with the antibiotic salinomycin, which selectively kills breast CSC^[243]. The plant-derived chemotherapeutic molecule rottlerin induces apoptosis in breast CSC by inhibiting PI3K/Akt/mTOR pathway^[244]. More recently, the PI3K/mTOR dual inhibitor VS5584 has shown promising results by delaying tumor recurrence through selective killing of CSC after chemotherapy^[245].

Notch

Notch signaling is known to be involved in different cellular processes, including differentiation and proliferation. Perturbation in these processes can be caused by mutations in Notch or one of its effectors. Mutations of the Notch pathway are the hallmark of many subtypes of cancer, including BC, where cells overexpressing Notch have increased CSC markers (SOX2 and OCT4) and phenotypes (tumorsphere formation)^[246-248]. Moreover, Notch promotes EMT and metastasis in TNBC cells and Notch inhibition can prevent EMT both *in vitro* and *in vivo*^[249]. For example, 3,6-dihydroxyflavone (3,6-DHF) causes a significant reduction of CSCs *in vitro* and blocks lung metastasis by specifically down regulating Notch, Hes-1 and c-Myc^[250]. 3,6 DHF shows potent chemo-preventive properties against breast carcinogenesis both *in vitro* and *in vivo*, although a mechanism has not been identified yet, besides an epigenetic increase in the synthesis of miR-34a, a potent down-regulator of Notch and thus of EMT in breast cancer^[251]. Furthermore, 3,6-DHF down-regulates the expression of Notch's target genes *Hes1*, *c-Myc* and the EMT mediators SNAIL, Twist and Slug by compromising the formation of the transcriptional complex NICD-CSL-MAML^[252,253]. More recently, it has been shown that Notch3 inhibition by siRNA silencing increases TNBC sensitivity to gefitinib in EGFR-Tyrosine kinase inhibitors (TKI)-resistant cells by blocking the nuclear translocation of activated EGFR^[254].

Wnt and β -catenin

The Wnt pathway is involved in the maintenance of breast CSCs by promoting self-renewal and plasticity through PAF (proliferating cell nuclear antigen-associated factor)^[255]. The Wnt ligand, Frizzled, is upregulated in high-grade tumors, including more aggressive forms of BC, and can cause EMT and metastasis through non-canonical STAT3 activation^[256]. Inhibitors targeting the Wnt pathway have been developed and are showing promise in BC models. In particular, the Wnt/beta-catenin inhibitor CWP232228, which blocks

beta-catenin binding to T-cell factor (TCF) in the nucleus, prevents the proliferation of breast CSC, selectively depleting CD133-positive and ALDH1-high cells both *in vitro* and *in vivo*^[257,258].

TARGETING SENESCENT POPULATIONS

As described in the previous section, cells escaping senescence exhibit increased invasive and tumor-initiating properties. On top of that, senescent cells secrete a variety of cytokines and growth factors as part of the SASP. The production of these factors into the TME has been shown to drive E-M/CSC plasticity in neighboring cells, as well as the senescent cells themselves, expanding the population that can facilitate metastasis and drug resistance. Moreover, the chronic presence of senescent cells can impair local tissue function, create a highly inflammatory environment, and in some instances exacerbate the side effects of chemotherapies^[259,260]. Considering conventional treatments such as chemo- and radio-therapy often induce senescence in both cancer and normal cells, it seems pertinent to target senescent cells and clear them from the local tissue. The concept for targeting senescent cells was brought to light by Lee *et al.*^[261] by exploiting the high lysosomal β -galactosidase activity in senescent cells, cytotoxic drugs encapsulated in galacto-oligosaccharides particles (galNP beads) can target chemotherapy-induced senescent cells in mice^[262]. Pre-clinical results showed a significant regression of tumor xenografts after treatment with galNP beads loaded with doxorubicin in combination with palbociclib^[263]. Moreover, senescent-cell accumulation in mice can be reduced by treatment with potential senolytic agent, Navitoclax (ABT-263), a small molecule inhibitor of the anti-apoptotic proteins BCL-2 and BCLxL^[264,265]. However, targeting senescent cells is a relatively new concept, and further insights into the signaling mechanisms which senescent cells rely on is needed.

CONCLUSION

To date our ability to target BC metastases have been largely unsuccessful. With patient survival falling to 22% for those that reach distant and wide-spread disease, the ability to target cells at various stages of the metastatic cascade is greatly needed. Here, we have focused on an epithelial cancer cell's ability to out-manuever cytotoxic agents by changing cell state; E-M/CSC plasticity. This induced reprogramming often reduces sensitivity to therapy by a number of mechanisms, creating an immense problem with effectively removing the disease. We propose to remove the molecular "escape hatch" which provides cells that have undergone E-M/CSC reprogramming a sustained advantage in survival and resurgence. An approach that combines readily available small molecule inhibitors of plasticity-inducing pathways in conjunction with commonly used front-line therapies should increase therapeutic sensitivities. Often, pathway-selective small molecule inhibitors that make it to the clinic are used with the objective of inducing growth inhibition or cell death. However, many of these inhibitors may present a wide range of side effects by acting on non-tumor cells or show little efficacy as a single agent^[266-268]. Instead, a low dosage may prevent toxicity or off-target effects while reducing a tumor cells ability to undergo reprogramming to a more MES/CSC-like state. In doing so, these combination therapies may overcome the MES/CSC-like programs which promote therapy failure and metastatic disease progression, ultimately rendering populations sensitive to currently used chemotherapies and increasing overall patient survival.

Cell plasticity is garnering significant interest in the field of cancer biology, as we attempt to better understand the metastatic process, and those drivers behind it. However, we do not yet fully understand what allows an epithelial cell to undergo MES/CSC reprogramming or what pathways maintain this newly attained phenotype. While most of the work understanding plasticity has been done on malignant populations, recent studies have hinted at the ability of pre-malignant populations to undergo MES/stem-cell reprogramming, albeit often halted by intact tumor suppressive mechanisms, leading to senescence. Here, we discussed the ability of pre-malignant epithelial cells to undergo a MES/stem-cell reprogramming that is comparable to that observed with malignant cells. However, much remains to be discovered about the importance of these pre-malignant populations. We still do not yet know which cells within a pre-malignant population have escaped the

senescence “barrier”, which in turn generate more aggressive sub-populations capable of driving metastasis. Identifying, or molecularly defining, which cells possess the capability to escape senescence may allow us to predict the aggressiveness of a patient’s metastatic burden and open potential avenues for targeting cells with the potential to escape senescence. Ultimately, targeting the signaling responsible for plasticity, both in pre-malignant and fully transformed cells, will enhance the efficacy of chemotherapies and suppress a key driving force responsible for patient death.

Abstract

Aim: Benign prostatic hyperplasia and prostate cancer is an internationally important health problem of the man, particularly in developed countries. The aim of this exploratory study was to evaluate whether significant difference in the levels of Zn and some other trace elements of prostatic fluid exist between the inflamed and malignantly transformed prostate.

Methods: Prostatic fluid levels of Br, Fe, Rb, Sr, and Zn were prospectively evaluated in 52 patients with benign prostatic hyperplasia and 24 patients with prostate cancer. Measurements were performed using ¹⁰⁹Cd radionuclide-induced energy dispersive X-ray fluorescent microanalysis. Prostatic fluid samples were divided into two portions. One was used for cytological study to exclude prostatitis, while the other was intended for trace element analysis.

Results: Mean values \pm standard error of means for concentration (mg/L) of trace element in the prostatic fluid of hyperplastic prostate were: Br 2.32 ± 0.30 , Fe 11.5 ± 1.8 , Rb 1.70 ± 0.23 , Sr 1.41 ± 0.26 , and Zn 488 ± 42 . The contents of Rb and Zn were significantly lower (approximately 3.2 and 7.7 times, respectively) in fluid of cancerous prostate compared with those in fluid of hyperplastic prostate.

Conclusion: There are significant differences in trace element contents in the fluid of hyperplastic and malignantly transformed prostate. The great decrease in levels of Rb and Zn in the fluid of cancerous prostate might demonstrate

an involvement of these trace elements in etiology and pathogenesis of malignant prostate tumors. It was supposed that the differences in Rb and Zn levels in prostatic fluid can be used as tumor markers.

Keywords: Benign prostatic hyperplasia, prostate cancer, prostatic fluid, trace elements, energy-dispersive X-ray fluorescent analysis

INTRODUCTION

Prostate cancer (PCa) is the most prevalent nonskin male cancer in many populations, including USA, Scandinavia, West European states, Australia, New Zealand, and others^[1,2]. Globally, PCa ranks second in incidence and the fifth in mortality in men, and represents a substantial public health burden^[1,2]. Although the etiology of PCa is unknown, several risk factors including age and diet have been well identified. Thus, the risk of having PCa drastically increase with age, being three orders of magnitude higher for the age group 40-79 years than for those younger than 39 years^[3,4]. The odds of PCa diagnosis by age 79 years are one in six among countries with a high sociodemographic index.

Benign prostatic hyperplasia (BPH) is an internationally important health problem of the man, particularly in developed countries, and represents the most common urologic disease among of men after the age of fifty^[4-7]. Incidence of histological BPH could be over 70% at 60 years old and over 90% at 70 years old^[4,8]. To date, we still have no precise knowledge of the biochemical, cellular and molecular processes underlying the pathogenesis of BPH. Although the influence of androgens and estrogens has been demonstrated, hormonal factors alone may not fully explain BPH development^[9,10].

Thus, the both PCa and BPH is the very common urologic disease in adult males. Moreover, use systematic review methods provide the statistical evidence that the association between PCa and BPH is significant^[11,12]. BPH can be a cause of an elevated prostate specific antigen level in blood^[13]. In these cases it is difficult to differentiate BPH from PCa because the findings of imaging modalities like TRUS and conventional MR Imaging can mimic those of PCa. Even biopsy doesn't play promising role in the diagnosis of BPH. As a result of this, BPH may be misdiagnosed as a malignant condition and end up in aggressive surgical management resulting in increased morbidity. This warrants the need of reliable diagnostic tool which has ability not only to diagnose BPH reliably but also to differentiate it from the PCa.

It was reported that the risk of having PCa and BPH depends on lifestyle and diet, including the intake of zinc (Zn) and some other trace elements (TE)^[14-18]. TE have essential physiological functions such as maintenance and regulation of cell function, gene regulation, activation or inhibition of enzymatic reactions, and regulation of membrane function. Essential or toxic (mutagenic, carcinogenic) properties of TE depend on tissue-specific need or tolerance, respectively^[19]. Excessive accumulation or an imbalance of the TE may disturb the cell functions and may result in cellular degeneration or death^[19-24].

In our previous studies a significant involvement of Zn and some other TE in the function of prostate was observed^[25-39]. Moreover, it was found that intracellular Zn and calcium (Ca) excess is one of the main factors in the etiology of prostate cancer^[16-18,24,25]. One of the main functions of prostate gland is a production of prostatic fluid^[40] with extremely high concentration of Zn and some other chemical elements. The first finding of remarkable high level of Zn concentration in human expressed prostatic fluid (EPF) was reported in the beginning of 1960s^[41]. Analyzing EPF expressed from prostate of 8 apparently healthy men aged 25-55 years it was found that Zn concentration varied in range from 300 to 730 mg/L. After this finding several investigators have suggested that the measurement of Zn level in EPF may be useful as a marker of prostate secretory function^[42,43]. It promoted a more detailed study of Zn concentration in EPF of healthy subjects and in those with different

prostate diseases, including PCa^[43,44]. A detailed review of these studies, reflecting the contradictions within accumulated data, was given in our earlier publication^[44].

In present study it was supposed by us that apart from Zn the levels of some other TE in EPF have to reflect a difference between possible functional suppression of hyperplastic prostate and functional disintegration of cancerous prostate. Thus, this work had four aims. The first one was to present the design of the method and apparatus for micro analysis of bromine (Br), iron (Fe), rubidium (Rb), strontium (Sr), and Zn in the EPF samples using energy dispersive X-ray fluorescence (EDXRF) with radionuclide source ¹⁰⁹Cd. The second aim was to assess the Br, Fe, Rb, Sr, and Zn concentration in the EPF samples received from patients with BPH and PCa. The third aim was to evaluate the quality of obtained results and to compare obtained results with published data. The last aim was to compare the concentration of Br, Fe, Rb, Sr, and Zn in EPF samples of hyperplastic and cancerous prostate gland.

METHODS

Specimens of EPF were obtained from 52 patients with BPH (mean age 63 ± 6 years, range 52-75 years) and from 24 patients with PCa (mean age 65 ± 10 years, range 47-77 years) by qualified urologists in the Urological Department of the Medical Radiological Research Centre using standard rectal massage procedure. In all cases the diagnosis of BPH or PCa has been confirmed by clinical examination, including morphological results obtained during studies of biopsy and resected materials. Patients with BPH combined with chronic prostatitis or prostatic stones were excluded from the study. Subjects were asked to abstain from sexual intercourse for 3 days preceding the procedure. Specimens of EPF were obtained in sterile containers which were appropriately labeled. Twice 20 μ L of fluid were taken by micropipette from every specimen for trace element analysis, while the rest of the fluid was used for cytological and bacteriological investigations to exclude prostatitis. The chosen 20 μ L of the EPF was dropped on 11.3 mm diameter disk made of thin, ash-free filter papers fixed on the Scotch tape pieces and dried in an exsiccator at room temperature. Then the dried sample was covered with 4 μ m Dacron film and centrally pulled onto a Plexiglas cylindrical frame.

To determine concentration of the elements by comparison with a known standard, aliquots of solutions of commercial, chemically pure compounds were used for a device calibration^[45]. The standard samples for calibration were prepared in the same way as the samples of prostate fluid. Because there were no available liquid Certified Reference Material (CRM) ten sub-samples of the powdery CRM IAEA H-4 (animal muscle) were analyzed to estimate the precision and accuracy of results. Every CRM sub-sample weighing about 3 mg was applied to the piece of Scotch tape serving as an adhesive fixing backing. An acrylic stencil made in the form of a thin-walled cylinder with 11.3 mm inner diameter was used to apply the sub-sample to the Scotch tape. The polished-end acrylic pestle which is a constituent of the stencil set was used for uniform distribution of the sub-sample within the Scotch surface restricted by stencil inner diameter. When the sub-sample was slightly pressed to the Scotch adhesive sample, the stencil was removed. Then the sub-sample was covered with 4 μ m Dacron film. Before the sample was applied, pieces of Scotch tape and Dacron film were weighed using analytical balance. Those were again weighed together with the sample inside to determine the sub-sample mass precisely.

The facility for radionuclide-induced energy dispersive X-ray fluorescence included an annular ¹⁰⁹Cd source with an activity of 2.56 GBq, Si(Li) detector with electric cooler and portable multi-channel analyzer combined with a PC. Its resolution was 270 eV at the 6.4 keV line. The facility functioned as follows. Photons with the 22.1 keV energy from ¹⁰⁹Cd source are sent to the surface of a specimen analyzed, where they excite the characteristic fluorescence radiation, inducing the K_{α} X-rays of trace elements. The fluorescence radiation got to the detector through a 10 mm diameter collimator to be recorded.

Table 1. Energy dispersive X-ray fluorescence data of Br, Fe, Rb, Sr, and Zn contents in the IAEA H-4 (animal muscle) reference material compared to certified values (mg/kg, dry mass basis)

Element	Certified values			This work results

	Zn	62.0	98.3	20.1	2.82	371	21.6	3.43	358

M: arithmetic mean; SD: standard deviation; SEM: standard error of mean; Min: minimum value; Max: maximum value; Per. 0.025: percentile with 0.025 level; Per. 0.975: percentile with 0.975 level; DL: detection limit; BPH: Benign prostatic hyperplasia

The duration of the Zn concentration measurement was 10 min. The duration of the Zn concentration measurement together with Br, Fe, Rb, and Sr was 60 min. The intensity of K_{α} -line of Br, Fe, Rb, Sr, and Zn for EPF samples and standards was estimated on calculation basis of the total area of the corresponding photopeak in the spectra.

All EPF samples for EDXRF were prepared in duplicate and mean values of TE contents were used in final calculation. Using the Microsoft Office Excel programs, the summary of statistics, arithmetic mean, standard deviation, standard error of mean, minimum and maximum values, median, percentiles with 0.025 and 0.975 levels was calculated for TE concentrations in EPF of hyperplastic and cancerous prostate. The difference in the results between two groups of samples (BPH and PCa) was evaluated by the parametric Student's *t*-test and non-parametric Wilcoxon-Mann-Whitney *U*-test.

RESULTS

Table 1 depicts our data for Br, Fe, Rb, Sr, and Zn mass fractions in ten sub-samples of CRM IAEA H-4 (animal muscle) and the certified values of this reference material. Of 4 (Br, Fe, Rb, and Zn) TE with certified values for the CRM IAEA H-4 (animal muscle) we determined contents of all certified elements [**Table 1**]. Mean values ($M \pm SD$) for Br, Fe, Rb, and Zn were in the range of 95% confidence interval. Good agreement of the TE contents analyzed by ^{109}Cd radionuclide-induced EDXRF with the certified data of CRM IAEA H-4 [**Table 1**] indicate an acceptable accuracy of the results obtained in the study of the prostatic fluid presented in **Tables 2-4**.

Table 2 presents certain statistical parameters (arithmetic mean, standard deviation, standard error of mean, minimal and maximal values, median, percentiles with 0.025 and 0.975 levels) of the Br, Fe, Rb, Sr, and Zn concentrations in EPF of patients with BPH and PCa.

Table 3. Median, minimum and maximum value of means of Br, Fe, Rb, Sr, and Zn concentration (mg/L) in prostate fluid of patients with BPH and PCa according to data from the literature

The comparison of our results with published data for Br, Fe, Rb, Sr, and Zn concentrations in EPF of hyperplastic and cancerous prostate^[41-44,46-50] is shown in Table 3. A number of values for Zn concentrations in EPF were not expressed on a wet mass basis in the cited literature. Therefore, we calculated these values using the published data for water - 93.2%^[50].

The ratios of means and the differences between mean values of Br, Fe, Rb, Sr, and Zn concentrations in EPF of patients with BPH and PCa are presented in Table 4.

DISCUSSION

The mean values and all selected statistical parameters were calculated for 5 (Br, Fe, Rb, Sr, and Zn) TE concentrations [Table 2]. The concentrations of Br, Fe, Rb, Sr, and Zn were measured in all, or a major portion of EPF samples of hyperplastic and cancerous prostate.

The mean of Zn concentration obtained for BPH group of prostate fluid, as shown in Table 3, agrees well with median of means cited by other researches^[41-44,46-50]. The mean of Rb concentration obtained for EPF samples of CP group agrees well with our data reported 38 years ago^[43]. No published data referring to Br, Fe, Rb, and Sr concentrations in EPF samples of patients with CP were found.

In the EPF samples of cancerous prostate our results were comparable with published data for Zn concentrations [Table 3]. The mean of Rb concentration obtained for EPF samples of PCa group was some lower than our data reported 38 years ago^[43]. No published data referring to Br, Fe, and Sr concentrations in EPF samples obtained from patients with PCa were found.

From Table 4, it is observed that in EPF samples of PCa group the concentrations of Rb and Zn are 3.2 and 7.7 times, respectively, lower than levels of these trace elements in EPS of patients with BPH.

The range of means of Zn concentration reported in the literature for EPF of untreated hyperplastic prostate (from 268 mg/L to 9,870 mg/L) and cancerous prostate (from 34.7 to 722 mg/L) varies widely [Table 3]. This can be explained by a dependence of Zn content on many factors, including age, ethnicity, mass of the gland, presence of benign prostatic hyperplasia, and others. Not all these factors were strictly controlled in cited studies. Another and, in our opinion, leading cause of interobserver variability was insufficient quality control of results in these studies. In many reported papers EPF samples were dried at high temperature or acid digestion. Sample digestion is a critical step in elemental analysis and due to the risk of contamination and analytes loss contributes to the systematic uncontrolled analysis errors^[51-53]. Thus, when using destructive analytical methods it is necessary to control for the losses of TE, for complete acid digestion of the sample, and for the contaminations by TE during sample decomposition, which needs adding some chemicals. It is possible to avoid these not easy procedures using non-destructive methods. Therefore, sample-nondestructive technique like ¹⁰⁹Cd radionuclide-induced EDXRF, which was developed and used by us^[54,55] is good alternatives for TE determination in EPF samples.

The ¹⁰⁹Cd radionuclide-induced EDXRF developed to determine TE concentrations in prostate fluid is micro method because sample volume 20 µL (one drop) is quite enough for analysis. It is another advantage of the method. Amount of human prostatic fluid collected by massage of the normal prostate is usually in range 100-500 µL^[56] but in a pathological state of gland, particularly after malignant transformation, this amount may be significantly lower. Therefore, the micro method of ¹⁰⁹Cd radionuclide-induced EDXRF developed to determine TE concentrations in prostate fluid is available for using in clinical studies.

Characteristically, elevated or deficient levels of TE and electrolytes observed in EPF of cancerous prostate are discussed in terms of their potential role in the initiation, promotion, or inhibition of prostate cancer. In our opinion, abnormal levels of TE in EPF of cancerous prostate could be the consequence of malignant transformation. Compared to other fluids of human body, the prostate secretion has higher levels of Rb and Zn and some other TE. These data suggests that these elements could be involved in functional features of prostate. The suppressed prostatic function can be both a cause and a consequence of BPH. However, malignant transformation is accompanied by a loss of tissue-specific functional features, which leads to a significant reduction in the contents of elements associated with functional characteristics of the human EPF (Rb and Zn).

Our findings show that concentration of Rb and Zn are significantly lower in EPF of cancerous prostate as compared to their concentrations in EPF of hyperplastic prostate [Table 4]. Thus, it is plausible to assume that levels of these trace elements in EPF can be used as tumor markers. However, this subjects needs in additional studies.

This study has several limitations. Firstly, analytical techniques employed in this study measure only five TE (Br, Fe, Rb, Sr and Zn) concentrations in EPF. Future studies should be directed toward using other non-destructive analytical methods which will extend the list of TE investigated in EPF of hyperplastic and cancerous prostate. Secondly, the sample size of PCa group was relatively small. It was not allow us to carry out the investigations of TE contents in PCa group using differentials like histological types of tumors, stage of disease, and dietary habits of healthy persons and patients with PCa. Despite these limitations, this study provides evidence on cancer-specific Rb and Zn level alteration in EPF and shows the necessity the need to continue TE research of EPF in prostatic diseases.

In conclusion, in this work, TE measurements were carried out in the EPF samples of hyperplastic and malignant prostate using non-destructive instrumental EDXRF micro method developed by us. It was shown

that this method is an adequate analytical tool for the non-destructive determination of Br, Fe, Rb, Sr, and Zn concentration in the EPF samples of human prostate. It was observed that in the EPF of cancerous prostate contents of Rb and Zn significantly lower in a comparison with those in the EPF of hyperplastic prostate. In our opinion, the decrease in levels of Rb and Zn in the EPF of cancerous prostate might demonstrate an involvement of these TE in etiology and pathogenesis of malignant prostate tumors. It was supposed that the changes of Rb and Zn levels in the EPF samples can be used as tumor markers.

DECLARATIONS

Acknowledgments

The authors are extremely grateful to Dr Tatyana Sviridova, Medical Radiological Research Center, Obninsk for supplying EPF samples.

Authors' contributions

Collected EPF samples, designed the EDXRF of samples, and carried out the statistical analysis of results: Zaichick V

Managed the literature searches, wrote the first draft of the manuscript, and translated the manuscript into English: Zaichick S

Read and approved the final manuscript: Zaichick V, Zaichick S

Availability of data and materials

Not applicable.

Financial support and sponsorship

None.

Conflicts of interest

Both authors declared that there are no conflicts of interest.

Ethical approval and consent to participate

All studies were approved by the Ethical Committees of the Medical Radiological Research Centre, Obninsk. All procedures performed in studies involving human participants were in accordance with the ethical standards of the institutional and/or national research committee and with the 1964 Helsinki declaration and its later amendments or comparable ethical standards.

Consent for publication

Not applicable.

Abstract

Breast cancer usually grows very quickly, becoming insensitive to blood flow in nearby veins; because of that, inside solid tumors it's possible to find a hypoxic environment, in other words, an environment where oxygen is less available. Another feature of cancer is its angiogenesis rate, because of the high energy demand, new blood vessels must be produced to take nutrients inside the solid tumor mass. Even with normal blood flow bringing the cancer oxygen and nutrients, its cells favor hypoxia, in an event known as Warburg Effect. According to the Warburg Effect, cells, even with normal oxygen rates, prefer to use fermentation instead of the citric acid cycle to produce ATP. For the cancer to operate normally in hypoxia, a transcription factor family is activated, known as hypoxia-induced factors (HIF), composed of a HIF-1 β and a HIF-1 α subunits. As HIF-1 α is expressed during hypoxia, it is a great target for treatments and a breast cancer biomarker. Because of the role of HIF-1 α in cancer and the high incidence of breast cancer worldwide, this review was performed in order to bring the most recent results concerning the role HIF-1 α can exert in breast cancer development and progression.

Keywords: Breast neoplasms, hypoxia-induced factor 1, HIF-1 α

INTRODUCTION

Cancer, an extremely aggressive heterogeneous disease, is the second leading cause of death in the world^[1]. The hallmarks of cancer are evasion of apoptosis, self-sufficiency in growth signals, insensitivity to anti-

growth factors, sustained angiogenesis, limitless replication potential, and tissue invasion/metastasis^[2]. To proliferate, tumors must form their own vascular network and blood supply, which is due to the influence of tumor angiogenesis factors. However, the new vascular network that is formed differs from that found in healthy tissues because it presents a series of structural and functional alterations. These alterations may interfere with the adequate supply of blood and oxygen, leading to hypoxia, a state in which the organism is functioning with reduced and/or no oxygen supply^[3]. In order for the cancer to prevent its metabolism from being diminished or ceased in this situation, a family of transcription factors called hypoxia-induced factors (HIF) is activated.

HIF is known to act on hematopoiesis, angiogenesis, apoptosis, cell reproduction, cancer cell metabolism among other functions^[2-5]. HIF-1 α action is complemented by the transcriptional co-activator with PDZ-binding motif (TAZ), activating different genes that are involved in the same cascade. Both HIF-1 α and TAZ play an important role in remodeling the extracellular matrix, one of the important steps for tissue invasion to occur; these genes act as co-activators of each other, potentiating the expression of HIF-1 α target genes^[6,7].

HIF-1 α is especially important in the metabolism of cancers, being part of several metabolic pathways that cancers use, such as metabolism in hypoxia, angiogenesis, cell reproduction, *etc.* Thus, cancers with a high rate of metastasis and recurrence - as is the case with breast cancer - have their physiology strongly linked to HIF-1 α . Based on that, this review sought to group the most recent experimental studies on the role that HIF-1 α plays in the development and progression of breast cancer - one of the most incident and deadly cancers worldwide - resistance to conventional treatments, as well as proposals for new treatments based on its expression and/or inhibition.

HIF-1 α MODULATION UNDER HYPOXIA

The genes in HIF family are composed of two subunits: HIF-1 α (or one of its isoforms, HIF-2 α or HIF-3 α) and HIF-1 β (which is expressed constitutively, acting on a range of transcriptional systems)^[8]. The HIF-1 α subunit, when in normoxia, is rapidly degraded via the 26S ubiquitin-proteasome pathway by the von Hippel-Lindau tumor suppressor protein; in situations of hypoxia, however, it has increased activity^[2-4].

Under periods of normoxia, proline residues of HIF-1 α are hydrolyzed by prolyl-4-hydroxylases. Hydroxylated HIF-1 α is then recognized by VHL and ubiquitinated by the E3 ubiquitin-protein ligase complex. After, its proteasomal degradation occurs^[9]. Breast cancer grows very rapidly and usually the tumor microenvironment has reduced oxygen distribution^[10]. In situations of hypoxia, hydroxylation of HIF-1 α does not occur, after which it is translocated and accumulates in the nucleus, where it binds to HIF-1 β ; the HIF-1 α /HIF-1 β complex binds to hypoxia-response element, adhering to hypoxia target genes such as vascular endothelial growth factor receptor (VEGF) and insulin-like growth factor 2 (IGF-2), stimulating angiogenesis and proliferation^[9]. Inhibition of HIF-1 α generated inhibition of signaling by VEGF/VEGFR2 factors, which in turn prevented angiogenesis^[10].

A model of HIF-1 α modulation in hypoxia involves receptor of activated protein C kinase-1 (RACK1) and heat shock protein-90 (HSP90)^[11]. In it, human rhomboid family-1 (RHBDF1) controls the competition between RACK1 and HSP90 for binding to HIF-1 α . The interaction between RACK1 and HIF-1 α results in its degradation, however prior to that RHBDF1 binds to RACK1, giving way for HIF-1 α to bind to HSP90, resulting in its stabilization. This model would explain the high levels of HIF-1 α , Rack1, HSP90 and RHBDF1 in various cancer cells, including breast cancer. This facilitation of HIF-1 α activity as a result of the action of RHBDF1 would also explain the relationship between the high protein level of RHBDF1 in distant metastases and lymph nodes^[11].

The RAS protein activator 1 (RASAL1) protein is known to be involved in the progression of hypoxia resistance in breast cancer cells. The increase of intracellular Ca²⁺ ions stimulates RASAL1, which leads to

attenuation of RAS activation and mitogen-activated protein kinase (MAPK) activity and contributes to tumor progression through weakened anti-RAS activity^[12]. In periods of hypoxia, reactive oxygen species accumulation activates PI3k/Akt (Protein-kinase B) and MAPK/ERK (extracellular signal-regulated kinase) pathways, essential for the maintenance of carcinogenesis, tumor angiogenesis and activation of HIF-1 α .

PROGNOSIS VALUE OF HIF-1 α EXPRESSION

Several genes are influenced by HIF-1 α expression. In addition to the high expression of HIF-1 α being directly associated with tumor growth rate, metastatic potential, and consequently to the poor prognosis of patients, it is also associated with tumor progression, since as the cancer stage advances, HIF-1 α expression increases^[13]. Thus, the possibility of using HIF-1 α as a prognostic marker has already been discussed by several authors^[14-16].

HIF-1 α up-regulates Snail expression - a gene involved in induction of the epithelial-mesenchymal transition (EMT) - promoting increased migration and aggressiveness of breast cancer cells. HIF-1 α together with Snail are responsible for the down-regulation of E-Cadherin expression, promoting EMT^[17]. After inhibiting HIF-1 α and Snail expression in triple negative breast cancer (TNBC) cells by adding small doses of farnesyltransferase inhibitors, the following mRNA levels of HIF-1 α expression pathway genes were also decreased: Snail, glucose transporter 1 (GLUT1), pyruvate dehydrogenase kinase 1 and lactate dehydrogenase A, all involved in the metabolism of hypoxia.

There is also a correlation between HIF-1 α protein expression and the erythropoietin receptor protein in aggressive breast cancer samples, which leads to the worsening of the cases, since both play an important role in angiogenesis^[18]. γ -secretase is an intramembranous protease that cleaves transmembrane proteins^[19]. HIF-1 α containing the γ -secretase complex also contributes to the migration and invasiveness phenotype of breast cancer cells. Another gene that is influenced by HIF-1 α is heregulin, a growth factor that binds to Erb-B2 receptor tyrosine kinase 3 (ErbB3) and ErbB4 receptors with a known role in cell proliferation, survival, motility and tumorigenesis^[20]. According to the authors, stimulation of the ErbB3 receptor and the activation of the P-Rex1/Rac1 pathway via induction of C-X-C Motif Chemokine Receptor 4 are transcriptionally mediated by HIF-1 α .

In breast neoplasms, SETD8, a methyltransferase that methylates H4K20, along with a transcription factor related to cancer progression, has the function of regulating the increase and of N-Cadherin expression and the decrease of E-Cadherin^[21]. This modulation would be responsible for the epithelial-mesenchymal transition (EMT) phenotype, which increases the invasive potential of breast cancer cells. An interaction between SETD8 and HIF-1 α was identified, as well as co-localization in the human embryonic kidney 293T and MDA-MB-231 cell nuclei, indicating that they interact with each other. SETD8 was seen to slightly regulate HIF-1 α expression, and SETD8 silencing increased the acetylation and hydroxylation of HIF-1 α , demonstrating that SETD8 plays a role in the stabilization of HIF-1 α . It was also found that SETD8 and HIF-1 α expression in patients with TNBC and HER2+ breast cancer were higher than in the Luminal A and Luminal B molecular profile^[21].

Interleukin-17 (IL-17) is a cytokine produced by T Helper lymphocytes associated with inflammatory diseases that has also been related to onset, development and metastasis of tumors^[22]. IL-17 can modulate the expression of some genes in breast cancer cells by altering their adhesion properties through pathways of expression including that of HIF-1 α . Tumor necrosis factor α (TNF- α), in turn, is a cytokine associated with cell survival, apoptosis, inflammation and immunity^[22]. In addition, TNF- α regulates the expression of cell adhesion proteins, which aid in the determination of a metastatic phenotype in tumor cells. Increased levels of HIF-1 α were also found in groups of cells treated with IL-17 and TNF- α in a dose-dependent manner^[22].

HIF-1 α expression in breast cancer cells influences AKT and ERK pathways, which promote angiogenesis, further worsening the patient's prognosis^[10]. Another transcription pathway that was also seen to be more expressed along with the high expression of HIF-1 α was the PI3K/AKT pathway, which is important in signaling proliferation, invasion, angiogenesis, etc.^[23].

HIF-1 α expression is directly related to the expression of VEGF^[16,24] and Axl (Tyrosine-kinase receptor), which is described as being more expressed in a hypoxic environment and acts in much the same way as HIF-1 α (angiogenesis, metastasis, invasion, etc.). It was also seen that both aided in the regulation of EMT, which in turn is an important step in the progression and metastasis of cancers^[24].

When the increase of HIF-1 α expression is regulated by lysophosphatidic acid receptor 2, it has been associated with increased proliferation, migration and cell invasion parameters^[15,24]. An increase in the expression of the *EZH2* gene (enhancer of zeste homologue 2, known to act on the aggressive profile of tumors) is completely linked to that of HIF-1 α ^[25]. Patients expressing high levels of HIF-1 α and *EZH2* had worse prognoses, data showing that both can potentially lead the individual to death^[25]. A direct relationship between the high HIF-1 α expression and a greater p53 expression has also been described, which is an aggravating factor for the progression of breast cancer, since the loss of p53 function implies an increase in vascular endothelial growth factor (VEGF) expression mediated by HIF-1 α , and consequently, increased angiogenesis^[13].

An assessment of HIF-1 α and nuclear factor-kappa B (NF- κ B) levels as prognostic factors in breast cancer, related to the sub-type of cancer and overall survival (OS) was done by Rajkovic-Molek *et al.*^[26]. Activation of HIF-1 α and NF- κ B (detected by nuclear staining) was found in 41% and 31% of tumors, respectively. In addition, HIF-1 α was related to worse OS, making its expression an unfavorable prognostic factor^[26].

HIF-1 α IN DRUG RESISTENCE

The high expression of HIF-1 α has been related to worse prognosis not only by the pathways affected that lead to more aggressive tumors, but also by its association with resistance to hormone, chemo - and radiotherapies in breast cancer^[27,28].

Tamoxifen is a drug which acts as an estrogen receptor antagonist, widely used in the treatment of breast cancer, as well as in prevention in women who are prone to develop breast cancer^[29]. Lactate generated through cell fermentation in breast cancer (mediated by HIF-1 α and the Warburg effect) is related to high rates of resistance to Tamoxifen, and can therefore be a marker of resistance to treatment^[29,30]. HIF-1 α expression inhibits estrogen receptor α (ER α), which contributes to Tamoxifen resistance and a worse prognosis. Tumors expressing HIF-1 α along with ER α were observed to have a much more aggressive profile^[29]. Letrozole, in turn, is an aromatase inhibitor, a class of drugs used to treat ER positive breast neoplasms^[31]. That the non-hypoxic expression of HIF-1 α mediated the resistance to Letrozole effected by HER2 was also seen. HIF-1 α protein synthesis increases when activation of phosphatidylinositol 3-kinase/Akt/mammalian target of rapamycin (mTOR) pathway by HER2 occurs in long term letrozole-treated cells. As a result, HIF-1 α up-regulates the expression of breast cancer resistant protein, which contributes to resistance to Letrozole^[31]. HIF-1 α is also involved in AI resistance in acquired cases and/or in *de novo* cases, showing a potential therapeutic target for resistance to Letrozole and other AIs.

Trastuzumab is a monoclonal antibody against the HER2 domain, one of the most commonly used drugs for the treatment of HER2+ breast cancers. The induction of resistance to Trastuzumab in breast cancer cells through the activation of the signal transducer and activator of transcription protein (STAT3) pathway/HIF-1 α / hairy and enhancer of split-1 (Hes-1) leading to a down-regulation of phosphatase and tensin homolog (PTEN)

was evaluated^[32]. Knockdown of HIF-1 α in Trastuzumab-resistant cells was observed to cause a decrease in the proliferation of HIF-1 α , just as the up-expression of HIF-1 α in cells caused resistance to the anti-proliferative effect of Trastuzumab, showing that there is a direct link between the levels of HIF-1 α expression and resistance to Trastuzumab. HIF-1 α up-regulates HES-1 expression, a negative regulator of the PTEN promoter, implying that HIF-1 α can modulate PTEN expression in Trastuzumab-resistant cells with the constitutive activation of the STAT3 protein^[32].

4-Hydroxynonenal (4-HNE) is produced in the lipid peroxidation of cells and is present at high levels in invasive breast cancer cells. The role of 4-HNE in the stabilization of HIF-1 α in breast cancer cells was assessed by Li *et al.*^[32]. Sirtuin-1 (SIRT1) and Sirtuin-3 (SIRT3) are covalently modified by 4-HNE, leading to SIRT3 deacetylase activity. SIRT3 was also observed to destabilize the HIF-1 α protein and inhibit its activity. Regulation of cell growth, invasion and expression of VEGF may be the result of the destabilization of the HIF-1 α protein by the inhibition of SIRT3, induced by 4-HNE. These results led researchers to conclude that 4-HNE is involved in resistance to chemotherapeutic drugs via up-regulation of HIF-1 α ^[33].

Zhong *et al.*^[34] studied the role of HIF-1 α in the regulation of radiation-induced autophagy in mammary neoplasia cells. Michigan Cancer Foundation-7 (MCF-7) in cultures mimicking hypoxia had greater survival of cells when exposed to ionizing radiation. Isogenic cells constitutively expressing HIF-1 α small hairpin RNA decreased the expression of HIF-1 α and also the formation of colonies. This fact suggested that the HIF-1 α knockdown increased radiosensitivity.

Long non-coding RNAs (LncRNAs) are non-coding transcripts involved in the modulation of various signaling pathways, acting as oncogenes or tumor suppressors during tumorigenesis^[35]. The urothelial carcinoma-associated 1 (UCA1) lncRNA, which induces adriamycin resistance in MCF-7 cells, was used to test for resistance to tamoxifen in breast cancer cells. Cells expressing UCA1 lncRNAs were transfected with an up-expressing HIF-1 α vector, and UCA1 lncRNA was found to be regulated in ER+ cells in a HIF-1 α -dependent manner^[35]. UCA1 expression was also observed to be increased by an miR-18 - HIF-1 α feedback loop.

HIF-1 α INHIBITION AS THERAPEUTIC AGENT

As seen previously, the high expression of HIF-1 α is associated with a worse prognosis and resistance to antineoplastic treatments. The low expression of HIF-1 α , by its turn, is linked to several metabolic alterations, since it influences the regulation of other genes that are important in the process of metastasis of breast cancer^[36,37]. The low expression of HIF-1 α leads to decreased expression of the *Snail* and twist-related protein 1 (*TWIST1*) genes, signaled by transforming growth factor β 1 (TGF- β 1), a protein that stimulates cell differentiation and proliferation that is known to regulate the EMT process in tumor cells^[36]. Both *Snail* and *TWIST1* are genes most commonly expressed in hypoxia. The silencing of HIF-1 α led to the termination of TGF- β -regulated breast cancer cell invasion^[36]. Reduced expression of HIF-1 α increased apoptosis when on serum starvation. At the same time, Caspase 3 fragments were identified with enhanced activity, indicating that HIF-1 α maintains cell growth and survival by inhibiting apoptosis^[38]. It was also observed that reduced expression of HIF-1 α inhibited TNBC migration and invasion ability^[38]. Thus, given the importance of the role of HIF-1 α in the development and progression of neoplasias, this gene has become the target of several studies that have been carried out to identify or create HIF-1 α inhibitors that could be used as therapeutical agent, as can be seen in the studies below.

Brachyury is a transcription factor of the T-Box family characterized by a highly conserved DNA binding domain called T-Domain, which is directly related with the progression of tumor cells^[39]. High Brachyury expression was related to a significant increase in HIF-1 α expression in MCF-7 and T47D cells. Akt/PTEN

signaling is known to be a regulator of HIF-1 α expression, and on that account the specific inhibitor LY290004, which inhibited Akt phosphorylation and consequently prevented Brachyury-induced HIF-1 α expression, revealing that Brachyury is a transcription factor that can be targeted in breast cancer treatments along with HIF-1 α ^[39].

A HIF-1 α putative inhibitor is T2A or TSN^[36,40-42]. Breast cancer cells treated with this drug showed a decrease in expression levels of HIF-1 α and VEGF proportional to the concentration of T2A administered^[36]. T2A was also used to inhibit EMT in breast cancer cells via HIF-1 α ^[40]. Two cell lines with hypoxia-induced doxorubicin (DOX) resistance in relation to T2A, MCF-1 and HCC1937, were analyzed. T2A decreased the DOX resistance of both lines in hypoxia partially via HIF-1 α ^[40,41]. It was also found that T2A reduced the viability and proliferation rate in both cell lines, indicating that T2A can target the cell cycle^[40].

Dutasteride, a double-blocker of type 1 and type 2 isoforms of the steroid-5 α -reductase (*SRD541*) gene is used in the treatment of benign prostatic hyperplasia. As *SRD541* is highly expressed in breast tumor cells, Dutasteride was tested in MDA-MB-231 and MDA-MB-468 cells *in vitro*^[43]. MDA-MB-231 cells showed a decrease in VEGF expression, while the detection of HIF-1 α was at the limit of detection of the technique employed. MDA-MB-468 cells had decreased VEGF and HIF-1 α , showing the potential effect of Dutasteride treatment in response to chemotherapy of TNBCs via altered protein expression of HIF-1 α and VEGF.

In order to verify the effects of pigallocatechin-3-gallate on the expression of HIF-1 α and VEGF in breast cancer cells, MCF-7 cells were treated with different concentrations of this compound^[44]. These cells had a dramatic decrease in growth and decreased expression of VEGF and HIF-1 α in a dose-dependent manner. Also working with cells, Dewangan *et al.*^[23] evaluated the inhibitory effects of centchroman, a non-steroidal oral contraceptive on HIF-1 α . As was expected, an elevated expression of HIF-1 α in cells prior to treatment was observed, which was inhibited with drug administration. After treatment, a decrease in VEGF/VEGFR2 expression was observed, with a consequent decrease in angiogenesis^[23]. Sarkar *et al.*^[10], on the other hand, demonstrated that the administration of phenethyl isothiocyanate, an organic sulfur of the Isotiosianate family found in cruciferous plants decreased HIF-1 α expression in normoxia and hypoxia. In addition, administration of N-acetyl cysteine, a known antioxidant, which had been used as a positive control was also observed to inhibit HIF-1 α expression. A correlation analysis was then performed to try to determine the association between the parameters involved in the low regulation of HIF-1 α by phenethyl isothiocyanate. A positive correlation was found between HIF-1 α and HSP90, and these two parameters were correlated with reactive oxygen species (ROS). According to the authors, ROS can be considered the main regulator of both HIF-1 α and HSP90^[10].

The drug M410 [(Z)-3,4,5-trimethoxystilbene-3'-O-phosphate disodium, a CA4 analog], which is a potent tubulin polymerization inhibitor in bovine brain *in vitro*, had its inhibitory potential for HIF-1 α evaluated by Yang *et al.*^[45] Upon treatment, the expression of HIF-1 β was found to be unaltered; however, HIF-1 α expression was decreased. The amount of VEGF and glucose transporter 1 messenger RNA in the cells was also analyzed, which was very low in relative to normality, showing that M410 was directly involved in the transcriptional activity of HIF-1 α ^[45].

DCQ (2-benzoyl-3-phenyl-6,7-dichloroquinoxaline 1,4-dioxide) contains an N-oxide portion (present in hypoxia-activated drugs used in cancer treatments) similar to tirapazamine (TPZ) used in treatments against other types of cancer, but inefficient in breast cancer^[46]. Similarly to the results with TPZ treatments found in the literature, DCQ induced an increase in p-Akt levels and a reduction in p-mTOR levels suggesting possible anti-translational activity in MCF-7 cells, which would decrease the rates of HIF-1 α . DCQ was identified as a promising drug in the treatment of breast cancer because it exhibits pro-apoptotic and anti-metastatic features by reducing HIF-1 α and the post-HIF-1 α gene signaling cascade^[46].

Extracellular matrix metalloproteinase inducer (EMMPRIN) glycoprotein, also known as cluster of differentiation 147 (CD147), is a densely glycosylated type I transmembrane glycoprotein, highly expressed in tumors^[47]. This glycoprotein is known to induce a number of malignancy characteristics in breast cancer cells, such as invasiveness, angiogenesis, anchorage independent growth and chemioresistance. SUM102 and BT474 cells were treated with human recombinant EMMPRIN, in which the levels of STAT3 and HIF-1 α were observed to be increased. To investigate the role of HIF-1 α , the cells were infected with lentivirus carrying HIF-1 α shRNA^[47]. HIF-1 α was observed to increase the percentage of CD24 surface markers (stem-like cells) and decreased the percentage of CD44 via STAT3. In addition, miR-106a/b targeted STAT3 and HIF-1 α , and mammary neoplasms treated with miR-106a/b had decreased STAT3 and HIF-1 α , and consequently a significant attenuation of stem-like characteristics^[47]. Also working with miRNA, Pakravan *et al.*^[48] evaluated whether the transfer of exosomes from mesenchymal stem cells (MSCs) containing miR-100 - a tumor suppressor - could have an effect on angiogenesis in breast cancer cells. The miR-100 present in MSCs exosomes was found to inhibit the expression of HIF-1 α and mTOR in MDA-MB-231 and MCF-7 cells, which consequently inhibited VEGF expression, contributing to the control of angiogenesis^[48].

To understand the functioning of pathways of acquisition of malignancy characteristics, notorious in breast cancer, Kuo *et al.*^[49] treated several breast cancer cell lines with pharmacological doses of dimethyl-2-ketoglutarate (DKG). DKG induced HIF-1 α in 6 cell lines, rapidly but transiently, and DKG treatment was shown to create a “pseudohypoxic” state in normoxia. An increase in succinate and fumarate rates was then seen, along with a decline in SDH and FH levels. This imbalance of metabolites may then impair PHD2 activity, stabilizing HIF-1 α and reprogramming the surface of breast cancer cells^[49]. The phenotype was maintained for up to 3 cell passages, and an increase of Carbonic anhydrase 9 (CAIX) (which is one of the genes downstream of the HIF-1 α signaling pathway) was seen in DKG-treated breast cancer cells. Taking into account that CAIX is seen in high-grade cancers, this result suggests mitochondrial dysregulation may induce tumorigenicity^[49]. Considering that, Tosatto *et al.*^[50] evaluated mitochondrial calcium uniporter (MCU) in the progression of breast cancer cells. The MCU is a selective channel that absorbs Ca²⁺ ions in the mitochondria, which is correlated with infiltration in lymph nodes and tumor size. Silencing of the MCU drastically decreased mitochondrial ROS levels and down-regulated HIF-1 α . When treated with Paraquat (a substance that generates superoxide production), there was an increase in the transcription of HIF-1 α , which led the researchers to relate HIF-1 α to an effector of MCU depletion^[50].

A novel class of an antigenic strategy known as the decoy approach was used by Zhu *et al.*^[51], who showed that cells treated with a HIF-1 α decoy had the transcriptional activity of HIF-1 α inhibited and entered apoptosis.

HIF-1 α INHIBITION BY NATURAL COMPOUNDS

Still considering the inhibition of HIF-1 α as antineoplastic therapy, we have listed here the most recent works dealing with natural compounds, be they extracted from animal plants or microbes.

Manassantin A (MA), a compound isolated from the organism *Saururus cernuus*, which was identified as a potent inhibitor of HIF-1 α was used in an attempt to inhibit the function of HIF-1 α in breast cancer cells^[9]. Several MA derivatives were synthesized in the search for one presenting low toxicity and a good inhibitory effect on HIF-1 α . LXY6090 was developed which initially inhibited HIF-1 α activity well. The compound was used in T47D, MCF-7 and MX-1 lines, and a decrease in the protein levels of HIF-1 α in the cells was observed in a dose-dependent manner. LXY6090 also inhibited the accumulation of HIF-1 α mRNA by promoting proteasome degradation in a VHL-dependent way. In addition to these effects, LXY6090 was also observed to inhibit the hypoxia-induced protein expression of HIF-1 α target genes such as VEGF and IGF-2, demonstrating a great potential as the target of further research for the treatment of breast cancer associated with an up-expression of HIF-1 α .

Another compound that is known to modulate glycolysis in tumor cells is oroxylin A (OA), an active flavonoid found in the plant *Scutellaria baicalensis* Georgi, widely used in Chinese medicine. In breast cancer cells, OA was observed to decrease HIF-1 α expression at the protein level. SIRT3 acts as a tumor suppressor by regulating the mitochondrial protein manganese superoxide dismutase, reducing ROS levels. In hypoxia, HIF-1 α is stabilized by the inhibition of prolyl hydroxylases by ROS generation. The regulation of O²⁻ (Superoxide anion) by SIRT3 plays an important role in the activation of PHD induced by OA, destabilization of HIF-1 α and suppression of glycolysis^[52].

Ascofuranone is an antibiotic with antifungal properties that has been isolated from cultures of the phytopathogenic fungus *Ascochyta viciae*. In addition to its antibiotic and antiviral effects, it also has some physiological effects such as hypolipidemic activity, suppression of hypertension, immuno-modulation, and amelioration of type II diabetes^[53]. Therefore, the effect of Ascofuranone on the expression of VEGF and HIF-1 α was examined, in order to determine if the antibiotic would also act on angiogenesis. Ascofuranone decreased HIF-1 α expression with a consequent decrease of VEGF expression in MDA-MB-231 cells in a dose-dependent manner. Ascofuranone was subsequently shown to inhibit the phosphorylation of Akt, mTOR and p70S6K, inhibiting epidermal growth factor-induced protein synthesis^[46]. Another compound that suppress HIF-1 α by the Akt/mTOR/p70S6K and MAPK pathways in a dose-dependent manner is Ft1 (notoginsenoside Ft1) a saponin isolated from *Panax notoginseng*^[54].

Andrographolide (Andro), a substance extracted from *Andrographis paniculata*, an Asian plant used for fever, diarrhea and infectious diseases, also has anti-tumor characteristics such as attenuation of cell invasion, inhibition of cell cycle progression, among others^[55]. Thus, the authors evaluated the relationship between Andro and HIF-1 α and its possible antitumor effect in breast cancer cells. In cultures of MDA-MB-231 and T47D cells with Andro, a decrease in HIF-1 α levels was observed in a dose-dependent manner^[55]. It was also found that Andro down-regulated HIF-1 α -mediated VEGF expression, which would be an indicator of improvement in angiogenesis.

That some lactobacilli have a cytotoxic effect on neoplastic cells has already been described in the literature. Based on that, Esfandiary et al.^[56] decided to use the culture supernatant of *Lactobacillus crispatus* (*L. crispatus*) (LCS - *L. crispatus* supernatant) and *Lactobacillus rhamnosus* (*L. rhamnosus*) (LRS - *L. rhamnosus* supernatant) in cultures of TNBC MDA-MB-231. It was found that LRS had a greater cytotoxic effect on MDA-MB-231 cells than LCS. Treatment with LRS led to a decrease in mRNA levels of HIF-1 α , HSP90 and SCL2A1 (GLUT1), whereas LCS treatment down-regulated the expression of HSP90, SHARP1 (gene encoding proteins that act on the degradation of HIF-1 α) and VHL.

Diallyl trisulfides is an organic sulfur compound present in garlic that modulates various biological processes and its effects were studied on the process of metastasis in breast cancer cells^[57]. According to the authors, the compound at different concentrations inhibited not only the transcription but also the translation of HIF-1 α ^[57].

Berberine is an alkaloid purified from a plant of the genus *Berberis*, widely used in Eastern medicine, and exhibits many pharmacological effects such as antihypertensive, antibacterial and antitumor effects. Berberine was observed to inhibit the expression of P-glycoprotein (P-gp), which when up-expressed is a marker of drug resistance. AMP-activated protein kinase (AMPK) is also seen in processes of resistance to antitumor treatments, since it is a P-gp modulator in human cancer cells in hypoxia^[58]. Hypoxia was observed to induce AMPK activation, elevating the protein levels of AMPK, P-gp and HIF-1 α in MCF-7 cells. HIF-1 α was subsequently found to be a protein of the AMPK pathway and that regulates P-gp expression in MCF-7 cells, and that small doses of Berberine increased DOX chemosensitivity by inhibiting AMPK, subsequently downregulating the expression of HIF-1 α and of P-gp. Yet high doses of Berberine down-regulated HIF-1 α , which induced p53 activation, leading the mammary tumor cells to apoptosis *in vitro*^[58].

CONCLUSION

In this review, several experimental studies the role of HIF-1 α in breast cancer, whether in *in vitro* or *in vivo* models, have been included. HIF-1 α has an immense potential both as a target for various breast cancer treatments and for the prevention and diagnosis of breast cancer. The importance of research with HIF-1 α is undeniable. Because of its wide range and several signaling pathways, it has a huge potential for use in the treatment, follow-up and diagnosis of breast cancer. Many innovative treatments using chemicals, drugs and substances exogenous to the body have been employed to better understand the way HIF-1 α works in the organism. Analysis of the different points in the HIF-1 α expression cascade is of upmost importance in order to gain greater knowledge about how to use HIF-1 α in favor of the treatment and prevention of breast cancer and other diseases in which this factor plays an important role.

However, that there is a dearth of studies using HIF-1 α directly has been observed, since most of the articles found used HIF-1 α as a complement to confirm the data obtained with other genes/proteins/signaling pathways, or only as one of the components of the work. It is hoped that in the future more research will be done using HIF-1 α to better understand its function, and new ways of using the knowledge of the functioning of this transcription factor to our advantage.

DECLARATIONS

Authors' contributions

Made substantial contributions to conception and design of the study and performed data analysis and interpretation: Carlos HFP, Glaucia LV, Fernando F, Beatriz CAA

Performed data acquisition, as well as provided administrative, technical, and material support: Carlos HFP, Jessica AE, Matheus MP, Glauco SAA, Beatriz CAA

Availability of data and materials

Not applicable.

Financial support and sponsorship

This work was supported by FAPESP Grant (2017/03558-3); Fellowship grant CNPq (133505/2018-9) to Carlos HFP.

Conflicts of interest

All authors declared that there are no conflicts of interest.

Abstract

The existence of mammary epithelial stem cell (MaSC) populations capable of mediating mammary gland development and homeostasis has been established for over a decade. A combination of lineage tracing and mammary gland transplantation studies has affirmed that MaSCs and their downstream progenitors are organized in a hierarchical manner; however, these techniques have failed to illuminate the complete spectrum of epithelial intermediate populations or their spatial and temporal relationships. The advent of single cell sequencing technology has allowed for characterization of highly heterogeneous tissues at high resolution. In the last two years, the remarkable advances in single cell RNA sequencing technologies have been leveraged to address the heterogeneity of the mammary epithelium. These studies have afforded fresh insights into the transcriptional differentiation hierarchy and its chronology. Importantly, these data have led to a major conceptual shift in which the rigid boundaries separating stem, progenitor, and differentiated epithelial populations have been deconstructed, resulting in a new more fluid and flexible model of epithelial differentiation. The emerging view of the mammary epithelial hierarchy has important implications for mammary development, carcinogenesis, and metastasis, providing novel insights into the underlying cellular states that may promote malignant phenotypes.

INTRODUCTION

Many of the processes that occur during mammary gland morphogenesis are appropriated during the formation and malignant progression of breast cancer. These include the regeneration and hormonally-driven proliferative expansion of the mammary epithelium, remodeling of the extracellular matrix and invasion into surrounding stroma, aversion of apoptosis, and recruitment of vasculature^[1,2]. Thus, understanding the endocrine, cellular, and molecular mechanisms that control mammary gland development should provide critical insights into the processes that also underlie breast cancer growth and metastases and reveal novel approaches for preventing and treating aggressive disease. This review focuses on recent advances in our understanding of the development of the mammary epithelial cell hierarchy, revealing the abundant progression of cell states, many of which could undergo malignant transformation and give rise to the heterogeneous disease known as “breast cancer”.

The mammary gland is a uniquely dynamic organ that undergoes extensive remodeling throughout life in response to cytokine signaling and hormonal cues^[3,4]. The primitive mammary epithelium is first detected around embryonic day 11.5 (E11.5) in the mouse. Between embryonic day 16 and embryonic day 18 (E18), this rudimentary structure invades the mammary fat pad, forming a primitive ductal structure. During puberty, the mammary epithelium expands to form a branched, ductal network that invades the stroma until it reaches the edge of the mammary fat pad. This ductal structure is maintained into adulthood where it remains highly flexible in response to oscillating levels of ovarian hormones during the estrous cycle, undergoing extensive proliferation and apoptosis^[5]. In pregnancy, a unique hormonal milieu triggers the formation of secretory alveolar structures to form at the terminal end of each duct. Alveolar units function to produce milk proteins during lactation. Once lactation has ceased, the gland undergoes a process of involution in which massive architectural remodeling occurs, resulting in an epithelial structure that resembles the pre-pregnant state. Although morphologically similar, genetically engineered mouse models permitted tracing of “terminally” differentiated lactating cells and revealed that these cells contribute to the remodeled post-involuting gland and are molecularly distinct from their virgin counterparts^[6,7]. The events of expansion, differentiation, and repopulation of the mammary tree reoccur with each subsequent pregnancy indicating extensive plasticity of the cells that comprise the gland. Closer examination reveals that the mammary gland consists of two main epithelial lineages, the inner luminal lineage and the outer myoepithelial lineage. The luminal lineage can be further subdivided into mature ductal and milk-producing alveolar cells. Myoepithelial cells are commonly referred to as “basal” since they are located on the basal side of the luminal cells^[8]. These cells are highly contractile, and function to facilitate the movement of milk through the ducts.

The ability of the gland to undergo successive rounds of reconstruction in response to multiple pregnancies implicates the existence of a mammary stem cell (MaSC) population capable of generating all mature cell types within the gland. Studies utilizing transplantation and lineage tracing techniques further established that mammary epithelial differentiation is organized in a hierarchical, branched pathway wherein multipotent MaSCs give rise to a series of downstream intermediates^[8-10]. With each differentiation step, cells become increasingly lineage-restricted moving from multi- to bi- to uni-potent progenitor states until terminally differentiating into mature epithelial populations.

Discoveries over the last 50 years have been integral to our understanding of the mammary epithelial cell hierarchy; however, the advent of single-cell (sc) sequencing technologies coupled with microfluidic cell sorting has recently uncovered intricacies in lineage relationships and heterogeneity of the mammary epithelium. Recent evidence has demonstrated that each cell is unique in its transcriptomic signature^[11-14]. This revelation has redefined the differentiation cascade as a continuous trajectory of heterogeneous populations passing through gradual transcriptional states. These studies suggest that historical, rigid, models of the epithelial hierarchy should be replaced by a model that incorporates the diverse transcriptional profiles and

paths represented throughout development, underscoring the immense diversity and flexibility that likely underlies mammary gland development and gives rise to breast cancer heterogeneity. Here we discuss the recent studies utilizing scRNA-sequencing of mammary epithelium and how these new findings have shifted our current perspectives of mammary gland development and breast cancer.

HISTORICAL PERSPECTIVE OF THE MAMMARY EPITHELIAL HIERARCHY

In 1959, DeOme and colleagues developed the mammary transplantation assay^[15]. Using this technique, transplantation of murine ductal fragments^[16,17] or dissociated suspensions of normal mammary epithelium^[18] into the cleared fat pad of a recipient mouse resulted in the regeneration of a complete ductal structure. Smith and Medina then reported that morphologically distinct cells with regenerating capacity could be found throughout the entire mammary tree and persisted throughout pregnancy, lactation, and involution^[19]. Both the frequency and regenerative ability of these cells was not affected by age or reproductive history^[19,20]. Later studies demonstrated that mammary gland reconstitution was achievable upon transplantation of a single cell. This was first reported by Kordon and Smith, using serial transplantation and limiting dilution assays of mammary epithelium labeled with unique viral insertions generated by mouse mammary tumor virus (MMTV)^[21]. Similarly, by labeling cells with a LacZ transgene, Shackleton *et al.*^[22] confirmed this finding and demonstrated that stem cell populations were enriched in the basal epithelial fraction (defined by Lin⁻CD29^{hi}CD24⁺ cell surface markers). Additionally, cells from reconstituted glands harbored the same repopulating activity of the original and were capable of fully differentiating into milk-producing alveolar cells during pregnancy. These studies implicated the existence of a long lived multipotent mammary stem cell population (MaSC), capable of giving rise to all downstream lineages within the gland.

Following the disclosure of MaSCs, the search for molecular markers specific to the stem cell population became a major focus within the field. Transplantation of luminal vs. basal epithelial populations revealed that cells exhibiting stem-like properties were located within the basal fraction and could be enriched by FACS sorting using CD49f^{hi}CD29^{hi}CD24^{+/mod}EpCAM⁺Sca1^{low} expression as markers^[22-25]. Additionally, expression of s-SHIP^[26], LGR5^[27-29], Lrp5/6^[30], and Axin2^[31] enriched for populations with repopulating activity upon transplantation; however, stem cell activity was not exclusive to these subsets and the degree to which these markers may enrich for overlapping stem cell populations was not clear^[10]. Difficulty surrounding the identification of MaSC markers was due, in part, to the rarity of MaSCs in the adult gland. The frequency of repopulating cells was found to be higher during embryogenesis (~7% of total cells by E18 compared to ~2%-5% frequency in the adult gland)^[22,23,32,33]; however, enriched populations of fetal (f)MaSCs displayed altered gene expression profiles from their adult counterparts further complicating the isolation and characterization of a multipotent population^[32].

Transplantation studies demonstrated the existence of a stem cell entity that was capable of multi-lineage differentiation within the adult gland. Yet, various studies employing lineage tracing analyses led to confusion surrounding these findings. While some groups provided evidence to support multipotent cells, others reported that only unipotent cells remain after birth. Early lineage tracing experiments by Van Keymeulen *et al.*^[34], used the promoters of the keratin 14, 5, and 8 (K14, K5, K8) genes, to drive tracer expression and track both luminal (K8) and myoepithelial (K14, K5) lineages. This analysis demonstrated that prior to birth, K14⁺ cells were multipotent; however, after birth, these cells became unipotent, only giving rise to myoepithelial cells. Cells labeled by the K8 promoter revealed a second unipotent population responsible for maintaining the luminal lineage after birth. These unipotent populations supported epithelial expansion during puberty and pregnancy underscoring their long lived capacity within the gland. Additionally, lineage tracing at the single cell level revealed that unipotent populations were dispersed throughout the ductal tree, estimating that within each major duct, ~20 luminal and ~15 basal unipotent cells contribute to ductal expansion during puberty^[35]. Furthermore, by employing clonal analyses at saturation using DOX-inducible systems to trace luminal (K8rtTA-CreTetO/

Rosa-TdTomato) and myoepithelial (K14rtTA-CreTetO/Rosa-TdTomato) lineages, Wuidart *et al.*^[36] also reported unipotent progenitors as solely responsible for maintenance of adult lineages. Evidence of luminal unipotent progenitors that are restricted to the alveolar fate has also been reported. In this case, the “parity-induced mammary epithelial cell” (PI-MEC) population consists of alveolar-like cells that originate during a female’s first pregnancy^[6]. Unlike the majority of alveolar cells, PI-MECs do not undergo apoptosis during involution. Rather, these cells remain as a residual population within the parous gland and serve as alveolar precursors during subsequent pregnancies^[6,37].

Contrary to these results, some genetic fate-mapping studies have supported the existence of multi- and bi-potent mammary epithelial cell populations within the adult. For example, tracing of the Wnt target protein C receptor (Procr) illustrated the presence of a multipotent cell within the basal layer of the adult gland that was capable of giving rise to all mature lineages^[33]. Furthermore, studies have also reported bipotent progenitors in the adult gland. By combining a multi-color Cre reporter with three dimensional imaging techniques, Rios and colleagues traced luminal (ELF5+) and basal (Keratin 5+) cells during puberty and adulthood^[28]. This analysis resulted in the tracing of discreet clonal patches of luminal or basal cells as well as patches containing both lineages, indicating a common cellular origin^[28]. Similarly, an inducible Cre reporter mouse line, driven by the Axin2 promoter, labeled both bipotent and unipotent cells within the adult gland^[38]. Further complicating these studies, Axin2+ cells can undergo cell fate switching^[38]. This phenomenon has also been reported in mammary epithelial cells that are positive for Lgr5^[29]. Interestingly, Axin2+ unipotent cells are basally-restricted during adulthood but become bipotent during pregnancy, suggesting that cell fate switching may occur in response to hormonal cues^[10,38]. Pregnancy-induced bipotent mammary epithelial cells were also recently reported in a study by Song *et al.*^[39]. Lineage tracing of K8+ luminal cells revealed bipotent luminal cells that gave rise to basal progeny during pregnancy or upon stimulation with estrogen or progesterone. Additionally, transplantation of luminal-derived basal cells into cleared fat pads of recipient mice, demonstrated their capacity to generate new mammary gland structures with normal morphology.

The conflicting results generated from transplantation studies with those from lineage tracing has been a source of controversy in the field. The primary question still remains: does a multipotent stem cell exist after birth as indicated by transplantation assays; or are progenitor populations solely responsible for postnatal development? Inherent flaws within transplantation and lineage tracing methods likely contribute to the conflicting evidence within the field.

Transplantation assays have been highly scrutinized since this method includes the dissociation of mammary epithelial cells from their normal tissue architecture followed by their reintroduction into a new mammary tissue environment that has undergone invasive surgical resection. The drastic micro-environmental changes that epithelial cells must endure for this procedure has raised concerns that this assay may impart multipotent potential onto cells that would otherwise be restricted to specific differentiation outcomes^[10]. For example, Wnt/-catenin-responsive cells only give rise to myoepithelial cells during puberty and pregnancy, however; upon transplantation these cells can regenerate both luminal and myoepithelial lineages^[38]. Additionally, in lineage tracing experiments, K14+ cells are restricted to the myoepithelial lineage after birth; however, transplantation of K14-labeled cells from 4-week old mice results in the formation of new ductal structures containing both myoepithelial and luminal cells^[34]. The ability of transplantation to alter stem cell fate has also been demonstrated in other systems, including hair follicle development^[40] and hematopoiesis^[41]. It is plausible that differences in the microenvironment such as stromal, hormonal, and inflammatory cues, may impart phenotypic changes in mammary epithelial cell populations, activating primitive precursor pathways in their lineage. This may be especially relevant in the case of mammary transplants as the surgical resection needed to clear the innate epithelia likely elicits a “wound healing” response in the local environment of the transplant. Thus, transplantation assays may not accurately represent stem cell biology as it would intrinsically occur *in vivo*.

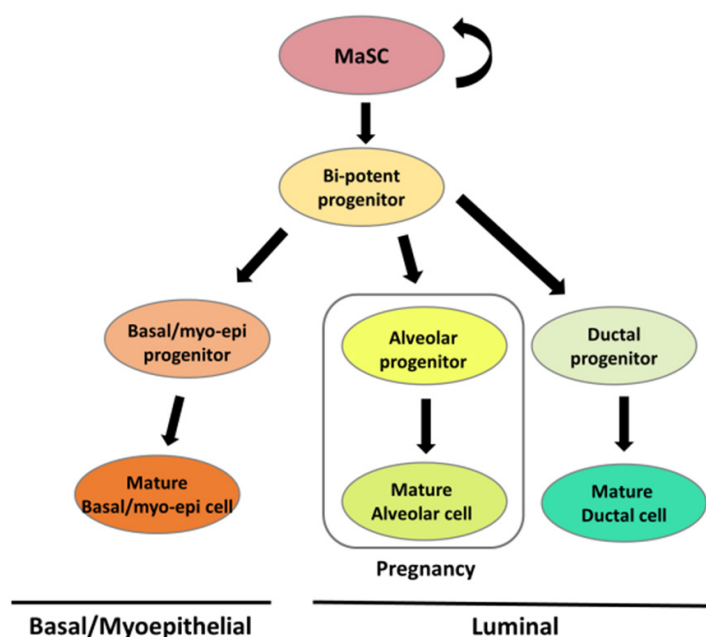

Figure 1. Historical model of the mammary epithelial cell differentiation hierarchy. Multipotent mammary stem cells (MaSCs) have the ability to self-renew and give rise to all downstream lineages. Bipotent stem cells give rise to committed unipotent progenitor populations that maintain basal/myoepithelial and luminal lineages. These unipotent cells are responsible for maintaining mature basal/myoepithelial and luminal lineages in the postnatal gland. Two luminal progenitor populations have been reported, one giving rise to alveolar cells during pregnancy and the other responsible for maintaining the mature ductal cells

Although lineage tracing allows for the visualization of cellular differentiation within the context of the normal tissue environment, it is not without its own set of limitations. The ability to detect rare heterogeneous populations of cells using genetic lineage tracing is highly dependent on recombination efficiency. High variability in the extent of recombination not only exists between mouse models (i.e., K5-Cre versus K14-Cre) but also between individual mice from the same strain^[42]. In addition, labeling efficiency varies significantly throughout the ductal tree of a single mammary gland^[42]. Several explanations for this variability have been postulated^[8,10,42]. Inadequate strength and specificity of the promoter driving recombination could result in inconsistent labeling. This may be particularly relevant to quiescent stem cells that are transcriptionally uncommitted to a certain lineage. Additionally, inducible creERT2 models are reliant on accurate dosing of Tamoxifen, a selective estrogen receptor (ER) modulator, to induce sufficient recombination. Since mammary gland development is highly dependent on ER signaling, tamoxifen administration, even at low doses, can alter normal mammary gland biology and lead to false readouts^[43].

Taken together, the results from both transplantation and lineage tracing studies have led to a highly compartmentalized view of the mammary epithelial hierarchy in which fetal MaSCs give rise to a common bipotent progenitor which differentiates into lineage-restricted and unipotent luminal and myoepithelial progenitors. Unipotent progenitors then give rise to mature myoepithelial and luminal lineages (for detailed reviews see Visvader and Stingl^[10], 2014, and Yang *et al.*^[44], 2017) [Figure 1]. Although transplantation and lineage tracing methods have been fundamental to our understanding of mammary epithelial biology, it has become increasingly evident that these methods are insufficient to fully characterize rare or highly heterogeneous cell populations. Gene expression signatures on bulk isolates of the major epithelial compartments including luminal progenitors, mature luminal, and MaSC-enriched basal epithelial cells, have been generated^[45]. However, the utility of these signatures to identify critical molecular regulators and markers of epithelial subsets has been limited due to the heterogeneity of each epithelial population in which only a small fraction of cells expresses the same set of transcripts (as in the case of stem populations within the basal fraction)^[22,32,46]. As a single cell can give rise to an entire mammary gland, it is imperative that the

molecular states and instructive signals occurring at the single cell level be examined to fully grasp how individual cells traverse the differentiation cascade as well as discern how specific cell states can re-emerge in breast cancer and contribute to metastasis.

A NEW VIEW OF THE MAMMARY HIERARCHY

Single-cell sequencing has emerged as a powerful tool capable of uncovering the transcriptional heterogeneity of diverse cell types within a tissue^[47]. Although transcriptome profiling of single cells was reported over 20 years ago^[48,49], only recently has it become a widely utilized technique. Technological advances in areas such as microfluidics and in situ barcoding have allowed for high throughput, cost effective sequencing of hundreds to thousands of cells within a given sample^[50]. Furthermore, the ability to analyze large numbers of cells at high resolution has mandated the development of innovative approaches for downstream data analysis. Software tools have recently become available to infer evolutionary history and lineage relationships within heterogeneous cell populations^[51].

Recently, several independent laboratories have utilized scRNA-seq to identify epithelial subpopulations and their differentiation trajectory within the mammary gland^[11-14]. Together these studies have examined the complete mammary developmental cycle encompassing embryonic through adult stages and pregnancy through post-weaning. The transcriptional landscape generated from these studies has provided critical insight into epithelial differentiation, transforming the way in which we view the mammary epithelial hierarchy. The new model emerging from these studies emphasizes the fluid and gradual progression of epithelial differentiation and reveals a greater degree of cellular heterogeneity than had previously been acknowledged.

SINGLE-CELL SEQUENCING OF THE MAMMARY EPITHELIUM

Prior to birth, sc-RNA sequencing has shown that the epithelium consists of a continuum of primitive cellular states in which unique subpopulations could not be detected^[12]. This supports previous findings generated from gene expression analysis of bulk fMaSCs, demonstrating that fMaSCs are comprised of a single CD24+CD49f+ population^[32]. During embryogenesis, the majority of mammary epithelial cells exhibit dual expression of both luminal and myoepithelial signature genes^[12,32,52]. This hybrid gene expression signature is associated with multipotent potential and a loss of dual lineage expression as cells become restricted to unipotent potential^[52].

At birth, many mammary epithelial cells maintain a hybrid gene expression profile^[12]. This dual lineage signature may include rare bipotent progenitor populations previously observed by lineage tracing studies^[28,38]. However, the majority of this population likely represents cells spanning various transitional stages of lineage restriction. Cells become increasingly more lineage restricted throughout puberty; however, the precise timing of the major bifurcation event between luminal and basal cells remains unclear. In work by Pal *et al.*^[53], scRNA-sequencing of mammary epithelium from 2 (pre-puberty), 5 (puberty), and 10 (adult) week-old mice demonstrated that before puberty, the mammary epithelial cell populations are largely homogeneous, expressing a basal (myoepithelial)-like gene signature. Upon puberty, a fraction of cells upregulate expression of luminal genes such as Epcam, and Keratins 8, 18, and 19, suggesting that bifurcation initiates at this time^[53]. However, Giraddi *et al.*^[12], specifically assessed changes in the early postnatal epithelium by examining glands from mice at day zero (PN0) and day 4 (PN4) after birth. In contrast to the report by Pal and colleagues, they found that two distinct cellular populations, one containing myoepithelial cells and the other containing luminal precursors, begin to emerge as early as PN4. While these studies confirm that the mammary epithelium remains in a primitive state until postnatal stages during which lineage restriction commences, the specific timing of those commitments remains unclear.

Sc-RNA sequencing of adult stages clearly demonstrate that mature epithelial cells are transcriptionally segregated into basal (myoepithelial) and luminal lineages^[11,12,53]. Within these overarching phenotypes, up to 15 transcriptionally distinct clusters (11 luminal and 4 basal) have been reported across nulliparous and reproductive stages^[11]. However, the majority of these subpopulations cannot be characterized by expression of a single gene, indicating that cells remain highly heterogeneous and many of these clusters may represent transient states of differentiation. The luminal lineage within the nulliparous gland undergoes multiple differentiation events. Luminal progenitors give rise to a series of intermediate states that bifurcate to generate a hormone responsive lineage (ER+) and a secretory alveolar lineage (ER-)^[11,12,14]. Upon pregnancy, ER- cells undergo massive expansion to produce the alveolar cells needed for lactation. The expanded population expresses genes associated with proliferation, fatty-acid transport, and lipid biosynthetic and homeostatic processes^[11]. Recent lineage tracing studies have proposed that ER+ and ER- luminal lineages arise from independent progenitor populations^[54,55]. In work by Wang *et al.*^[54], PROM1+ progenitors were found to give rise to ER+ luminal cells whereas SOX9+ progenitors give rise to ER- cells. Thus, as heterogeneous luminal populations undergo gradual differentiation, the acquisition of SOX9 or PROM1 expression may be a major determinant of further luminal cell fate specification.

STEM AND PROGENITOR POPULATIONS DETECTED BY SINGLE-CELL RNA SEQUENCING

The sc-RNA-sequencing studies reported to date have not detected a single transcriptionally distinct multipotent stem cell population within the adult murine gland^[11,12,53]. However, dormant populations that possess stem potential under specific environmental cues may exist. In a study by Sun *et al.*^[13] mammary epithelial stem cell markers including Bcl11b^[56], Tspan8^[57], and Procr^[33] were detected in the adult gland; however, expression on these genes was mutually exclusive, indicating each labels an independent population. Further analysis of a novel population marked by Cdh5+, revealed increased stem activity within this group of cells as demonstrated by both mammosphere and *in vivo* transplantation assays^[13].

In human breast, bipotent progenitor populations within the adult gland have been identified in cells isolated from reduction mamoplasties^[14]. Using Monocle software analysis of sc-RNA sequencing data collected from seven individuals, Nguyen *et al.*^[14], mapped both luminal and myoepithelial lineages to a common cellular origin. These cells exhibited a basal gene expression signature as well as expression of ZEB1. This contrasts with the inability to identify subpopulations of bipotent progenitors using sc-RNA sequencing of mouse mammary glands. Discrepancies between mouse and human studies may be due to differences in the methodologies employed to generate scRNA-seq profiles [Table 1]. These include epithelial cell isolation methods, read depth, and data analysis and interpretation. For example, in work by Giraddi *et al.*^[12] (2018) and Bach *et al.*^[11] (2017), sc-RNA sequencing clustering results were based on epithelial cells that were positive for EPCAM expression. Thus, there remains the possibility that an EPCAM-stem cell population was overlooked in the murine studies. Additionally, cells double positive for the major luminal and basal cell markers, cytokeratin 8 and 14 respectively, are detected within the basal epithelial layer of human adult breast tissue^[14]. This is in contrast with mouse basal epithelium where double positive cells are not detected after birth^[22]. This difference in dual cytokeratin expression coupled with the interpretation that cells expressing both luminal and basal markers represent bipotent progenitors may contribute to the differences between mouse and human scRNA-seq findings. Furthermore, evidence from transplantation assays suggests that stem populations are widely distributed within the gland^[16,17,19]; however, it is unknown if specific subpopulations are spatially restricted. In this regard, it has been reported that a group of highly quiescent MaSCs, marked by Tspan8 expression, are located within proximal regions of the adult murine gland, closest to the nipple^[57]. Thus, discrepancies between data sets may also arise depending on area of the mammary gland from which the sequenced cells were collected.

Luminal progenitors that are first identified as mixed lineage cells gradually gain luminal orientation during postnatal development^[53]. By puberty, a distinct luminal progenitor population can be detected. However,

Table 1. Comparison of scRNA-seq methodologies used to examine the mammary epithelial hierarchy

scRNA-sequencing has further uncovered novel subcategories within the greater luminal progenitor population. For example, prior to puberty, CD55 is a marker of rare basal cells that give rise to a subset of luminal progenitors during adulthood^[53]. CD55+ cells within the luminal fraction exhibit increased colony forming ability compared to CD55- cells^[53]. In addition, populations positive for both CD55 and the progenitor marker, CD14 possess an even greater colony-forming ability. Luminal progenitors acquire additional complexity during pregnancy. Single-cell analysis of luminal progenitors in the nulliparous adult compared to post-involution glands revealed permanent transcriptomic alterations within a subset of post-involution cells^[11]. Following involution, luminal progenitors retain expression of genes associated with lactation and milk production. It is likely that this population overlaps with the previously described PI-MEC population^[6].

CELLULAR PLASTICITY OF THE MAMMARY EPITHELIUM

The ability of mammary epithelial cells to express both luminal and myoepithelial signature genes at various stages of maturation and reproduction suggests that a fraction of cells may maintain lineage plasticity throughout life^[12,14,52,53]. Studies investigating chromatin accessibility within the mammary epithelium at fetal and adult stages have demonstrated that bi-lineage gene expression is achievable due to epigenetic regulation of genes associated with multiple lineages^[12,58]. In a recent study by Dravis *et al.*^[58], gene expression profiles and open chromatin regions were compared between fetal (f)MECs, luminal progenitors, and mature lineages using RNA-seq and ATAC-seq, respectively. fMaSCs expressed both canonical luminal and basal genes and gene loci were associated with open chromatin, reflecting their immature, multi-lineage state (consistent with Giraddi *et al.*^[12]). While, the chromatin architecture of adult myoepithelial cells resembled that of fMaSCs in which luminal and myoepithelial gene loci were associated with open chromatin; only genes associated with the myoepithelial lineage were expressed. These results indicate that although myoepithelial cells express lineage-restricted genes, they retain the flexibility to adopt a luminal identity similar to multipotent fMaSCs^[58]. This may explain the multipotent capacity of basal cells observed

upon transplantation^[22,23]. Several epigenetic factors have been shown to play a role in defining mammary epithelial cell fate. These include the histone methylation reader POGZ^[59], the polycomb-repressive complex-1 member, BMI1^[60,61], and the polycomb-repressive complex 3 member, EZH2^[62]. BMI1 and EZH2 also play key roles in metastasis of breast cancers, likely due to their activation of more primitive cell fates^[63-66]. Yet how these players collaborate to orchestrate the epigenetic continuum that drives fate determination and heterogeneity is not fully understood.

Differential chromatin accessibility of both myoepithelial and luminal genes in basal cells may explain the ability of transcriptional drivers to induce cell fate switching in committed cells. In a recent example, overexpression of Notch1 in Smooth muscle actin (SMA)+ or K5+ myoepithelial cells, was sufficient to commit cells to a luminal fate^[67]. Complementary to this, overexpression of p63 in luminal cells was sufficient to reprogram them into a myoepithelial state^[52]. Although the mechanism of p63-mediated cell fate switching is unknown, chromatin remodeling is likely required as mature luminal cells exhibit repressed chromatin at basal gene loci^[58]. SOX10 has also emerged as a major transcriptional regulator of epithelial cell fate^[58]. Within fMaSCs, SOX10 motifs are enriched at accessible chromatin regions flanking highly expressed genes. Furthermore, tumors expressing high SOX10 levels exhibit neural crest-like features^[58] and high SOX10 expression is correlated with the aggressive, basal-like breast cancer subtype. As embryonic neural crest cells are multipotent and highly mobile^[68], SOX10 reprogramming may lead to primitive cellular states that could contribute to aggressive tumor phenotypes.

A NEW MODEL FOR THE MAMMARY EPITHELIAL HIERARCHY

Cumulative evidence from the recent papers utilizing sc-RNA-sequencing has revealed that the historical models by which the mammary epithelial hierarchy has been traditionally represented do not accurately portray the complexity of the system^[11-14,53]. Previous models in which cellular states are depicted as discrete populations that differentiate along restricted paths is an oversimplification [Figure 1]. Instead, recent results indicate that heterogeneous cell populations gradually advance, and likely also retreat, through a differentiation trajectory^[11,12,53]. This is supported by the work from several groups, reporting a vast array of epithelial transcriptional profiles throughout the stages of mammary gland development^[11-14,53]. Similar findings have redefined the hierarchical visualization of hematopoiesis^[69]. Using the new visual representation of hematopoietic differentiation suggested by Laurenti and Gottgens as an example, we propose a similar paradigm to represent the mammary epithelial hierarchy [Figure 2]. As depicted in this model, groups of heterogeneous epithelial cells traverse through the differentiation landscape, passing through cellular states that have been previously defined including fMaSCs, luminal and myoepithelial progenitors, and mature luminal and myoepithelial lineages. The newly reported heterogeneity of these populations implies that each cell may take a slightly different transcriptional path from the next as it undergoes differentiation. Additionally, the array of cellular states detected within the gland at any one time suggests that variation in temporal dynamics of differentiation may exist between individual cells. Moreover, this model implies significant forward and reverse plasticity of cell states that could be impacted by the microenvironment. This could partially explain historical difficulty in attempting to isolate and characterize specific subpopulations; however, further studies are needed to test these predictions.

IMPLICATIONS FOR TUMOR INITIATION AND METASTASIS

Breast cancer is an amalgam of diseases that exhibit both inter- and intra-tumoral heterogeneity^[70]. Gene expression profiling has led to the classification of five overarching subtypes, including luminal A, luminal B, HER2+, basal-like, and claudin-low^[71-74]. However, within each subtype, tumors can exhibit further variability in gene expression, molecular function, and drug susceptibility conveying distinct patient outcomes. The heterogenic nature of breast cancer is thought to arise from the combination of cellular origin, genetic and epigenetic changes, and environmental context^[1,10,70,75].

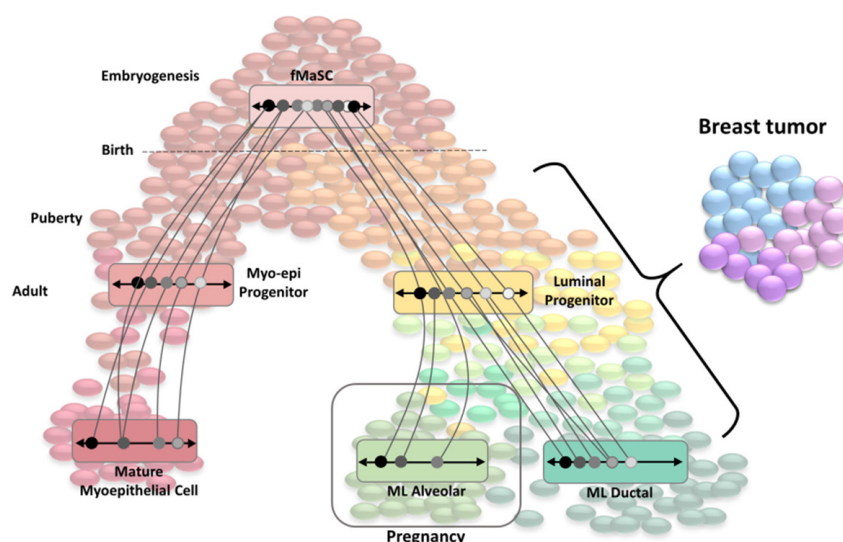

Figure 2. A progression model of mammary epithelial cell fate specification. Mammary epithelial differentiation occurs as cells pass through a continuous cascade of transcriptional states, with the majority of cells becoming increasingly more lineage-restricted throughout life and in response to pregnancy. Progressive lineage restriction is represented by gradual changes of the colors of cells (red, orange, yellow, green and blue). As cells differentiate, they pass through previously defined phenotypic compartments [fetal mammary stem cells (fMaSCs), Luminal and myoepithelial (myo-epi) progenitors, mature luminal (ML) ductal and alveolar cells and mature myoepithelial cells (rectangles)]. Grayscale circles (ranging from white to black) on the horizontal lines represent the various epigenetic and transcriptomic states found within each phenotypic compartment with the number and different shading patterns representing the degree of heterogeneity within each major phenotypic group. Arching and angled lines connecting those circles reflect the various transcriptional and epigenetic trajectories that cells pass through before eventually terminating into mature, differentiated lineages (myoepithelial, luminal, and alveolar). Cells at various points along the differentiation cascade may serve as tumor initiators, leading to inter- and intra-tumoral heterogeneity. Figure adapted from Girardi *et al.*^[12]

Molecular profiling studies have revealed that the gene expression patterns of cancer subtypes align with those of normal mammary epithelial cell lineages^[76,77]. This suggests that tumor subtypes may originate from distinct mammary epithelial subpopulations. It is widely speculated that epithelial stem/progenitor populations may serve as tumor initiating cells since their longevity and ability to self-renew affords the accumulation of genetic mutations. This has been supported by gene expression profiling studies. For example, the gene expression profile of claudin-low tumors most closely resembles that of MaSC/basal epithelial cells, whereas basal-like tumors more closely resemble luminal progenitors^[45,72,76,78]. Further evidence supporting luminal progenitors as the cell of origin for the basal-like subtype has been shown in tumors harboring BRCA-1 mutations^[76,77,79]. More recently, sc-RNA-sequencing of human breast epithelial cells demonstrated that cells expressing luminal progenitor genes correlated most highly with basal-like breast cancers from the METABRIC dataset^[14]. Despite these findings, not all cancer subtypes have been correlated with a cell of origin and the inability to isolate pure populations of mammary stem/progenitor cells has impeded functional testing. Moreover, it is also feasible that cancers acquire the transcriptional profiles of specific cell states due to the mutations that drive tumor development or progression and that the cells of origin may not be consistent with final tumor deposition. In this case, identifying the contextual cues that promote normal epithelial hierarchical progression would likely reveal pathways that are also activated or suppressed in tumors that promote their phenotypes.

The new view of the mammary epithelial hierarchy suggests that the continued search for a tumor cell of origin based on molecular profiles that have historically been used to characterize the major epithelial populations (mature luminal, myoepithelial, luminal progenitor ext.) is unlikely to reveal discreet cells from which different breast cancer subtypes emanate. The complexity of the normal epithelium suggests a similar heterogeneity is present in the primary and secondary tumors that arise from it. Indeed, a study comparing sc-RNA-seq profiles generated from triple-negative patient tumors revealed that a subset of cells within

each tumor expressed profiles resembling a spectrum of epithelial differentiation statuses^[80]. It now can be presumed that cells residing anywhere along the continuous differentiation trajectory may acquire tumor-initiating mutations [Figure 2] and that the location of the cell within the differentiation hierarchy will determine its transcriptional status and influence whether acquired mutations will be oncogenic. This is most consistent with the inability to identify a single lineage that contributes to HER2/Neu-induced tumors because amplification or overexpression of the ERBB2 gene may occur in an array of cell states rather than a single cell of origin for all tumors^[81,82]. Similar findings have been reported in leukemia, in which progenitor cells rely on the activation of the β -catenin pathway for oncogenic transformation^[83]. Although it is noted that some populations may be more susceptible to mutagenic events than others^[84,85], the possibility that phenotypically similar tumors arise from cells residing in the exact same cellular state is slim. This notion is supported by the transcriptional heterogeneity observed across breast cancer patient tumors within the same subtype^[86]. Several genetic mutations have been associated with the stratification of breast cancer subtypes. These include mutations in GATA3, RUNX1, or NCOR1 which are associated with the Luminal A subtype; whereas mutations in the tumor suppressor retinoblastoma, RB1, or CDH1 have been associated with luminal B tumors^[10,87,88]. Although these mutations are associated with the acquisition of a specific breast cancer subtype, it is likely the combination of the preexisting epigenetic and transcriptional status of the cell along with the transforming mutations that explain tumor heterogeneity and give rise to the variable therapeutic responses observed between patients.

Accumulating evidence suggests that a rare population of stem-like progenitor cells are responsible for tumor initiation, progression, metastasis, and therapeutic resistance^[89]. These cells are referred to as cancer stem cells (CSCs) or “tumor initiating cells” and share many characteristics with normal mammary epithelial stem cells including the ability to self-renew and differentiate. Additionally, CSCs share gene expression profiles that closely resemble those of primitive mammary epithelial cells, including the expression of stem and EMT associated genes^[90]. This has led to many to posit that CSCs arise from mammary stem/progenitor cells, however definitive evidence for the origin of CSCs in breast cancer is lacking^[91]. The extensive heterogeneity within the mammary epithelium that has been revealed by scRNA-seq makes it reasonable to presume that many cellular states have the potential to give rise to CSCs. Furthermore, the unique transcriptional and epigenetic context of an epithelial cell prior to transformation likely determines the aggressive nature of the arising tumor, including its ability to metastasize. Indeed, many studies have identified transcriptional regulators of normal mammary development that also encourage aggressive behaviors during cancer. This is the case for transcriptional drivers of stem cell and EMT programs including SOX9^[92], SLUG^[92], and SOX10^[58]. In a study by Guo *et al.*^[92], expression of both SOX9 and SLUG was found to be necessary for maintenance of the MaSC phenotype. Moreover, coexpression of SOX9 and SLUG in breast cancer cell lines was sufficient to induce stem cell-like properties, including activation of an EMT program and metastasis-seeding abilities. Similar results were observed for SOX10^[58]. Binding of SOX10 within regions of open chromatin that flank genes associated with EMT or with embryonic neural crest cells (NCC) was found to promote migratory and invasive behavior within mammary tumor cells. Thus, it is possible that epithelial cells expressing high levels of transcriptional drivers of EMT and stem-like states at the time of transformation may be predisposed to malignant phenotypes. Likewise, the chromatin accessibility of genes associated with processes such as EMT and NCC may ‘prime’ cells for aggressive behaviors associated with CSC phenotypes.

The formation of CSCs and their ability to seed new tumors at distant sites is also highly dependent on the surrounding microenvironment^[93-95]. Notably, contextual stimuli such as exposure to TGF β , can initiate stem cell and EMT programs in normal mammary epithelial cells that then promote their transition to a CSC state^[94]. The resulting CSCs remain highly susceptible to surrounding cues. This is especially relevant in the context of metastasis, in which Paget’s “seed and soil” hypothesis proposes that a tumor-permissive environment is required for disseminating tumor cells to engraft and metastasize into new tissue sites^[93,96]. As breast cancer arises from the normal epithelium, the contextual cues regulating normal epithelial

behavior are likely mirrored in breast cancer cells. Therefore, understanding the reciprocal interactions between epithelial cells and their niche should also inform the mechanisms underlying tumor initiation and metastasis.

In this regard, the recent studies using sc-RNA-sequencing outside the context of disruptive transplantation assays, have revealed that epithelial populations may be more highly influenced by the surrounding environmental cues than previously appreciated. As discussed earlier, previous studies using transplantation assays demonstrated the multipotent potential of rare mammary epithelial cells within the adult gland^[22,23]. However, lineage tracing analyses were unable to replicate these results and recent sc-RNA-sequencing has further supported the lack of multipotent cells during adulthood. Thus, it has become increasingly apparent that introduction of isolated cells into wounded stromal environment may elicit cellular phenotypes that are not supported under normal physiological conditions. A similar phenomenon is likely to occur with breast cancer initiation and progression. While acquisition of an “oncogenic” mutation may occur in varied cells along the differentiation hierarchy, its impact on tumorigenesis and progression may rely upon the stromal microenvironment, particularly an environment that is reflective of wound repair such as that which occurs with high breast density^[97], obesity^[98], and in post-lactational remodeling^[99]. The same is also likely to be true with metastasizing cancer cells. Instructional interactions between the epithelium and surrounding stroma are well established. This was most exquisitely demonstrated in extensive studies by Smith and colleagues revealing that the local microenvironment of the mammary gland is sufficient to reprogram progenitor cells from completely different tissues (including testicular and embryonic stem cells) into mammary progenitors that were capable of forming normal mammary gland structures^[100-104]. Furthermore, alterations in the microenvironment may influence cellular transformation. In work by Barcellos-Hoff and Ravani^[105], irradiating the cleared fat pads of recipient mice, lead to alterations in growth factor activity and extracellular matrix composition. Following irradiation, implantation of non-tumorigenic mammary epithelial cells resulted in tumor formation more readily in irradiated mice. Conversely, epithelial tumor cells injected into non-irradiated mammary fat pads reverted to form normal mammary gland ducts rather than tumors^[106].

The effects of contextual cues on the epigenetic and transcriptional status of major transcriptional regulators has also been recently highlighted. Although SOX10 is highly expressed in cells isolated from MMTV-PyMT tumors, this expression was lost when cells were grown in 2D culture conditions^[58]. The loss of SOX10 expression was associated with a switch from open to closed chromatin at the SOX10 locus, emphasizing the role of environmental cues on epigenetic status. This is not a new concept, as changes in the epigenetic landscape are known to occur in response to hormonal exposure^[62,107].

CONCLUSION

The scRNA-sequencing studies reviewed here have provided a detailed transcriptional map of mammary epithelial differentiation. However, these data indicate that previously underappreciated complexity undoubtedly underlies the regulation of the heterogeneous transcriptional networks observed. The unique transcriptional status within each epithelial cell is likely correlated with a unique epigenetic profile and it is anticipated that these profiles have a considerable level of plasticity that is dictated by the microenvironment and, in the case of tumors, mutational status. Studies examining the chromatin accessibility within bulk isolations of epithelial populations (MaSCs, basal, luminal and luminal progenitors) have demonstrated that each population is associated with distinctive active and repressed regions, many of which are associated with functional consequences and specific tumor subtypes^[12,58,107]. The emerging ability to simultaneously assess both the transcriptional and epigenetic status at a single cell level should allow for clearer understanding of the lineage relationships in the normal gland and in tumors as well as reveal whether tumor cells can readily transition through states as has been observed in the normal breast. It is important to note, however, that

while single cell sequencing technologies can provide high resolution maps of cellular states, they cannot make definitive predictive connections to the resulting cellular fates. The use of newly developed technologies, such as “CellTagging” that allow for early transcriptional statuses to be linked to cellular fates will allow for a clearer understanding of epithelial lineage relationships within the mammary gland^[108]. Furthermore, studies layering single cell technologies that assess transcriptional, epigenetic, and proteomic data within the normal gland, primary tumor, and associated metastatic lesions should provide important information regarding the extent of plasticity of primary and metastatic tumor cells that can be therapeutically leveraged to promote differentiation of breast cancers into less malignant states.

Abstract

Aim: Paxillin is a well-known multidomain scaffold protein that is involved in the regulation of cell-matrix adhesion dynamics, a process required for the tumor cell migration and invasion. Phosphorylation of the serine residue 178 requires c-Jun NH2-terminal kinase (JNK) activation, which occurs downstream of epidermal growth factor receptor (EGFR)-mediated signaling and drives cell migration. In this study, we investigated the significance of paxillin Ser178 phosphorylation in breast cancer progression.

Methods: We employed the rat mammary carcinoma MTLn3 cell line with which we established stabile variants of both wild type and mutant GFP-paxillin constructs. With those, we next performed several in vitro assays including cell proliferation, migration and focal adhesion dynamics. Finally, we monitored the metastatic spread of both cell line variants in an orthotopic mouse model for breast cancer.

Results: Here we show that expression of the phospho-defective mutant paxillinS178A in the metastatic mammary adenocarcinoma MTLn3 cell-line significantly decreased EGF-induced cell migration, which was correlated with impaired focal adhesion dynamics. Moreover, paxillinS178A attenuated lung metastasis formation in an orthotopic *in vivo* mammary gland tumor/metastasis model, demonstrating the importance of JNK-mediated paxillin phosphorylation in breast cancer progression. Expression of paxillinS178A caused a decrease in EGFR expression,

while re-expression of EGFR in MTLn3-paxillinS178A cells fully restored EGF-driven cell motility and focal adhesion dynamics. Furthermore, re-expression of EGFR in MTLn3-paxillinS178A rescued spontaneous metastasis from breast to lung.

Conclusion: Overall our data show an important role for JNK-mediated paxillin Ser178 phosphorylation in the regulation of EGFR expression and thereby, in EGF-driven cell migration and metastasis formation.

Keywords: Paxillin, c-Jun NH2-terminal kinase, focal adhesion, epidermal growth factor receptor, cell migration, metastasis, breast cancer

INTRODUCTION

Breast cancer represents the most common type of cancer among women. The formation of metastases, which is a determinant of the prognosis of cancer patients, involves distinct cellular processes including cell migration, invasion, intra- and extravasation and proliferation. These processes are regulated by growth factors, cytokines and cellular matrix molecules^[1-6]. An important regulator of cell proliferation and migration is the receptor tyrosine kinase epidermal growth factor receptor (EGFR) whose stimulation by epidermal growth factor (EGF) results in the activation of downstream signaling pathways including different mitogen-activated protein kinases cascades: extracellular signal-regulated kinase (ERK), p38 and c-Jun NH2-terminal kinase (JNK)^[7-11].

The JNK group of kinases has essential roles in cancer development including regulation of the survival/proliferation balance as well as cell migration^[7,9,12,13]. Dual Thr and Tyr phosphorylation of JNK by upstream MAP kinases results in JNK activation and nuclear translocation. In the nucleus, JNKs phosphorylate and activate transcription factors including members of the AP-1 family such as c-Jun. The JNK-AP-1 pathway regulates the expression of genes involved in the cell cycle, survival and apoptosis and extracellular matrix homeostasis^[14-22]. Besides phosphorylation of transcription factors, several cytoskeleton-associated adaptor and signaling proteins have recently been identified as direct JNK substrates including β -catenin^[23] and paxillin^[24,25]. Since both proteins are well known to be involved in cell-matrix and cell-cell contacts, the direct JNK-mediated phosphorylation of these targets may also influence cell migration.

Paxillin is a 68 kD multidomain adaptor protein associated with focal adhesions^[26-31]. It is long known to function as a scaffold to integrate multiple signaling pathways involved in matrix adhesion dynamics and cell migration^[27,31-36], and recently, it was shown to play a role in the nucleus in relation to mRNA transcription and subsequent translation^[37,38]. Few studies have identified paxillin as a JNK substrate^[8,24,25]. EGF-driven JNK activation results in JNK-mediated phosphorylation of paxillin at Ser178 and is required for cell migration^[9,13,19,25,39]. In addition, expression of a phospho-defective Ser178 to Ala mutant of paxillin inhibited cell migration^[9,19,24]. How JNK-mediated phosphorylation of paxillin regulates cell migration is still under investigation. It is still unclear how this phosphorylation event is relevant for breast cancer metastasis formation^[40,41].

Here we explored the role and mechanism of paxillin Ser178 phosphorylation in breast tumor progression using the highly metastatic breast tumor cell line MTLn3 as a model. We show that ectopic expression of paxillinS178A significantly decreased EGF-dependent signaling and cell migration. Using an orthotopic mammary gland tumor/metastasis model, we demonstrate that the JNK-mediated phosphorylation of paxillin at Ser178 is essential for efficient metastasis of MTLn3 cells to the lung. Expression of mutant paxillinS178A was found to reduce EGFR expression, whereas re-expression of EGFR rescued the defected tumor cell migration and metastasis formation. Our data indicate that the phosphorylation of Ser178 of

paxillin by JNK can regulate cell migration and metastasis formation via modulation of the EGFR-signaling pathway.

METHODS

Chemicals and antibodies

Alpha modified minimal essential medium without ribonucleosides and deoxyribonucleosides (α -MEM), fetal bovine serum (FBS), phosphate-buffered saline (PBS), trypsin and geneticin (G418 sulphate) were from Life Technologies. Rat tail collagen type I was from Upstate Biotechnology. LipofectAMINE Plus transfection reagents were from Invitrogen. Primary antibodies were anti-paxillin (BD), anti-tubulin, anti-GFP (Sigma, St. Louis, MO), anti-pT183/pY185-JNK (Promega), anti-Phospho-Thr202/Tyr204 ERK1/2, anti-pSer473-AKT (Cell Signaling), anti-pSer178-paxillin (Abcam, Cambridge, UK), anti-EGFR for Western blot (rabbit polyclonal, Cell Signaling Technology) and FACS/immunostaining (mouse monoclonal, Calbiochem). All secondary antibodies were from Jackson. The Western-Star immunodetection system (Tropix kit) was from Applied Biosystems and ECL Plus reagent was from Amersham. Hoechst 33258 and rhodamine-phalloidin were from Molecular Probes and Aqua Poly/Mount was from Polysciences.

Cell culture

MTLn3 cells were cultured as before^[42]. To generate stable cell lines, MTLn3 cells were transfected with GFP-paxillin or GFP-paxillinS178A kindly provided by Huang et al.^[24] were transfected using LipofectAMINE plus reagents according to manufacturer's procedures. Stable transfectants were selected using G418 and individual clones were picked and kept at 100 μ g/mL G418. For EGF experiments, 70%-80% confluent cells were starved for 4 h followed by exposure to EGF (10 nmol/L). Human EGFR was expressed in GFP-paxillin S178A using retroviral transfection followed by FACS sorting as described previously^[43]. Retroviral transduction of GFP-paxillin cells with a pMSCV-blast-hEGFR retroviral vector, followed by blasticidin selection (12.5 μ g/mL) was used to generate GFP-paxillin S178A EGFR cells.

Luciferase reporter assay

MTLn3 cells were transiently transfected with the reporter constructs pGL3-Tata-5xE3AP1^[44], pGL3-Tata-5xCol1TRE, pGL3-Tata-5xJun2 kindly provided by Dr. Hans van Dam (LUMC) using Lipofectamine Plus reagent^[42]. 1 μ g of expression reporter plasmids together with 1 μ g of a renilla-luciferase construct (as an internal control for transfection efficiency) were transfected in both clones WT and S178A. After 48 h, cells were serum starved for 4 h then lysed and analyzed for luciferase activity using a luminescence plate reader.

Proliferation, attachment and wound healing assay

For proliferation assay, cells were plated in complete medium in 6 wells-plates and cultured for 24, 48, 72 or 96 h at which time point the amount of cells was determined by counting. For cell attachment assay, 1 h serum-starved cells were seeded in complete medium on collagen-coated 6 wells-plates for 30, 60, 90 and 120 min, and following a PBS wash, attached cells were trypsinized and counted. For wound healing assays, monolayer cells were scratched using a pipette tip to generate a wound followed by a wash with medium and incubation in α -MEM supplemented with 1% (v/v) FBS for 20 hrs. Wounds were photographed using phase contrast microscopy with a Nikon Coolpix digital camera directly after scratching and after 20 h. Wound closure was determined using Image J software.

Live cell imaging

Random cell migration

Cells were cultured in glass-bottom plates overnight and starved for 4 h followed by imaging for 1-3 h on a Nikon TE 2000-E microscope in a humid climate of 37 °C and 5% CO₂ with either DIC (Differential Interference Contrast) or fluorescence microscopy. Subsequently, cells were treated with EGF and time-

lapses were captured with 20× objective. Per biological replicate, there were 3 wells treated similarly and 2 positions per well were imaged. About 30–40 cells were followed over time in each field of view, which means that we analyzed the behavior of more than 120 cells per biological replicate. When used, the JNK inhibitor SP600125 (20 μmol/L) was added 30 min prior to stimulation. Cell speed was determined with a homemade macro written in Image-Pro Plus (Media Cybernetics Inc., Silver Spring, MD).

Total internal reflection fluorescence and fluorescence recovery after photobleaching

Total internal reflection fluorescence (TIRF) microscopy was performed with a Nikon TE 2000-E microscope in a climate control chamber. To determine the turnover of GFP-tagged paxillin proteins in individual focal adhesions, fluorescence recovery after photobleaching (FRAP) was performed as follows: photobleaching was applied to a small area covering a single focal adhesion for 1 s with laser intensity of 50 μW. Redistribution of fluorescence was monitored with 100 ms time intervals at 7.5 μW starting directly after the bleach pulse. Approximately 20 focal adhesions (each in distinct cells) were averaged to generate one FRAP curve for a single experiment. All measurements were performed at 37 °C and the experiment was performed on three different days. The relative fluorescence intensity of individual focal adhesion was calculated at each time interval as follows: $I_{rel}(t) = (F_{at}/F_{A0})$, where F_{at} is the intensity of the focal adhesion at time point t after bleaching and F_{A0} is the average intensity of the focal adhesion before bleaching.

Gel electrophoresis and immunoblotting

Equal protein amounts (25 μg; Bradford protein assay) were separated on 7.5% polyacrylamide gels and transferred to PVDF membranes (Millipore). Membranes were blocked in 5% (w/v) BSA in TBS-T and probed with primary antibody overnight followed by sufficient washes and incubation with secondary antibodies. Alkaline phosphatase-conjugated secondary antibodies for phospho-proteins were detected with the Western-Star immunodetection system. For detection of horseradish peroxidase-conjugated antibodies, ECL Plus reagent was used, followed by visualization on a Typhoon Imager 9400.

Immunofluorescence

Cells were plated on collagen-coated glass coverslips. Cells were briefly washed in PBS, followed by fixation in 3.7% formaldehyde for 10 min at room temperature. After washing, coverslips were blocked in TBP (0.1% (w/v) Triton X-100, 0.5% (w/v) BSA in PBS, pH 7.4). Incubation with primary antibodies diluted in TBP containing 0.05% (w/v) NaN₃ was carried out overnight at 4 °C. Coverslips were mounted on glass slides using Aqua Poly/Mount.

RNA isolation and DNA array analysis

Total RNA was isolated from all MTLn3 clones using TRIzol reagent (Invitrogen Corp.). Five microgram of RNA was used for cDNA synthesis. A custom cDNA kit (Invitrogen Corp.) with T7-(dT)₂₄ primer was used for this reaction. Biotinylated cRNA was generated from the cDNA reaction using the BioArray high yield RNA transcript kit (Affymetrix Inc., Santa Clara, CA). cRNA was then fragmented (5X fragmentation buffer: 200 mmol/L Tris acetate, pH 8.1, 500 mmol/L potassium acetate, 150 mmol/L magnesium acetate) at 94 °C for 35 min before chip hybridization. Following the manufacturer's protocol, fragmented cRNA was added to the hybridization mixture. For DNA array, HG-U133A from Affymetrix were hybridized for 16 h in a GeneChip Fluidics Station 400 and scanned with a GeneArray Scanner. The Human Genome U133A set of microarray represents ~14,500 human genes. Affymetrix GeneChip Microarray software was used for basic analysis. Samples were normalized to the average hybridization intensity on each chip. The study was performed for all 6 clones in duplicate. Gene Spring 6.0 (Silicon Genetics, Redwood City, CA) software was used for data analysis. Data mining of the list of genes was done using Enrichr (<http://amp.pharm.mssm.edu/Enrichr/>), an online gene set enrichment analysis web tool from the Ma'ayan Lab^[45,46].

Stable shRNA-mediated gene knockdown

MC7 cells were transduced with lentiviral shRNA constructs coding for a non-targeting control sequences shCtrl (SHC002) and a sequence targeting the coding region of PXN (TRCN0000123138) (Mission/

Sigma-Aldrich, Zwijndrecht, The Netherlands). The cells were selected by puromycin (sc-108071, Santa Cruz Biotechnology, Heidelberg, Germany). Knockdown efficiency was verified by Western Blot and immunofluorescent staining.

***In vivo* tumor growth and metastasis formation**

Six-week-old Rag2^{-/-}γC^{-/-} mice were obtained from in-house breeding. Animals were housed in individually ventilated cages under sterile conditions containing 3 mice per cage. Sterilised food and water were provided *ad libitum*. To measure spontaneous metastasis, tumor cells (5×10^5) were injected into the right thoracic mammary fat pads as described previously^[10]. After 4 weeks, the lungs were excised as well as the primary tumor which was also weighed. For quantification of all GFP-paxillin positive macro- and micro-metastases, the flat side of the right lung was analysed with the immunofluorescence microscope using a 10× objective lens (NA 0.25). Next the right lung and primary tumor were fixated in 4% paraformaldehyde. Paraffin sections of the lungs (5 μm) were stained with hematoxylin and eosin followed by histological analysis.

Statistical analysis

When not indicated, all experiments were performed in biological triplicates. As all data sets in this study follow a normal distribution, therefore were compared with Student's *t*-test (two-tailed, equal variances) using GraphPad Prism 6.0. Results were considered to be significant if *P* value < 0.05.

RESULTS

EGF-induced cell migration of MTLn3 cells is dependent on JNK activation and associated with paxillin Ser178 phosphorylation

First we determined the role of JNK-paxillin signaling in EGF-induced migration of the highly metastatic MTLn3 rat mammary adenocarcinoma cell line. EGF exposure caused membrane ruffling [Supplementary Figure 1], random cell migration and scattering of MTLn3 cells [Figure 1A and Video 1]. An inhibitor of JNK, SP600125, blocked the migration almost completely, which was associated with increased cell clustering of the MTLn3 cells. This clustered phenotype was associated with increased localization of β-catenin at cell-cell contacts [Figure 1B and Supplementary Figure 2]. Visual inspection of the movies indicates that inhibition of JNK reduces persistent movement [Figure 1C] and quantitative analysis of the cellular tracks reveal that the velocity of both individual and clustered cells was significantly impaired [Figure 1D]. By immunofluorescence, we observed that active phosphorylated JNK co-localizes with paxillin at focal adhesions in MTLn3 cells [Supplementary Figure 3B] as was previously observed in renal epithelial cells^[47,48]. EGF treatment induced a transient phosphorylation of paxillin at Ser178 in association with JNK activation, while SP600125 prevented phosphorylation of JNK, c-Jun as well as paxillin at Ser178 indicating the importance of EGF-induced JNK activation for paxillin phosphorylation [Figure 1E and Supplementary Figure 3C]. Together, these data indicate that in MTLn3 cells EGF-induced JNK activation mediates cell migration possibly via the phosphorylation of paxillin at Ser178.

PaxillinS178A mutant inhibits MTLn3 cell motility *in vitro*

To further investigate the role of paxillin Ser178 in cell migration, we generated MTLn3 cell-lines stably expressing either GFP-tagged paxillin-wt or phospho-defective mutant GFP-paxillin in which the serine residue 178 was replaced by alanine (further referred to as paxillinS178A). Three independently obtained paxillin-wt clones and paxillinS178A clones were selected for further experiments. MTLn3 clones stably expressing GFP-wt-paxillin or GFP-paxillinS178A were evaluated by flow cytometry, Western blotting [Supplementary Figure 4A] and immunofluorescence [Figure 2A]. Expression levels were approximately equal in all clones. Although GFP-paxillinS178A still localized at focal adhesions, cells were smaller and clustered with enhanced β-catenin-containing cell-cell contacts while cells expressing the GFP-wt-paxillin were stretched with large lamellipodia and almost no cell-cell contacts [Figure 2A and Supplementary Figure 4B]. The paxillinS178A-induced cell clusters [Figure 2B and Supplementary Figure 4C] resembled

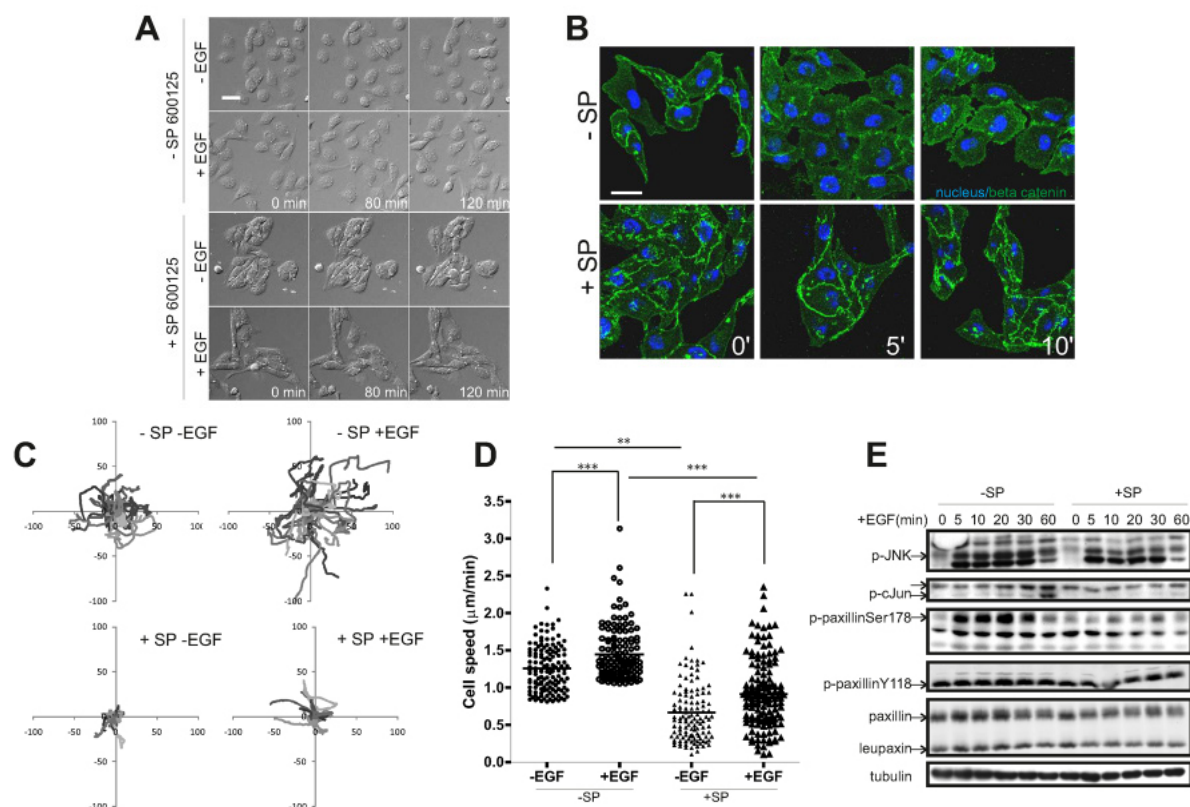

Figure 1. c-Jun NH2-terminal kinase (JNK)-mediated phosphorylation of paxillin Ser178 plays a role in tumor cell migration. MTLn3 cells were either untreated or treated with EGF (10 nmol/L) in the absence or presence of the JNK inhibitor SP600125 (20 μ mol/L). A: migration of these cells was observed by live DIC microscopy. Snapshots of the time-lapse made for 2 h are shown, scale bar is 50 μ m. See movie M1; B: at 0, 5 and 10 min after treatment cells were fixed and stained for the nucleus (blue) and β -catenin (green). Scale bar is 20 μ m; C: overall migration trajectories of individual cells of one representative experiment (only one position from the 6 technical replicates of one biological replicate); D: average cell speeds of about 100 cells per treatment imaged in one biological replicate were plotted. This graph shows the data for one representative biological replicate. * $P < 0.05$, ** $P < 0.01$, *** $P < 0.001$; E: the JNK signaling pathway was analyzed by Western Blotting using the indicated antibodies. The arrows indicate the phospho specific bands of the different antibodies. The paxillin antibody detects also a paxillin family member leupaxin encoded by LPXN, which has a much lower molecular weight than paxillin encoded by PXN

those formed in SP600125 treated cells [Figure 1B]. Given the prominent role of paxillin in focal adhesion formation and dynamics, a process required for cell spreading, we next examined the effect of paxillinS178A expression on cell attachment and spreading. Significantly less paxillinS178A cells adhered shortly after plating compared to paxillin-wt cells [Figure 2Ca]. Furthermore, while most of paxillin-wt cells had already spread most of the paxillinS178A cells remained rounded and presented a smaller surface area even after three hours of spreading [Figure 2Cb]. We also determined the effect of paxillinS178A on directed cell migration in an artificial wound healing assay [Figure 2D and Supplementary Figure 4D]. While wt-paxillin cells closed the wound by 83%, paxillin-S178A cells had only closed 25% of the wound after 20 h.

PaxillinS178A affects EGF-induced cell migration and focal adhesion dynamics

In a random cell migration assay paxillin-wt cells rapidly formed lamellipodia and became highly motile while paxillinS178A cells showed decreased cell motility and responded less to EGF stimulation [Figure 3A and Video 2]. Since paxillinS178A most likely acts as a dominant negative construct in these cells, it may compete for the localization of endogenous paxillin at focal adhesions and prevent the phosphorylation of endogenous paxillin at Ser178 by JNK. Indeed, EGF stimulation of paxillinS178A cells induced negligible Ser178 phosphorylation of endogenous paxillin whereas in paxillin-wt cells, both endogenous and GFP-paxillin-wt were phosphorylated at Ser178 after EGF treatment [Supplementary Figure 5]. Importantly, an

Figure 2. Expression of paxillinS178A decreases cell spreading and directed cell migration. GFP-paxillin-wt and GFP-paxillinS178A MTLn3 cells were generated and three independent clones were used for further research. A: endogenous paxillin (red) colocalized with ectopically expressed GFP-paxillin-wt and GFP-paxillinS178A (green). Scale bar is 10 μ m; B: cell clusters were detected using β -catenin (red) and GFP-paxillin (green) staining. Scale bar is 20 μ m; C: cells were analyzed for cell adhesion (a). Cells were replated on collagen-coated plastic culture dishes. The number of attached cells was counted at different time points after replating. Columns show the mean of three independent experiments; bars show SE, *** $P < 0.001$. The spreading after 3 hrs of both wildtype and mutant cells was assessed using phase-contrast pictures (b); D: directed cell migration capacity was assessed using a woundhealing assay. The wound closure was measured at three different location in the wound after 24 h. The assay was repeated three times. Columns show the mean of three independent experiments; bars show SE, *** $P < 0.001$. All three adhesion related assays were demonstrating a defect in the GFP-paxillinS178A cells

EGF-induced mobility shift of endogenous paxillin was observed in both WT and S178A cell-lines, indicating that most of the other paxillin modifications were unaffected [Supplementary Figure 5].

To understand the mechanism of the inhibitory effect of paxillinS178A on cell migration, we determined the dynamics of focal adhesions in WT and S178A cells using TIRF microscopy. MTLn3 cells expressing paxillin-wt showed a high focal adhesion turnover which was enhanced upon EGF stimulation. In contrast, paxillinS178A cells showed a much slower rate of FA disassembly either in the presence or absence of EGF [Figure 3B and Video 3]. The decreased focal adhesion dynamics could not be explained by a changed in mobility of GFP-paxillinS178A as determined by FRAP experiments. Indeed, both under serum-free conditions and upon EGF stimulation, the rates and percentages of fluorescence recovery of GFP-paxillin-wt and GFP-paxillinS178A were similar [Figure 3C].

GFP-paxillinS178A expression impairs metastasis formation of MTLn3 cells in an orthotopic breast tumor model

We next determined whether paxillin Ser178 was important for spontaneous lung metastasis formation. The MTLn3 cell line has been established as a suitable cell model to study metastasis formation from mammary gland tumors to the lung^[10]. We injected GFP-paxillin-wt (clone #2) and GFP-paxillinS178A (clone #2) cells into the mammary fat pads of immunodeficient Rag2^{-/-} γ ^{-/-} mice. After three weeks mice were sacrificed for the analysis of the primary mammary gland tumors as well as lung metastases. All primary tumors remained GFP-positive, indicating expression of wt or paxillinS178A GFP-paxillin continuously during the experiment. The edges of the GFP-paxillin-wt tumors were more invasive-like compared to those of GFP-paxillinS178A tumors [Figure 4A]. Yet, the weight of the primary tumor was not significantly altered

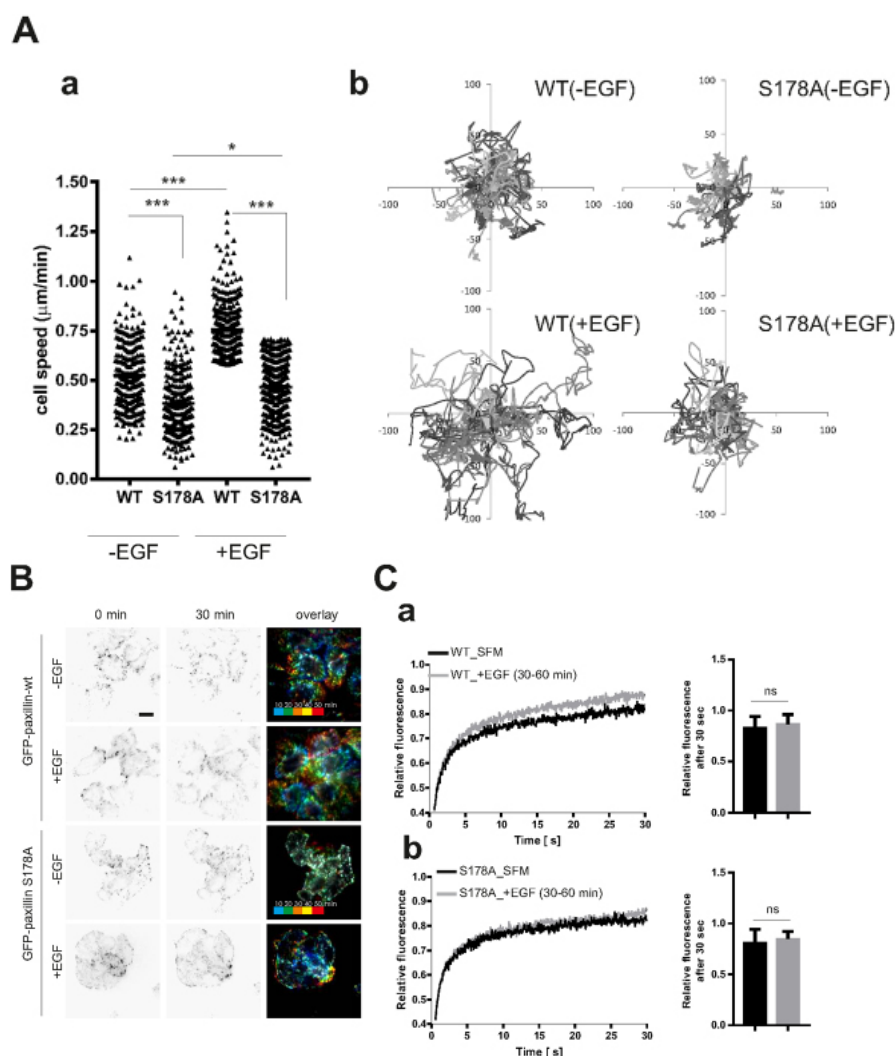

Figure 3. EGF-driven cell migration is inhibited in paxillinS178A cells because of impaired focal adhesion turnover. MTLn3 cells were either untreated or treated with EGF (10 nmol/L). A: migration was observed for 10 h by epi-fluorescence microscopy PaxillinS178A reduced cell speed average (about 100 cells per condition were imaged in one biological replicate). This graph shows the data for one representative biological replicate. $^*P < 0.05$, $^{**}P < 0.01$, $^{***}P < 0.001$ (a) and directional cell movement (b). See also Supplementary movie M2; B: matrix adhesions dynamics in MTLn3 cells was visualized with TIRF microscopy. See also Supplementary movie M3. Overlay of different timeframes were generated in red, green and blue. Focal adhesions in white, as observed for PaxillinSer178, represent unchanged (less dynamic) focal adhesions. Scale bar is 20 μm ; C: protein dynamics was measured with the spot bleaching technique and showed similar dynamics for both GFP-paxillinS178A (b) and GFP-paxillin-wt (a). Approximately 20 focal adhesions (each in distinct cells) were averaged to generate one FRAP curve for a single experiment. The mean relative fluorescence of both GFP-paxillin-wt and GFP-paxillinS178A both in SFM and upon EGF stimulation shows no significant difference after 30 s of recovery

by GFP-paxillinS178A [Figure 4B]. GFP-paxillinS178A MTLn3 cells formed significantly less spontaneous lung metastases than GFP-paxillin-wt MTLn3 cells [Figure 4C and D], and these metastases also had a less invasive phenotype [Figure 4C]. Our data show for the first time an important role for phosphorylation of paxillin on Ser178 in breast cancer progression.

Ectopic paxillinS178A expression results in EGFR down regulation at mRNA and protein levels

Next we sought to determine the possible mechanism by which paxillinS178A affects tumor cell migration and metastasis formation. Using Affimetrix microarrays, we analyzed the differentially expressed genes (DEG) between GFP-paxillinWT and GFP-paxillinS178A MTLn3 clones. Using a very low p-value, a comparison between WT and mutant clones delineated 134 genes that were differentially expressed of which 84 were down-regulated and 50 up-regulated [Supplementary Table 1]. In Figure 5Aa, we plotted

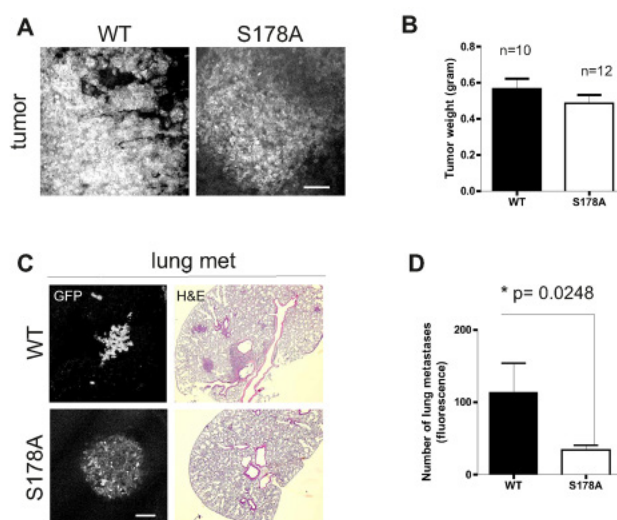

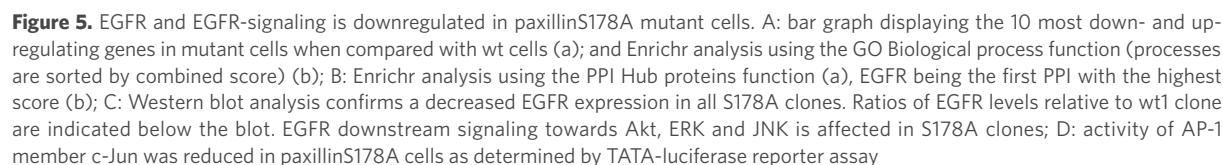

Figure 4. Expression of paxillinS178A impairs lung metastasis formation *in vivo*. One representative clone of either GFP-paxillin-wt or GFP-paxillinS178A MTLn3 cell-lines were used for *in vivo* experiments. A: Primary tumors were imaged using two-photon intravital imaging. Scale bar is 100 μ m; B: no significant difference in tumor weight was measured between the wt mice ($n = 10$) and S178A mice ($n = 12$); C: two-photon intravital microscopy, H&E staining of lung slices; D: quantification of the number of GFP-positive lung metastases demonstrated that paxillinS178A reduced lung metastasis formation. Scale bar is 100 μ m

the fold changes of the 10 most down- and 10 most up-regulated genes. Strikingly, EGFR was significantly down-regulated in the mutant clones. A pathway analysis of the complete set of genes using Gene Ontology revealed that pathways involved in intermediate filament assembly, cell proliferation and regulation of β -catenin transport were significantly altered when compared to the wt clones [Figure 5Ab]. Furthermore, a protein-protein interaction analysis of those same DEGs highlighted the EGFR network as most significantly altered [Figure 5B]. Paxillin localizes at focal adhesions and EGFR signaling is regulated and trans-activated at focal adhesions by both integrins^[49,50] and FAK^[51,52]. Therefore we reasoned that paxillinS178A may disturb the EGFR signaling pathway. In agreement with our microarray analysis, all three paxillinS178A clones had much lower levels of EGFR protein than wt clones. As a consequence, downstream EGFR signaling towards Akt and ERK were also reduced in S178A clones [Figure 5C]. Since EGF also caused JNK activation in control MTLn3 cells [Figure 1], we also determined the activation of JNK signaling pathway in these cells. Indeed, paxillinS178A expression also inhibited EGF-induced JNK activation [Figure 5C], which was associated with a reduction in c-Jun transcriptional activity as determined by luciferase reporter assays [Figure 5D]. These data indicate that paxillinS178A affects the expression of EGFR possibly through the regulation of c-Jun-mediated EGFR transcription^[53,54], thereby disturbing downstream signaling pathways that are essential in the cell migration process.

Ectopic expression of human wt-EGFR in paxillinS178A cells restores EGF-driven cell motility and lung metastasis formation

To determine whether paxillinS178A reduced tumor cell migration and metastases formation via EGFR downregulation, we re-expressed EGFR in the mutant cells [Supplementary Figure 6A]. The EGFR re-expression induced a more spread phenotype in paxillinS178A cells [Figure 6A and Supplementary Figure 6B]. The EGF-driven cell migration was rescued and the protein turnover of paxillinS178A at focal adhesions was slightly faster only upon EGF stimulation [Figure 6B and Supplementary Figure 6C]. This was associated with a sustained activation of both JNK and ERK after EGF exposure [Supplementary Figure 6D]. Next we determined whether EGFR re-expression also restored the capacity of MTLn3 paxillinS178A cells to metastasize to the lungs. For this purpose, we injected GFP-paxillinS178A cells and EGFR-GFP-paxillinS178A cells into the mammary fat pads of immunodeficient Rag2^{-/-} mice, although we were aware that EGFR expression would decrease during the course of the experiment. The tumor growth of paxillinS178A and EGFR-paxillinS178A

cells was similar in the both groups [Figure 6Cb] and all tumor cells in the primary tumors were GFP-positive [Figure 6Ca]. Mice injected with GFP-paxillinS178A cells that expressed EGFR showed an approximately threefold increase in the lung tumor burden in [Figure 6D]. These data indicate that the reduced metastasis formation of GFP-paxillinS178A cells is directly related to the expression levels of EGFR.

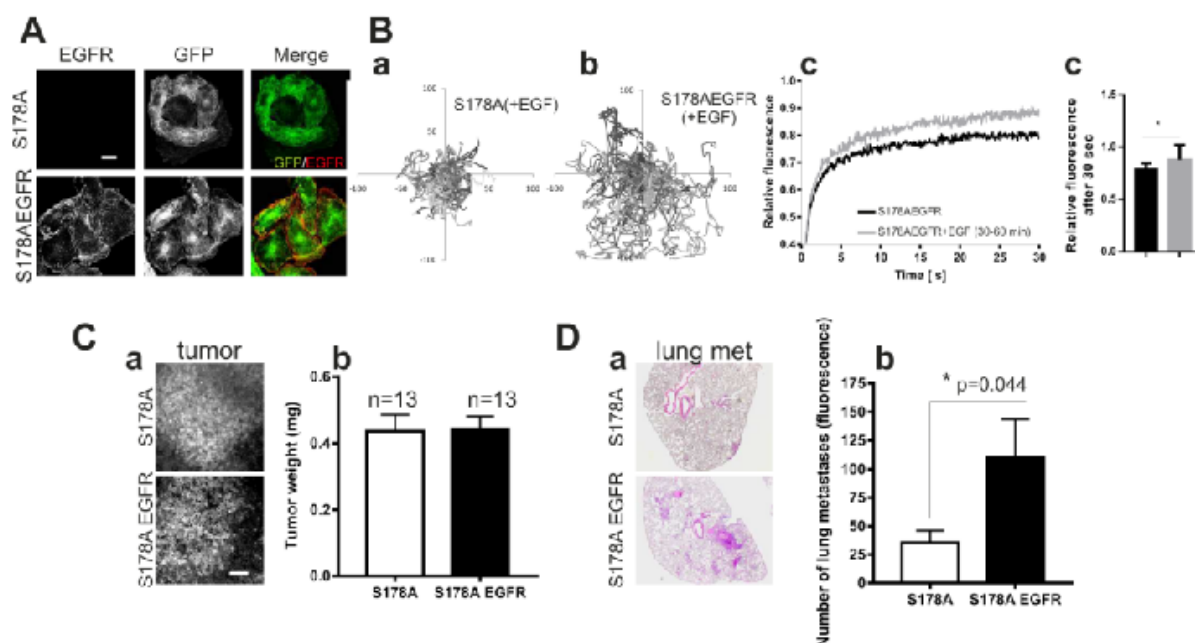

Figure 6. Re-expression of wt-EGFR fully restores EGF-driven cell motility and lung metastasis formation. A: immunostaining with a specific mouse monoclonal antibody against human EGFR confirmed the ectopic expression of EGFR in S178A cells; paxillinS178A (green) and human EGFR (red). Scale bar is 10 μm ; B: trajectories of the movements of S178A and S178AEGFR cells are plotted in (a) and (b) respectively (X and Y are in μm). Protein dynamics was quantified with spot bleaching technique and the fluorescence recovery after 30 sec was slightly faster upon EGF stimulation, * $P < 0.05$. (c); C: two-photon imaging of GFP-positive lung metastases, scale bar is 100 μm . (a). There was no significant difference in tumor weight of S178A ($n = 13$) and S178AEGFR ($n = 13$) groups (b); D: H&E staining of lung slices of S178A and S178AEGFR groups (a). Number of GFP-positive metastases counted in the fresh lungs at time of sacrifice is shown (b)

DISCUSSION

Our data indicate that EGF-induced JNK activation is essential for MTLn3 cell migration. Phosphorylation of paxillin on Ser178 in MTLn3 cells was induced upon EGF stimulation in a manner sensitive to the JNK inhibitor, and expression of paxillinS178A inhibited cell motility. Such a role for paxillin Ser178 in cell migration is in agreement with observations made in different tumor cell lines^[7,9,13,24,25,40,55-60]. Here we further demonstrate that the JNK-paxillin axis regulates both the dynamics of focal adhesions through modulation of paxillin protein dynamics at focal adhesions as well as the stability of β -catenin-based adherence junction formation. We propose that Ser178 phosphorylation may induce a conformational change, thereby affecting paxillin interactions with other focal adhesion components. Alternatively, the decreased EGFR expression in paxillinS178A cells affects downstream signaling pathways that indirectly modifies focal adhesion dynamics as well as adherence junction stability. Indeed, re-expression of EGFR in paxillinS178A cells reversed the epithelial-like phenotype and rendered paxillinS178A again less immobile at focal adhesions, suggesting that this is not an intrinsic characteristic of paxillinS178A, but is rather due to altered signaling in cells mediated by downstream EGFR signaling pathways. This needs further investigation.

So far no *in vivo* data on the specific role of paxillin Ser178 in metastasis formation have been presented. Here, we demonstrate that the Ser178 of paxillin is essential for spontaneous metastasis formation in an orthotopic breast tumor/metastasis model. Our *in vivo* data on the specific role of paxillin Ser178 in metastasis formation is in line with previously published data using a knock-down of MLK3 in MDA-MB-231. Indeed in the later study, they found that Ser178 phosphorylation of paxillin was associated with the metastatic phenotype^[40,59]. Importantly in our study, we demonstrate that specifically the Ser178 of paxillin is essential for spontaneous metastasis formation in an orthotopic breast tumor/metastasis model. Our findings are indicative for a role for the JNK-paxillin pathway in the regulation of the expression of EGFR, thereby severely affecting the capacity of tumor cells to migrate and metastasize. Indeed, reduced levels of EGFR were observed in

three independent paxillinS178A MTLn3 clones, resulting in decreased EGF-induced activation of signaling pathways downstream of EGFR. Given the fact that EGFR is often highly expressed in advanced breast cancer, and that EGFR antagonists inhibit spontaneous metastasis formation of MTLn3 cells, we anticipated that the reduced EGFR expression was an essential component of the inhibited cell migration and metastasis formation. Indeed, re-expression of the wt-EGFR in the paxillinS178A cells did rescue the migratory phenotype of MTLn3 paxillinS178A cells as well as their metastatic capacity under *in vivo* conditions. This regulation of the EGFR by paxillin phosphorylation has not been described before. Curiously, a recent study demonstrated that knockdown of MCLK in mammary MCF10A cells induces increase in cell migration through enhanced phosphorylation of paxillin at Ser178 which was linked to an increase in JNK activity and very interestingly to a significant up-regulation of EGFR at protein level^[60]. This is striking and yet would suggest that our findings might not be specific to our cell model. In our study, paxillinS178A MTLn3 cells showed reduced c-Jun transcriptional activity. In MCF7 cells stable overexpression of c-Jun induces an increase in EGFR expression suggesting that AP-1 transcription factors can regulate EGFR transcription levels^[53]; such a regulation is also observed in keratinocytes^[54]. Therefore, we propose a role of the JNK-c-Jun signaling pathway in the regulation of EGFR expression at transcriptional level. Our own data in MCF7 cells that have increased ectopic expression of EGFR show that depletion of paxillin results in significant downregulation of EGFR expression as well as downstream signaling such as AKT and ERK [Supplementary Figure 7]. Thus, an alternative explanation may be that JNK-mediated phosphorylation of paxillin Ser178 is required for efficient EGFR endocytosis and recycling, an essential component in its activation^[61]. Hence this will affect proper JNK activation and AP-1 transcription factor activation thereby providing a positive feedback for EGFR expression^[62]. Alternatively, paxillin may affect the expression of EGFR by its known role in the regulation of gene expression through its interaction with ERK^[63,64], poly-A-binding protein^[65], Abl^[66,67] and steroid receptors, or through its own ability to undergo nucleocytoplasmic shuttling^[37,38,68-71].

Our findings indicate that the JNK-paxillin axis modulates the scattered phenotype of MTLn3 cells. Both inhibition of JNK as well as ectopic expression of paxillinS178A reversed the scattered phenotype towards a more epithelial-like morphology with the formation of E-cadherin/ β -catenin cell-cell junctions. This morphological switch was observed under serum-starved and EGF-treated conditions. The (in)direct tyrosine phosphorylation of β -catenin by EGFR and other receptor tyrosine kinases such as c-Met is known to destabilize its binding to E-cadherin. Because of the low EGFR expression in the paxillin mutant cells, we anticipate that this results in de-phosphorylation of β -catenin leading to its localization to the cell-cell contacts. These data suggest that paxillinS178A does not affect the intrinsic molecular components and machinery required for the scattered phenotype and support the notion that the effect of paxillinS178A is rather related to the defects in the EGFR signaling pathways. Consequently, the defects in *in vivo* metastasis formation of MTLn3 paxillinS178A cells are most likely largely due to defects EGF signaling. This fits with our observations that ectopic EGFR expression itself is sufficient to again allow metastasis formation of paxillinS178A cells.

In summary, in MTLn3, engagement of EGF receptors by EGF triggers rapid activation of JNK, leading to the phosphorylation of paxillin on Ser 178 which facilitates adhesion turnover thus promoting rapid migration. In the MTLn3 cell lines that ectopically express GFP-paxillin-S178A mutants, we found that the EGF receptor is downregulated at both the protein and mRNA levels. Paxillin S178A mutant protein might associate with JNK preventing its activation and consequently affecting AP1 activity (c-Jun phosphorylation) and consequently EGFR expression. In our model [Figure 7], still some links need to be further determined such as how exactly paxillin regulates via JNK EGFR expression. Given the essential role of Ser178 phosphorylation in the migration and metastasis formation, monitoring this paxillin phosphorylation in tumor samples from patients may be indicative of the activation of this pro-metastatic pathway and possibly predictive for the disease prognosis. Moreover, with the further development of specific JNK inhibitors^[72,73] it is anticipated that novel targeted therapies that antagonize the migratory/invasive behavior of tumor cells may be used in the clinic in the future. Further work in this area is required.

Figure 7. Diagram depicts the hypothesized signaling pathways for JNK-paxillin dependent cell migration. Engagement of EGF receptors by EGF triggers rapid activation of JNK, leading to the phosphorylation of paxillin on Ser 178 which might facilitate adhesion turnover thus promoting rapid migration. Upon EGF stimulation, JNK phosphorylates also c-Jun which regulates EGFR transcription and β-catenin which delocalizes from the cell-cell contact breaking down the adherens junctions. Paxillin S178A mutant protein might associate with JNK preventing its activation and consequently affecting AP1 activity and EGFR expression. Inactive JNK as well as down-regulation of EGFR result in de-phosphorylation of β-catenin and formation of stable cell-cell contact in MTLn3 cells

DECLARATIONS

Acknowledgments

We would like to thank H. de Bont for assistance with live cell imaging experiments and ImagePro Plus analysis. We thank H. van Dam for luciferase reporter constructs.

Authors' contributions

Carried out the experiments: Verkoeijen S, Ma YF, van Roosmalen W, Lalai R, van Miltenburg MHAM, Le Dévédec SE

Wrote the manuscript with support from van de Water B: Verkoeijen S, Ma YF, Le Dévédec SE

Conceived the original idea and helped supervise the project: van de Water B

Abstract

In oncology, liquid biopsy is applied to detect with high efficiency clinically relevant analytes, such as tumor cells, cell-free nucleic acids, and exosomes in peripheral blood and other body fluids of cancer patients. Liquid biopsy is considered one of the most advanced non-invasive diagnostic systems useful, in the next future, for enabling personalized treatments in precision medicine. Medical actions include, but are not limited to, early diagnosis, staging, prognosis, anticipation (lead time) and prediction of therapy responses, as well as follow up. Experimental system for validation of the proposed liquid biopsy approaches is highly needed. In this review article we will discuss the establishment of xenotransplanted mouse model systems for the validation of liquid biopsy protocols aimed to identify changes in the miRNA plasma content. Human colon cancer HT-29 and LoVo cells have been xenotransplanted and miR-221-3p and miR-222-3p have been comparatively analyzed in cultured HT-29 and LoVo cells, xenotransplants and plasma samples.

Keywords: Liquid biopsy, circulating tumor RNA, microRNA, xenograft

LIQUID BIOPSY: A NEW FRONTIER FOR CANCER DIAGNOSTICS

In the field of cancer diagnosis and treatment, liquid biopsy is a new diagnostic tool that investigates circulating tumor cells (CTC) and/or cell-free nucleic acids in the peripheral blood [Figure 1A]. Liquid biopsy is considered one of the most advanced non-invasive diagnostic systems. It provides key molecular information relevant to important clinical decisions and, being “longitudinal” (it can be repeated as many times as needed), it fits the idea of precision medicine possibly more than other “static” techniques based on the analysis of tissue nucleic acids^[1-5]. Diagnostic actions made possible by liquid biopsy include, but are not limited to, early diagnosis, staging, prognosis, prediction of therapy response and follow up during therapeutic intervention^[6-11].

In addition to the use of CTCs^[12-15] and circulating tumor DNA (ctDNA)^[16-18], other important targets for liquid biopsy are circulating microRNAs (miRNAs)^[19-24], a family of small (19 to 25 nucleotides in length) noncoding RNAs playing important roles in controlling post-transcriptional gene expression. Regulatory miRNAs reduce protein synthesis through selective interactions with complementary sequences of target messenger RNAs (mRNAs)^[25-27]. Single or multiple mRNAs can be targeted at their 3'-UTR, CDS, 5'-UTR sequences, and it is calculated that more than 60% of human mRNAs are microRNA targets^[26]. Dysregulation of microRNAs has been associated with a variety of human pathologies, including cancer^[28-31]. In this case miRNAs behave both as tumor promoters (oncomiRNAs and metastamiRNAs) and tumor suppressor molecules^[29], depending on their mRNA targets (oncosuppressor mRNAs or mRNA coding oncoproteins, respectively) with opposing activity on cancer cells. Based on this, it is not surprising that circulating cell-free miRNAs have been actively investigated as liquid biopsy analytes. OncomiRNAs are abundant in several extracellular body fluids, where they are protected and stabilized by exosome-like structures and small intraluminal vesicles produced by a variety of cells (including cancer cells)^[32-36]. Hence, elevated levels of several miRNAs (including miR-221, miR-222, miR-141, miR-92a, miR-21, miR-155, miR-506, miR-4316, miR-4772-3p, and miR-29a) are present in the blood from patients with colorectal carcinomas (CRC) and may contribute to diagnosis and prognosis^[21,37-42]. Furthermore, it is well established that miRNAs may help in monitoring therapeutic approaches. For instance, Ogata-Kawata *et al.*^[22] reported that serum exosomal miRNA levels (let-7a, miR-1229, miR-1246, miR-150, miR-21, miR-223, and miR-23a) were higher in CRC patients than controls, were already detectable at early disease stages, and that they were significantly down-regulated after surgical resection.

TECHNOLOGIES FOR MICRORNA ANALYSIS

In order to quantify miRNAs in the plasma and other body fluids isolated from cancer patients, several types of technologies for RNA analysis have been proposed^[43-51]. Quantitative real-time PCR (RT-qPCR)^[52], NGS RNA sequencing^[53], miRNA microarray analysis^[54], and digital PCR^[55] are the most used [Table 1] and can be employed not only for tissue or cells but also for highly diluted samples, such as body fluids. One of the major limits of RT-qPCR and ddPCR is the limited number of miRNAs that can be quantified for single run. This problem was partially solved by introduction of TaqMan low density arrays, that allows to quantify the content of a significant number of miRNAs (about 700 miRNAs) using PCR-based methods^[56]. In addition to these methodologies, other technologies have been described for direct miRNA detection from serum samples. For example, Chapin *et al.*^[57] proposed rolling circle amplification (RCA) based on the use of a universal adapter ligated to the targets captured on encoded gel microparticles. The system allows the multiplexed profiling of miRNA at sub-femtomolar concentration. Interestingly, Williams *et al.*^[58] proposed a miRNA detection technique able to amplify miRNAs directly in body fluids, avoiding upstream sample preparation. The technique, based on isothermal target amplification, has a sensitivity positioned in the femtomolar range. Other conventional technologies normally proposed for miRNA detection in cells or tissues, such as northern blotting^[59], are not suitable for miRNA detection in body fluids, due to the low sensitivity of the technology, requiring therefore large amounts of RNA. Other unconventional miRNA

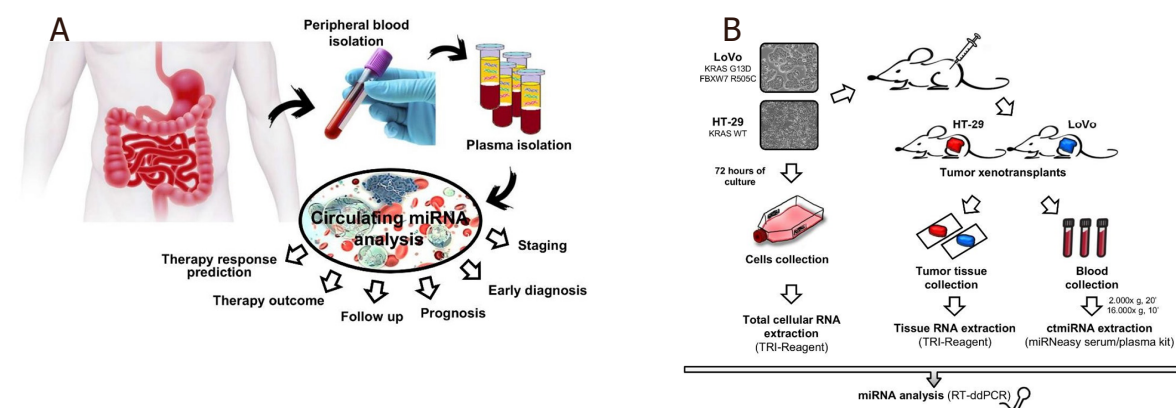

Figure 1. Flow chart describing the experimental *in vivo* model system. All the procedures have been performed according to Directive 2010/63/EU and Italian Decree Law 26/2014. They were approved by the EU Research Executive Agency, the Intramural Regina Elena Board for Animal Welfare, and the Italian Ministry of Health (700-2015-PR, dated July 17, 2015). Tumor xenotransplants were established by inoculating 3×10^6 cells from the HT-29 and LoVo cell lines in the flank of 4-month old Nu/CD1 mice (Charles River Laboratories, Italy). Xenotransplants were allowed to grow to two different sizes (300 and 1000 mm^3 , 6 mice per group for each of the two cell lines). Tumors were taken at sacrifice along with blood. Frozen tissues were used as the source of miRNAs. Blood was collected in 6 mL BD Vacutainer K2E tubes (BD, 368857) and centrifuged within 1 h at $2000 \times g$ for 20 min at 4°C . Plasma was recovered and further centrifuged at $16,000 \times g$ for 10 min at 4°C to remove cell debris, and stored at -80°C until extraction

Table 1. Technologies applied to miRNA detection

Technologies	Biological fluid	Major results obtained	Ref.
Real-time quantitative PCR	Plasma	RNA was isolated from human plasma samples of healthy donor and the content of three miRNAs chosen to represent moderate- to low-abundance plasma miRNAs (miR-15b, miR-16, and miR-24) was evaluated using TaqMan RT-qPCR assays	[52]
NGS RNA sequencing	Serum	A NGS RNA sequencing (Solexa sequencing) approach, followed by RT-qPCR data validation was employed to identify miRNAs able to predict prognosis of non-small-cell lung cancer. Four miRNAs (miR-486, miR-30d, miR-1 and miR-499) were significantly associated with overall survival	[53]
MicroRNA microarray analysis	Serum	A global miRNA profiling was performed, using GeneChip miRNA Arrays (Affymetrix) in prostate adenocarcinoma transgenic mouse models identifying 46 miRNAs significantly altered compared to healthy controls	[54]
Droplet digital PCR	Plasma	Droplet digital PCR platform was used to assess levels of miRNAs (miR-221, miR-222 and miR-141) released into the culture supernatants of colorectal carcinoma cell lines and mouse blood plasma obtained from xenograft models	[55]
MicroRNA low Density Arrays	Plasma	Circulating miRNAs profile was examined in mice bearing human small cell lung cancer tumor xenografts using human TaqMan Low Density Array. The analysis allows to identify a panel of differentially expressed miRNAs, in a stage dependent manner	[56]
Rolling circle amplification	Serum	The rolling circle amplification of a universal adapter sequence selectively ligated to targets captured on encoded gel microparticles is employed for multiplexed profiling of miRNAs at sub-femtomolar concentration. The protocol was optimized to cover a dynamic range of magnitude (300 aM to 40 pM). Moreover, miRNAs can be directly detected in small quantities of unprocessed serum samples avoiding RNA extraction or target-amplification steps	[57]
Isothermal ramification amplification (RAM)	Plasma	Isothermal RAM allows the direct amplification of miRNAs without upstream sample preparation. The presence of microRNA promotes base-stacking hybridization, and subsequent amplification between two universal strands, under isothermal conditions. A sensitivity in the range of femtomolar is provided	[58]
Northern blotting	Tissues	An highly efficient microRNAs detection method based on northern blot analysis was set-up using LNA (locked nucleic acid) probes able to increase the sensitivity of at least 10-fold compared to conventional DNA probes	[59]
Bead-based flow Cytometry	Tissue/cell lines	Oligonucleotide-capture probes complementary to miRNAs of interest were coupled to carboxylated 5- micron polystyrene Beads impregnated with variable mixtures of two fluorescent dyes each representing a single miRNA. After the reverse transcription miRNAs are amplified by polymerase chain reaction and hybridized to the capture beads, beads were then analysed using a flow cytometer capable of measuring bead colour	[60]

detection techniques have been proposed in recent years such as bead-based flow cytometry^[60] but at the moment they are employed only for miRNA detection in tissues or cellular samples.

EXPERIMENTAL MODEL SYSTEMS FOR LIQUID BIOPSY

Given the fast pace of technological evolution and the clinical complexity of human cancers, there is an increasing need for experimental *in vivo* systems and associated validation technologies. A robust analysis of bio-fluids must acknowledge the fact that liquid biopsy is a complex strategy requiring the achievements of several key points, including pre-analytical steps, post-analytical optimization, and careful selection of optimal analytes for specific biological queries. *In vivo* model systems might be very useful to address and isolate these many individual variables (that are both technical and biological), and validate complex multi-step approaches. It is surprising, in this respect, that only few reports are available focusing on the use of animal models. *In vivo* model systems for the detection of circulating tumor cells and DNA have been proposed^[61-63]. These include injection of cancer cells into their orthotopic site of origin (e.g., a “recap” of natural tumor onset), injection of tumor cells directly into the bloodstream of the animal (to recap distant seeding), genetically engineered mouse and mice xenografted with patient-derived tumors^[64-69] (to mimic “true” tumors). As to the analysis of circulating miRNAs in these experimental settings, several reports are available^[52,54-56,70,71] [Table 2].

Mice xenografted with human tumor cell lines or patient-derived tumor

The pattern of circulating miRNAs has been extensively studied in mice xenografted with tumor cells and patient-derived tumors. Different independent studies firmly demonstrated that miRNAs released in the circulation by the tumor xenograft are distinct from the “background” mouse miRNAs pattern. This is a key point, since pre-existing miRNAs present in the mouse body fluids are identical in sequence to most human miRNAs and hence they might be a powerful confounding parameter, possibly altering conclusions and implications of any circulating miRNA signature. In this respect, the use of laboratory mouse strains has the advantage that its “background” mouse miRNA pattern is stable and easily quantifiable. Mitchell *et al.*^[52] demonstrated that several miRNAs originating from xenografted human prostate cancer cells are present in the mouse circulation (one of the most interesting being miR-141), and are readily measured in plasma, allowing a clear distinction between tumor xenografted and control tumor-free mice. Waters *et al.*^[70] observed a complex miRNAs dysregulation in the circulation of athymic nude mice subcutaneously injected with MDA-MB-231 cells. Some miRNAs (such as miR-10b) were undetectable in the circulation, others (miR-195 and miR-497) were significantly decreased, miR-221 content did not change, and a positive correlation was observed between miR-497 and miR-195. This study highlighted distinct roles of miRNA subsets in the circulation and in disease dissemination and progression, all of which may be candidates as molecular targets for diagnosis as well as design of systemic therapy. Gasparello *et al.*^[55] studied liquid biopsy in mice bearing CRC xenografts, demonstrating gateways regulating the levels of circulating tumor-derived miRNAs (ctmiRNAs), e.g., cell-specific roadblocks that determine whether a given cell xenotransplants releases or retains a specific miRNA. These roadblocks are often not present in cultured cells, and build “barriers” to detection in a liquid biopsy format.

Genetically engineered mouse model systems

Genetically engineered mouse models (GEMMs) manipulate target oncogene or tumor suppressor expression in mice in order to promote tumor development. Transgenic and knockout GEMMs have provided important models for identifying tumor-associated and metastasis-associated genes that can lead to tumor formation and disease progression. In addition, GEMMs have been applied to the development of liquid biopsy methods based on the analysis of circulating microRNAs. Selth *et al.*^[54] performed a global miRNA profiling and identified a set of miRNAs exhibiting significantly altered serum levels in transgenic mice models of prostate cancer (i.e., Transgenic Adenocarcinoma of Mouse Prostate mice). Global miRNA profiling identified 46

Table 2. Examples of experimental systems to study miRNA content in liquid biopsy

Experimental mouse system	miRNA studied	Major results obtained	Ref.
Mouse models of prostate cancer xenografted with 22Rv1 human prostate cancer- derived cells	miR-141-3p	MicroRNAs derived from human prostate cancer xenografts are readily measured in plasma of mouse models allowing a clear distinction between tumor-xenografted mice and controls	[52]
Transgenic mouse model of prostate cancer	miR-141-3p miR-375 miR-298 miR-346	Global miRNA profiling allows to identified a set of ten miRNAs significantly altered in serum of transgenic mice compared to healthy controls	[54]
Mice bearing colorectal carcinoma cell lines xenografts	miR-141-3p miR-221-3p miR-222-3p	Evidences of gateways regulating the levels of circulating miRNA	[55]
Mouse models bearing human small cell lung cancer (SCLC) tumor xenografts	miR-95 miR-141-3p miR-200a-3p miR-200b-3p miR-200c-3p miR-210-3p miR-335-3p miR-375 miR-429	A panel of 10 miRNAs are dysregulated in tumor bearing mouse models. The same miRNAs were also confirmed to be altered in stage dependent manner in plasma isolated from SCLC patients	[56]
Mouse models of breast cancer xenografted with MDA-MB-231 cells	miR-10b-5p miR-195-5p miR-497-5p miR-221-3p	A complex miRNA dysregulation in the circulation athymic nude xenografted mice was detected compared to tumor-free controls	[70]
Foxp3 heterozygous Scurfy mutant (Foxp3 ^{sf/+}) female mice. The loss of Foxp3 expression, due to the frameshift mutation leads to the spontaneous development of breast cancer and lung metastases.	miR-200c-3p miR-141-3p	Despite levels of miR-200c and miR-141 were found to be lower in Foxp3 ^{sf/+} tumor cells than in normal breast epithelial cells, plasma levels of miR- 200c and miR-141 in the Foxp3 ^{sf/+} mice increased during tumor progression and metastasis	[71]

miRNAs at significantly altered levels in the serum of mice with advanced prostate cancer compared to healthy mice used as controls. Interestingly, four miRNAs altered in mice (mmu-miR-141, mmu-miR-298, mmu-miR-346 and mmu-miR-375) were also found to be expressed at higher levels in the serum of patients with metastatic prostate cancer compared with control subjects. Moreover, three of these (hsa-miR-141, hsa-miR-298 and hsa-miR-375) were upregulated in prostate tumors compared with normal prostate tissue, suggesting that they are directly released from the tumor into the blood as disease progresses. This study was the first to demonstrate that specific serum miRNAs (miR-141, miR-298 and miR-375) are common between human prostate cancer and a mouse model of the disease, highlighting the potential of such models for the discovery of novel biomarkers.

Zhang *et al.*^[71] investigated FOXP3-inducible breast cancer cells, Foxp3 heterozygous Scurfy mutant (Foxp3^{sf/+}) female mice, and patients with breast cancer for characterization of the formation and regulation of the miR-200 family in breast cancer cells and circulation. While levels of miR-200c and miR-141 were lower in Foxp3^{sf/+} tumor cells than in normal breast epithelial cells, plasma levels of miR-200c and miR-141 in the Foxp3^{sf/+} mice increased during tumor progression and metastasis. Interestingly, the levels of miR-200c and miR-141 were higher in plasma from patients with metastatic breast cancer than in plasma from those with localized breast cancer, with benign breast tumors, with a family history of breast cancer, or from healthy controls. The conclusion of the work reported by Zhang *et al.*^[71] supports the concept that miR-200c and miR-141 are regulated by a FOXP3-KAT2B axis in breast cancer cells, and circulating levels of miR-200c and miR-141 are potential biomarkers for early detection of breast cancer metastasis. Moreover, they highlight the idea that roadblocks evolve during the natural history of tumors.

LIQUID BIOPSY IN MICE BEARING COLORECTAL CARCINOMA XENOGRAFTS OBTAINED AFTER IMPLANTATION OF HT-29 AND LOVO CARCINOMA CELLS

Analysis of miRNA content has been recently performed in mice xenografted with colon cancer cell lines^[55]. Among the different xenografted models the one based on the implantation of the HT-29 and LoVo CRC

cells was found the most efficient for miRNA detection. The HT-29 cells were derived from a KRAS-WT, differentiated colorectal adenocarcinoma^[72,73], while LoVo cells (originally described as Dukes' type C, grade IV) harbor a heterozygous KRAS c.38G>A mutation (G13D)^[74].

TUMOR XENOGRAPHS AND PLASMA PREPARATION

Figure 1B shows the study workflow based on the tumor xenografts as models for liquid biopsy to assess plasma levels of circulating miRNAs. In this study workflow, miRNAs are compared considering (1) *in vitro* cultured tumor cells; (2) tumor xenografts; and (3) blood plasma samples. The HT-29 and LoVo cell lines were selected as proxies of clinically evident cancers and sources of soluble analytes. MicroRNAs were extracted from both cell lines, matched tumor tissue and blood plasma samples and were then subjected to ddPCR and RT-qPCR analysis. Tumor xenotransplants were established by inoculating HT-29 and LoVo cells in the flank of 4-month old Nu/CD1 mice. Tumors were taken at sacrifice along with blood. Frozen tissues were used as the source of miRNAs. For the analysis of ctmiRNA, blood plasma was treated to disrupt exosomes and denature miRNA-binding proteins with QIAzol Lysis Reagent. After the addition of 400 amoles of cel-miR-39-3p (an equalizer), total RNA was purified and reverse transcribed. Finally, droplet digital PCR (RT-ddPCR) assays for microRNA content analysis were performed to quantify the levels of miR-221-3p^[37,75] and miR-222-3p^[76]. Droplets were analyzed using the QX200 Droplet Reader, and data analysis was performed with QuantaSoft version 1.7.4 (Bio-Rad, Hercules, CA, USA).

TUMOR XENOGRAPHS AND PLASMA PREPARATION: MAJOR RESULTS

The main point of this study is focused on determining whether the pattern of plasma miRNA content recapitulates HT-29 and LoVo cells and xenografted tumors. A representative example of miR-222-3p content is shown in Figure 2A and all the quantitative data for miR-221-3p and miR-222-3p are presented in Figure 2B. The miRNA levels were independently assessed by RT-qPCR and ddPCR results, obtaining similar results, as reported elsewhere^[55]. Of course, in the quantitative analysis shown in Figure 2B and concerning the plasma miRNA quantitation, we have taken into account the fact that cross-species miRNA homology might influence our *in vivo* results. Accordingly, we quantitated baseline, endogenous miR-221-3p and miR-222-3p levels in tumor-free, healthy nude mice. As expected (the sequences of mouse miR-221-3p and miR-222-3p are identical to those found in human cells) both RT-ddPCR and RT-qPCR demonstrated that circulating miRNAs were detectable even in the absence of tumor growth. However, the differences between tumor-bearing and tumor-free mice were clearly appreciable for both miRNAs. Figure 2B shows that the miR-222-3p content is higher than miR-221-3p content in HT-29 and LoVo cells, and in tumor and plasma samples isolated from HT-29 and LoVo xenografted mice, despite the miR-222/miR-221 ratio is much higher in plasma in comparison with cell and tumors. This is consistent with the “gateway” effect mentioned above and discussed in deep in Gasparello *et al*^[55]. This issue is particularly of interest, since detailed knowledge of the molecular mechanisms underlying the release of circulating analytes is still lacking. Alternatively, the *in vivo* response of xenotransplanted mice to tumor cell injection might contribute to the reported unbalanced content of miR-222/miR-221. The proposed system is expected to help in verifying the underlying cellular mechanisms.

CONCLUSION

Circulating miRNAs have been recently used as biological markers for early diagnosis, prognosis, prediction of response to therapy and clinical outcome, particularly in a liquid biopsy setting^[1-11,77-79]. Liquid biopsy is a powerful tool applicable to all or most human cancers, including colorectal, lung, melanoma, and breast neoplasms^[80,81]. From a more general viewpoint, tumor-xenotransplanted mice and other *in vivo* models may have an important role because they resolve biological variables from technical variables (such as handling and storage of biological fluids, pre-analytical processing, as well as DNA and RNA isolation protocols) that

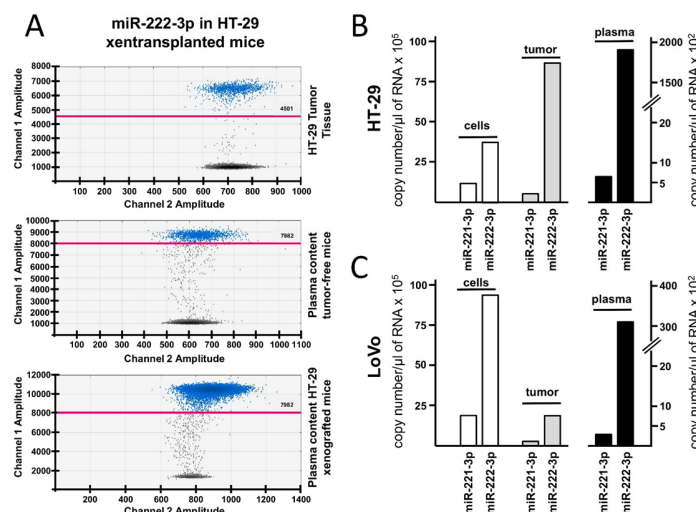

Figure 2. Content of microRNA miR-221-3p and miR-222-3p in HT-29 and LoVo cells, HT-29 and LoVo tumors and plasma isolated from HT-29 and LoVo xenotransplanted mice. A: representative Reverse Transcription droplet digital PCR plots performed using RNA isolated from tumor cells, plasma from tumor-free mice, and plasma from xenografted mice; B, C: content of miR-221-3p and miR-222-3p in cells, xenotransplanted tumors and plasma. RNA was extracted from frozen cell (5×10^5) pellets by the TRI-Reagent (Sigma-Aldrich, St.Louis, MO, USA), the procedure is described in Gasparello *et al.*^[55]. All RNAs were stored at -80°C until the use. Reverse Transcription droplet digital PCR assays for microRNA expression analysis were performed to quantify the levels of miR-221-3p and miR-222-3p. 300 ng of total RNA (from cells and tissues) and the RNA isolated from 150 μL of plasma were reverse transcribed and analyzed for miR-221-3p and miR-222-3p as described by Gasparello *et al.*^[55]

might affect efficient marker detection by liquid biopsy^[82,83]. Liquid biopsy of cancer is mainly based on the analysis of circulating tumor cells and/or cell-free nucleic acids in the peripheral blood of cancer patients, as well as in other body fluids suitable for diagnostic assessment. Among these, cerebrospinal fluid for tumors of the central nervous system, saliva for tumors affecting the head and neck, pleural effusion in the case of respiratory tract cancers and urine for urinary tract cancers. We propose that *in vivo* xenotransplant models monitoring miRNAs may find application in all the body fluids, contributing to assess the relevance of clinical liquid biopsy. The importance of *in vivo* model systems adds to the established role of liquid biopsy in complementing key limitations of surgical tissue biopsy. These include, but are not limited to: (1) invasiveness and inherent patient compliance; (2) a static representation of the tumor pathology strictly limited to the tumor tissue sampling; (3) ethical and practical issues preventing repeated tissue biopsy, particularly at unaccessible (or difficult to access) body sites; (4) tumor heterogeneity, especially during progression and metastatic dissemination (making multiple sampling necessary); (5) easier and real-time patient monitoring by non-invasive liquid biopsy. Therefore, although liquid biopsy approach still suffers from important drawbacks (fragmentation of cfDNA, instability of RNA, low yield of isolated samples to be analyzed and variable presence of normal DNA and RNA), this approach is generally deemed of great potential interest for future applications, patent development, and clinical trials, and mouse xenotransplants may be an important “shortcut” to application and technical streamlining.

Among possible application of mouse models we suggest: (1) studies on the relationship between the tumor size and the plasma miRNAs content (e.g., miR-222/miR-221 ratios); (2) analysis of the “gateway” hypothesis involved in the selection of released microRNAs (e.g., miR-221 and miR-222); (3) studies concerning the possible local and systemic responses of normal cells and tissues to xenotransplant procedure (tumor seeding); (4) analysis of the effects on miRNA plasma content on the susceptibility to experimental treatment of xenografted mice with physical and/or chemotherapeutic agents; (5) verification of the selectivity of the effects on plasma miRNA content of miRNA targeting and relative delivery approaches; (6) usage as key tools for the comparison of different analytical strategies including, among others, different PCR/RT-qPCR and NGS platforms, instruments and protocols, as well as PCR-free methods^[84-86]. Among possible limits of

the mouse xenograft model systems here presented are the differences between man and mouse with respect to ctDNA and microRNA dynamics in respect to their vasculature. Therefore we should carefully consider the sharply different ratios between the dimension of implanted tumors, the mouse body weight and the blood volume on one hand and those related the same parameters (i.e., tumor weight, body weight and blood total volume) in CRC patients. In this respect the analysis of the miRNome in liquid biopsy obtained when tumors of different dimensions are employed in mouse xenograft model systems might clarify whether the ratio between tumor size and mouse body weight or blood volume might affect the results. This might also be of interest for developing algorithms in human clinical settings.

DECLARATIONS

Authors' contributions

Revised and approved the final manuscript: Gasparello J, Allegretti M, Papi C, Giordani E, Giacomini P, Gambari R, Finotti A

Wrote the manuscript: Allegretti M, Giacomini P, Gambari R, Finotti A

Performed the literature search: Allegretti M, Giacomini P, Gambari R, Finotti A

Critically analyzed the existing literature: Allegretti M, Giacomini P, Gambari R, Finotti A

Designed the figures and created the tables: Gasparello J, Papi C, Giordani E, Gambari R, Finotti A

Abstract

Small-cell lung cancer (SCLC) has a high propensity to metastasize into the brain. Radiotherapy plays a major role in the treatment of brain metastases (BM) from SCLC. Whole-brain radiotherapy (WBRT) is the standard treatment of BM from SCLC. However, the neurocognitive toxicity and modest efficacy of this approach have led to the increased use of stereotactic radiosurgery. We have no strong evidence for the use of different forms of radiation (WBRT vs. radiosurgery) in SCLC, because BM from this primary tumor were excluded from clinical trials. In this review, the use of radiation in form of WBRT or radiosurgery is discussed in distinct clinical indications: as a primary treatment and at relapse; without prior use of prophylactic cranial irradiation (PCI); and after PCI. Combinations of radiotherapy with chemotherapy are discussed as BM in SCLC occur rarely as a sole event.

Keywords: Small-cell lung cancer, brain metastases, whole-brain radiotherapy, radiosurgery

INTRODUCTION

Small-cell lung cancer (SCLC) has a higher propensity than other solid tumors to spread to the brain. As many as 40%-50% of SCLC patients will develop brain metastases (BM) during the course of their disease^[1]. Apart from a higher risk of occurrence than in other cancers, BM from SCLC have distinct clinical characteristics that differ from BM from all other solid tumors. These differences are reflected in radio- and chemo-sensitivity and high aggressiveness with rapid propagation in the brain. The latter property makes BM from SCLC hardly suitable for local treatment such as surgery or radiosurgery. Unlike BM from

other cancers whole brain radiotherapy (WBRT) remains a standard treatment even if BM are suitable for radiosurgery. The well recognized radio- and chemo-sensitivity of SCLC are also present in the case of BM. Despite their radio- and chemo-responsiveness, the prognosis of BM from SCLC remains very poor with median survival after WBRT of 3.0-4.7 months in both retrospective and prospective studies^[2-5]. The high risk of developing BM with a dismal disease course once BM have occurred and their high radiosensitivity have led to many trials assessing the value of prophylactic cranial irradiation (PCI). To date, SCLC is the only solid tumor in which the prolongation of survival with the use of PCI has been demonstrated for localized stage (LS) SCLC in a meta-analysis^[6]. A total dose of 25 Gy in 10 fractions was established in a randomized trial as a standard dose of PCI for responders to initial therapy of LS SCLC^[7]. In addition, for extensive stage (ES) SCLC, there were some indications that the use of PCI is of value for prolongation of survival^[6] and this was demonstrated in one randomized trial^[8].

The present review summarizes the problems related to radiotherapy of BM from SCLC with an emphasis on the distinctiveness of this approach in relation to management of BM from solid tumors. Different approaches in specific indications for treatment of BM from SCLC are discussed.

PROGNOSTIC FACTORS

Patients with BM from SCLC are usually excluded from trials on management of BM due to the different biological behavior of the primary tumor. The question arises if existing prognostic scores for overall survival in patients with BM are also relevant for BM from SCLC. The pivotal RTOG prognostic score was published after carrying out a recursive partitioning analysis (RPA) of pretreatment characteristics of patients in the randomized trials on BM. The prognosis of BM patients was related to the presence of three prognostic factors: performance status, presence of extracranial disease and age. Class 1 with the best prognosis included patients younger than 65 years, with control of extracranial disease, and with performance status ≥ 60 in Karnofsky performance status (KPS) score. Class 3 with the poorest prognosis included patients with KPS < 70 regardless of the presence of all other factors. Class 2 with intermediate prognosis included patients who did not meet the criteria of classes 1 or 3^[9]. These three prognostic factors are still the basis of all contemporary, more refined prognostic scores, even if new factors are included. However, in the original RTOG database, only 4% of patients had SCLC histology^[9]. Retrospective studies have confirmed the validity of the prognostic stratification of BM from SCLC according to the RTOG RPA class criteria. In 132 SCLC patients who received WBRT, the median survival for classes 1, 2, and 3 was 2, 4.5, and 2 months, respectively ($P = 0.003$). However, there were only eight (4%) patients in class 1^[2]. In 154 patients with BM of whom 98% received WBRT as part of their treatment, the median survival for classes 1, 2, and 3 was 8.6, 4.2, and 2.3 months, respectively ($P = 0.002$). Only 5% of patients from this group met the criteria of RPA class 1^[2]. The rarity of RPA class 1 among patients treated for BM from SCLC is related to the aggressiveness of the primary tumor. Brain-only metastases from SCLC with cured primary are an extremely rare event, as demonstrated by EORTC phase II trial, in which the accrual of patients with brain-only metastases was so slow that the study was stopped before the required number of patients was reached^[4].

In the more contemporary disease-specific graded prognostic assessment (DS-GPA), the prognostic factors for patients with BM were attributed separately for respective primary tumors. For lung cancer, based on the results of 1833 NSCLC and 281 SCLC patients, apart from the prognostic factors from RTOG RPA class (extracranial disease, age and KPS) the number of BM (1 vs. 2-3 vs. > 3) reached prognostic significance. When patients with SCLC were analyzed separately, the number of BM was also significantly prognostic for survival^[10]. The retrospective study demonstrated that median survival for 30 patients with single BM was 7 months compared with 2.9 months for 98 patients with multiple BM from SCLC ($P = 0.005$)^[2]. In another small retrospective study, the number of BM also had an impact on survival^[11]. The prognostic significance of the number of BM for SCLC may be counterintuitive, because we still treat this disease with WBRT based

on the rationale that due to rapid progression, the subclinical disease foci exist in the whole brain at the onset of macroscopic BM. On the other hand, published data indicate that also in the case of SCLC, biological behavior may differ in a single BM compared with multiple BM. Thus, a disease that occurs with single or oligo- brain metastases may have different, more favorable prognosis than poly-metastatic brain disease at its onset. The latter would have greater inherent aggressiveness. However, we cannot exclude that in the case of less advanced brain involvement, more aggressive treatment strategies are employed. In the retrospective analysis of 52 patients who received WBRT for single BM, the use of surgery in combination with WBRT was related to improved survival compared with WBRT alone, with median overall survival of 19 and 5 months, respectively ($P = 0.03$)^[12]. In the largest retrospective study on patients with BM from SCLC that included 229 patients treated with WBRT, the number of BM did not retain prognostic significance. Apart from the factors included in the RTOG RPA score, the time of occurrence of BM in relation to the diagnosis of the primary (synchronous *vs.* metachronous BM) and initial response to chemotherapy had a significant impact on survival. Patients presenting with synchronous BM and initial good response to chemotherapy had improved overall survival compared with patients presenting with metachronous BM and non-/poor responders to initial chemotherapy^[13]. The authors proposed a new BM from SCLC score (BMS-score), which included RTOG RPA class and synchronous *vs.* metachronous BM presentation. Initial response to chemotherapy was not included in the score, because the evaluation of the response to chemotherapy may not be practical and as a result may prevent the use of the score on a large scale^[14].

Concluding the discussion of the issue of prognostic factors in BM from SCLC, we should emphasize the unquestioned value of the RTOG RPA classes. The role of the number of BM should be reconfirmed, especially in the era of rapid expansion of local treatment of BM, also in SCLC. The timing of occurrence of BM, that is, synchronous *vs.* metachronous presentation, and the initial response to chemotherapy require further evaluation.

TREATMENT OF BM WITH SYNCHRONOUS PRESENTATION

BM that occur synchronously with primary diagnosis of SCLC represent different clinical scenarios and require different management compared with BM that are diagnosed metachronously, that is, at the relapse of SCLC. We may distinguish four categories of this synchronous presentation that require different management.

BM diagnosed during an initial staging of SCLC

When asymptomatic BM are part of the dissemination of SCLC, either as a sole distant site or as one of many distant locations, treatment usually starts with chemotherapy. The efficacy of chemotherapy for BM was questioned in the past, because the brain was considered a pharmacological sanctuary due to the brain-blood barrier (BBB) that prevented drugs from penetration into the brain. However, tumor invasion likely disrupts the BBB, because there are many clinical observations of the efficacy of chemotherapy in BM from SCLC. Pooled data from five studies reported a 66% response rate (RR) in 64 patients with synchronous BM^[15]. However, there are also contrary data indicating that the RR in the brain is lower than the systemic RR; with 27% *vs.* 73% RR for brain and extracranial sites, respectively, in 24 asymptomatic patients with BM from SCLC who received cyclophosphamide, doxorubicine, and vincristine^[16]. However, an aggressive and rapid disease course prompts the initiation of systemic therapy so as not to miss the opportunity to administer chemotherapy that may stop extracranial systemic and local disease progression that causes bothersome and/or life threatening symptoms.

The question remains, whether chemotherapy should be followed by WBRT in such patients, even if the use of chemotherapy results in a complete response in the brain. We have no prospective data on this point. However, one randomized trial compared the use of teniposide alone *vs.* teniposide + WBRT 30 Gy in 120

patients with progression in the brain after or during first-line treatment. The data from this study showed that omission of WBRT in the treatment of BM led to a significantly shorter time to progression in the brain in patients managed without WBRT, with 8% vs. 35% of patients free of progression in the brain at 6 months in those treated with and without WBRT, respectively. Overall survival was short (~ 3.5 months) in both groups^[5]. The demonstrated risk of rapid progression in the brain without the use of WBRT suggests the benefit of combining chemotherapy with WBRT also in these patients, regardless of the chemotherapy response-with the awareness that no strong evidence for such an approach exists.

Histology of SCLC found during a craniotomy performed for brain tumor without prior diagnosis of lung primary with this histology

This is a special case when the unexpected SCLC histology of a removed brain tumor leads to performing diagnostic procedures to find a lung primary and evaluate its extension. When the lung primary is found, further management does not differ from the scenario when BM are found during initial staging of SCLC, namely chemotherapy followed by WBRT. Patients with BM from SCLC were not included in the trials on the use of tumor bed radiosurgery with the omission of WBRT, because of the increased risk of dissemination outside the tumor bed^[17,18]. Thus, also in these cases, WBRT remains the standard of care. A special presentation of BM SCLC represents a situation in which after removal of the brain tumor neither primary, nor signs of extracranial extension are found despite meticulous diagnostic procedures including PET-CT and bronchoscopy. In such a scenario, the justification for the use of chemotherapy may be questioned - again, we have very limited evidence. The omission of chemotherapy as first-line treatment in such patients with careful monitoring may be an option in more fragile patients.

BM developed during first-line treatment for ES-SCLC when no baseline brain imaging was performed

Brain imaging in asymptomatic patients with ES-SCLC is not systematically performed. In the EORTC trial which demonstrated a survival advantage with the use of PCI, brain imaging was not part of the standard staging procedures and only 19% of randomized patients had baseline brain CT or MRI^[8,19]. Obviously, if in such patients during first-line chemotherapy symptomatic BM occur, WBRT is given and chemotherapy is continued or discontinued after completion of brain irradiation depending on the systemic chemotherapy response and performance status of the patient.

BM diagnosed before PCI for LS SCLC or ES SCLC in the case of pre-PCI MRI

Brain imaging has not always been a standard procedure before PCI qualification in either LS SCLC or ES SCLC. Some prospective studies reported using CT scans, some did not require any imaging, and some did not mention any requirements for imaging use^[20]. NCCN guidelines recommend pre-PCI MRI for patients with response to initial therapy^[21]. These guidelines are strictly followed in the USA; as highlighted in a recent survey, up to 96% out of 309 US radiation oncologists performed pre-PCI MRI^[22]. In contrast, some European IASLC and ESTRO experts indicated in a survey on the practice of PCI use for ES SCLC that the restrictions in reimbursement for MRI and problems with its availability were the main reasons of performing PCI in such patients. With MRI surveillance, patients would avoid brain irradiation, unnecessary in some cases^[23]. In one study, patients with initial diagnosis of LS SCLC had baseline MRI performed. Complete responders who qualified for PCI after treatment completion had a second, pre-PCI MRI; 13 out of 40 (32.5%) patients had BM in pre-PCI MRI. Patients with pre-PCI detected BM had worse prognosis than those without BM in pre-PCI MRI (17% vs. 74% for 1-year survival, respectively, $P = 0.0001$). This difference was seen despite the higher and more intense WBRT doses in patients with BM. However, one major limitation of this study was that PCI was applied late, that is, 4-10 months after diagnosis. Moreover, this finding does not support the routine use of pre-PCI MRI, because even giving higher WBRT doses did not reverse the poor prognosis in these patients^[24]. Similar observations from a larger group of patients were presented at the IASLC World Conference on Lung Cancer in 2018. From 119 LS SCLC patients referred for PCI after

definitive chemoradiotherapy with baseline brain MRI, 25 (21%) harbored BM on pre-PCI MRI, and 23 were asymptomatic. The duration of chemo-radiotherapy was the only prognostic factor for occurrence of pre-PCI BM. Patients with BM in pre-PCI MRI and duration of chemo-radiotherapy that exceeded 4.5 months had significantly shorter survival^[25]. These findings are in line with modeling radiobiological studies that sought to elucidate dose-response relationship for PCI in SCLC as a function of time interval between time of treatment of primary tumor and initiation of PCI. The nearly linear dose-response relationship for reduction in BM was demonstrated for “early PCI” (up to 60 days from the start of treatment of the primary tumor) in doses of 0-35 Gy given in 2-Gy fractions. When PCI was delayed for over 60 days, a significant threshold in dose-response was observed, which is consistent with a fast growth rate of untreated subclinical BM from SCLC^[26]. Thus, it is important to initiate PCI early from the start of treatment. However, the guidelines do not recommend the concomitant use of PCI with chemotherapy because of apprehension concerning the toxicity of such an approach. What we learn from these studies is that every effort should be made to avoid unnecessarily prolonging chemo-radiotherapy for SCLC and to start PCI as quickly as possible after the end of treatment of the primary tumor. Pre-PCI MRI and higher WBRT dose not change a prognosis of asymptomatic patients in which progression in the brain occurs during initial therapy. However, in some patients with ES SCLC without BM on pre-PCI MRI, MRI surveillance without baseline PCI may be recommended as in a Japanese trial, in which patients with MRI surveillance did not have a survival benefit with the addition of PCI^[27]. Pre-PCI MRI is also a pre-requisite for PCI with hippocampal avoidance.

TREATMENT OF BM WITH METACHRONOUS PRESENTATION

Despite a high initial response rate on chemotherapy, the majority of patients with LS SCLC and practically all with ES SCLC will relapse within the first year after treatment. After first-line chemotherapy, only extremely limited therapeutic options exist. Median survival after second-line chemotherapy is 3-6 months in clinical trials^[28]. In addition, BM occur rarely as a sole event. The majority of patients with BM simultaneously have extracranial disease progression^[4]. The limited therapeutic options and poor survival after relapse determine the poor outcome of treatment of metachronous BM. Thus, a metachronous presentation, that is, occurrence after first-line treatment, appears as an adverse prognostic factor^[13,14]. Treatment strategies for BM that occur at the relapse differ with regard to the earlier use or not of PCI.

Radiotherapy for BM that occur without prior PCI

When the use of chemotherapy for asymptomatic BM that occur simultaneously with the diagnosis of primary is not debatable, the use of chemotherapy for metachronous BM is conditioned by a number of factors, such as the site of progression, brain only vs. brain and extracranial site, previous response to chemotherapy, the time interval from the last line of chemotherapy, the extent of extracranial disease, and performance status. We have no strong evidence for the use of chemotherapy for BM from SCLC. In the Cochrane Database of Systematic Reviews, only three small randomized trials involving 192 participants that dealt with chemotherapy for BM from SCLC were identified^[29]. In one study, 120 patients with BM and concurrent systemic failure were randomized to receive teniposide with and without WBRT. Patients in the combined modality arm had higher RR in the brain (57%) than patients treated with teniposide alone (22%), ($P < 0.001$). Patients who received WBRT also had longer time to progression in the brain than patients treated with chemotherapy alone, ($P = 0.005$). Overall survival did not differ greatly between the groups (median survival: 3.5 months in the combined modality arm and 3.2 months for chemotherapy alone arm; $P = 0.087$)^[5]. Only one trial compared chemotherapy with no chemotherapy; 33 patients received WBRT for BM from SCLC (first line, $n = 5$; recurrence, $n = 28$) and were randomized to WBRT alone vs. WBRT plus topotecan. No significant difference in survival was found between these two groups^[30]. The Cochrane Database of Systematic Reviews identified one other chemotherapy trial that compared two schedules - sequential and concomitant-of combination chemotherapy (teniposide plus cisplatin) with WBRT. This trial included only 39 patients and no difference in overall survival and response rate for either combination was demonstrated, although patients

in the concomitant arm had a higher rate of myelosuppression^[31]. Thus, the available evidence is insufficient to determine the effectiveness of chemotherapy for the treatment of BM from SCLC. We have no evidence that chemotherapy improves brain tumor control and overall survival in those patients. However, when BM are accompanied by systemic progression and the option of giving chemotherapy for a specific patient exists, chemotherapy is given based on the recognized chemo-responsiveness of this SCLC.

Although WBRT remains the standard therapeutic strategy for these patients, this approach is not based on the results of randomized trials. In addition, the effectiveness of WBRT in patients with widespread metastatic disease is debatable. We cannot exclude that some of these patients may be treated with chemotherapy alone. Another dubious indication for WBRT in these patients involves BM in RTOG RPA class 3, that is, patients with poor performance status (KPS < 70). In one retrospective analysis of 132 patients with BM from SCLC who received WBRT, the median survival for 27 (20%) patients from RPA class 3 was 2 months^[2]; similarly, in another trial that included 154 such patients, the median survival for 51 (33%) patients from RPA class 3 was 2.3 months^[3]. With such a short survival, the benefit of WBRT is doubtful. One prospective trial that also included patients with SCLC histology aimed to determine whether WBRT had any benefit in terms of symptoms palliation in 91 RTOG RPA class 3 patients. All patients received WBRT and were asked to complete a questionnaire about their symptoms before and 1 month after WBRT. Only 43 (47%) patients completed the questionnaire after WBRT, the other patients died or were not able to respond to the survey questions because of further deterioration of performance and/or neurological status. In the group of patients who completed both questionnaires, the intensity of symptoms of the disease significantly increased after WBRT. This result challenges the value of WBRT for patients with poor performance status^[32]. Recently, the limited value of WBRT in patients with BM from NSCLC who were unsuitable for resection or radiosurgery in terms of survival, quality of life, and reduction of the dose of steroids was demonstrated in a large randomized trial^[33]. Taking into account, the short survival of patients with BM from SCLC, the value of considering WBRT in these patients as a standard of care should be subject to further research.

Radiotherapy for BM that occur after PCI

PCI reduces the risk of BM in both LS SCLC and ES SCLC, as shown in a meta-analysis and prospective randomized trials^[6,8,27]. Nevertheless, a substantial proportion of patients still develop brain failure after PCI. The 3-year BM rate after PCI was 33% vs. 59% without PCI in a meta-analysis of 987 patients from seven randomized trials that compared treatment of SCLC with and without PCI^[6]. In ES SCLC, the risk of symptomatic BM after PCI was 15% vs. 40% without PCI^[8]. In a Japanese prospective trial that compared treatment with and without PCI with staging and strict surveillance with brain MRI, the 1-year BM rate was as high as 33% with PCI vs. 59% in patients without PCI^[27]. These results indicate that 15%-30% of patients will still develop BM after PCI. Such failure represents a special therapeutic challenge, because reirradiation of the whole brain that has already received a biological dose of ~ 30 Gy risks meaningful neurotoxicity. On the other hand, the short survival of such patients may prevent them from the occurrence of late toxic effects, and in the short term, reirradiation at moderate doses may be beneficial, especially in symptomatic patients, taking into account the radio-sensitivity of SCLC. Even if localized treatment options like radiosurgery or less often resection appear as appropriate strategies in the irradiated region, most of these patients recur as multifocal BM that are unsuitable for radiosurgery. At the 2018 IASLC World Conference on Lung Cancer, one study reported that 60% of 32 patients who recurred in the brain after PCI were unsuitable for radiosurgery and WBRT may be considered for such patients^[34]. There are very few reports about whole brain reirradiation after PCI. The largest series of patients treated with brain radiation after PCI with a median time of 14 months (range, 4-42 months) demonstrated that in 76 patients receiving a PCI dose of 30 Gy in 15 fractions, repeat WBRT with doses of 20-30 Gy in fractional doses of 2 Gy was given to 66 (88%) patients and radiosurgery of 18-24 Gy in a single fraction to 13 (18%) patients. Median survival after repeat WBRT and radiosurgery was 3 months and 5 months, respectively, with a range of 0-12 months for both treatment types; 40% of 44 symptomatic patients improved after reirradiation. No serious, grade > 2 toxicity was observed in these patients^[35]. These results indicate that WBRT with moderate doses may be beneficial in

Table 1. Characteristics and outcome of patients undergoing radiosurgery (RS) for brain metastases (BM) from small-cell lung cancer (SCLC)

Author, year	Number of included patients	Number of BM treated/doses of SRS	Number of patients undergoing prior WBRT (details on previous treatment)	Median overall survival from RS (months)	Local control	Distant control in the brain

patients who are not candidates for radiosurgery and the short survival of such patients prevents them from the development of serious late neurotoxicity.

In the case of a limited number of BM < 3 cm in diameter, the minimal invasiveness and ease of use of radiosurgery make it the preferred salvage method after prior PCI for patients with life expectancy > 3 months. Retrospective data indicate that for patients with good performance status, radiosurgery for BM in SCLC gave results that were at least comparable with WBRT in terms of survival, with the median range of 3-9 months^[30-36]. However, some reports reported lower local control after radiosurgery for BM from SCLC than for BM from other solid tumors. One-year local control rates were < 70% in evaluated patients^[36-41], whilst in prospective trials on radiosurgery with the exclusion of SCLC histology, these rates were 70%-90%^[42,43]. Distant brain control was also at the lower limit or < 60% as reported in prospective trials on radiosurgery alone^[36-41]. This may be related to the known aggressiveness of SCLC, but also to the inclusion of patients with multiple (> 4) BM, which may affect these results. Recently, it was demonstrated that radiosurgery without WBRT in patients with 5-10 BM was not inferior to that in patients with 2-4 BM in terms of survival^[44]. Table 1 summarizes the results of radiosurgery for BM from SCLC used as a salvage method after WBRT, as well as a first-line irradiation. To conclude, radiosurgery is an attractive treatment option after prior PCI and should be used if the technical possibilities for its use exist; however, WBRT at moderate doses is also feasible. WBRT is the treatment of first choice in patients who are unsuitable for radiosurgery or symptomatic patients with limited life expectancy (< 3 months).

REDUCTION OF NEUROTOXICITY IN BRAIN RADIOTHERAPY FOR SCLC

WBRT in SCLC plays a role in prevention in the form of PCI and remains the standard in the treatment of BM. However, we have evidence that WBRT has a detrimental effect on neurocognitive functioning. In a

phase III trial of standard-dose *vs.* high-dose PCI for LS SCLC (RTOG0212), patients underwent evaluation for cognitive toxicity and quality of life effects. Patients receiving the higher-dose PCI were found to have a 25% increase in the rate of chronic cognitive toxicity compared with the standard-dose arm. However, 62% of patients receiving the standard-dose PCI also developed cognitive toxicity, as assessed by the Hopkins Verbal Learning Test (HVLT) Delayed Recall score^[45]. These data indicate that even the standard-dose of PCI is associated with neurocognitive toxicity. It is also argued that with the improvement of survival, neurotoxicity has greater chance to occur and negatively impact quality of life^[46]. Thus, the strategies to reduce neurotoxicity in PCI and WBRT warrant further investigation. One of these strategies is hippocampal avoidance (HA) during WBRT, based on the principle that proliferating neuronal progenitor cells in the subgranular zone of the hippocampus play an essential role in memory function. Thanks to technological advances and the availability of IMRT techniques, PCI and WBRT for BM with HA have been extensively explored and even used in routine practice. The RTOG 0933 trial demonstrated that HA during WBRT for BM was associated with a mean relative decline in the HVLT-Revised Delayed Recall score from baseline to 4 months of 7.0% (95% confidence interval, 4.7%-18.7%), which was a significant improvement compared with the historical control ($P = 0.0003$)^[47]. Recently, for the first time, the benefit of HA in WBRT for BM in terms of preservation of neurocognitive function without compromising intracranial control was confirmed in 518 patients included in a phase III trial (NRG Oncology CC001). The 6-month neurocognitive function failure rate was 69% after WBRT without HA compared with 58% when using HA^[48].

However, the safety of this approach for SCLC remains to be demonstrated, because the risk of impaired intracranial control *via* underdosing some parts of the brain in the HA area persists in this very aggressive malignancy. Some reports support the safety of such an approach, indicating the risk of failure in the HA zone to be $< 5\%$ ^[25,49]. In contrast, other reports warn of the rapid implementation of HA in SCLC, with an increased risk of failure of $> 10\%$ in the HA zone^[50,51]. These contradictory data suggest that a potential small benefit of hippocampal sparing in limiting the neuropsychological sequelae of brain radiation may be obtained at the risk of failure in the spared region. In modeling studies, HA PCI in SCLC was more cost-effective than conventional PCI provided that the risk of developing BM was not increased by more than 14%, or if neurocognitive dysfunction rates were reduced by at least 40%^[52]. These findings strongly support the continued enrollment in ongoing cooperative group randomized trials on the value of HA PCI in SCLC: NRG CC003 (USA), PREMER (Spain)^[53], NCT01780675 (Holland).

Other strategy to reduce neurocognitive deterioration in patients after brain irradiation is the use of neuroprotective medication. The only agent that seems to be effective in this indication is memantine. It was shown in the prospective study, that it delayed cognitive deterioration after WBRT, although at 24 weeks this did not reach significance ($P = 0.059$)^[54]. Recently performed systematic review concluded that studies on other medications, like methylphenidate and donepezil remain inconclusive in this regard^[55].

CONCLUSION

To conclude, a standard radiation method for BM from SCLC remains WBRT. Stereotactic radiosurgery is reserved for relapses after PCI or prior WBRT for overt BM. However, the advancement in technologies allow for treatment of multiple metastases with omission of WBRT. Safety and benefit of such an approach remain to be confirmed in a prospective trial. All such efforts are welcomed. The ENCEPHALON trial launched at Heidelberg University Hospital randomizes patients with up to 10 metastases from SCLC to radiosurgery of all lesions *vs.* WBRT. Primary endpoint of the study is neurocognitive function. Secondary endpoints are intracranial control, overall survival and toxicity^[56]. Only such direct comparisons will give evidence for safety of omission of WBRT in BM from SCLC. Mature data from the trials evaluating safety of HA in SCLC are also eagerly awaited. Short survival of such patients with both WBRT and stereotactic methods shows also that radiotherapy is not a sufficient treatment method in this indication. Combinations

of radiotherapy with chemotherapy should be further evaluated. It was demonstrated in a randomized trial that Atezolizumab added to standard chemotherapy with Carboplatin and Etoposide in ES SCLC improved overall survival, however patients with BM represented only 8.5% of the included cohort^[57]. Thus, further research is needed to investigate the role of immunotherapy in patients with BM from SCLC.

Abstract

Brain metastasis are the most common intracranial malignancy in the adult population. Their incidence has increased dramatically over the last 20 years, as a result of the increasing number of cases stemming from lung and breast cancer together with the higher cancer survival rates due to diagnostic and therapeutic advances. More than 40% of cancer patients develop brain metastases during the course of their disease: specifically, they appear in 50% of patients with lung cancer, more than 25% of patients with breast cancer, and 20% of patients with melanoma. Diagnosis is made using different imaging approaches, such as computed tomography and magnetic resonance imaging, accompanied by clinical manifestations and a history of malignancy supporting the diagnosis of a brain metastasis. Current treatment options should be oriented to the patient's current performance, the number of intracranial and extracranial lesions, and related factors. Although surgical resection and whole-brain radiotherapy have been standard treatments for many years, numerous treatment modalities have become more easily available and accepted worldwide, producing more favorable and reliable results. Among these is stereotactic radiosurgery, and the latest clinical trials support this treatment.

Keywords: Brain metastases, whole-brain radiation therapy, stereotactic radiosurgery, graded prognostic assessment

INTRODUCTION

Brain metastases are the most common intracranial malign neoplasms in adult patients, with 170,000 new cases per year reported in the USA alone^[1]. The incidence of brain metastasis has been on the rise the last 20 years, resulting from an increase in the number of cases of lung and breast cancer^[2] and the fact that cancer survival rates have been increasing thanks to new therapeutic advances and the availability of central nervous system imaging technologies for diagnosis. More than 40% of patients with cancer develop brain metastases: specifically, they appear in 50% of patients with lung cancer, more than 25% of patients with breast cancer, and 20% of patients with melanoma^[3,4].

Multiple epidemiological studies have been conducted regarding brain metastases. These have had different methods and limitations; however, a comparison between them can bring an understanding of the incidence of brain metastasis. Such studies include the initial work done by Goumudsson in Iceland, which reported an incidence of 2.8 cases per 100,000 people^[5], and Percy *et al.*^[6], where the incidence found was as high as 11.1 cases per 100,000. The Barnholtz-Sloan *et al.*^[7]'s study derived greater validity from its use of the register of the Metropolitan Detroit Cancer Surveillance System from 1973 to 2001, carrying information on an approximate population of 4.5 million patients, in which the observed incidence of brain metastasis in patients with any kind of neoplasm was 9.6%.

Considerable variability in the incidence of brain metastasis has been found, which may be attributable to limited available data, such as autopsy reports or general hospital records; nevertheless, beginning with the first records of cancer, a similar incidence of brain metastasis has been observed, which may be attributable to the fact that it is an exclusively oncological population limited to a particular state or region and follow-up of the same patients^[8,9].

Generally, lung cancer is the foremost cause of brain metastasis, with studies reporting incidences of 12% to 65%^[10] of all patients with primary lung cancer. Among the most commonly associated histologies for brain metastasis are small-cell lung cancer and adenocarcinoma. In a high percentage of patients with lung cancer, diagnosis is performed after the onset of neurological symptoms.

Breast cancer is the main cause of brain metastases in women, with reported incidences between 5% and 30% of all breast cancer cases. Unlike the case of lung cancer, in breast cancer the diagnosis of brain metastasis usually follows well after the initial diagnosis of cancer. Diagnoses of melanoma have increased over the last several years, and this malignant neoplasm has the greatest capacity to develop into brain metastasis, with incidences from 12% to 90% [Figures 1-3]. Incidences of 7% to 10% of all patients with renal cancer and 1% to 4% of all gastrointestinal tumors have been reported^[11].

The therapeutic management of patients with brain metastases depends on the localization and number of brain lesions, primary tumor biology, and disease extension. The overall survival from the moment of diagnosis for untreated patients is 1-2 months, which can be extended to 6 months in patients who receive conventional radiotherapy and chemotherapy^[4].

PATHOPHYSIOLOGY

The genesis of metastasis requires several complex and sophisticated steps to occur first. These include genetic, epigenetic, and biological changes known as the “metastatic cascade”^[12,13]. This process begins with the detachment of a tumor cell from its primary lesion and the invasion of the surrounding tissue,

Figure 1. Left parietal lesion

Figure 2. Macroscopic view of a lesion located in the left temporal lobe, with dimensions of 5 cm× 4 cm× 3 cm, from the cystic-necrotic center. A subepidural lesion appears in the parietal region on the same side

Figure 3. Histologically, this lesion is composed of epithelioid-like cells with moderate eosinophilic cytoplasm and well-defined cytoplasmic junctions between some cells. The nuclei are vesicles with an apparent nucleolus. A brown pigment characteristic of melanocytic cells is seen

including the basement membrane, which is followed by intravasation in the blood vessels, hematogenous and lymphatic dissemination, the production of circulating tumor cells in brain capillaries, and then extravasation. Finally, the cancer cells must colonize the surrounding tissue and induce angiogenesis and cell proliferation, forming secondary lesions^[14].

The blood-brain barrier is a functional and anatomical barrier that plays an important role in the interaction between the cerebral microenvironment and metastatic colonization^[15]. In this process, tumor cells survive

an inflamed cerebral microenvironment that is appropriate for their development and growth, which is known as their niche^[16].

Tumor cells can evade growth-suppressing factors and inhibitors of cell proliferation through mechanisms that include resistance to apoptosis, overexpression of Bcl-2 and Bcl-xL, and the inhibition of proapoptotic pathways Bax and Bim^[12]. Tumor cells can be dedifferentiated, migrate to a distant site, survive apoptosis, disseminate, and redifferentiate. The activation of cells in the adjacent stroma by paracrine signaling with pro-tumor factors maintains the growth of the tumor, intensifying genomic instability and epigenetic dysregulation^[11,13].

Tumor cells adhere to the endothelium of recipient tissue and act as macrophages, creating pseudopods and penetrating cell-to-cell junctions, subsequently gaining access to normal tissue parenchyma to activate angiogenesis and develop new vessels for its nutrition, in this way promoting the growth of secondary injuries^[17]. Circulating cells attract platelets due to the proteins they express on their surface, which protects them from the immune system. Likewise, metastatic cells activate mechanisms to escape immunity by reducing the expression of TAP1, which decreases the effects of T-cell-mediated death^[18].

DIAGNOSIS

Although clinical manifestations of a history of malignant disease with central nervous system metastasis potential may obviously occur, it will not always be possible to obtain histological confirmation of these lesions [Figure 3]. In such cases, complementary image studies may play an important role in determining the best management for these patients.

Image studies

Magnetic resonance imaging (MRI) is the tool of choice when brain metastasis is suspected, due to its high sensitivity and specificity, which support its high capacity to detect smaller lesions than those that appear in computed tomography (CT) with or without contrast; it is also associated with fewer bone artifacts in posterior fossa. However, if MRI cannot be used, CT is still a valid option^[19].

CT will show isodense lesions in contrast with brain parenchyma, which will intensify with the application of intravenous contrast medium. When lesions appear hyperdense, one may suspect secondary bleeding, especially in histologies associated with high spontaneous bleeding risk (including choriocarcinoma, melanoma, and renal carcinoma); there are also other findings that are secondary to lesions and that can be easily visualized, such as hydrocephaly, ring-enhancing cerebral lesions, and brain herniation^[19,20].

The sensitivity and specificity of CT scans are 92% and 99%, respectively, and they are considerably higher in tumors that have a high incidence of central nervous system metastasis, such as non-small-cell lung cancer^[21]. MRI exhibits an ability to detect lesions smaller than 1 cm, up to 70% more sensitive than CT, and this increases in cases of multiple metastases^[19]. MRI has other beneficial characteristics, for example, in the use of distinct sequences such as T1, T2, FLAIR, diffusion, and perfusion, which can be used along with spectroscopy to increase sensibility and specificity^[22].

The majority of metastatic lesions are hypointense in T1 sequence images, which can be an indication of hemorrhage and necrosis. In T2 weighted images, the majority of lesions appear hyperintense [Figure 4]. Bleeding appears as acutely hypointense and becomes hyperintense as chronicity develops, while vasogenic edema appears hyperintense. The use of contrast significantly increases its sensitivity and specificity for the detection of brain metastases relative to simple MRI^[23].

Figure 4. Magnetic resonance imaging of a patient with multiple brain metastases. Axial T2 slice sequence shows perilesional edema in the junction of white and gray matter

Table 1. Spectroscopy

Metabolite/marker	Function	As found in brain metastases	Range (parts per million)
Creatine	Metabolism	Internal standard	3.0
Choline	Cellular membrane turnover	Increased	3.2
Lipids	Necrosis	Increased	0.9-1.4
Lactate	Anaerobic metabolism/necrosis	Increased	1.3
N-acetylaspartate	Neuronal viability	Decreased	2.0

SPECTROSCOPY

Spectroscopy is an MRI technique that allows the metabolic characteristics of lesions to be evaluated, which may help distinguish between benign lesions and malignant lesions which would be difficult to differentiate using MRI alone. Spectroscopy can be performed for single or multiple tumor regions (unique voxel or multivoxel) to detect certain ranges of specific metabolites in brain tissue, such as choline, creatinine, lipids, lactate, and N-acetyl-aspartate (NAA)^[22,23].

The analysis of these metabolites is helpful for distinguishing metastasis from necrosis, gliosis, and vasogenic edema [Table 1].

Creatine is the most stable metabolite in brain tissue, although it can be diminished in malignant primary tumors such as high-grade gliomas. It is present in both white and gray matter, which enables it to be used as an internal reference for the remainder of metabolites, which can change in the context of metastatic brain disease^[24,25].

Choline is a marker of cell change: it is a structural part of cell membrane phospholipids, with a greater presence in white matter than in gray matter. It is elevated where there are high-grade cell changes, and it has a relationship with creatine, such that both appear elevated, which helps orient a diagnosis of brain metastasis^[26].

Because lipids are a structural component of cell membranes, they appear elevated in the case of severe cell damage, even with necrosis. Lactate is a main metabolite associated with anaerobic metabolism, and necrosis is common in brain metastases^[26]. NAA is found at high concentrations in normal brain tissue, making it a marker for cell integrity and normal tissue structure; this marker appears at low concentrations in brain metastases^[25,26].

Spectroscopy may increase the accuracy of MRI in differentiating tumors from necrosis in patients with metastases who have been irradiated, using choline/NAA and choline/creatine ratios^[26]. According to a meta-analysis of 261 patients, it can also guide a clinician's therapeutic approach by adding information that could contribute to a differential diagnosis of primary malignant tumors such as high-grade gliomas; the study concluded that the most useful spectroscopy parameter is the choline-NAA ratio, preferably using a multi-voxel technique in the peritumoral region^[27]. However, in contrast, a meta-analysis of advanced MRI metrics that included 24 spectroscopy studies found no reliability of this technology in distinguishing high-grade gliomas from metastases using the choline-creatine ratio; the authors had excluded cases in which the choline-NAA ratio was used due to insufficient data^[28].

Hence, there is a lack of robust data supporting the routine use of MRI spectroscopy for differentiating metastases from high-grade gliomas, but it remains an important tool supporting the differential diagnosis of brain metastases from benign and low-grade gliomas and necrosis in irradiated patients^[29].

TREATMENT

The therapeutic approach to patients with brain metastasis is intended to relieve symptoms, such as headache, vomiting, and neurological focalization; the success of this largely depends on the presence of cerebral hypertension syndrome secondary to perilesional cerebral edema. Surgical management continues to be the standard of treatment, accompanied by radiotherapy using two different techniques: stereotactic radiosurgery (SRS) or whole-brain radiation therapy (WBRT) (or a combination of these)^[30].

Management of brain edema

The treatment of cerebral edema with systemic steroids such as dexamethasone has been practiced for more than five decades^[31]. Its efficacy is well known in terms of the clinical improvement of symptoms associated with vasogenic edema through its reduction of capillary permeability and regulation of the elevation of tight endothelial junctions involved in the physiology of the blood-brain barrier by binding to glucocorticoid receptors^[32-34].

In actuality, the pharmacological measures previously adopted for the management of edema, including osmotic diuretics such as mannitol and glycerol and loop diuretics such as furosemide, are no longer considered standard for the treatment of cerebral edema secondary to metastasis. Because osmotic diuretics cause a redistribution of fluid from the intracellular space to the extracellular space, they reach a plateau within a few hours, reducing their effectiveness^[35].

Even though there is not a defined dexamethasone scheme, the most utilized dose in patients with clinical cerebral edema is 4 to 8 mg/day^[33].

According to a recent joint update of the American Society of Clinical Oncology and the Society for Neuro-Oncology, they endorse a practice guideline regarding the role of steroids in brain tumors. The recommended dose depends on symptom severity with an initial dose of 8 mg in mildly symptomatic patients and 16 mg in severely symptomatic patients^[36].

Management of seizures

In patients who have not presented with seizures, the use of an antiepileptic agent in a prophylactic manner is currently not recommended, following a systematic review by Perry *et al*^[37]. In that study, no significant differences were found in reduction of risk of convulsive episodes in patients who were recently diagnosed with brain metastases and had never presented with seizures, between administration of the drug and only observation.

Table 2. RPA classes

Prognostic factors	Class I	Class II*	Class III
Age (years)	< 65	Any	Any
Controlled primary tumor	Yes	Any	Any
KPS	> 70	> 70	<7 0
Extracranial metastasis	No	Any	Any
Estimated survival (months)	7.1	4.2	2.3

Abbreviations: RPA: recursive partition analysis; KPS: Karnofsky performance score. *All patients not in class I or III.

By contrast, the use of anticonvulsants in patients with seizures, although it does not have an impact on overall survival, is useful for the relief and decrease of the number of convulsive episodes. The drugs used most often that have been proven to be effective and safe include levetiracetam, oxcarbazepine, and topiramate^[38,39].

INITIAL ASSESSMENT

A therapeutic approach must be preceded by an adequate assessment of the patient's condition, evaluating parameters such as functional status and extracranial disease so that the best available treatment may be offered, without compromising the oncological outcome or overtreating patients in whom poor survival may be anticipated and for whom support measures are more adequate.

PROGNOSTIC SCALES IN BRAIN METASTASES

At present, several useful prognostic scales are available for the clinical decision-making process, the first of which is recursive partition analysis (RPA by Gaspar *et al.*^[40]), developed in 1997. This scale was formed by the Radiation Therapy Oncology Group (RTOG) clinical trials that defined three prognostic classes according to four prognostic factors: performance according to the Karnofsky performance scale (KPS), control of the primary disease, presence or absence of extracerebral disease, and age greater or less than 65 years, dividing patients with brain metastases and their respective median survivals into three prognostic classes [Table 2].

Patients with a class III RPA are usually candidates for only supportive care, with local management performed either through surgery or radiotherapy for patients with classes I and II^[40,41].

The histological type of the primary tumor should also be considered an important prognostic factor; however, the previous scale does not take this into account. There is a more specific scale for primary disease that takes melanoma, gastrointestinal tumors, breast cell carcinoma, renal cell carcinoma and non-small-cell lung carcinoma into account. This scale is known as DS-GPA^[42,43].

The prognosis derived from these scales depends on various prognostic factors in relation to each histology, namely, age, KPS score, presence or absence of extracranial metastasis in the case of lung carcinoma, number of cerebral metastases in the case of lung carcinoma, melanoma, and renal cell carcinoma. Likewise, breast cancer, with its several molecular patterns that determine prognosis, is integrated into this scale [Table 3].

For more information on the estimation of global survival according to tumor type and characteristics, we recommend visiting a website made for this purpose: <http://brainmetgpa.com/>.

SURGICAL MANAGEMENT

Surgery plays an important role in the management of brain metastases, enabling a definitive histologic diagnosis in patients with no previously known history of cancer, allowing clinicians to alleviate the symptoms of intracranial hypertension (thus providing immediate relief to patients), and serving as a

Table 3. Disease-specific GPA

Disease-specific GPA

primary therapeutic approach. However, in recent years it has been displaced by advanced radiotherapy techniques such as SRS.

The American Society for Radiation Oncology recommends surgical resection in patients with an expected survival of at least 3 months, lesions larger than 3-4 cm, and who are amenable to safe, complete resection followed by WBRT or SRS to the cavity^[44].

Whole-brain radiotherapy

WBRT has been considered a mainstay treatment for brain metastases since the publication of Chao *et al.*^[45], who proposed irradiating the whole brain through two opposed lateral fields with the inferior margin of each field lying along the line running from the supraorbital ridge through the external auditory meatus to the foramen magnum; the other margins of the rectangular field project 2 cm beyond the forehead, vertex, and occiput onto bolus bags that surround the head. This was the first WBRT technique described using 250 kv X-rays in 38 patients with brain metastasis. The authors reported that 63% of the enrolled patients demonstrated reduced symptoms associated with brain metastasis, with a relief duration of 3-4 months^[45].

Dose and fractionation for WBRT

Dose and fractionation schemes are based, not on the radiation sensitivity of the primary tumor, but rather on the tolerance of healthy brain tissue as described in the QUANTEC report from 2010 (maximum dose [Dmax] of 60 Gy with an estimated rate of symptomatic brain necrosis of 3%)^[46]. Taking this into account and with a biologically equivalent dose (BED) with an α/β ratio of 3 for a normal brain, we cite the most used radiation schemes with their BED in Table 4.

Because the primary objective of this type of treatment is the palliation of symptoms, the most common prescription is 30 Gy in 10 fractions. This is based on the results of the first two randomized trials conducted by the RTOG, in which they compared four different radiation schemes including 3000 rad delivered in 2 weeks and 2000 rad in 1 week, and reported no differences in survival, time to progression, and symptom relief [Table 5]^[47].

Table 4. Most used radiation therapy schemes for WBRT

Dose and fractionation	BED (Gy)
30 Gy/2 weeks	60
20 Gy/1 week	46.67
37.5 Gy/3 weeks	68.75
40 Gy/4 weeks	66.67

Abbreviations: BED: Biologically equivalent dose. Gy: Gray

Table 5. Former RTOG dose and fractionation protocols for brain metastases

RTOG brain metastasis protocols			
First study		Second Study	
Scheme	# patients	Scheme	# patients
3000 rad/2 weeks	233	2000 rad/2 weeks	447
3000 rad/3 weeks	217		
4000 rad/3 weeks	233	3000 rad/2 weeks	228
4000 rad/4 weeks	227	4000 rad/3 weeks	227

Considerations that can be taken into account as the physician decides on one fractionation scheme over another are the patient's performance status, estimated survival, and histology of the primary tumor because choriocarcinoma, melanoma, and renal cell carcinoma, among other types, present a higher risk of bleeding^[43,48,49].

The shorter-course fractionation of 20 Gy in 1 week is preferable for most patients with poor performance status, to avoid unnecessary treatment time, as it has demonstrated similar survival benefits as longer treatment schemes^[50]. However, other fractionation schemes such as 37.5 Gy in 3 weeks is recommended in patients who have received a stereotactic radiosurgery boost with one metastatic lesion and should be considered in patients with one to three lesions^[51].

WBRT, unlike SRS, is associated with lower intracranial relapse, but when the whole brain is irradiated with this technique, it may also lead to greater cognitive deterioration (reflected as short-term memory loss), especially in patients with a longer life expectancy (> 6 months). In Aoyama *et al.*^[52], global survival did not significantly differ between treatment techniques (8.0 vs. 7.5 months) but there was a difference in the presentation of new metastases (63.7% vs. 41.5%) WBRT as shown [Figure 5](#).

Role of Radiosurgery in the treatment of brain metastases

SRS-based treatment began in 1951, with its implementation by Lars Leksell. It uses multiple rays of radiation, which converge three-dimensionally on a localized objective, either static or mobile, giving a high dose to a unique fraction with a high fall-off. This minimizes the damage to the adjacent tissue^[53].

Luckily, more than half of brain metastasis patients present with three or fewer lesions at diagnosis. It has been demonstrated that both surgical treatment and SRS lead to longer overall survival in these patients, especially for lone lesions smaller than 30 mm, where SRS has an overall survival comparable to microsurgery. However, it is important to take into account that although brain metastases tend not to invade more than a few millimeters of adjacent tissue, local recurrences are common after resection, meaning that adjuvant treatment with radiotherapy after surgery is imperative^[54]. To reduce cognitive impairment in such patients, the use of SRS has grown in use as an alternative to WBRT in the first 6 weeks following surgery, with the goal being to maintain local control in surgery and preserve neurocognitive functions without lowering quality of life^[52].

Clinical presentation with a single metastasis appears in only 10% to 20% of patients, where treatment with SRS following surgery improves both local recurrence rates and death due to neurological causes^[55,56].

Figure 5. Whole-brain radiation therapy treatment plan using a 3D conformal technique with two opposite lateral fields

One of the first aleatorized studies employed SRS as a boost in patients with one to three brain metastases that had previously received treatment with WBRT, showing an improvement in functional status in all patients and an improvement in overall survival in patients with a single metastasis^[52,57].

The retrospective series published by Wang *et al.*^[58] in 2015 analyzed patients with brain metastases, comparing GammaKnife SRS alone, GammaKnife SRS with WBRT, surgery and SRS (as an adjuvant treatment to the surgical cavity), and a triple modality (surgery, SRS, and WBRT). For patients with a single metastasis and those with multiple lesions, the triple modality treatment was found to have greater positive effects on median survival than GammaKnife SRS alone. That study was not a prospective trial, and it also found better results for bimodal treatment than for GammaKnife surgery alone (as opposed to previous clinical trials). The authors concluded that WBRT is a good alternative as a rescue treatment for patients who had previously received SRS^[58,59].

SRS has broadened the terrain of the primary treatment of brain metastasis, especially in patients with good functional status and in those who have one to three metastases at diagnosis with limited extracranial disease^[58] [As shown in Figures 6 and 7]. Therefore, it is important to note that better global control of metastasis can be obtained with WBRT and SRS, which have an impact on local control and overall survival^[51]. Patients whose disease is more limited in extent (up to four metastases for SRS protocols) may be treated with WBRT and SRS or SRS alone without improvement in their overall quality of life. A worsening of cognitive performance is found in patients treated with WBRT plus SRS, which affects their quality of life and ultimately their overall survival. These results were found by the trials conducted by Brown *et al.*^[60] and Chang *et al.*^[61]. ASTRO and NCCN guidelines agree in recommending management with SRS in patients with a limited number of brain metastases.

The utility of SRS for patients with five or more brain metastases is unclear. The only prospective study that has evaluated patients with these characteristics was conducted by Yamamoto *et al.*^[62], who assessed 208 patients with 5 to 10 metastases, 531 patients with 2 to 4 metastases, and 455 patients with a single metastasis, with a maximum lesion diameter of 3 cm. The most important result was that the number of brain metastases did not affect overall survival, while the volume of intracranial tumors ranged from 0.02 to 13.9 cc, and the average survival for patients with 5 to 10 metastases was 10.8 months. Deaths from neurological causes did not exceed 10% and there were no significant differences among groups. Finally, it was concluded that the progression of systemic disease was the main cause of death, the initial number of

Figure 6. Treatment-planning dose for SRS of a single lesion, with the dose distribution for one target prescribing 20 Gy 95% with the following specification: isodose lines: red 20 Gy, yellow 18 Gy, blue 16 Gy, brown 12 Gy, pink 6 Gy. Software: Eclipse External Beam Planning system version 15.5 HD MLC

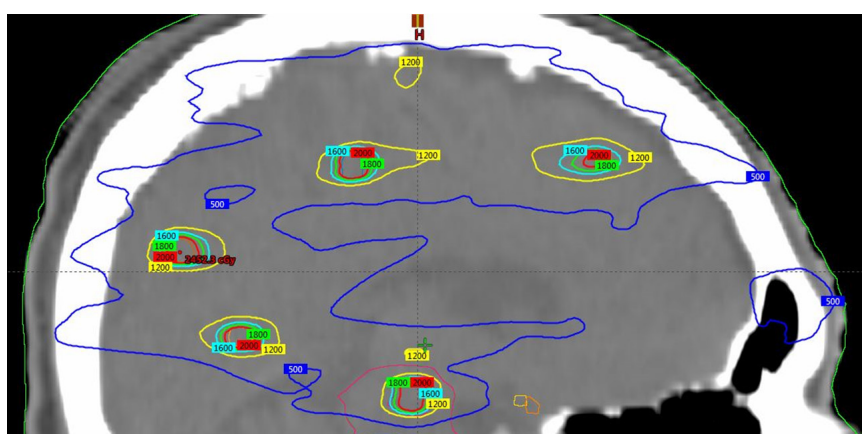

Figure 7. Multiple-target planning showing the dose distribution for multiple targets, prescribing 20 Gy 95% to each of them with the following specification: isodose lines: red 20 Gy, green 18 Gy, light blue 16 Gy, yellow 12 Gy, dark blue 6 Gy. Software: Eclipse External Beam Planning system version 15.5 HD MLC

metastases did not impact local control, and the rate of distant metastasis failure was lower in patients with a single metastasis, although this advantage seemed to be lost for those with two or more metastases^[62].

Because 50% of patients with brain metastases will present with new lesions, it is necessary to continue surveillance using serial MRI when only SRS is used, with the intention of identifying the progression of the disease and enabling early management to limit neurological deficits. Success in the control of new distant metastases varies from 22% to 90%, with different results reported by different studies. Many such studies have reported a correlation between the initial number of metastases and the progression of disease (according to Chang *et al.*^[61], the presence of 15 or more metastases is a risk factor). In addition to age, KPS, histology, and RPA, the total irradiated volume is also likely to impact overall survival, however, neither the number of metastases nor the total volume of treatment is yet considered a criterion for the selection of patients for treatment with SRS^[51].

Brown's and Chang's trial^[60,61] indicated that treatment with WBRT affects cognitive function in a significant way in all analyzed aspects, and opinions on the management of brain metastases converge on the use of SRS, even for multiple brain metastases, to avoid cognitive deficit^[55].

SRS TREATMENT DOSE

As described in the protocol RTOG 9005, treatment dose is inversely proportional to metastatic lesion size. The suggested dose is 24 Gy for tumors smaller than 20 mm, 18 Gy for tumors from 21 to 30 mm, and 15 Gy for tumors from 31 to 40 mm^[63]. It is not known whether the dose used for lesions smaller than 20 mm can be safely incremented above 27 Gy; hence, the general consensus still recommends a 24 Gy dose. However, because the organs at risk are so near, a single-dose treatment modality is associated with higher rates of toxicity, meaning that hypofractionated treatment plans are more appropriate for local control with acceptable toxicity^[64].

In 2014, Minniti published results of a study of hypofractionated SRS in which lesions under 20 mm received 36 Gy in three fractions, and lesions larger than 20 mm received 27 Gy in three fractions, resulting in 2 years of local control and an overall survival rate of 72% and 25%, respectively^[65]. In 2016, Navarra published the results of a similar study, administering a dose of 27 Gy in three fractions to lesions of 21 to 30 mm and a dose of 32 Gy in four fractions to lesions of 31 to 50 mm. The technique resulted in local control and an overall survival at 2 years of 96% and 33%, respectively^[66].

CONTOURING OF BRAIN METASTASES

Before a treatment plan is complete, an MRI with gadolinium contrast should be performed for fusion with axial CT. GTV is defined as gadolinium enhancement, identified in MRI with a 1 mm margin. A 1-3 mm margin is used for GTV in a geometrical form to obtain the total treatment volume (planning target volume)^[63].

SRS boost after WBRT

Several randomized trials that employed SRS as a boost after WBRT in newly detected patients with one to three surgically unresectable brain metastases have reported no added toxicity and improved performance in all patients and also an important benefit in the overall survival of patients with a single metastasis^[51,52,57]. In addition, a recent review of five studies involving 2,728 patients reported a survival benefit in all patients who received a combined modality based on prognostic criteria (RPA or DS-GPA) regardless of the number of brain metastases^[67].

Cavity radiation therapy

A panel of international experts has recommended the following to contour CTV in SRS for patients with completely resected brain metastases. CTV must include the entire surgical cavity showing enhancement of contrast, using axial images in the T1 sequence of brain MRI with gadolinium contrast, excluding edema as determined by MRI. CTV must include the surgical path shown in the MRI or CT. If the presurgical tumor is in contact with the dura mater, CTV must include a 5-10 mm margin, until overlap with bone structures is achieved. If the presurgical tumor is not in contact with the dura mater, the CTV must include a 1-5 mm margin, until contact with bone structures is achieved. If a presurgical tumor is in contact with the venous sinus, CTV must include a 1-5 mm margin along the sinus^[68].

Late toxicity implications: radiation cognitive syndrome

Radiation cognitive syndrome is a poorly understood entity, and currently there is no validated long-term treatment or prevention; 50%-90% of patients who receive WBRT exhibit disabling cognitive function including declines in learning capability, processing speed, memory, and attention. This undermines the patient's overall quality of life. Radiation is associated with inflammation, gliosis, demyelination, vascular abnormalities, and necrosis, which in turn may lead to such cognitive issues^[69].

Cognitive deterioration is usually reported 6 months to 1 year after WBRT, but may be seen as early as 1 month after treatment. In addition, cognitive decline tends to be progressive and irreversible. Many

radiation and pharmacologic approaches to address this syndrome are being studied, and while further data are needed for any one medical solution to become the standard of care, the results generated to date suggest a positive outlook for future treatment options^[70].

As new radiotherapy techniques have appeared, treatment plans have been developed that, in addition to tumor control, aim to reduce cognitive deterioration through the preservation of the hippocampus. Indeed, the RTOG 0933 trial^[71] demonstrated the preservation of cognitive function by reducing the dose to the hippocampus to not more than 9 Gy at 100% of the volume and a maximal hippocampal dose of 16 Gy. This was achieved by manually contouring the hippocampus on a fused MRI-CT image set and expanding by 5 mm to generate “hippocampal avoidance regions.” The mean relative cognitive decline from baseline to 4 months was 7.0%, significantly lower than in controls. The study demonstrated that conformal avoidance of the hippocampus during WBRT was associated with preservation of memory and quality of life. Nonetheless, this procedure poses a risk of generating new brain metastases within the avoidance regions. However, this risk is not fully quantified and further data are needed to validate this technique within a phase III setting.

CONCLUSION

Although brain metastasis is the most common malignant intracranial tumor, it is closely linked to unfavorable outcomes. Its incidence has increased dramatically, due to a greater number of newly diagnosed cancer patients and the broader therapeutic options available today, which have led to better disease control and longer overall survival. The majority of patients are not candidates for surgical resection, so radiotherapy remains the standard of care. The possibility of a cure for an oligometastatic disease has been gaining increasing attention in recent years. The management of these patients has changed immeasurably over the past few decades: not many years ago, the prognosis and survival of such patients was for a short life expectancy, with poor disease control. At present, there are several treatment options available. The choice among these modalities depends on several factors, such as the functional state of the patient and the availability of equipment and treatment techniques at the given medical center. Before the 1990s there was no GPA prognostic scale, much less an RPA, which are quite useful for decision making.

To date, no prospective studies have evaluated the use of SRS relative to WBRT for patients with more than four brain metastases. However, the current tendency in several hospitals around the world is to avoid WBRT, due to the toxicity and neurological deterioration attendant on that treatment, especially in developed countries. Consequently, there has been a shift to highly sophisticated techniques, such as SRS. A randomized phase III study is currently running at The Odette Cancer Center and the Princess Margaret Cancer Center (University of Toronto) in patients with 5 to 20 cerebral metastases who are receiving treatment with SRS without WBRT versus SRS plus WBRT, with the primary outcome being to compare neurocognitive decline between the approaches, as this is a common late side effect in patients receiving radiotherapy.

DECLARATIONS

Authors' contributions

All the authors contributed in an equitable way in the conception, bibliographic search and writing of this review article.

Availability of data and materials

Abstract

A large and incremental number of non-coding RNAs, including microRNAs (miRNAs) have been recently demonstrated to play a very important role in human pathologies, including cancer. Therefore, microRNAs have been proposed as therapeutic targets and molecules exhibiting anti-miRNA activity or mimicking functional miRNAs have been developed. Among biomolecules proposed in anti-miRNA therapy, peptide nucleic acids (PNAs) are appealing, in consideration of their stability and efficacy in recognizing RNA targets. PNAs against tumor associated miRNAs have proven to be efficient in inducing anti-tumor effects both *in vitro* and *in vivo*. For instance, PNAs targeting miR-155-5p are able to induce apoptosis in glioma cell lines and to enhance the sensitivity to temozolomide (TMZ) in TMZ resistant glioma cells. *In vivo*, PNAs anti-miR-21 were found to exhibit anti-tumor effects associated with improved survival when administered to animals with intracranial gliomas.

Keywords: Peptide nucleic acids, glioma, microRNAs, miRNA targeting, delivery, apoptosis, temozolomide

MICRORNAS IN ONCOLOGY

MicroRNAs (miRNAs) are a family of evolutionary conserved small (19 to 25 nucleotides in length) non-coding RNAs playing important roles in the post-transcriptional control of gene expression. This control is operated at the level of mRNA translation and is based on the miRNA-dependent recognition of 3'UTR, CDS and 5'UTR mRNA sequences. This molecular recognition leads to a reduction of protein synthesis^[1-4]. Single or multiple mRNAs can be targeted by a single miRNA, while a single mRNA can be recognized and

functionally controlled by several miRNAs (eventually differentially expressed in cells of different histotype); following these considerations, it is calculated that more than 60% of human mRNAs can be considered molecular targets of miRNAs^[5,6]. It has been reported in different studies and reviews that the miRNA/mRNA interaction occurs at the level of the RNA-induced silencing complex (RISC), a ribonucleoprotein which incorporates one strand of a single-stranded RNA (in our case a microRNA), acting as a template to recognize complementary mRNA transcripts^[1-4]. This molecular interaction is associated to (1) repression of translation or (2) mRNA degradation, depending on the level of miRNA complementarity with nucleotide sequences of the target mRNA^[3,4]. Since their discovery and first characterization, the number of human microRNAs identified and deposited in the miRBase database (miRBase v.22, www.mirbase.org) is much more than 2600^[7-9] and the research studies on microRNAs have confirmed the very high complexity of the networks constituted by miRNAs and RNA targets^[7].

Changes of microRNA expression have been demonstrated to be associated with different human pathologies, and guided alterations of specific miRNAs have been suggested as novel approaches to develop innovative therapeutic protocols^[10-13]. Several reports conclusively demonstrated that microRNAs are deeply involved in tumor onset and progression, behaving as tumor promoting miRNAs (oncomiRNA and metastamiRNAs) as well as tumor suppressor miRNAs^[14-19]. In general, a miRNA able to promote cancer targets mRNA coding for tumor-suppressor proteins, while microRNAs exhibiting tumor-suppression properties usually target mRNAs coding oncoproteins^[15].

Targeting oncomiRNAs and mimicking tumor-suppressor miRNAs: overcoming drug resistance

With respect to targeting oncogenic RNAs and mimicking tumor-suppressor miRNAs in translational medicine, it should be underlined that these non-coding RNAs are suitable targets for therapeutic interventions, as summarized in Figure 1^[10-13]. The use of modified miRNA mimetics, either synthetic or produced by plasmid or lentiviral vectors, might lead to potentiation of miRNA functions (miRNA replacement therapy)^[20-24]. In this case the miRNA replacement molecules (mimicking the miRNA functions to be up-regulated) are transfected to target cells [Figure 1A, step “a”] where interact with the mRNA to be modulated [Figure 1A, step “b”]. This interaction leads to down-regulation of this mRNA and associated suppression of protein production [Figure 1A, step “c”, dotted arrows]. According to this procedure, it is possible to mimic the activity of tumor-suppressor miRNAs (down-regulated in tumors) to achieve down-regulation of miRNA-regulated oncogenes^[23,24].

On the contrary, forced down-regulation of miRNA biological functions can be obtained using a large variety of well-characterized miRNA-inhibitor oligomers (such as in the case of direct miRNA antisense therapy based on RNA, DNA, LNA and other DNA analogues)^[25-31], miRNA sponges^[32-38], mowers^[39] or through miRNA masking strategy that interferes with miRNA function by masking the miRNA binding site of target mRNA through hybridization with complementary molecules^[40-42] [see Table 1]. In this case the miRNA inhibitors [“a”, “b” and “c” of Figure 1B, suppressing the miRNA functions to be down-regulated] are transfected to target cells where they interact with the microRNA target [Figure 1B, step “d”]. This interaction prevents the target miRNA (for instance an oncomiRNA in protocols designed to develop anti-tumor therapy) to bind the specific 3'UTR sequence of the regulated mRNA, causing up-regulation of this mRNA and the associated increase of protein production [Figure 1B, step “e”]. According to this procedure, it is possible to inhibit the activity of oncomiRNAs (up-regulated in tumors) to achieve up-regulation of miRNA-regulated tumor suppressor genes.

Interestingly, in the case of the development of anti-cancer protocols, targeting miRNAs in drug-resistant tumor cell lines has been associated with partial or total reversion of the drug-resistance phenotype, as reported in different studies^[43-48].

Figure 1. Scheme summarizing the miRNA replacement (A) and anti-miRNA (B) approaches to modify miRNA-regulated gene expression. In panel A the miRNA replacement molecule is transfected to target cells (a) where it interacts with the mRNA to be modulated (b) causing inhibition of protein production (c, dotted arrow). In panel B the miRNA inhibitors (a-c) are transfected to target cells (d) where they interact with the microRNA target preventing its binding to the specific 3'UTR sequence (dotted arrow) of the regulated mRNA (d). This causes up-regulation of this mRNA with increased protein production (e). Three examples of antagomiRNA molecules are shown: microparticle delivered antagomiRNAs (a), peptide-delivered molecules (b, peptide in green), or chemically-modified molecules (chemical modifications in yellow) to increase biological functions (for instance resistance to enzymatic degradation or delivery efficiency to target cells)

PEPTIDE-NUCLEIC ACIDS

Peptide Nucleic Acids (PNAs) are DNA analogues described for the first time by Nielsen *et al.*^[49], in which the sugar-phosphate backbone has been replaced by N-(2-aminoethyl)glycine units^[50-53] [see Figure 2 for the chemical general structure]. PNAs are very interesting molecules for sequence-specific alteration of gene expression, since are capable of forming Watson-Crick double helices after efficient sequence-specific hybridization with complementary DNA and RNA^[54]. Furthermore, they are able to generate triple helix with double-stranded DNA and to perform strand invasion^[55]. In virtue of these biological activities, PNAs have

Figure 2. Scheme outlining the differences between DNA (left) and PNA (right) monomers

been demonstrated to be very efficient tools for pharmacologically-mediated alteration of gene expression, both *in vitro* and *in vivo*^[56,57].

Summarizing, PNAs and PNA-based analogues were employed as antisense molecules targeting mRNAs, triple-helix forming molecules targeting eukaryotic gene promoters, artificial promoters, decoy molecules targeting transcription factors^[54-56]. Relevant in the context of the present review article, PNAs have been demonstrated to be able of altering miRNA functions, both *in vitro* and *in vivo*^[58-62]. This has been recently reviewed by Manicardi *et al*^[63].

While well-controlled studies are needed to compare the *in vivo* activity of PNAs to those of LNA, RNA and other molecules exhibiting anti-sense potential, several *in vivo* studies on PNAs have been already reported to sustain the usefulness of these molecules and their derivatives.

Gupta *et al.*^[64] tried to target miR-210 with an antisense γ -peptide nucleic acids (γ PNAs), exhibiting superior RNA-binding affinity, improved solubility, and favorable biocompatibility. The rationale for this approach is that miR-210 is overexpressed in hypoxic cancer cells and is a key player for the adaptation of tumor cells to hypoxia. For cellular delivery, they encapsulated the γ PNAs in poly(lactic-co-glycolic acid) (PLGA) nanoparticles. The results obtained show that γ PNAs targeting miR-210 cause significant delay in growth of a human tumor xenograft in mice compared to conventional PNAs. Furthermore, histopathological analyses show considerable necrosis, fibrosis, and reduced cell proliferation in γ PNA-treated tumors compared to controls^[64]. In another paper, Cheng *et al.*^[11] efficiently inhibited the function of oncomiRNA miR-155 in a tumor mouse model after the design and realization of a peptide-(anti-miRNA)PNA construct able to target the tumor microenvironment and to transport the anti-miRNA PNA across the cellular plasma membranes under the acidic conditions which characterize solid tumors. A final example is that published by Yan *et al.*^[65], demonstrating that PNA-mediated targeting of miR-21 causes inhibition of growth and migration of breast cancer MCF-7 and MDA-MB-231 cells *in vitro*, and tumor growth *in vivo* when nude mice were employed.

GLIOBLASTOMA

Glioblastoma multiforme (GBM), a grade IV glioma, is a lethal malignant tumor accounting for 42% of the central nervous system tumors, the median survival being 12-15 months^[66-71]. The current standard therapeutic management of GBM is based on neurosurgery followed by chemoradiotherapy by fractionated external-beam radiotherapy and systemic chemotherapeutic treatment with temozolomide (TMZ) and other agents, including repurposed drugs (such as metformin, disulfiram, rapamycin and derivatives, chloroquine, ionidamine)^[71]. There are only very limited possibilities for the treatment of subsequent recurrences, generally with minimal clinical efficacy^[69]. Among novel therapeutic strategies for GBM, of interest are inhibitors of aberrantly activated cell signaling pathways, including those regulated by growth factors and their receptors, such as epidermal growth factor family and their receptors^[72], platelet-derived growth factors and their receptors^[73]. In addition, innovative targets for GBM experimental therapy might

be insulin-like growth factors, fibroblast growth factor and their receptors^[74,75]. Excellent review articles describing current therapeutic approaches and novel trends in GBM management are available^[69,76-82].

In conclusion, since no curative treatment is available and the most used first-line drug, temozolomide (TMZ), is only able to cause an increase of the life expectancy^[69], new drugs are urgently needed for the implementation of therapeutic protocols for anti-glioma treatments. Moreover, a high proportion of gliomas become with time TMZ-resistant. Therefore, a deep interest does exist for combined treatments on TMZ-resistant glioma cells in order to induce therapeutic relevant response, including, but not limited to, apoptosis^[81,82].

MICRORNAS IN GLIOMAS: VARIABILITY AMONG THE PATIENTS HAMPERS THE IDENTIFICATION OF POSSIBLE THERAPEUTIC TARGETS FOR PERSONALIZED TREATMENTS

Several studies available from the recent literature clearly support the involvement of microRNAs in gliomas^[83-93], outlining a large number of miRNAs demonstrated to be dysregulated in these tumors. Of course, these studies might indicate miRNA targets to be proposed for the development of protocols for therapeutic intervention in glioma, including strategies useful to tackle the issue of drug resistance^[94-96]. Comprehensive analysis of microRNA expression profile in malignant glioma tissues has been reported by Piwecka *et al.*^[97], Banelli *et al.*^[98], Ciafrè *et al.*^[99]. The analysis of microRNAs is also associated with tumor onset and progression. For instance a miRNA signature was found associated with glioblastoma tumor tissues. Up-regulated miRNAs were miR-221, miR-222, miR-22, miR-296-3p, miR-195, miR-155, miR-152, miR-132, miR-146b-5p, miR-149, miR-129-3p, miR-34a, miR-671-5p, miR-10a. Down-regulated miRNAs were let-7b, miR-767-5p, miR-505, miR-301b, miR-181a, miR-20a, miR-19a, miR-19b, miR-106a^[97-99]. In any case, a large consensus does exist on the fact that tumor tissues are highly heterogeneous with respect to molecular and genetic features, supporting the concept that GBM represents a heterogeneous type of neoplasm when the microRNA patterns are considered^[100,101].

However, due to global high-throughput profiling it is possible to select miRNAs that are at high risk of being deregulated in the majority of patients. Thus, there is a considerable hope for utilizing miRNAs as targets in prospects of glioma therapy. A partial list of validated miRNAs dysregulated in gliomas (with their proposed mRNA targets) is reported in [Supplementary Table S1](#).

Among the possible microRNA targets involved in glioma, miR-155-5p appears to be of relevant interest for the following reasons: (1) miR-155-5p may play an important role in the transformation of normal neural stem cell toward glioma stem cells^[102]; (2) the elevated expression level of miR-155-5p promotes the proliferation and invasion of glioblastoma cells through suppressing GABA receptors^[103], FOXO3a^[104] and MXI1^[105]; (3) an oligonucleotide targeting miR-155-5p was shown to sensitize glioma cells to taxol-induced apoptotic death^[106]; and (4) miR-155-5p overexpression is considered as a major molecular feature of glioblastoma, which can discriminate this malignancy from a similar intracranial tumor, oligodendroglioma^[107]. Therefore, miR-155-5p alone or together with other miRNAs is a predictive biomarker for glioma prognosis^[107,108]. On the other hand, glioma-targeting therapy based on miR-155-5p anti-oligonucleotides is believed to be efficient to inhibit the progression of glioma^[109].

However, several recent studies have pointed out that the translation of the analysis of the expression and content of miR-155-5p and other miRNAs in gliomas into therapeutic strategy is hampered by the high variability of microRNAs among patients^[92,100,101]. For instance, in analyzing 31 tumor specimens against paired normal tissue, Yan *et al.*^[92] found a significant upregulation of miR-155 in tumor tissues. This study was based on the analysis of surgically dissected glioma specimens and their surrounding brain tissues. In spite of the increased miR-155 expression, a large proportion of tumor samples exhibited a nearly normal

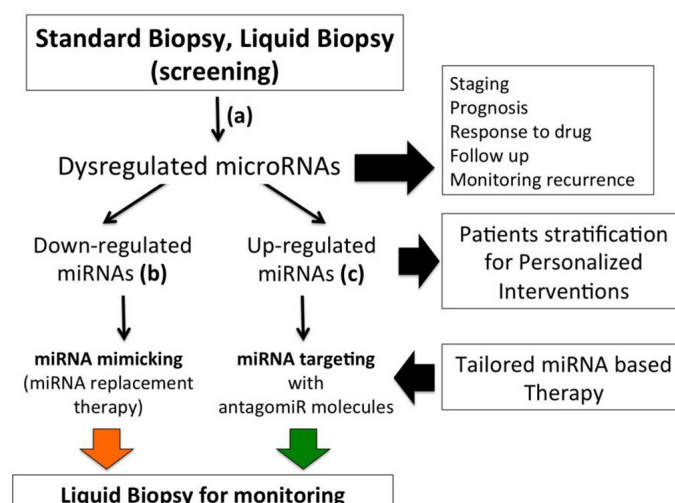

Figure 3. Scheme outlining the strategy to identify dysregulated microRNAs (a) in tumor patients and design possible therapeutic approaches based on anti-miRNA therapy and miRNA-replacement. The activity of down-regulated miRNA might be replaced with the use of miRNA mimicking molecules (b); the activity of up-regulated miRNAs might be counteracted with antagomiRNA molecules (c). A partial list of dysregulated miRNAs in gliomas is depicted in Supplementary Table S1

level of miR-155, supporting the concept that characterization of the GBM patients is required before the activation of a miRNA-155 targeting approach. Therefore, the analysis of the miRNA pattern appears to be a required step in the road of personalized therapy on precision medicine based on miRNA therapeutics.

Figure 3 indicates an overall strategy for determining miRNA targets in cancer patients, on the road of personalized therapy in precision oncology. The first step (step “a”) is the characterization of the miRNA profile in tumor tissues, performed with either surgery-based biopsy or liquid biopsy. The characterization of dysregulated miRNAs (down-regulated, “b” and up-regulated, “c”) will be helpful for staging, prognosis of the neoplasia as well as for determining the response of the patients to drugs. In addition, the analysis of dysregulated miRNAs might allow stratifying patients with respect to expression of specific miRNAs, with the final objective to propose a therapeutic intervention (either based on anti-miRNA or miRNA-replacement approach, as outlined in Figure 1). Liquid biopsy will be the best choice to monitor the outcome of this tailored therapeutic approach^[110].

PEPTIDE NUCLEIC ACID-MEDIATED TARGETING OF MICRORNAS IN GBM CELL LINES

The studies focusing on the possible use of PNAs targeting microRNAs are few. The first report was published by Brognara *et al.*^[62], who found that a PNA targeting miR-221 (R8-PNA-a221), bearing an oligoarginine peptide (R8) enabling efficient uptake by glioma cells^[58,59,62], strongly inhibited miR-221-3p in U251, U373 and T98G glioma cells. This inhibition of miR-221-3p activity was associated with increased expression of the miR-221 target p27Kip1, analyzed by RT-qPCR and by Western blotting^[62,66]. In a second study, Bertucci *et al.*^[111] reported the efficient combined delivery of temozolomide and the same anti-miR221 PNA using mesoporous silica nanoparticles^[111]. More recently, high levels of apoptosis on glioma cell lines were obtained following co-treatment with two PNAs, one targeting miR-221-3p, the other targeting miR-222-3p. In addition, Seo *et al.*^[113] showed the use of a PNA targeting miR-21 as *in vivo* inhibitor of glioma U87 cells.

A further example is a PNA against miR-155-5p. The possibility of obtaining clinically-relevant effects following targeting miR-155-5p with PNA-based molecules is shown in Figure 4 and elsewhere reported in the study by Milani *et al.*^[109], describing the synthesis and validation of a PNA targeting miR-155-5p on the temozolomide-resistant T98G glioma cell line^[66].

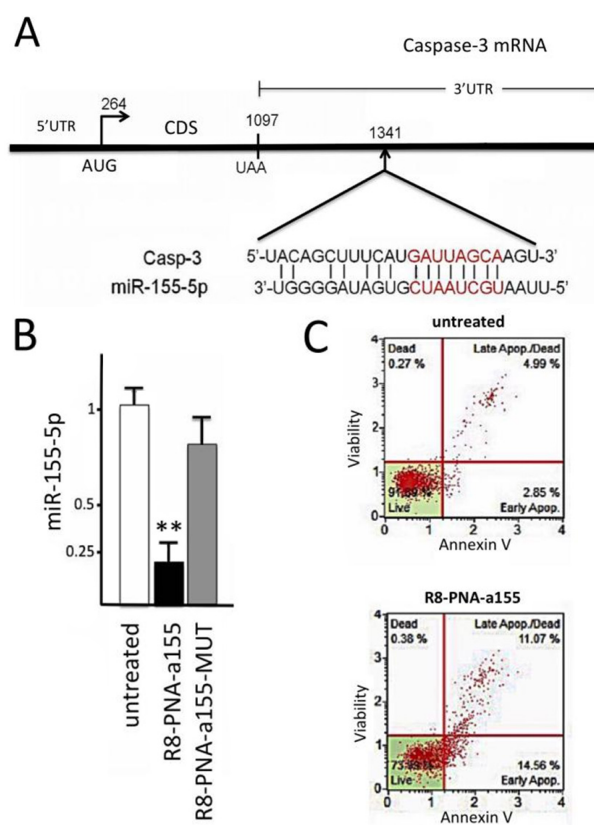

Figure 4. A. Location of a miR-155-5p binding site within the 3'UTR sequence of Caspase-3 mRNA. B. Effects of cell treatment with 4 μ M R8-PNA-a155 and R8-PNA-a155-MUT for 48 h on the miR-155-5p hybridization signal. C. Increase of T98G apoptotic cells after treatment for 48 h with 4 μ M R8-PNA-a155. Modified from Milani *et al.*^[109]

For efficient delivery, the PNA was conjugated with an octoarginine tail (R8-PNA-a155). Apoptosis was analyzed, and the effect of this PNA was associated with a reversion of drug-resistance phenotype. The specificity of the PNA effects at the cellular level was analyzed by RT-qPCR [see Figure 4B], suggesting that the effects of R8-PNA-a155 are specific. The studies on apoptosis [Figure 4C] confirmed that the R8-PNA-a155 demonstrated the pro-apoptotic effects, inducing apoptosis of TMZ-treated T98G cells.

FINAL REMARKS ON MIRNA THERAPEUTICS BASED ON PNA MOLECULES: FROM THE PAST TO FUTURE THERAPEUTIC APPLICATIONS

The data available on the recent literature support the concept that the anti-miRNA strategy [see Figure 1] could lead to therapeutic relevant inhibition of miRNA dependent effects and that PNA-based anti-miRNA molecules are very promising reagents to regulate tumor cell growth. Further research on PNA analogues to increase efficiency of delivery, stability and control of intracellular distribution for specific targets, i.e., mature miRNA, pre-miRNA or pri-miRNA, are further steps for the selection of best candidate drugs. Finally, the studies on miRNA targeting strongly indicate that multiple miRNA targeting, might lead to significant improvement in the efficacy of the treatment. This last conclusion supports also the concept of designing multifunctional PNA-containing systems enabling to perform targeting of different mRNA sequences.

Considering PNAs as anti-miRNA reagents, it should be underlined that one of the most important challenges in PNAs technology is their delivery to cells^[114,115], in particular their low uptake by eukaryotic cells. In order to solve this drawback, several approaches have been considered. One of the several approaches

Figure 5. A: Structure of the macrocyclic multivalent tetraargininocalix[4]arene **1** used as non-covalent vector for anti-miRNA PNAs; B,C: Effects of compound **1** on morphology of U251 glioma cells: lack of cytotoxic effects. D. Effects of free PNA (a221-PNA) and a221-PNA delivered with compound **1** on miR-221-3p in treated U251 cells. Inhibition of miR-221-3p expression is obtained only when a221-PNA is vehiculated by compound **1**. Modified from Gasparello *et al.*^[125]

undertaken to solve this issue is the conjugation with carrier peptides^[116-118], in particular those sensitive to microenvironment changes^[11]; anti-miRNA activity was indeed observed for instance by conjugation of PNAs to polyarginine (poly-R) tails^[58,59,62] or by modification of the PNA backbone with cationic amino acid side chains^[58,119]. An alternative strategy to chemical modification of PNAs is the use of carriers able to perform non-covalent and reversible interactions with the PNA structure.

In this context, it was actually already explored the delivery of PNAs and PNA derivatives or analogues with liposomes^[120], polymer nanoparticles^[121] and pseudovirions^[122], and by co-transfection with partially complementary DNA^[123]. Inorganic nanocarriers, such as nanozeolites^[124] or mesoporous silica nanoparticles^[111] have been also used for cellular delivery of PNAs, maintain their biological functions. Recently, we have reported results relative to the delivery ability of a macrocyclic multivalent tetraargininocalix^[4]arene “**1**” [Figure 5].

In conclusion, several studies demonstrate that efficiently delivered PNAs might be of great interest in the inhibition of miRNA activity. This opens new and still unexplored avenues to non-viral gene therapy, especially when PNA-based strategies to target multiple miRNA sequences will be available^[126]. In consideration of the high patient-to-patient variability of the miRNome, multiple miRNA targeting should be considered a key feature in the road of personalized therapy in precision medicine.

As far as delivered PNAs *in vivo* to experimental models of GBM, local delivery of nanoparticles should be considered a promising therapeutic strategy that bypasses the blood-brain barrier, minimizes systemic toxicity, and enhances intracranial drug distribution and retention. In this respect, Seo *et al.*^[113] developed nanoparticles loaded with PNAs inhibiting miR-21, a microRNA overexpressed in GBM and retaining oncogenic features. These authors employed a block copolymer of poly(lactic acid) and hyperbranched polyglycerol to deliver an anti-miR-21 PNA, showing that efficient intracellular delivery was facilitated, leading to miR-21 suppression and PTEN upregulation and apoptosis of human GBM cells. This anti-miR-21 PNA was also administered by convection-enhanced delivery to animals with intracranial gliomas, inducing significant miR-21 knockdown and chemosensitization, resulting in improved survival when combined with chemotherapy^[113]. This study demonstrates the feasibility and promise of local administration

of nanoparticles carrying an anti-miR-21 PNAs for the development of protocols for adjuvant therapy for GBM. Interestingly, the delivered PNAs were found to cause long-term survival in treated mice at a level much higher with respect to antisense RNAs.

Abstract

Cancer cells often have an increased amount of glycans, such as sialic acid (SA), on the cell surface, which normally play an important role in cell growth, proliferation and differentiation. In this study, SA expression is determined by fluorescent nanoprobe, molecularly imprinted polymers, SA-MIPs. The nanoprobe is synthesized with an imprinting approach to produce tailor-made fluorescent core-shell particles with high affinity for cell surface SA. Inflammation and cytokine production are well known tumor promoters, modulating the cellular microenvironment, including an aberrant cell surface glycan pattern. The recombinant cytokines IL-4, IL-6, IL-8 and a cocktail of cytokines collected from stimulated T leukemia Jurkat cells were used to induce *in vitro* inflammation in two cell lines, and thereafter analyzed with the use of SA-MIPs and flow cytometry. One of the cell lines showed a different binding pattern of SA-MIPs after treatment with recombinant cytokines and the cytokine cocktail. This study shows that SA-MIPs can be an important tool in the investigation of overexpressed glycans in the tumor microenvironment.

Keywords: Cancer, cytokine, glycans, molecularly imprinted polymers, sialic acid

INTRODUCTION

Abnormal cell growth can be initiated through inflammation^[1]. Cancer cells are able to reshape the microenvironment by expression of tumor-promoting chemokines and cytokines^[2,3]. Fast growing cancer

cells outpace their blood supply and become nutrient and oxygen deprived. This results in necrotic cell death at the tumor's core and this releases pro- inflammatory cytokines, such as IL-1.

Cytokines act as cell regulators of many different biological processes including cell growth, differentiation, metabolism, immunity and inflammation. Cytokines can enhance cancer cell growth by modulating the cellular microenvironment or by affecting the cells directly. Pro- inflammatory cytokines can be oncogenic and thereby inducing elevated levels of pro- invasive factors such as metalloproteinase-2 (MMP-2) and epithelial growth factor.

Pro-inflammatory cytokines including TNF- α , IL-1 β , IL-6 and IL-8 are regulated by the transcription factor NF- κ B, which is involved in activating genes in neoplastic transformation^[1,4]. Highly glycosylated intestinal mucins, such as MUC2 and MUC4, are regulated through NF- κ B and by the gp130/STAT3 pathways, respectively^[5,6].

Sialic acid (SA), or neuraminic acid, is the outermost sugar molecule of glycans, thus forming the outer surface of cells by being attached to proteins or lipids bound to the plasma membrane. SA is very important for the function of living organisms since it is involved in cell processes like proliferation, differentiation, angiogenesis, invasiveness and metastasis^[7,8]. The over-expression of SA creates a negative charge on the cell surface, which is important in cell-cell and cell-matrix communication. An increased level of SA on the cell membrane, which have been reported on malignant and metastatic cancer cells, makes cells repel each other leading to an increased motility^[9]. In addition, it has been proven that aberrant expression of in particular the α 2,3-SA variants are related to tumor adhesion and invasion^[10,11].

Today, there is a lack of tools for specific targeting to glycans with high affinity. Lectins and glycan-specific antibodies have been used by many research groups to detect altered glycosylation, but the current tools do not perform with high specificity or affinity^[12]. We have developed fluorescent nanoprobes to make convenient targeting and imaging of cell surface SA possible^[13]. Based on other glycan specific receptors, we have developed SA-imprinted molecularly polymers (SA-MIPs) by using silica core particles and implemented NBD-fluorophores, which have favorable spectroscopic properties^[13,14].

In this study, two different cancer cell lines, MCF-7 and RAW 264.7, were stimulated with recombinant IL-4, IL-6, IL-8 and a cocktail of cytokines obtained by stimulating Jurkat T leukemia cells with phytohemagglutinine (PHA). The resulting expression of SA on the membrane of the stimulated cancer cells was analyzed with flow cytometry using both lectins and the SA-MIPs. One of the cell lines showed an increased binding of the SA-MIPs after treatment with recombinant cytokines and with the cytokine cocktail from PHA-stimulated Jurkat cells.

MATERIAL AND METHODS

Cell culture

The cell lines MCF-7 (ATCC HTB-22), RAW 264.7 (ATCCTIB-71) and Jurkat (ATCCTIB-152) were obtained from the American Type Culture Collection (ATCC/LGC Standards, Teddington, UK). MCF-7 and Jurkat cells were cultured in RPMI-1640 medium (Invitrogen, San Diego, CA, USA) supplemented with 10% fetal bovine serum (FBS, Invitrogen) and 50 μ g/mL gentamycin (Invitrogen) (complete medium). RAW 264.7 cells were cultured in RPMI-1640 medium supplemented with 10% FBS and penicillin-streptomycin (Invitrogen). The cell lines were incubated in 37 °C with 5% CO₂ in 100 % humidity.

Stimulation of Jurkat cells

5 \times 10⁶ Jurkat cells in 5 mL of were stimulated in complete medium with the addition of 10 μ g/mL of PHA (Sigma Aldrich, St Louis, USA) for 72 h. The cells were harvested and centrifuged at 300 xg for 10 min. The supernatant was kept at 4 °C until used for cell experiments.

Addition of recombinant cytokines

2×10^6 of each of MCF-7 and RAW 264.7 cells were seeded in T25 flasks. Next day, the medium was removed and the different recombinant cytokines IL-4, IL-6, IL-8 (Peprotech, Rocky Hill, NJ, USA), all added at a final concentration of 40 ng/mL, or undiluted PHA- stimulated Jurkat supernatant was added to the cell culture flasks. One flask served as control with cells and medium alone. The cells were harvested after 3 days of incubation by trypsinization, two washes with phosphate buffered saline (PBS, Invitrogen) and thereafter stained with SA-MIPs according to below.

Preparation of polymers

The polymers (SA-MIPs) were prepared as described previously by Shinde *et al*^[13]. Before the SA-MIPs were used for cell-based experiments, the dried SA-MIPs were resuspended in PBS and sonicated for 8 min with a VWR sonicator. The stock solution of 1 mg/mL was further sonicated and diluted in PBS prior to use.

Flow cytometry analysis

SA-MIPs

1×10^6 cells/sample were stained with SA-MIPs or left unstained as a control. The cells were washed twice with 2 mL PBS and thereafter 100 μ L of SA-MIPs with indicated concentration was added to the cells. 100 μ L of PBS was used as a negative control. The cells were incubated with SA-MIP for 30 min at 4 °C in the dark, and were thereafter washed three times with 2 mL PBS and analyzed using flow cytometry (BD Biosciences, Accuri C6 Flow Cytometry, NJ).

Lectins conjugated with biotin

1×10^6 cells/sample were stained with biotin-conjugated lectins (Vector Labs, Burlingame, CA, USA) or left unstained as a control. The cells were washed twice with 2 mL PBS. 100 μ L of biotin-conjugated lectins, MAL I (from *Maackia amurensis*) or SNA (from *Sambucus nigra*) at concentrations of 10 μ g/mL was added to the cells and 100 μ L of PBS was used as a negative control. The cells were incubated with biotin- conjugated lectins for 30 min on 4 °C and were thereafter washed three times with 2 mL PBS. Thereafter 100 μ L of a 1:100 dilution of streptavidin-FITC (Agilent Technologies, Santa Clara, CA, USA) was added to the cells and incubated for 20 min at 4 °C in the dark. After the incubation, the cells were washed three times with 2 mL PBS and analyzed using flow cytometry (Accuri C6 Flow Cytometry).

ELISAs for IL-2, IL-6, IL-8 and TNF- α

96-well ELISA plates were coated overnight at room temperature with 100 μ L/well of diluted capture antibody against IL-2, IL-6, IL-8 or TNF- α , respectively, according to the manufacturer's instructions (R&D Systems, Minneapolis, MN, USA). The plates were washed three times with PBS-Tween (PBS-T), blocked by adding 300 μ L/well of blocking buffer (1% BSA in PBS) and thereafter incubated at room temperature (RT) for 1 hr. After three washes with PBS-T, the plates were incubated with 100 μ L/well IL-2, IL-6, IL-8 or TNF-standards, respectively, diluted in reagent diluent, and 100 μ L/well of samples collected from the Jurkat cell supernatant. After an incubation of 2 h at RT, the plates were washed three times and thereafter 100 μ L/well of 50 ng/mL biotin-linked detection antibody against IL-2, IL-6, IL-8 or TNF- α , respectively, were added and incubated at RT for 2 h. Then washed the plates three times and incubated with streptavidin-HRP at room temperature for 20 min. After three washes with PBS-T, the plates were incubated with 100 μ L/well with substrate solution (1:1 mixture of H₂O₂ and tetramethylbenzidine, TMB) at RT for 20 min. After that, 100 μ L/well of stop solution was added and the plates were analyzed with a spectrophotometer at 450 nm.

Statistical methods

Mean and standard deviation were used for statistical analysis of all calculations.

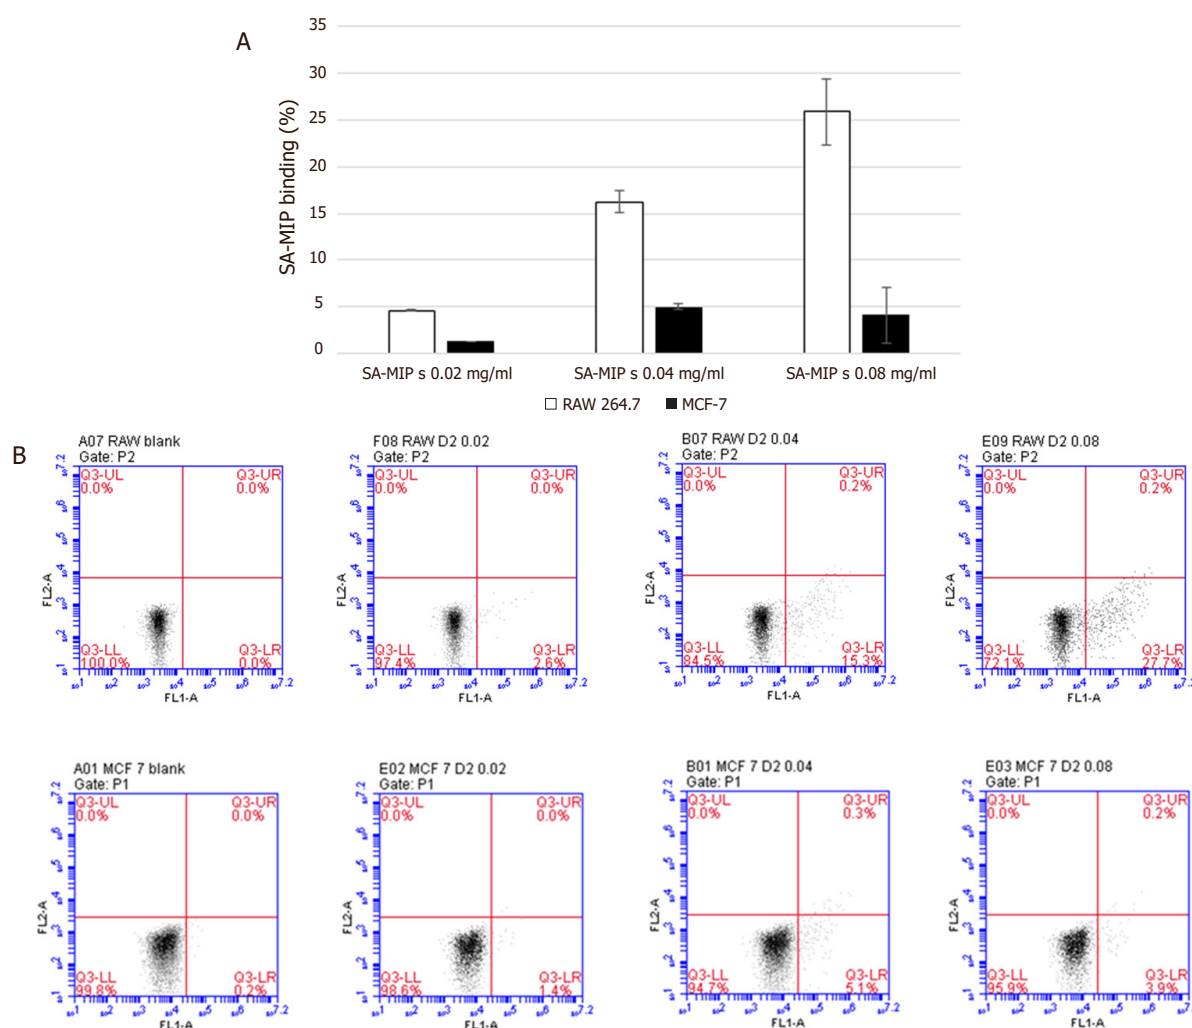

Figure 1. SA-MIP binding to RAW 264.7 cells and MCF-7 cells. A: Results of cells RAW 264.7 cells and MCF-7 cells stained with different concentrations of SA-MIP. B: Flow cytometry diagrams present the positive cells for SA-MIP concentrations 0.02, 0.04 and 0.08 mg/mL, as dot-plot diagrams, respectively. The experiment shown in A represents the average of least three performed

RESULTS

Evaluation of SA-MIP binding to MCF-7 and RAW 264.7 cells

The breast cancer cell line MCF-7 and the macrophage cell line RAW 264.7 were tested for SA-MIP binding at different concentrations. Addition of increased concentration of SA-MIP resulted in higher SA-MIP binding [Figure 1A]. At the highest concentration of SA-MIPs used, 0.08 mg/mL, the staining result was around 5% cell binding for MCF-7 cells and 65% cell binding for RAW 264.7 cells. The dot-plot diagrams for RAW 264.7 cells (Upper figures) and MCF-7 cells (Lower figures) are shown in Figure 1B.

SA-specific lectins show an increased binding to MCF-7 and RAW 264.7 cells after treatment with a cytokine cocktail

First, the expression of SA on the cell lines were confirmed by using the lectins MAL I and SNA [Figure 2]. Then, the cells were treated with the cytokine cocktail from PHA-stimulated Jurkat cells, and a significant increased binding of the lectins could be detected in both cell lines [Figure 2].

Cytokine treated MCF-7 and RAW 264.7 cells show a variation in SA-MIP binding

Both cell lines were treated with the recombinant cytokines IL-4, IL-6 or IL-8. Alternatively, the cytokine cocktail from PHA-stimulated Jurkat cells was used. For the RAW 264.7 cells, treatment with IL-4 showed

Figure 2. Lectin binding to RAW 264.7 cells and MCF-7 cells. Results of cells RAW 264.7 cells and MCF-7 cells stained with the MAL I and SNA lectins. Flow cytometry results present the mean fluorescence intensity for the lectins and a small increase in binding of the lectins after treatment with the cytokine cocktail. The experiment shown represents the average of least three performed

Figure 3. Flow cytometry of cytokine-treated RAW264.7 cells showing increase in SA-MIP binding after IL-4, IL-6, IL-8 or cocktail treatment. Results of cells RAW 264.7 cells and MCF-7 cells stained with SA-MIP. Flow cytometry results were re-calculated to fold change of response compared to control. The experiment shown represents the average of least three performed

an increase in SA-MIP binding in both cell lines, whereas IL-6 and IL-8 showed an even larger decrease [Figure 3]. The cytokine cocktail with unknown content influenced the SA-MIP binding in a similar manner as IL-6 and IL-8. All additions of cytokines to RAW 264.7 cells were found to be significantly different from the control, as determined by statistical calculations.

For the MCF-7 cell line, addition of the recombinant cytokines IL-4, IL-6 or IL-8 did not influence any increase of SA-MIP binding to the cells [Figure 3]. No statistical significant difference could be determined for cytokine treatment of MCF-7 cells. However, addition of the cytokine cocktail induced a 2-fold significant increase of SA-MIP binding in MCF-7 cells. To elucidate the cytokine content in the cocktail, ELISA was performed.

Table 1. Cytokine content in PHA-stimulated Jurkat cells was analyzed with sandwich ELISAs detecting IL-2, IL-6, IL-8 and TNF-, respectively

Cytokines analyzed with ELISA in PHA-stimulated Jurkat cell sample	Cytokines detected (pg/mL)
IL-2 negative control	0
IL-2 stimulated sample	17
IL-4 negative control	n.d.
IL-4 stimulated sample	n.d.
IL-6 negative control	0
IL-6 stimulated sample	0
IL-8 negative control	0
IL-8 stimulated sample	427
TNF-negative control	0
TNF-stimulated sample	12

PHA-stimulated Jurkat cells produce high amounts of IL-8

The supernatants from stimulated and unstimulated Jurkat cells were investigated with sandwich ELISA specific for IL-2, IL-6, IL-8 and TNF- respectively [Table 1]. The levels of IL-2 and TNF- were low, but showed an increase compared to control. In contrast, more than 400 pg/mL of IL-8 was detected in the PHA-stimulated Jurkat cell supernatant. No IL-8 could be detected in the unstimulated control. IL-6 could not be detected in either stimulated or unstimulated samples.

DISCUSSION

In the tumor microenvironment, the cells of the immune system communicate with each other by releasing chemokines and cytokines to either favor antitumor immunity or enhance tumor progression. Thereby the cells control the immune and inflammatory milieu in a sophisticated fashion.

In this study we demonstrate that the SA-expression of RAW 264.7 and MCF-7 cells treated with recombinant cytokines *in vitro* could be analyzed with the use of SA-MIPs and flow cytometry. Interestingly, the cytokine-treated cells showed a modulated SA-MIPs binding pattern compared to the unstimulated controls. Stimulating macrophage RAW264.7 cells with IL-4, IL-6 or IL-8 cause an up-regulation of SA-MIP binding, while for the MCF-7 cells no increase could be determined. The effect of inflammatory cytokines on pancreatic cancer cells has been reviewed by Roshani *et al.*^[1]. In other studies, IL-4 did not have any effect, but IL-6 and IL-8 were associated with poor prognosis and increased aggressiveness, respectively. IL-4 is an anti-inflammatory cytokine expected to down-regulate SA, while IL-6 and IL-8 both up-regulate the SA expression. Indeed, IL-6 and IL-8^[15-17], as well as anti-inflammatory cytokines IL-10 and tumor growth factor-beta (TGF- β)^[15,18,19] have been commonly shown to be elevated in pancreatic patients. Also, TNF- and IL- were upregulated compared to controls, but all studies in pancreatic cancer patients did not come to the same conclusions^[1]. Other studies have proven that the levels of IL-4, IL-6 and IL-8 in pancreatic cancer patients is higher than normal^[15]. An important remark is that the pattern of cytokine expression varies between studies and even contradicting results have been obtained. Bassaganas *et al.*^[20] studied pancreatic ductal adenocarcinoma cell lines treated with different cytokines. They found that treatment with either IL-1 or IL-6 resulted in an increased carbohydrate antigen and SA level. Also, the levels of mRNA of precursor of carbohydrate antigens was enhanced. Moreover, Dima *et al.*^[19] found an association between higher levels of circulating TNF- α with poorer prognosis. These findings indicate that inflammatory cytokines can be pursued as potential prognostic biomarkers as well as therapeutic targets.

Escaping immune recognition is now a recognized hallmark of cancer^[21]. Chemokines and cytokines can play a critical role in the immune evasion. Tumor cells can escape host immunity by producing immunosuppressive cytokines as well as by recruiting regulatory immune cells with immunosuppressive functions.

The cellular expression pattern of glycosyltransferases and Lewis antigens detected in the normal mucosa can change during neoplastic transformation. The stomach mucosa was investigated for Lewis antigens in the presence of pro-inflammatory cytokines^[4]. The level of one type of Lewis antigen decreased after treatment with IL-1 or IL-6, whereas the levels of other carbohydrate antigens were unaffected^[4].

Lectins are plant-derived macromolecules specific for carbohydrate moieties. The MAL lectin specifically bind the sialyl α 2,3 Gal β 1,4GlcNAc/Glc trisaccharide sequence^[22]. Expression of α 2,3-SA residues of N-cadherin was shown to be altered in metastatic melanoma cell lines^[23]. The expression of α 2,3-SA residues in breast cancer using MAL-staining were analyzed by Cui *et al.*^[24] The results suggested that high levels of α 2,3-SA residues was closely associated with lymph node metastasis and invasive depth in breast cancer patients. The highly metastatic breast cancer cell line MDA-MB-231 had higher expression of α 2,3-sialic acid residues compared to T-47D and MCF-7 depending on the mRNA levels of α 2,3-ST genes. Indeed, the tumor microenvironment can direct the level of inflammation. Also, the metastatic potential and malignancy of cancer cells is closely associated with aberrant sialylation pattern^[24].

The enzyme that adds α 2-6linked sialic acids, β -galactoside α 2-6 sialyltransferase (ST6Gal-I), is known to be upregulated in many tumor types including colon adenocarcinomas^[25], and high expression levels have been associated with poor prognosis and metastasis. ST6Gal-I sialylation of membrane glycoproteins contributes to metastasis by enhancing cell motility and invasion through the extra cellular matrix (ECM). Increased negative charged properties of sialic acids was correlated with reduced adhesiveness of tumor cells and may be suitable for conformational change of integrin and enhances its function in cell-ECM interactions^[26].

Interestingly, in our study we show a high expression of α 2,3-SA on both cell lines, whereas the α 2,6-SA, as analyzed with the lectin SNA, displayed a lower expression on the MCF-7 cells. It has been shown that high levels of sialylation of cell surface glycoconjugates can significantly increase metastasis of colon carcinoma cells and human melanoma cells.

In addition to directly modulating cell motility, α 2,3-SA residues are involved in the synthesis of sialyl Lewis X determinants, which are the major ligands for endothelial E-selectin^[27]. The sialyl Lewis X structure on malignant cells is suggested to facilitate tumor cell dissemination by mediating the tumor-endothelial cell interactions^[28,29]. Overall, many studies support the hypothesis that an increase of sialylation of cancer cells play an important role in tumor metastasis.

In the present study, the MCF-7 cell line showed a small increase of the SA-MIP binding after treatment with the cytokine cocktail derived from PHA-stimulated Jurkat cells. On the other hand, the SA-MIP binding when treating the RAW264.7 cell line with the same cocktail was not different compared to the effect of recombinant IL-6 or IL-8. Interestingly, an increase in binding of the lectins MAL and SNA was also detected after cytokine cocktail treatment. By analyzing with ELISA, we show that the cocktail contains increased amounts of IL-8, as well as low levels of IL-2 and TNF- α . IL-6 could not be detected in the PHA-stimulated samples. IL-8 is a chemokine, functioning by attracting cells to a site of infection, and it is therefore tempting to speculate that the increased SA-MIP binding seen by the RAW264.7 cells, could be due to a regulated SA-expression in response to IL-8. The natural ligands for SA are selectins and siglecs^[30]. Indeed, the rolling of cancer cells ectopically expressing the selectin ligands on endothelial cells is potentially a crucial step favoring the metastatic process *in vivo*^[31]. The combined analysis of SA and the targeting of SA to the ligands selectins and siglecs will be attractive for further investigations.

In conclusion, cancer cell migration and invasion is controlled by protein glycosylation and the ECM. SA is one of several important players in this crucial process. Inflammation and cytokine production will modulate the cellular microenvironment. We have studied cell lines *in vitro* that showed that one of the cell

lines showed a significantly increased binding of the SA-MIPs after treatment with recombinant cytokines and with the cytokine cocktail from PHA-stimulated Jurkat cells. Here we demonstrate that SA-MIPs can be an important tool in the investigation of overexpressed glycans in the tumor microenvironment.

DECLARATIONS

Authors' contributions

Made substantial contributions to conception and design of the study and performed data analysis and interpretation: Zhang Y, Llapashtica K, Wingren AG

Abstract

Aim: Exon 18 expression of NCAM has been recognized as a biomarker for small cell lung cancer (SCLC). To use this finding for an improved diagnosis of SCLC and personalized treatment of patients, techniques to identify and quantitate E18, the exon 18 encoded protein moiety of NCAM, are needed. We developed three monoclonal antibodies for this purpose.

Methods: The his-tagged E18 antigen was expressed in *E. coli* and, after purification, used to immunize mice. Hybridoma's were isolated by standard procedures and tested for their reaction with E18.

Results: Three monoclonal antibodies, MUM-1, MUM-4 and MUM-6 were obtained. They reacted with E18 in western blots, with SCLC cell line NCI-H82, but not with unrelated his-tagged proteins. Only permeabilized NCI-H82 cells stained with the antibodies, confirming the intracellular position of E18. Next an enzyme-linked immunosorbent assay was developed using the earlier isolated monoclonal antibody MUMi-21B2, coated on the surface of microtiter wells as capture antibody and biotinylated MUM-6 as second antibody. Using streptavidin conjugated to horse radish peroxidase a linear dose response curve to his-tagged E18 antigen was obtained between 0 and 5 µg/mL with a sensitivity of at least 0.5 µg/mL or 50 ng/well.

Conclusion: Four monoclonal antibodies are available to be used in assays for the identification and quantification of SCLC biomarker E18. This will enable the development of liquid biopsies to follow the tumor load in patients.

Keywords: Small cell lung cancer, tumor biomarker, monoclonal antibodies, NCAM exon 18

INTRODUCTION

Small cell lung cancer (SCLC) is strongly associated with smoking. It is a very aggressive form of cancer due to resistance to chemotherapy and rapidly dividing metastatic disseminations. SCLC represent about 15% of all lung cancer cases and annually kills about 250,000 people^[1]. At the initial diagnosis metastatic lesions are already present in about two thirds of the patients^[2]. Patients die as a result of the disease at a median of 10 to 12 months after diagnosis^[3]. Over many decades survival rates have not improved^[4]. SCLC is a neuroendocrine tumor. There are three other types of neuroendocrine lung tumors [Table 1]. A hallmark of these tumors is the presence of neuroendocrine peptides such as NCAM. NCAM is expressed as 120, 140 and 180 kDa isoforms, all derived through alternative splicing from a single gene. NCAM has been described as a biomarker for SCLC, but is also present on other cell types^[5].

Biomarkers for SCLC could lead to an important improvement in the treatment of SCLC. These markers could be used to monitor the tumor load in patients, allowing early diagnosis and monitoring the effect of therapeutic interventions. We recently described the expression of NCAM exon 18 as a potential biomarker for SCLC^[5]. More recently we have further validated this biomarker. More SCLC biopsies were tested. These were all positive for NCAM exon 18 expression. Expression was also found in large cell neuroendocrine carcinoma (LCNEC) (unpublished data). In this paper we describe the generation and characterization of monoclonal antibodies directed to E18, the exon 18 encoded moiety of NCAM. We intend to use these antibodies for the quantification of E18 in extracellular vesicles present in the blood of SCLC patients.

METHODS

Production of monoclonal antibodies

Preparation of antigen

Recombinant his-tagged E18 was prepared in *E. coli*, using a plasmid with a codon usage optimized for *E. coli* (GeneArt/Thermo Fisher Scientific), and purified on a Ni²⁺-NTA agarose column and E18-encoding DNA was cloned into the pCI mammalian expression vector as described^[5].

Immunization of mice and preparation of hybridoma's

Three Balb/c mice were immunized 4 times. At zero time intramuscularly with 2 times 50 µg in 50 µL of the pCI vector containing E18-encoding DNA and at 3 and 8 weeks subcutaneously with 10 µg his-tagged E18 and 12 µg (in 25 µL) AbISCO-100 (Isconova, Sweden). The final immunization was at 10 weeks with 10 µg his-tagged E18 without adjuvant subcutaneously and the same amount intraperitoneally. Three days after the last immunization spleen cells were isolated and fused with SP2/0 myeloma cells according standard procedures^[9]. Cells were plated in nine 96 well microtiter plates.

Screening and characterization

The supernatants of the microtiter wells were tested in an enzyme-linked immunosorbent assay (ELISA) as described^[5]. Wells were coated with his-tagged E18 or an unrelated his-tagged protein. This resulted in 6 candidates positive for E18 and negative for unrelated his-tagged proteins. These hybridoma's were subcloned and characterized by four methods. First, an ELISA was carried out on full length E18 and a shortened version of E18 (Supplementary Figure 1 by Vander Borghet *et al.*^[5]). Second, immunohistochemistry on SCLC cell line NCI-H82 and control cell line HCT116. Third flow cytometry of intact and permeabilized NCI-H82 cells and last western blotting. Experimental details can be found in the study by Vander Borghet *et al.*^[5]. Isotyping was carried out with the MMT1 kit of AdD Serotec (presently Biorad).

Table 1. Neuroendocrine tumors of the lung

Name	Smoking-associated	% of all cases of lung cancer	Overall Survival 5 y	Mitotic index*	Ki-67 index [#]
SCLC	Yes	15-20	< 5%	Median = 80	50%-100%
LCNEC	Yes	3	15%-57%	Median = 70	40%-80%
TC	No	1-2	92%-100%	< 2	< 5%
AC	No	0.1-0.2	61%-68%	2-10	< 20%

Data from Ref.[6,8]. *Measure for rate of cell division; [#]Ki-67 is a marker protein for cell division. SCLC: small cell lung cancer; LCNEC: large cell neuroendocrine carcinoma; TC: typical carcinoid; AC: atypical carcinoid.

**Figure 1.** Reaction of monoclonal antibodies MUM-1, MUM-4 and MUM-6 with (truncated) E18 measured by an ELISA

Setting up of an ELISA

An ELISA was set up, using one antibody coated to the microtiter wells as a capture antibody and a second biotinylated antibody for detection. The best combination of antibodies was MUMi-21B2 as a capture antibody and MUM-6 as second antibody. Full experimental details can be found in [Supplementary Figure 1](#).

RESULTS

Three monoclonal antibodies, MUM-1 (IgG1 kappa), MUM-4 (IgG1 kappa) and MUM-6 (IgG1 lambda), were fully characterized and produced. The ELISA confirmed that they all react with E18. MUM-6 also reacted with the truncated form of E18 that was used to generate MUMi-21B2 [\[Figure 1\]](#).

The monoclonal antibodies were also tested in immunohistochemistry assays on SCLC cell line NCI-H82 and control colon carcinoma cell line HCT116. In comparison antibody RNL-1, directed to an extracellular part of NCAM, was used. [Figure 2](#) shows the results for MUM-4 and MUM-6. A strong reaction of RNL-1 to NCI-H82 cells and no reaction to HCT116 cells that lack NCAM is seen. The signal with MUM-4 and MUM-6 is weaker but clearly present. A stronger signal was obtained when the cells were permeabilized with 4% paraformaldehyde/0.5% triton X-100 (data not shown). Intact cells did not stain with the MUM-1, MUM-4 and MUM-6. This could be demonstrated most convincingly by flow cytometry. The results for MUM-1 are shown in [Figure 3](#).

DISCUSSION

The further validation of NCAM exon 18 expression in cancer cells is ongoing. More SCLC and LCNEC biopsies will be analyzed. These are the two most aggressive neuroendocrine lung cancers, but it will be also of interest to analyze the milder [\[Table 1\]](#) “typical carcinoid” and “atypical carcinoid”. However, our focus

Figure 2. Immunohistochemistry of SCLC cell line NCI-H82 and colon carcinoma cell line HCT116. The results for MUM-4 and MUM-6 are shown, together with the staining with RNL-1, a monoclonal antibody directed to an extracellular part of NCAM. Cells were permeabilized with methanol/acetone as described^[5] or, for the MUM-6 panel, with 4% paraformaldehyde (15 min) and 0.5% Triton-X100 (10 min)

Figure 3. Reaction of MUM-1 with SCLC cell line NCI-H82 measured with flow cytometry. Methanol/acetone permeabilized cells were compared with intact cells. A signal was only found in permeabilized cells. This difference was not found with antibody RNL-1 directed to an external region of NCAM

will be on clinical applications of E18 as a biomarker for SCLC. A main problem in the treatment of SCLC is that patients initially respond well to first line chemotherapy, even in advanced disease, but most patients relapse within 6 months. Promising alternative targeted and immune therapies have been identified^[10-12], but due to the rapid progression of the disease the time window to study these alternatives is limited. Ideally clinical treatment should be guided by closely monitoring the evolution of the disease^[12,13]. Our assumption is that the presence of E18 will reflect the tumor load. We intend to develop methods to analyze the presence of E18 in liquid biopsies. Serial sampling would give information on disease burden, responses to treatment and on disease relapse. Promising results have been obtained with circulating tumor cells (CTCs)^[14], but there is a large variation in CTC numbers and heterogeneity in the expression of NCAM^[14]. Our present strategy is to use tumor derived extracellular vesicles (EVs) as a correlate of tumor load. EVs are constantly formed by cells, either from endosomal membrane compartments (exosomes) or from the

Figure 4. Strategy for the isolation of extracellular vesicles (EVs) derived from SCLC cells. SCLC-specific EVs are enriched and purified by RNL-1 and/or 123C antibodies, specific for the extracellular moiety of NCAM^[19-21], coupled to magnetic beads. In the next step the presence of E18 in the EVs will be measured with one of the specific antibodies. We will choose the antibody with the best signal to noise ratio

plasma membrane. The membranes of EVs contain in principle all cellular surface proteins and, within the membrane, all cytoplasmic components^[15]. Virtually all SCLC cells express NCAM^[16,17]. We will enrich for NCAM-containing EVs, using immunoaffinity capture methods^[18] [Figure 4].

Abstract

Estrogen disrupting chemicals are environmental compounds which mimic, antagonize or interfere in the action of physiological estrogens. They occur naturally (plant phytoestrogens) but the majority are man-made compounds, which, through their use in agricultural, industrial and consumer products, have become widely present in human tissues including breast tissue. Since exposure to estrogen is a risk factor for breast cancer, estrogen disrupting chemicals may also contribute to breast cancer development. This review discusses evidence implicating estrogen disrupting chemicals in increasing migratory and invasive activity of breast epithelial cells, in epithelial-to-mesenchymal transition, and in growth of breast tumours at metastatic sites as well as the primary site. Mechanisms may be through the ability of such chemicals to bind to estrogen receptors, but unlike for proliferation, effects on cell migration and invasion are not limited to estrogen receptor-mediated mechanisms. Furthermore, whilst effects on proliferation can be measured within hours/days of adding an estrogen disrupting chemical to estrogen-responsive breast cancer cells, effects on cell migration occur after longer times (weeks). Most studies have focused on individual chemicals, but there is now a need to consider the environmentally relevant effects of long-term, low-dose exposure to complex mixtures of estrogen disrupting chemicals on mechanisms of metastasis.

INTRODUCTION

Estrogen disrupting chemicals are exogenous environmental compounds that can interfere in the action of endogenous estrogens. Through their ability to bind to estrogen receptors, they may be able to mimic or antagonize the cellular actions of physiological estrogens^[1]. They may also influence synthesis, transport, metabolism and clearance of physiological estrogens^[1]. Some are found naturally in plants (phytoestrogens) or fungi (mycoestrogens), but the majority are man-made compounds to which the human population is widely exposed through their use in agricultural, industrial and consumer products^[1]. Such compounds are used as components of pesticides and herbicides in agricultural, urban and domestic environments. They are widely used in industrial applications and occur as byproducts of combustion from vehicles, aircraft and ships. These compounds are found as components in plastics, with applications from building materials to food/water containers, in detergents used for cleaning in industrial and domestic settings, and as flame retardants in soft furnishings. A range of components added to personal care products are also now known to possess estrogen disrupting activity^[1]. Some more specific examples are shown in Table 1. Intake to the human body may be by the oral route (food/water) or inhalation (air pollution) or dermal absorption (products applied to skin or present in the air). So ubiquitous are the many estrogen disrupting chemicals in modern life that exposure is almost never from a single source but rather from multiple sources reflecting not only occupational exposures but also personal lifestyle choices.

Since exposure to estrogens is an established risk factor for breast cancer^[2], it is thought that estrogen disrupting chemicals may also contribute to breast cancer development if they are present in human breast tissue at sufficient concentrations^[1]. Development of cancer is a lengthy and complex process, that originates from a loss of growth control, and culminates in metastatic tumour spread. Both genetic and environmental influences interact to enable the associated hallmarks of cancer to develop^[3]. The hallmark of sustained cell proliferation in breast cancer is well established as involving estrogens^[4] and probably also estrogen disrupting chemicals^[5]. Since metabolism of some endogenous estrogens gives rise to genotoxic compounds^[6] and since some estrogen disrupting chemicals are also genotoxic^[1], a role has been recognized in generating genomic instability which is an underlying enabling characteristic of cancer^[3]. However, the role of endogenous and exogenous estrogens in contributing to the processes of metastatic tumour spread are less well established. This is especially important in the context of breast cancer where the main cause of mortality arises from growth of metastatic tumours^[2,7]. This review will discuss current evidence suggesting that endogenous and exogenous estrogens can contribute to increasing migratory and invasive activity of breast epithelial cells which are hallmarks of cancer required for the metastatic process^[3].

ENDOGENOUS ESTROGENS AND METASTASIS

Cellular actions of estrogens are mediated through binding to specific receptor proteins^[8]. There are two types of nuclear estrogen receptors, estrogen receptor α (ER α) and estrogen receptor β (ER β) which exist as multiple isoforms and which function as ligand-activated transcription factors to influence patterns of gene expression^[8]. Final outcomes are dependent on the affinity of ligand binding to receptor, the concentrations of receptors in the target cells and the presence of co-acting factors/transcription factors^[8]. In addition, estrogenic ligands can also act through binding to membrane-associated molecules such as the G-protein-coupled estrogen receptors^[8,9].

Metastasis involves a complex series of events whereby the malignant cells break away from the primary tumour, invade through local tissue, infiltrate circulatory vessels (blood and/or lymph) and at distant sites exit the vessels to form new foci of cancer cell growths (colonization)^[7]. Endogenous estrogens can influence all these processes including immune evasion and the angiogenesis needed for effective metastatic colonization^[10]. In their capacity to regulate growth of estrogen-responsive human breast cancer cells^[2,4], estrogens can influence metastatic tumour growth at both the primary and secondary sites^[2].

Table 1. Estrogen disrupting chemicals: example compounds, uses in the environment, and sources of human exposure

Use in the environment	Example compounds	Source of human exposure
Plant phytoestrogens	Genistein, daidzein	Edible plant material (diet, dietary supplements)
Pharmaceuticals	Ethinylestradiol	Contraceptive pill, hormone replacement therapy, cosmetics
Pesticides	DDT, lindane, pyrethroids	Pesticide products, animal fat (diet)
Herbicides	Glyphosate	Garden weedkillers
Industrial	Polychlorinated biphenyls	Animal fat (diet)
By-product of incineration	Polychlorinated dioxins	Inhaled; animal fat in diet
Flame retardant	Polybrominated organics	Domestic environment from use on soft furnishings
Plastics, epoxy resins	Bisphenol A	Storage of food and beverages (diet); domestic environment
Plastics	Phthalate esters	Domestic consumer products
Detergent	Alkyl phenols	Domestic environment
Preservative	Parabens	Personal care products, food, pharmaceuticals
Antiperspirant	Aluminium chlorohydrate	Underarm antiperspirants
Antimicrobial	Triclosan	Personal care products, domestic consumer products
Absorb ultraviolet light	Benzophenones	Suncare products, other cosmetics, clothing
Fragrance	Butylphenylmethylpropional, benzyl salicylate, musks	Personal care products, domestic consumer products
Conditioning/spreading agent	Cyclic volatile methylsiloxanes	Personal care products
Cigarettes	Cadmium	Cigarette smoking

DDT: dichlorodiphenyltrichloroethane

However, endogenous estrogens are also now known to be able to influence cell motility, cell migration and invasive behavior of human breast cancer cells through altering expression of proteins and transcription factors key to the process of epithelial to mesenchymal transition (EMT). EMT is a process in which the epithelial cells lose their polarity and strong cell-cell adhesion properties in order to assume a more mesenchymal phenotype lacking the polarization and the strong cell-cell interactions. The cell adhesion junctions of epithelial cells are reliant on high levels of E-cadherin which is a transmembrane protein linked to the cytoskeleton by α - and β -catenin, and EMT is typically associated with reduction in levels of these adhesion proteins. It is also associated with altered levels of transcription factors (such as slug and snail) which control expression of the adhesion proteins^[7]. This allows the cells to break away from neighbouring cells and to become generally more motile. Human breast cancer cell lines which possess ER α (ER α +) tend to be less invasive, less metastatic and possess higher levels of E-cadherin than those which lack ER α (ER α -)^[11]. Knockdown of ER α in the ER α + cell lines has been shown to result in decreased E-cadherin and increased slug expression^[12]. Conversely, transfected overexpression of ER α in the ER α - cell lines has been shown to enable estrogen-mediated increase in E-cadherin and decrease in slug^[12]. In the ER α + MCF-7 human breast cancer cell line, estradiol can increase EMT whilst the antiestrogen tamoxifen can reduce EMT^[13] suggesting that the mechanism is ER-dependent. However, there appear to be multiple molecular mechanisms involving not only genomic alterations to levels of E-cadherin and associated transcription factors such as slug^[12] but also non-genomic alterations via c-src and phosphorylation of focal adhesion kinase^[14,15].

In order to facilitate invasion through local tissue, the cells need also to secrete greater levels of extracellular proteases which aid in the digestion of the surrounding extracellular matrix (ECM). Some of the extracellular proteases identified specifically in human breast cancer cells are matrix metalloproteinases (MMPs)^[16,17] and cathepsin D^[18]. It is notable that one of the first estrogen-regulated genes to be identified was cathepsin D^[19] and studies now also show effects of estrogen on expression of MMPs^[16]. These studies attest to the role of estrogen in altering proteases which can degrade the ECM.

Estrogens are also known to play a role in the processes of angiogenesis^[10,20]. Vascular endothelial growth factor (VEGF) is a key angiogenesis promoting factor and the VEGF gene has been shown to possess functional estrogen response elements indicating it is an estrogen-responsive gene^[21]. Estrogen treatment

has also been reported to increase intra-tumoural angiogenesis^[22] and VEGF levels^[23] in mouse models of breast cancer.

ESTROGEN DISRUPTING CHEMICALS AND METASTASIS

On the basis that endogenous estrogens can influence processes necessary for metastasis, it would seem plausible that estrogen disrupting chemicals will also contribute if they can enter breast tissue and target metastatic tissues at sufficient concentrations. Whilst endogenous estrogens are subject to physiological regulation in terms of both concentration and timing, it is noteworthy that the estrogen disrupting chemicals are not regulated in this manner. The presence of estrogen disrupting chemicals in the body will follow rather intake from environmental exposures balanced by rates of elimination and ability of individual chemicals to bioaccumulate. Many estrogen disrupting chemicals tend to be lipophilic accumulating in body fat over the years such that body burdens increase with age^[1]. In this context it may be significant that 80% of breast cancers occur in women over the age of 50^[24] at a time when endogenous estrogens are reduced following menopause but exogenous estrogen disrupting chemical body burdens would be continuing to increase.

Estrogen disrupting chemicals and metastatic colonisation

Metastasis of breast cancer cells begins with local spread within the breast and to the underarm lymph nodes. The pattern of more distant dissemination is less predictable with preferred sites of colonization being brain, bone, lungs and liver^[7]. Stephen Paget's original "seed and soil" hypothesis proposed that preferred sites of metastasis would reflect a favourable organ microenvironment in which the metastatic breast cancer cells could grow^[25]. His hypothesis was based on the tenet that "when a plant goes to seed, its seeds are carried in all directions, but they can only live and grow if they fall on congenial soil". For breast cancer cells, one important favourable element for cell growth would be an "estrogenic" environment and it is in this context that estrogen disrupting chemicals may influence sites of metastatic spread. Estrogen disrupting chemicals have been widely measured in human populations across the globe in body fluids such as blood and urine and in various body tissues^[1]. With such widespread contamination of the human body, it is becoming accepted that there are ramifications for human health including effects on male and female reproduction and on cancers in reproductive tissues^[1]. The presence of estrogen disrupting chemicals across many body tissues could act to change a previously non-favourable location into a favourable environment for colonization and growth of human breast cancer cells into metastatic tumours.

Evidence for effects of estrogen disrupting chemicals on the metastatic process

There is now mounting evidence for effects of the parabens, ultraviolet (UV) filters, aluminium salts, triclosan, phthalates, bisphenol A (BPA), dioxins and phytoestrogens in the processes of EMT, motility, migration and invasion, and relevant studies of breast cells are discussed below. Most studies to date have been based *in vitro* but there are some animal models which demonstrate measurable effects also *in vivo*. Many of the mechanisms may involve mimicking the action of endogenous estrogens through the ability of these estrogen disrupting chemicals to bind to estrogen receptors, but unlike for proliferation, the effects on migration and invasion do not seem to be limited to ER-mediated mechanisms. Furthermore, whilst effects on proliferation can be measured within hours/days of adding an estrogen disrupting chemical to estrogen-responsive breast cells, effects on migration tend to occur after a longer time frame of weeks. The reasons why the time taken is longer remain unknown but would be important to determine in future research.

Parabens

The alkyl esters of *p*-hydroxybenzoic acid (parabens) are added as preservatives to personal care products, pharmaceuticals and foods^[1]. Of the five commonly used esters (methylparaben, ethylparaben,

n-propylparaben, *n*-butylparaben and isobutylparaben) 99% of the human breast tissues were found to contain at least one of the esters, and 60% contained all five esters^[26]. Although the parabens bind more weakly to estrogen receptors than do the endogenous estrogens, their efficacy is not weak provided sufficient concentration is present^[27]. It is therefore noteworthy that the concentrations of parabens measurable to human breast tissues are considerably higher (in the micromolar range)^[26] than the levels of endogenous 17 β -estradiol (in the nanomolar range)^[2,28]. Previous work has demonstrated that parabens can increase proliferation of estrogen-responsive human breast cancer cells in cell culture at concentrations measurable in some human breast tissue samples^[29] through estrogen receptor-mediated mechanisms^[27]. However, parabens have now been found to also increase migratory and invasive activity of human breast cancer cells in culture^[30]. Migratory activity was measured using scratch assays, time-lapse microscopy and xCELLigence technology^[30]. Invasive activity was measured using matrix degradation assays and invasion through matrigel on the xCELLigence system^[30]. Unlike the proliferative effects which were measurable within days of addition of the parabens^[27,29], the increased migratory and invasive properties only developed in the cells after long-term exposure (20 weeks)^[30]. Western immunoblotting showed an associated downregulation of E-cadherin and β -catenin in the long-term paraben-exposed cells, which could be consistent with a mechanism involving EMT^[30].

One technology which has been particularly useful in determining adhesion, migration and invasion of breast cells following exposure to estrogen disrupting chemicals has been the ACEA BioSciences xCELLigence technology, and the increased cell migration following long-term exposure of MCF-7 human breast cancer cells to paraben which was measured using this technology is shown in Figure 1A. This technology works on the basis of a modified Boyden chamber in which two chambers are separated by a membrane. Migration of cells through the membrane on the base of the upper chamber can be monitored in real time at any pre-determined time interval as the cells move onto the undersurface of this membrane located at the top of the lower chamber. The CIM-plate-16 contains 16 wells which can be monitored independently but simultaneously to measure cell migration/invasion in real time through 8 μ m pores in the membrane onto gold electrodes on the underside of the membrane using the ACEA BioSciences xCELLigence analyser system. Cell movement onto the gold electrodes is measured as electrical impedance (cell index). Collated traces of cell index are shown in Figure 1A for cell migration through uncoated membranes following 20 weeks of prior treatment with or without 5×10^{-4} M methylparaben or 10^{-5} M *n*-butylparaben (conditions as published in reference 30).

UV filters

Chemicals which can absorb UV light (UVA and/or UVB) are added to consumer products either to protect the skin of the user from UV damage (sunscreen products) or to protect the product itself from UV damage during storage^[31]. They are also used in textiles marketed as UV protective clothing^[32]. Widespread use of benzophenone-3 (BP-3), octylmethoxycinnamate (OMC) and 4-methylbenzilidenecamphor (4-MBC) has led to their detection in environmental water and soil samples^[33] and they have been recently also measured as present in human breast tissues^[34]. One or more of these UV filters were quantifiable in 84% of the breast tissue samples and in at least one breast region of 95% of the women^[34]. BP-3, OMC and 4-MBC all possess estrogenic activity in reporter gene assays in estrogen-responsive MCF-7 human breast cancer cells^[31,35]. Long-term exposure (23 weeks) to any one of these three compounds has now also been found to increase migratory activity in MCF-7 cells using scratch assays, time-lapse microscopy and xCELLigence technology, and to increase invasion through matrigel as measured using xCELLigence technology^[35]. The increased cell migration following long-term treatment (23 weeks) of the MCF-7 cells with or without 10^{-5} M of BP-3 or OMC is shown in Figure 1B using xCELLigence technology (conditions as published in reference 35). However, increased motility of estrogen-unresponsive MDA-MB-231 human breast cancer cells was also observed after long-term exposure to each of the three compounds, implying the increased migratory activity was not confined to estrogen responsive cells^[35]. Furthermore, molecular mechanisms

Figure 1. Increases in migration of MCF-7 human breast cancer cells following prior long-term exposure to several estrogen disrupting chemicals contained in personal care products. Cell migration was measured in real-time as electrical impedance (cell index) using xCELLigence technology with uncoated CIM-16 plates. Prior to the assay, cells had been grown: A: for 20 weeks with no addition, 5×10^{-4} M methylparaben or 10^{-5} M n-butylparaben; B: for 23 weeks with no addition, 10^{-8} M 17β -estradiol, 10^{-5} M octylmethoxycinnamate or 10^{-5} M benzophenone-3; C: for 32 weeks with or without 10^{-4} M aluminium chlorohydrate; D: for 9 weeks with or without 10^{-7} M triclosan. Conditions were as published for the parabens^[30], UV filters^[35], and aluminium chlorohydrate^[42]. Data for triclosan are unpublished personal results. UV: ultraviolet

differed between compounds and cell lines, with a noted loss of β -catenin only after long-term exposure to OMC in the MCF-7 cells and an increase in MMP-2 after long-term exposure to OMC and 4-MBC in the MDA-MB-231 cells^[35].

Aluminium-based antiperspirant salts

Aluminium-based salts are used as antiperspirant in underarm cosmetics and dermal absorption of aluminium from this use has been implicated in the development of breast cancer^[36]. Aluminium has been measured in human breast tissue^[37] and breast cyst fluid^[38] at higher levels than in blood, and in nipple aspirate fluid at higher levels in samples taken from women with than without breast cancer^[39]. Aluminium, as well as several other metal ions, is a metalloestrogen^[40] and in the form of the antiperspirant salts aluminium chloride or aluminium chlorohydrate it can displace radiolabeled 17β -estradiol from estrogen receptors and regulate estrogen-responsive gene expression^[41]. However, aluminium has also been shown to increase migratory and invasive activity of human breast cancer cells, although since effects were found not only in estrogen-responsive MCF-7^[42] but also estrogen-unresponsive MDA-MB-231^[43] cells, estrogen-independent mechanisms of action must also exist. The increased cell migration following long-term (32 weeks) treatment of MCF-7 cells with or without 10^{-4} M aluminium chlorohydrate are illustrated in Figure 1C using xCELLigence technology (conditions as published in reference 42). More recent animal model research has shown that non-transformed murine mammary gland (NMuMG) epithelial cells exposed to aluminium chloride *in vitro* were transformed as judged by soft agar assay, and then when injected into three mouse strains with increasing immunodeficiency formed tumours and metastasised *in vivo*^[44]. Untreated cells formed tumours and metastasized to a limited extent in the highly immunodeficient and natural killer (NK) cell deficient NSG mouse strain but not in the less permissive and NK cell competent NOD SKID strain or nude strains. In contrast, NMuMG cells transformed *in vitro* by the aluminium chloride formed large tumours and metastasized in all three mouse models^[44].

Triclosan

Triclosan [5-chloro-2-(2,4-dichlorophenoxy)phenol] is a chlorinated aromatic compound which is added as a broadspectrum antimicrobial agent to consumer goods. It was first used as a hospital scrub but is now added widely to personal care products and homeware products^[45]. It possesses estrogenic activity^[46] and has been detected in human milk^[45] implying its presence in the human breast. It can increase proliferation of estrogen-responsive human breast cancer cells^[45]. More recently, exposure of MCF-7 human breast cancer cells to triclosan has been shown to increase migration and development of EMT associated with downregulation of E-cadherin and upregulation of N-cadherin, snail and slug^[47]. The increased cell migration observed in our laboratory following long-term (9 weeks) exposure of MCF-7 cells to 10^{-7} M triclosan is shown in Figure 1D using xCELLigence technology (personal unpublished data).

Phthalates

Esters of phthalic acid (phthalates) are used as plasticisers in the manufacture of plastics. However, in addition to plastic goods, they are also found in many personal care products, adhesives, paints, air fresheners, food products, pharmaceuticals and textiles^[1]. Many of the esters are listed by the Organisation for Economic Cooperation and Development (OECD) as high production volume chemicals^[48], with some of the most used being diethylphthalate (DEP), dibutylphthalate (DBP), benzylbutylphthalate (BBP) and di-(2-ethylhexyl)phthalate (DEHP). Metabolites of these esters are widely detected in human urine samples of the US population^[49] and can be measured in human milk^[50] implying their presence in the human breast. Many of these widely used esters and their metabolites possess estrogenic activity and can increase growth of estrogen-responsive human breast cancer cells^[51,52]. Using a stem cell-derived human breast epithelial cell line R2d, DBP and BBP were found to induce EMT through an ER-mediated increase in mesenchymal markers and decrease in epithelial markers^[53]. Furthermore, BBP has been reported to increase growth of tumours and lung-derived metastases in an *in vivo* mouse xenograft model using breast cancer stem cells. The mechanism was linked to an arylhydrocarbon receptor-mediated increase in sphingosine-1-phosphate receptor 3 (S1PR3) signaling since downregulation of this pathway reduced both the tumour growth and the lung metastasis but the role of estrogen in this remains unknown^[54].

Bisphenol A

BPA is used in the manufacture of polycarbonate plastics and epoxy resins which are found ubiquitously in building materials and consumer products^[55]. It is used to line food storage containers and water bottles from which it can leach out when heated^[56]. It is listed by the OECD as a high production volume chemical^[48]. A large literature links BPA to adverse health effects in animals and humans^[55], and it is measurable in human body tissues including breast milk^[57] which implies its presence in the human breast. Through its estrogenic activity, it is known to stimulate the proliferation of estrogen-responsive human breast cancer cells^[56]. Animal models have revealed that prenatal exposure can enhance breast carcinogenesis in the chemically induced DMBA-mouse model^[58] and alone can also cause disruption to the mouse mammary tissue increasing susceptibility to breast cancer^[59]. However, chronic exposure to BPA in drinking water during adulthood was also shown to increase tumour burden and incidence of metastasis in a transgenic mouse model that spontaneously develops tumors through overexpression of erbB2^[60]. More recent *in vitro* experiments with human breast cancer cells are beginning to suggest that BPA may increase cell migration and invasion. Exposure of SkBr3 human breast cancer cells to BPA (10^{-8} M) increased cell motility and downregulated the transcription factor FOXA1^[61]. FOXA1 repression is thought to be characteristic of EMT because it is an activator of the E-cadherin gene^[62]. Exposure of the human breast cancer cell lines MDA-MB-231 and BT-549 led to increased invasiveness with an associated increased expression of MMP-2 and MMP-9^[63].

Dioxins

Polychlorinated dibenzodioxins (PCDDs) (dioxins) are highly toxic, bioaccumulative environmental pollutants generated as byproducts of combustion^[64]. They are carried by air, washed off the land by

rainwater into rivers and lakes and then pass up the food chain dissolved in animal fat. They are measured ubiquitously in human tissues^[64]. There are 75 congeners of which the most toxic is 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD)^[64] and has been shown to exert molecular actions both through ER-mediated and AhR-mediated mechanisms^[65]. Gene targets of the AhR include activation of slug and some MMPs^[66]. In the ER+, AhR+ MCF-7 human breast cancer cells, TCDD has been found to downregulate E-cadherin and reduce cell-cell contacts in a JNK-dependent mechanism^[67]. However, antiestrogenic actions of TCDD have been repeatedly reported over the years^[65], and so it is noteworthy that TCDD has been reported to inhibit mammary tumour metastasis *in vivo*^[68,69].

Phytoestrogens

Phytoestrogens are found in over 300 plant species and can be ingested by humans through consumption of plant material either in diet or as dietary supplements^[70]. Flavonoids include genistein and daidzein found in soybeans and other legumes, coumestans in clover and young sprouting legumes, prenylflavonoids in hops. The most prevalent non flavonoids are lignans in cereals, fruits and vegetables. Although many purified phytoestrogens display estrogenic activity *in vitro*, the estrogenic actions on cell proliferation are concentration-dependent with only the lower doses increasing proliferation of estrogen-responsive human breast cancer cells, whilst higher doses inhibit^[71], and many phytoestrogen-containing plant products are considered to have anti-tumour activity^[70]. It is interesting therefore that emerging data seem to suggest that several phytoestrogens can act to reduce breast cancer cell migration and invasion including lignans^[72], soy-derived daidzein^[73], and formononetin^[74]. Triclosan-induced EMT can be reversed by kaempferol^[47]. However, one mouse model of breast cancer has shown that consumption of soy isoflavones increased growth of metastatic tumours in bone and lung^[75].

THE ISSUE OF LOW-DOSE MIXTURES

The studies discussed above provide evidence that some individual estrogen disrupting chemicals can influence components of EMT and processes of migration and invasion in human breast cancer cells. However, since many hundreds of estrogen disrupting chemicals have now been measured in the human breast^[1], the environmental reality is that, in today's world, human breast cells *in vivo* are not exposed to single chemicals but to complex mixtures of pollutant chemicals. This is especially poignant in view of many estrogen disrupting chemicals being lipophilic and the human breast being a fatty organ. It is also highly relevant in the context of the many non-monotonic responses which have been reported for environmental endocrine disrupting chemicals in general, often with stronger responses at the relatively lower doses tested^[76]. There are therefore outstanding questions as to the effects of exposure to complex mixtures of estrogen disrupting chemicals where each is present at low dose. For proliferation, it has been shown that mixtures of such chemicals can increase cell proliferation where the same concentrations of the estrogen disrupting chemicals individually do not, in what has now been nicknamed "the something from nothing" effect^[77]. Even mixtures of the different esters of parabens can add together to give increased cell proliferation^[29]. This is relevant environmentally where human breast tissue samples were found to contain differing levels of the individual paraben esters^[26] and implies that the same outcomes can arise from different mixtures of estrogen disrupting chemicals^[29]. Clearly in ER-mediated mechanisms, such as in increasing cell proliferation, each chemical will act according to its relative estrogen receptor binding affinity but low doses of different chemicals can add together until a maximum proliferative signal is achieved. As yet, there seems to be no published information as to whether the same effect of mixtures can be achieved on development of EMT or on increasing cell migration/invasion. Furthermore, since these studies are technically long and labour-intensive, the range of concentrations are often lacking in order to determine the extent to which non-monotonic responses may be occurring.

Figure 2. Diagrammatic representation of how estrogen disrupting chemicals may influence metastasis of breast cancer cells. Through their estrogenic activity, they may increase growth of cells at the primary site in the breast or at metastatic sites. They may enable EMT, increase cell migration and cell invasion. Through their widespread presence in the human body, they may provide a favourable microenvironment for colonization and metastatic tumour growth

CONCLUSIONS

It can be concluded that there is mounting evidence for a role of estrogen disrupting chemicals in contributing to the processes of metastatic tumour spread and this is summarized in Figure 2. Estrogen disrupting chemicals may contribute to loss of cell-cell adhesion, development of EMT and increased secretion of ECM-degrading proteases leading to increased cell motility, migration and invasion. However, estrogen disrupting chemicals are also likely to play a role in creating a favourable microenvironment for colonization and growth of metastatic tumours at distant sites. Unpredictable awakening from dormancy^[7] could result from altered environmental exposures or indeed sudden release of estrogen disrupting chemicals from fat stores such as at times of weight loss. It is well established that estrogen disrupting chemicals are passed from mother to child in breast milk as they are mobilized with the fat in the milk^[78]. Such detoxification of the the mother's breast may provide an alternative explanation for the protective effect of breast feeding on incidence of breast cancer^[79]. Likewise, release of estrogen disrupting chemicals from storage could change the microenvironment for "dormant niches"^[7] causing renewed proliferation.

Research is now needed to answer outstanding questions concerning the effects of long-term exposure to low doses of chemicals and the effects of complex mixtures of chemicals^[80]. Since estrogen disrupting chemicals are widely measurable in human tissues and some can bioaccumulate with age, then it follows that breast cells are exposed long term which requires long term cell culture modelling for further understanding. This is especially poignant in the acquisition of increased migratory and invasive properties described above which generally took weeks rather than days to develop. The effects of mixtures of chemicals each at low dose will be more difficult to resolve because personal lifestyle choices will inevitably result in differing chemical contents between individuals. Furthermore, due to the additive and complementary mechanisms of estrogen disrupting chemicals^[81], different mixtures may have the same outcomes which makes tracing individual culprit chemicals impossible. However, if specific environmental exposures can be uncovered, then avoidance would be a good strategy for prevention. In 2001, I proposed a hypothesis that regular application of constituents of underarm cosmetics might play a role in the rising

incidence of breast cancer if sufficient of the constituent chemicals were absorbed either from long-term exposure on the skin (these products are not washed off) or from damaging the skin by shaving prior to cosmetic application^[82,83]. This was proposed partly due to the disproportionately high incidence of breast cancer in the upper outer quadrant of the breast which is coincidentally also the site of application of these chemicals. Many years on, it is now known that many of the constituent chemicals can be absorbed through even intact skin after a single application^[84,85] and that they are measurable in human breast tissue or human milk (see above for references). Published studies have linked the levels of some of these estrogen disrupting chemicals in the body tissues with personal care product usage^[86,87]. However, it is also clear that these chemicals are getting into many body tissues other than breast and therefore could be expected to create distant estrogenic microenvironments which could influence not only the growth of the primary tumour but also growth of metastatic tumours. If excessive use of personal care products is involved in the development of metastatic breast cancer, then reduction or cessation in use could provide a prevention strategy.

Abstract

Syndrome of inappropriate antidiuresis (SIAD) is a common paraneoplastic syndrome commonly associated with thoracic malignancies, gastrointestinal cancers and kidney tumors. It is defined as hyponatremia in euvolemic patients, often due to abnormal secretion of antidiuretic hormone by tumor cells. Tolvaptan, a vasopressin-2-receptor antagonist, is currently recommended for patients affected by SIAD with mild or moderate symptoms. Among patients with prostatic cancer, SIAD represents a rare condition but it is frequently associated with poorly differentiated adenocarcinoma or pure small-cell carcinoma histotype. We report a case of SIAD appeared at disease progression in a 60-year-old male patient with acinar adenocarcinoma with neuroendocrine differentiation together with a literature review.

Keywords: Hyponatremia, prostate cancer, syndrome of inappropriate antidiuresis, neuroendocrine differentiation

INTRODUCTION

Prostate cancer is the most common non-cutaneous cancer in Western men, with estimated 1,600,000 cases annually^[1]. The recent World Health Organization (WHO) 2016 classification

© The Author(s) 2019. **Open Access** This article is licensed under a Creative Commons Attribution 4.0 International License (<https://creativecommons.org/licenses/by/4.0/>), which permits unrestricted use, sharing, adaptation, distribution and reproduction in any medium or format, for any purpose, even commercially, as long as you give appropriate credit to the original author(s) and the source, provide a link to the Creative Commons license, and indicate if changes were made.

of neuroendocrine (NE) tumors of prostatic adenocarcinoma (PAC) includes the following four categories: Adenocarcinoma with neuroendocrine differentiation, Well-differentiated NE tumor (carcinoid tumor), Small cell NE carcinoma and Large cell NE carcinoma. Gleason score and grade group are the standard approach to histologic grading of PAC, but not for the NE components, and it is an important independent prognostic factor^[2,3]. Clinical presentation and prognosis usually depend on local infiltration and metastatic spread. Paraneoplastic syndromes including syndrome of inappropriate antidiuresis (SIAD) are rare, mostly in poorly differentiated PAC, frequently with NE features^[4]. SIAD is commonly associated with small cell lung cancer (SCLC), non-small cell lung cancer (NSCLC), gastrointestinal cancers, kidney cancers and mesothelioma^[5]. In the last few years, several international and national guidelines have been published in order to improve clinical managing of this electrolyte disorder^[6]. Oral tolvaptan, a vasopressin-2-receptor antagonist, has been approved by FDA and EMA for treatment of euvolemic hyponatremia due to SIAD with mild or moderate symptoms. Vaptans demonstrated to improve serum sodium concentration in patients with SIAD but there are still few data about their possible effect on survival of cancer patients^[7].

CASE REPORT

A 60-year-old male with PAC and abdominal lymph nodes and axial bone metastasis came to our Department. An informed consent to procedures and therapy was obtained from the patient. At first observation, the patient was in good clinical condition (Performance status according to Eastern Cooperative Oncology Group-ECOG-PS = 0) and he did not present significant comorbidities other than well-controlled arterial hypertension.

PAC diagnosis occurred in June 2014 when, after onset of urinary frequency and dysuria, patient underwent prostate biopsies. Histological examination reported prostatic acinar adenocarcinoma Gleason score 5 + 4 = 9 (grade group 5, with NE differentiation = 5%) [Figure 1]. PSA was 22 ng/mL.

After diagnosis, a CT scan showed left iliac chain, para-aortic and inguinal bilateral lymphadenomegalies and osteoblastic metastasis to lumbar spin, multiple ribs and hip with no fracture risk. A bone scintigraphy confirmed bone involvement [Figure 2]. Laboratory values did not show clinically significant abnormalities.

In August 2014 the patient started complete androgen deprivation therapy with oral Bicalutamide 50 mg daily along with intramuscular Leuporelin 11.25 mg/mL quarterly. Denosumab 120 mg monthly was started to prevent skeletal events. Serum PSA showed initial complete biochemical response (0.3 ng/mL). In November 2014 PSA raised to 10 ng/mL. The patient presented with clinical worsening including increased urinary frequency and dysuria. Considering biochemical and clinical progression, Bicalutamide was stopped and first-line chemotherapy with Docetaxel 75 mg/m² intravenously every three weeks was started. The patient underwent five cycles of chemotherapy until May 2015, continuing Denosumab and Leuporelin. PSA decreased to 8.2 ng/mL, with limited clinical benefit. After multidisciplinary evaluation, the patient was considered eligible for radiotherapy on the prostatic region. This treatment was performed between May 2015 and July 2015 (total dose: 5400 cGy).

After radiation therapy, PSA raised to 17.4 ng/mL and the patient was referred to our department for dorsal and abdominal pain. A total-body CT scan performed in August 2015 showed disease progression, including rectal thickening, multiple liver metastasis, peritoneal carcinosis and increase of abdominal and pelvic lymphadenomegalies. CT also showed disseminate osteoblastic metastasis [Figure 3].

A: Prostate biopsy extensively involved by acinar adenocarcinoma with NE differentiation (5%) at low magnification (hematoxylin and eosin-H&E); B: prostate biopsy with solid area of adenocarcinoma at high magnification (H&E); C: prostate biopsy with diffuse positivity for prostate specific membrane antigen (PSMA, immunohistochemistry); D: prostate biopsy with focal positivity for synaptophysin (immunohistochemistry)

Figure 2. Bone scintigraphy confirming skeletal involvement

Figure 3. CT scan showing liver metastatization and rectal thickening

Figure 4. A: Liver metastasis at low magnification (H&E); B: Liver metastasis at high magnification showing small cell carcinoma (H&E); C: Liver metastasis showing diffuse positivity for synaptophysin (immunohistochemistry); D: Liver metastasis showing high proliferation rate (Mib1, immunohistochemistry)

Patient was hospitalized at the Surgery Department in our hospital where he underwent colostomy to palliate bowel obstruction and third-segment liver lesion biopsy. The histological examination of the liver showed metastasis of small cell NE carcinoma (Mib1 = 90%) without prostatic features at immunohistochemistry [Figure 4 and Table 1].

After that, the patient came back to our observation in September 2015 in fair conditions (ECOG-PS = 1), with partial pain control, constipation and mild mental confusion. At physical examination, no neurological impairment was reported.

Laboratory evaluation showed PSA = 26.7 ng/mL, NSE = 1238 ng/mL, chromogranin A = 454 ng/mL, rise of cholestasis values grade 1 according to Common Terminology Criteria for Adverse Events (CTCAE) v4.0 and first occurrence of moderate hyponatremia (125 mEq/L).

Table 1. Comparison between prostate and liver histology

	Prostate	Liver
Morphology	Acinar adenocarcinoma with neuroendocrine differentiation (5%), Gleason score 5 + 4 = 9 (grade group 5)	Small cell neuroendocrine carcinoma
PSMA	Diffuse positivity	Negative
Synaptophysin	Focal	Diffuse
Mib1	50%	90%

PSMA: prostate specific membrane antigen

After Endocrinological Consultant, we performed the following evaluations: glucose = 96 mg/dL, serum creatinine = 0.35 mg/dL, blood urea nitrogen = 9.8 mg/dL, plasma osmolality = 259 mOsm/kg, urinary osmolality = 322 mOsm/kg, urinary calcium = 2.4 mg/dL, urinary sodium = 115 mEq/L, urinary potassium = 5.3 mEq/L, TSH = 1.1 mcU/mL, ACTH = 14 pg/mL, plasmatic cortisol = 9.9 mcg/dL, venous bicarbonates = 25 mmol/L. Therefore, considering also euvolemic status and no concomitant use of diuretics, we diagnosed SIAD and started treatment with Tolvaptan 15 mg/die in October 2nd 2015 carefully monitoring plasmatic sodium every six hours. Sodium increase was < 10 mmol/die up to Na^+ = 133 mEq/L and the patient continued progressively to reduce Tolvaptan dosage till a maintenance dose of 3.75 mg/die, monitoring plasmatic sodium daily.

Considering last histological examination and the clinical benefit with vaptan, after evaluation, the patient started a second-line chemotherapy with Cisplatin 80 mg/m² i.v. day 1 and Etoposide 100 mg/m² i.v. days 1-3 every three weeks. After three cycles of chemotherapy, the patient experienced grade 3 anemia, grade 2 thrombocytopenia, grade 4 leucopenia and grade 4 neutropenia, requiring blood transfusion and administration of granulocyte growth factor and antibiotics. No other toxicities were reported. Patient underwent a fourth cycle with reduced doses. PSA value was stable, while NE tumor markers increased.

In December 2015, patient experienced bone disease progression at CT scan. A month later, he died due to liver failure.

DISCUSSION

Hyponatremia is defined as serum sodium concentration (Na^+) lower than 135 mmol/L^[8,9] and it is one of the most common electrolyte disorders occurring in cancer patients with an estimated incidence between 5% and 20%^[10,11]. The most frequent causes include SIAD, due in most cases to ectopic production of antidiuretic hormone, extracellular fluid depletion or renal toxicity of chemotherapy, especially platinum-based^[5].

The main diagnostic criteria for SIAD are: euvolemic status, reduced plasma osmolality < 275 mOsm/kg, increased urine osmolality > 100 mOsm/kg, increased urinary sodium > 30 mEq/L, normal kidney, thyroid and adrenal function. Additional diagnostic criteria are: no use of diuretics, reduced blood uric acid < 4 mg/dL, reduced blood urea nitrogen (BUN) < 10 mg/dL, increased sodium renal excretion fraction > 1% and increased urea excretion fraction > 55%^[6].

Correct management of hyponatremia represents an important issue for cancer patients considering its well-demonstrated role in increasing mortality, costs and length of hospitalization^[12-14]. Treatment depends on underlying causes of hyponatremia but also on severity and time of onset. In the context of SIAD, vaptans represent a relevant therapeutic option for mild-moderate reduction^[15].

Literature review revealed that most PAC-associated SIAD cases are high grade and high stage adenocarcinoma. Actually, SIAD can be linked to neuroendocrine evolution at disease progression. Pure small-cell carcinoma of the prostate is extremely rare, accounting for < 0.5% of all cases^[16]. About 50% of small cell carcinomas (SCC) have a history of usual PAC. Frequently, at initial diagnosis SCC are seen admixed with adenocarcinoma of the prostate^[17]. In these cases, Gleason score is assigned only to the conventional adenocarcinoma component. According to the SEER database, the presence of concomitant high-grade PAC is an independent predictor of poorer cancer-specific mortality^[18].

Recent data on *in vitro* and *in vivo* studies related to the molecular mechanism of NE transdifferentiation of PCa cells suggest that PCa cells undergo a transdifferentiation process to become NE-like cells, acquiring NE phenotype and NE markers. Common molecular alterations between PAC and SCC components of mixed prostate tumors under conditions of androgen deprivation sustain the hypothesis that small cell carcinoma represents a transdifferentiation from PAC^[19]. The model of divergent-differentiation consider instead the hypothesis of a common stem cell progenitor that can differentiate into both adenocarcinoma and SCC. According to this model, hormonal therapy determinates a selective pressure resulting in development of SCC from a subpopulation of hormone-independent cells and consequently inducing hormonal resistance^[20]. The more aggressive behavior compared with conventional PAC is due to expression of genes involved in cellular proliferation, mitosis, neuroendocrine differentiation, along with downregulation of genes encoding cell adhesion molecules^[21]. This biological molecular phenotype is the reason behind the high proliferation rate, the rapid spreading and the great tendency to metastasize. Further preclinical results, deriving mostly from SCLC cell lines, seem to confirm the relation between hyponatremia, directly or through vasopressin receptors and cell proliferation, resistance to programmed cell death, angiogenesis and metastatization. Mitogen-activated protein kinase (MAPK) pathway is the main intracellular signalling which leads to tumoral growth and spreading^[22,23]. SIAD onset may guide physicians to perform a tumor biopsy in order to obtain a new morphological and immunohistochemical characterization^[24].

Neuroendocrine prostatic cancer is generally managed by chemotherapy regimens similar to those for SCLC. Prognosis is poor with a median survival of 7 months.

It is still unclear how SIAD arises from prostatic carcinoma with neuroendocrine differentiation but it may involve an ectopic production of ADH from carcinoma cells, as detected immunohistochemically in the tumor tissue^[25].

In our case-report, SIAD appeared at progression of disease, with metastatic spread to the liver. In particular a dedifferentiation of cancer cells was reported, which lost prostatic markers to acquire fully neuroendocrine characteristics. Only focal neuroendocrine prostatic markers were reported in the primary prostatic cancer [Figure 1], while liver metastasis presented neuroendocrine carcinoma [Figure 4]. Our case supports the hypothesis that histological evolution to neuroendocrine features accompanies to metastatic spread and often with paraneoplastic syndrome as SIAD.

It is my pleasure, as one of the editorial board members, to introduce the readers of *JCMT* to this special issue entitled “Autophagy and Cancer: current biology and drug development”.

Autophagy is a fundamental process for cells to degrade unwanted proteins/damaged organelles and also to recycle cellular components. Since its discovery on 1960's, a vast amount of effort has been made in understanding the physiological role/s of this process. For example, it is now known that mitosis, apoptosis, and autophagy are inter-connected and inter-regulated in cells^[1]. It is also known that upregulation of autophagy is a double-edged sword that promotes both cell survival and cell death, depending on the circumstances. However, the pathological role/s of autophagy in normal-to-cancer cell transformation, tumor development, and tumor drug resistance was not clear until the arrival of various breakthrough discoveries in the past 15 years. Noticeably, it has been demonstrated that dysregulation of autophagy (and probably downregulation) induces genomic instability in non-cancerous cells and subsequently promotes tumorigenesis^[2]. In contrast, upregulation of autophagy has been shown to enhance the survival ability of cancer cells in response to various micro-environmental stresses and different chemotherapeutic agents^[3]. Therefore, autophagy is currently a “hot” cellular pathway target for the development of cancer therapeutics^[4-7].

This special issue contains reviews focusing on recent understandings on the regulation of autophagy in non-cancerous cells and dysregulation of this process in cancer cells. Reviews on recent advances in the development of autophagy modulators for cancer treatment are also included in this special issue.

Abstract

Cancer cachexia is a debilitating syndrome mainly characterized by muscle and fat wasting, leading to the progressive loss of body weight and complicating the management of cancer patient. In particular, the loss of muscle weight is a negative prognostic factor, being associated with chemotherapy toxicity and reduced survival. Increased inflammation and protein dysmetabolism are some of the impairments that lead to muscle wasting in cancer patients. Together with these alterations, tumor growth and chemotherapy administration may affect mitochondrial function, impinging on the muscle energy metabolism. Indeed, therapeutic approaches poised to correct both hypercatabolism and mitochondrial alterations could be effective in preventing cancer-induced muscle wasting. Among the non-pharmacological approaches, exercise training is one of the best modulator of muscle physiology able to impinge on both protein and energy metabolism. However, the wasting phenotype that characterizes cancer patients could be not compatible with physical training, prompting the development of different strategies to improve muscle metabolism. The aim of this mini-review is to discuss both the beneficial effects and the limitations of exercise training in cancer cachexia and the adoption of drugs able to modulate exercise-induced pathways.

INTRODUCTION

Cachexia is a metabolic disorder that occurs in different chronic diseases, including cancer, heart failure, kidney disease, chronic obstructive pulmonary disease, sepsis and rheumatoid arthritis^[1]. The prevalence of cachexia is particularly high in cancer patients, ranging from 50% to 80%, depending on tumor type^[2]. Cancer cachexia is characterized by body weight loss, systemic inflammation and metabolic alterations. The occurrence of this syndrome affects patient's quality of life and increases both morbidity and mortality due to cardiovascular complications, immune disorders and nutritional deficiency^[3,4]. Body weight loss is mainly due to the consistent depletion of muscle and fat mass, that is frequently worsened by chemotherapy toxicity^[5]. Humoral mediators and altered energy balance activate proteolysis in the skeletal muscle of cancer hosts, ultimately leading to protein and organelle disposal^[6]. However, the specific blockade of intracellular muscle proteolytic systems does not prove effective in counteracting cancer-induced wasting^[7-9], focusing the investigation to upstream pathways that regulate muscle metabolism and energetics. In particular, several lines of evidence show that alterations of the energy metabolism and mitochondrial impairments may contribute to the onset and progression of muscle wasting in cancer^[10]. In this regard, cancer hosts are characterized by low nutrient intake and increased energy expenditure^[1]. Whereas the former is induced by anorexia, dysphagia and/or altered absorption, due to chemotherapy or to tumors with esophageal/gastrointestinal localization^[11], the latter is enhanced by tumor metabolism, inflammation and mitochondrial alterations^[1]. Notably, one of the first evidences of energy wasting in cancer cachexia derive from studies on uncoupling proteins (UCPs), whose expression is increased in the skeletal muscle and adipose tissue of tumor-bearing animals and cancer patients^[12-15]. Along this line, a time-course analysis in lewis lung carcinoma (LLC)-bearing mice has shown that mitochondrial ROS emission, mitochondrial degradation and respiratory function are impaired prior to the loss of muscle mass in the host mice and, interestingly, some of these alterations appear early after tumor implantation^[16]. A proteomic profiling of both skeletal and cardiac muscles of C26-bearing mice, another syngeneic model of cancer cachexia, has revealed an impaired expression of proteins involved in energy homeostasis and mitochondrial function^[17]. Consistently, cachectic cancer patients show altered levels of proteins accepted as markers of mitophagy, such as Parkin, PTEN-induced putative kinase 1 (PINK1) and BCL2/adenovirus E1B 19 kDa protein-interacting protein 3 (BNIP3), and mitochondrial dynamics, such as mitofusin 2 (Mfn2) and mitochondrial fission 1 protein (Fis1)^[18,19]. In addition, it is well established that anti-cancer treatments alter mitochondrial homeostasis. In this regard, healthy mice treated with FOLFOX or FOLFIRI (the combination of 5-fluorouracil and leucovorin with either oxaliplatin or irinotecan, respectively) present with reduced mitochondrial mass and oxidative capacity in the skeletal muscle^[20]. Similar results have been reported in C26-bearing mice treated with chemotherapy (oxaliplatin and 5-fluorouracil)^[21], showing that anti-cancer treatment significantly increased the lifespan of C26-bearing mice but exacerbate muscle wasting as compared to untreated C26 hosts^[21]. Such wasting effect has been associated with reduced peroxisome proliferator-activated receptor gamma coactivator 1-alpha (PGC-1α) and cytochrome c expression and with increased markers of mitophagy, together with impaired oxidative capacity and ATP levels^[21]. Using a proteomic approach, alterations of the tricarboxylic acid (TCA) cycle and impaired expression of markers of mitochondrial fusion, fission and biogenesis have been reported in both untreated and chemotherapy-treated C26-bearing mice^[22]. A metabolic profiling performed in the same C26 hosts exposed to chemotherapy shows that glycolysis and β-oxidation are also impaired^[23].

Overall, since muscle metabolic phenotype in cancer hosts is severely impaired by both tumor growth and chemotherapy, strategies targeting mitochondria and/or improving the oxidative capacity could usefully integrate a multimodal therapy for cancer cachexia.

EXERCISE AS A MODULATOR OF MUSCLE METABOLISM

Physical activity is associated with several metabolic adaptations that particularly affect the skeletal muscle^[24]. Depending on the type and frequency of exercise, different targets are preferentially regulated.

Acute exercise leads to transient muscle molecular changes (e.g., temporary increase in specific mRNA expression), whereas chronic exercise induces physiological adaptations that could modify muscle phenotype^[25]. Regarding the differences in terms of exercise type, resistance training imposes a low-repetition and high-intensity demand on the skeletal muscle, whereas endurance exercise does the opposite^[26], resulting in specific skeletal muscle adaptations. Thus, resistance training leads to the induction of myofibrillar protein synthesis and increased anaerobic capacity, whereas endurance exercise sessions mainly lead to improved mitochondrial density and function, oxygen delivery and uptake, anti-oxidant defenses and resistance to fatigue^[25]. The beneficial effects of exercise have been tested in different chronic conditions, including coronary heart disease, type 2 diabetes mellitus, obesity and aging^[24,27]. Notably, both exercise types exert beneficial effects in cachectic animals. Resistance training by ladder climbing has been reported to relieve body weight loss, muscle wasting and inflammation in tumor-bearing rats^[28,29] and to increase the expression of factors associated with myogenesis in cachectic mice^[30]. In *Apc^{+/-Min}* mice overexpressing IL-6, endurance exercise prevents body weight loss, improves insulin sensitivity, increases mitochondrial biogenesis and muscle oxidative capacity and restores normal signaling through Akt and 5' AMP-activated protein kinase (AMPK)^[31,32]. Endurance exercise by voluntary wheel running is effective also in C26-bearing mice, reducing body weight loss, muscle wasting and the expression of markers of autophagy and proteasome-dependent degradation^[33]. However, the combination of the two types of exercise could result in better outcomes in cancer hosts. This was suggested by the results of an exercise protocol in which the slope was increased in a mild intensity run protocol using a motorized wheel. Indeed, this protocol mixed endurance exercise, due to the moderate and continuous training, to the resistance exercise, resulting by the increased hill as compared to the flat treadmill run. Notably, C26 hosts performing this exercise protocol have shown improved muscle wasting and strength, together with reduced autophagy and oxidative stress markers^[34]. On the contrary, endurance exercise with treadmill in a flat mode does not succeed in improving cachexia in C26 hosts^[35]. The effect of exercise through a motorized wheel has also been tested in a model of cancer (C26 tumor) and chemotherapy-induced muscle wasting, partially preventing the loss of muscle mass and strength^[21]. These improvements are associated with a partial restoration of mitochondrial homeostasis^[21]. Notably, exercise increases mitochondrial mass, normalizes the levels of PINK1, BNIP3 and Mfn2, improves the succinate dehydrogenase (SDH) activity and increases energy stores^[21]. In a recent study, the resistance exercise component has been further increased by combining the motorized wheel to the ladder climbing. This combined protocol relieves muscle wasting in C26-bearing mice, reducing autophagy markers and increasing muscle oxidative metabolism^[36].

The effects of physical training in cancer patients may vary depending on tumor type, stage and exercise modalities. A systematic review analyzing the effectiveness of aerobic exercise during chemotherapy treatment in cancer patients, has shown beneficial effects in terms of both quality of life and muscle function^[37]. In chemotherapy-treated breast cancer patients, exercise increases muscle fiber cross-sectional area, citrate synthase activity, mitochondrial complex protein levels and muscle capillarization^[38]. Supervised progressive resistance training increases muscle strength in pancreatic cancer hosts^[39]; similarly, it decreases fatigue and improves quality of life in head and neck cancer patients^[40]. Although these encouraging data, exercise has some limitations in terms of feasibility and patient compliance. In this regard, a study in a cohort of 196 cancer patients with established cachexia has shown a scarce adherence to exercise programs, with low ability to perform either aerobic or resistance training^[41]. Along this line, cancer patients with severe or refractory cachexia have a lack of interest in, or cannot cope with, exercise or do not complete the initially planned program^[42]. In addition, exercise is not free of risks and may harm cancer patients presenting with co-morbidities (anemia or cardiac dysfunctions)^[43] or with excessive loss of muscle mass and low energy availability. Depending on exercise type and duration, physical activity may worsen body and muscle wasting also in cachectic animals. Notably, in C26-bearing mice 2-week-long treadmill run exacerbates body and muscle wasting as compared to sedentary tumor bearers^[35]. In

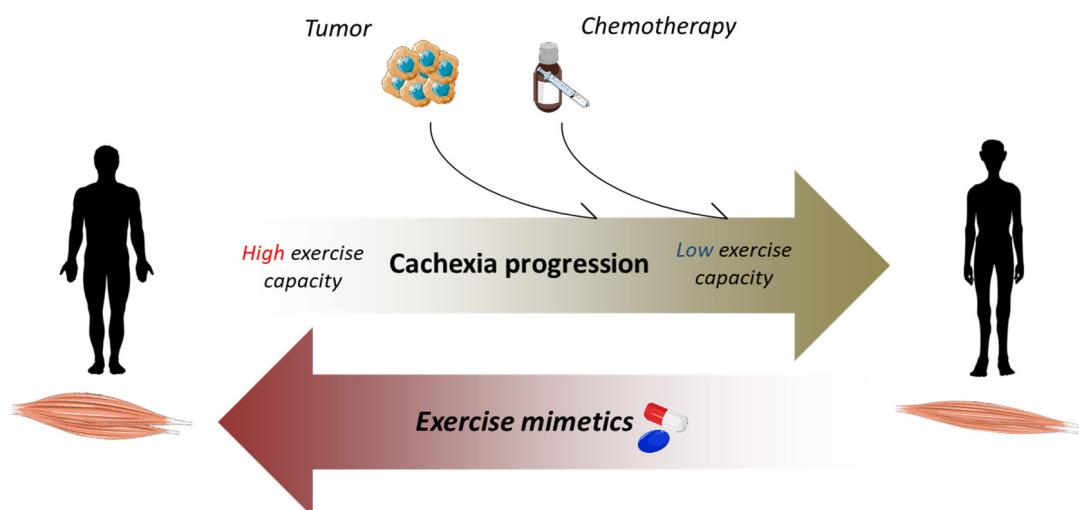

Figure 1. Exercise mimetics may positively affect cachexia progression and low exercise performance. In cancer patients, tumor growth and chemotherapy may induce anemia, cardiac dysfunction and mitochondrial alterations, leading to loss of muscle mass and reduced exercise performance. Exercise-like drugs may relieve muscle wasting and/or support cancer patients practicing exercise

addition, exercise performed in late-stage cachexia reduces the survival of C26-bearing mice exposed to chemotherapy^[21]. Given these premises, strategies that circumvent the limitations of exercise or improve exercise capacity could be useful for cancer hosts who are intolerant to physical training^[44] [Figure 1].

TARGETING EXERCISE-INDUCED PATHWAYS AND MUSCLE METABOLISM AS THERAPEUTIC STRATEGY

One of the most relevant player in the exercise-induced adaptations in the skeletal muscle is the co-transcription factor PGC-1 α , that responds to energy demand by enhancing the transcription of genes involved in mitochondrial biogenesis and turnover, leading to increased muscle oxidative capacity^[44,45]. In this regard, the ablation of PGC-1 α in mice has been shown to blunt the increase of autophagy and mitophagy induced by exercise, to decrease mitochondrial mass and to impair exercise performance^[45,46]. Conversely, PGC-1 α overexpression increases mitochondrial content, fast-to-slow muscle fiber switch and induces a set of genes associated with energy metabolism^[47,48]. Moreover, PGC-1 α transgenic animals show an improvement of satellite cell activation and proliferative potential^[49]. Indeed, PGC-1 α plays an important role in modulating muscle homeostasis and its downregulation is correlated with different wasting conditions, such as aging, muscle disuse and denervation^[50-52]. In aged mice, PGC-1 α overexpression has been shown to counteract the loss of muscle mitochondrial enzymes, to increase markers of autophagy and to preserve both neuromuscular junctions^[47] and exercise capacity^[53]. In muscle disuse and denervation, increased PGC-1 α expression prevents muscle atrophy and the activation of catabolic pathways^[50,52]. In cancer cachexia, muscle PGC-1 α protein expression is reduced in different animal models and such impairment does not always reflect a reduction of the transcript level^[54]. Otherwise, some studies also reports an increase of PGC-1 α gene expression^[54]. Independently from PGC-1 α , muscle mitochondrial mass and metabolism are severely affected in tumor-bearing animals^[10], suggesting that PGC-1 α is not the only determining factor in impaired mitochondrial function. In cachectic animals, conflicting results are also reported regarding PGC-1 α overexpression. Whereas Wang *et al.*^[55] demonstrate that the muscle-specific upregulation of PGC-1 α does not protect LLC-bearing mice from muscle atrophy in the same animal model Pin *et al.*^[35] show increased muscle mass and reduced atrogin-1 and muscle RING-finger protein-1 (*MuRF-1*) gene expression as compared to wild-type tumor bearers. However, both the studies suggest that forcing the expression of PGC-1 α in the skeletal muscle could have some limitations, such as the increase in tumor mass^[35,55].

The effects of boosting mitochondrial biogenesis have been tested also in cancer and chemotherapy-induced muscle wasting. In this condition, PGC-1 α overexpression does not improve muscle mass, whereas this effect is achieved by moderate exercise^[21]. This could suggest that enhancing mitochondrial biogenesis is not sufficient to mimic the effects of exercise and that it does not necessarily reflect an increase of mitochondrial function, both being affected in chemotherapy-treated tumor hosts^[21].

The modulations triggered by exercise may be mimicked by pharmacological and dietary compounds^[44,56]. Some of them have been extensively studied, such as 5-aminoimidazole-4-carboxamide ribonucleoside (AICAR), glitazones, metformin and sirtuin 1 (SIRT1) activators, also reporting their effectiveness in preventing cancer-induced muscle wasting^[10,44]. Also erythropoietin (EPO), an endogenous cytokine essential for the growth and differentiation of red blood progenitor cells, has shown some exercise-like effects that go beyond the increase in oxygen delivery. Indeed, the EPO receptor (EpoR) is expressed in different tissues other than hematopoietic cells, such as heart, skeletal muscle, adipose tissue, brain and pancreas^[57]. In this regard, EPO stimulates SIRT1 signaling in human cardiomyocytes treated with doxorubicin, increasing the levels of PGC-1 α , nuclear respiratory factor 1 (NRF1), citrate synthase and cytochrome *c* oxidase IV^[58]. EPO exposure of C2C12 myocyte cultures and primary skeletal myoblasts *in vitro* results in increased mitochondrial mass, PGC-1 α levels, citrate synthase activity and oxygen consumption rate^[59]. Similarly, transgenic mice expressing high levels of EPO show increased proportion of oxidative fibers and improved mitochondrial activity in the skeletal muscle, together with increased PGC-1 α and AMPK activation^[59]. Recombinant EPO administration to humans also results in increased mitochondrial oxidative phosphorylation and electron transport capacity^[60]. Consistently, LLC-bearing mice treated with EPO show increased SDH activity, ATP content and PGC-1 α expression in the skeletal muscle^[35]. These effects are enhanced by combining exercise training and EPO, protecting the mitochondrial compartment and resulting in increased muscle strength as compared to untreated sedentary cancer hosts^[35].

Another modulator of muscle metabolism is trimetazidine (TMZ). The effects of TMZ are primarily related to the ability to block β -oxidation, by inhibiting the 3-ketoacyl-CoA thiolase (3-KAT) activity in the mitochondrial matrix^[61]. This inhibition results in a metabolic shift towards glucose oxidation, optimizing oxygen utilization and decreasing lactate levels^[62]. TMZ is used to treat chronic stable angina and ischemic cardiomyopathy^[63], reducing symptoms and improving exercise performance^[63,64]. The effects on patients with cardiovascular diseases could be also related to the protection of the mitochondrial compartment. In this regard, TMZ is able to correct the toxicity induced by palmitate in cultured cardiomyocytes, increasing mitochondria mass, volume and function^[65]. Positive effects have been achieved by TMZ also on C2C12 myotubes exposed to TNF- α or to growth factor deprivation. Notably, TMZ induces the activation of anabolic pathways and reduces the expression of atrogin-1 and MuRF1, protecting C2C12 myotubes from atrophy^[66]. Of relevance, TMZ is also able to induce autophagy *in vitro*^[66]. Moving to *in vivo* models, TMZ improves muscle strength of aged mice, coupled with a muscle metabolic shift towards oxidative metabolism, suggested by increased levels of the slow myosin heavy chain (MyHC) isoform^[67]. Similarly to aged muscle, TMZ induces exercise-like effects also in the skeletal muscle of tumor-bearing animals. In this regard, TMZ administration partially protects C26-bearing mice from muscle atrophy (myofiber cross sectional area) and dysfunction, increasing slow MyHC content, SDH-positive myofibers and markers associated with mitochondrial mass and biogenesis^[68]. An increase in vascular endothelial cadherin (Ve-cadherin) and vascular endothelial growth factor (VEGF) expression, two known markers of angiogenesis, has also been detected in tumor-bearing mice after TMZ administration^[68]. Of relevance, TMZ seems to induce its effects quickly in the skeletal muscle. Indeed, 15 min *ex-vivo* TMZ treatment of EDL muscle (mostly composed by glycolytic fibers) is enough to reduce both contraction and relaxation rates^[68], favoring the occurrence of a phenotype typical of slow-twitch muscle^[69].

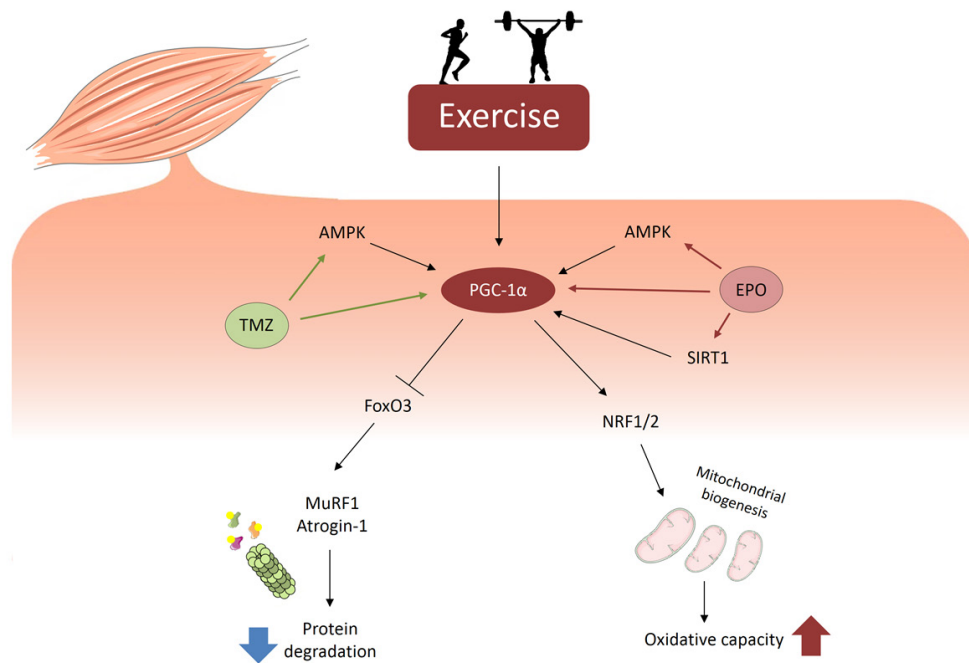

Figure 2. Exercise-like responses in the skeletal muscle may be induced by drugs acting on PGC-1 α expression and activity. Exercise modulates different pathways involved in the regulation of protein homeostasis and energy metabolism. During exercise, PGC-1 α activation increased mitochondrial biogenesis, favoring oxidative capacity, and inhibits FoxO3, reducing proteasome-dependent degradation. Similarly to exercise, EPO and TMZ are able to activate energy sensors, such as AMPK and SIRT1, that induce PGC-1 α and its downstream targets

Exercise is also able to activate myogenesis, impinging on satellite cells (SCs) proliferation and differentiation^[70]. Accordingly, TMZ treatment modulates the behavior of differentiating murine myoblast, increasing fusion capacity, markers of myogenesis and MyHC levels^[71]. These effects are associated with increased expression of metabolic regulators such as PGC-1 α and activated AMPK, suggesting an increase in oxidative metabolism^[71]. Similar results have been obtained in isolated murine SCs, in which TMZ increases some markers of differentiation as compared to control^[71]. Myogenesis is impaired in cachectic animals and cancer patients, likely contributing to muscle wasting^[72,73]. In this regard, the effect of TMZ on myogenesis markers has been tested on C26-bearing mice, showing increased levels of MyoD and Myogenin^[71]. Such results suggest that TMZ could potentially protect against myogenesis impairments.

CONCLUSION

The research on the etiopathogenesis of cancer cachexia has unraveled different metabolic alterations that lead to the wasting phenotype of cancer patients. Exercise training is one of the best approaches able to correct the metabolic impairments of tumor hosts, such as inflammation, hypercatabolism and energy deficit. However, being the skeletal muscle severely affected in cancer cachexia, often the physical (and psychological) state of cancer patients is not permissive for practicing exercise. Also due to these reasons the search for pharmacological strategies able to modulate exercise-induced pathways is rapidly growing. In this regard, exercise beneficial effects in cancer cachexia could depend, partially at least, on the expression of PGC-1 α . Consistently, drugs able to enhance the expression of this co-transcription factor, together with strategies that increase mitochondrial function, could be effective in improving muscle wasting [Figure 2]. However, beyond the alterations of the mitochondrial homeostasis, muscle depletion relies also on inflammation, activation of catabolic pathways and, frequently, depression of protein synthesis. Along this line, a combinatorial therapy targeting each of these alterations could be the best choice to counteract cancer-induced muscle wasting.

Abstract

Aim: There is increasing appreciation of the role of the renin-angiotensin system (RAS) in carcinogenesis with recent evidence showing expression of the RAS by cancer stem cells (CSCs) in different types of cancer. We have recently demonstrated the presence of three CSC subpopulations within metastatic melanoma (MM) to the brain: a Melan-A⁺ subpopulation and a Melan-A⁻ subpopulation within the tumor that express OCT4, SALL4, SOX2 and NANOG; and a pSTAT3⁺ subpopulation localized to the CD34⁺ endothelium of microvessels within the tumor. In this study we investigated the expression and localization of components of the RAS in relation to these CSCs in MM to the brain.

Methods: 3, 3-diaminobenzidine immunohistochemical (IHC) staining of components of the RAS: pro-renin receptor (PRR), angiotensin converting enzyme (ACE), angiotensin II receptor 1 (AT1R1) and angiotensin II receptor 2 (AT1R2) was performed on the same ten samples of MM to the brain included in our previous study. Immunofluorescence IHC staining of these components of the RAS was performed with embryonic stem cell markers OCT4 and NANOG, and endothelial marker CD34, on two of the samples of MM to the brain from the original cohort of ten patients. Western blotting ($n = 5$) and NanoString mRNA analysis ($n = 4$) were performed on samples of MM to the brain to confirm protein and mRNA expression of these components of the RAS, respectively.

Results: DAB IHC staining showed the presence of PRR, ACE, ATIIR1 and ATIIR2 in all ten samples of MM to the brain. IF IHC staining showed that the CSC subpopulations in MM to the brain expressed PRR, ATIIR1 and ATIIR2; and a CSC subpopulation on the endothelium of the microvessels expressed ACE. Western blotting and NanoString mRNA analysis confirmed protein and mRNA expression of these components of the RAS, respectively.

Conclusion: CSCs in MM to the brain expressed components of the RAS. Targeting the CSCs using modulators of the RAS may be a novel therapeutic approach for treating this aggressive cancer.

Keywords: Malignant melanoma, metastatic, cancer stem cells, renin-angiotensin system, cancer, brain

INTRODUCTION

Metastatic melanoma (MM) to the brain occurs in 30% of melanoma patients and accounts for 5%-8% of all brain tumors^[1]. For many years, the median survival of MM to the brain is 6-9 months following mainstay treatments including surgical excision, stereotactic radiosurgery and external beam radiotherapy^[2-5]. Investigations into MM to the brain have identified real time preferential hematogenous dissemination of tumor cells^[6], with survival of these cells within brain capillaries, migration to breach the blood brain barrier, angiogenesis and intraparenchymal proliferation^[7].

Although immunotherapies that enhance T-lymphocyte activity such as Ipilimumab, anti-cytotoxic T-lymphocyte associated antigen-4 and anti-programmed cell death-1 inhibitors can improve the median survival, some cause significant toxicities^[8,9]. Up to 50%-60% of MM patients harbor the BRAF V600 somatic mutation^[10]. Vemurafenib, a BRAF inhibitor, increases the median survival to 16 months^[11] but despite an initially good response, progression-free survival remains poor, at seven months^[5]. Used together, kinase inhibitors, BRAF-targeted and MEK-targeted small molecule drugs relieve intracranial symptoms and induces remission but cessation due to toxicity causes rapid intracranial and/or extracranial disease progression^[12]. The short period of remission after neuro-mimicry and individualized tumor targets^[13] has been attributed to the initiation, propagation and differentiation of cancer stem cells (CSCs)^[14].

The CSC concept proposes that cancer is caused by CSCs that possess the ability for uncontrolled growth and propagation^[15]. CSCs have been demonstrated in many types of cancer including breast carcinoma^[16], glioblastoma^[17] and oral cavity squamous cell carcinoma (OCSCC)^[18-20]. We have recently identified and characterized three CSC subpopulations within MM to the brain: a Melan-A⁺ subpopulation and a Melan-A⁻ subpopulations that express embryonic stem cell (ESC) markers OCT4, SALL4, SOX2 and NANOG within the tumor, and a pSTAT3⁺ subpopulation localized to the CD34⁺ endothelium of microvessels within the tumor^[21].

The RAS has been linked to carcinogenesis for some time^[22]. In the classical RAS, angiotensinogen (ANG) is converted to angiotensin I (ATI) by renin. ATI is then converted to angiotensin II (ATII) by angiotensin converting enzyme (ACE). The RAS is implicated in central nervous system disorders such as Parkinson's disease and dementia with neuroprotective and neurotoxic features although its role in carcinogenesis is not discussed in a recent review^[23]. GB cells in culture express ANG, pro-renin, ACE, ATII, angiotensin II receptor 1 (ATIIR1) and angiotensin II receptor 2 (ATIIR2); and renin inhibitors decrease DNA synthesis, induce apoptosis and reduce viable cell numbers^[24]. Renin and its precursor pro-renin bind to pro-renin receptor (PRR) to activate the MAPK signaling cascades. PRR is associated with increased cell proliferation, decreased apoptosis and highly expressed in pancreatic ductal adenocarcinoma^[25]. CSC subpopulations in GB^[26] and OCSCC of different subsites^[27-29] express components of RAS.

We here hypothesized expression of the RAS by CSCs in MM to the brain and investigated the expression and localization of components of the RAS: PRR, ACE, ATIR1 and ATIR2, in relation to the putative CSC subpopulations we have recently identified^[21], using immunohistochemical (IHC) staining, Western blotting (WB) and NanoString mRNA analysis.

METHODS

Tissue samples

Samples of MM to the brain from ten patients were sourced from the Gillies McIndoe Research Institute Tissue Bank and used in this study that was approved by the Central Health and Disabilities Ethics Committee (Ref. 15CEN28) with written informed consent from all participants.

Histology and IHC staining

Hematoxylin and eosin (H&E) staining was performed on 4 µm thick formalin-fixed paraffin-embedded sections of MM to the brain from ten patients included in our previous study^[21], to confirm the presence of the tumor by an anatomical pathologist (HDB). 3,3-diaminobenzidine (DAB) IHC staining for CD34 (ready-to-use, cat# PA0212, Leica), Melan-A (ready-to-use, cat# PA0233, Leica), ACE (1:100; cat# MCA2054, AbD Serotec, Kidlington, UK), PRR (1:2000; cat# ab40790, Abcam), ATIR1 (1:30; cat# ab9391, Abcam), ATIR2 (1:2000; cat# NBP1-77368, Novus Biologicals, LLC, Littleton, CO, USA) as well as NANOG (1:100; cat# ab80892, Abcam, Cambridge, UK), OCT4 (1:1000; cat# ab109183, Abcam) and ERG (1:200; EPII, Cell Marque, Rocklin, CA, USA), diluted with BondTM primary antibody diluent (cat# AR9352, Leica), was performed as previously described^[30].

To localize the components of the RAS in relation to the putative Melan-A⁺ and Melan-A⁻ OCT4⁺/SALL4⁺/SOX2⁺/NANOG⁺ CSC subpopulations within the tumor, and the pSTAT3⁺ subpopulation on the endothelium of microvessels within MM to the brain^[21], immunofluorescence (IF) IHC staining was performed on two representative samples of MM to the brain from the original cohort of ten patients included for DAB IHC staining. Components of the RAS were co-stained with ESC markers OCT4 or NANOG as the surrogate markers for the Melan-A⁺ and the Melan-A⁻ OCT4⁺/SALL4⁺/SOX2⁺/NANOG⁺ CSC subpopulations, or endothelial markers ERG or CD34 for the pSTAT3⁺ subpopulation on the endothelium of microvessels within the tumor. Antibodies used for PRR and ATIR2 detection were VectaFluor Excel anti-rabbit 594 (ready-to-use; cat# VEDK-1594, Vector Laboratories) and Alexa Fluor anti-mouse 488 (1:500; cat#A21202, Life Technologies). Antibodies for ACE and ATIR1 detection were VectaFluor Excel anti-mouse (ready-to-use; cat# VEDK2488, Vector Laboratories) and Alexa Fluor anti-rabbit 594 (1:500; cat# A21207, Life Technologies).

Human tissues used for positive controls were placenta for PRR, liver for ATIR1, and kidney for ATIR2 and ACE. Negative controls were used in secondary and tertiary antibody staining by omitting the primary antibodies on a randomly selected sample of MM to the brain.

Image analysis

DAB IHC stained-slides were viewed and images were captured with an Olympus BX53 light microscope fitted with an Olympus SC100 digital camera (Olympus, Tokyo, Japan), and processed with the CellSens 2.0 software (Olympus). IF IHC-stained images were captured using an Olympus FV1200 biological confocal laser-scanning microscope and processed with CellSens Dimension 1.11 software using 2D deconvolution algorithms (Olympus).

WB

Five snap-frozen samples of MM to the brain from the original cohort of ten patients underwent WB as described previously^[28], using the primary antibodies: anti-PRR (ATP6IP2, 1:500; cat# ab40790, Abcam),

Figure 1. Representative DAB IHC-stained sections of metastatic melanoma to the brain showing endothelial staining of ACE (A, brown), and mostly cytoplasmic staining of PRR (B, brown), ATIIR1 (C, brown) and ATIIR2 (D, brown). Nuclei were counter-stained with hematoxylin (A-D, blue). Original magnification: 200 \times . DAB: 3, 3-diaminobenzidine; IHC: immunohistochemical; ATIIR1: angiotensin II receptor 1; ATIIR2: angiotensin II receptor 2; PRR: pro-renin receptor; ACE: angiotensin converting enzyme

anti-ATIIR1 (AT2R1, 1:500; cat# sc-1173, Santa Cruz, CA, USA), anti-ATIIR2 (1:5000; cat# ab92445, Abcam), anti-ACE (1:200; cat# sc-12184, Santa Cruz) and anti- β -actin (1:2000 cat# ab8226, Abcam). Secondary antibodies used were Alexa Fluor 647 rabbit anti-mouse for β -actin (1:2000 cat# A21202, Thermo Fisher Scientific), donkey anti-goat HRP (1:10000; cat# ab97120; Abcam) and a rabbit anti-goat SuperclonalTM biotin conjugated secondary antibody (1:20000; cat# A27013, Thermo Fisher Scientific) followed by a PierceTM Streptavidin Poly-HRP (1:5000, cat# 21140, Thermo Fisher Scientific) at 4 °C for 10 min for the ACE tertiary cascade. β -actin antibody probing was performed with the iBindTM Flex device (cat# SLF2000, Life Technologies) using primary mouse monoclonal anti- β -actin (1:2000; cat# ab8226, Abcam) and secondary donkey anti-mouse AlexaFluor 488 (1:2000; cat# A21202, Thermo Fisher Scientific). Clarity Western ECL (cat# 1705061, Bio-Rad) was used to visualize HRP detected bands and the Chemi Doc MP Imaging System (Bio-Rad) and Image Lab 5.0 software (Bio-Rad) were used for detection and analysis. Positive controls were mouse brain extract for PRR and ATIIR1, mouse lung protein extract for ACE and PC3 cell lysate for ATIIR2. Negative controls were mouse kidney for PRR, human tonsil for ACE, mouse kidney for ATIIR1 and NTERA2 for ATIIR2.

NanoString mRNA analysis

RNA extraction, as previously described^[27], was performed on four snap-frozen samples of MM to the brain from the same cohort of ten patients included in DAB IHC staining underwent. RNA was subjected to NanoString nCounterTM Gene Expression Assay (NanoString Technologies, Seattle, WA, USA) as completed by New Zealand Genomics Ltd (Dunedin, NZ). Probes for the genes encoding PRR (NM_005765.2), ATIIR1 (NM_000685.3), ATIIR2 (NM_000686.3), ACE (NM_000789.2) and the housekeeping gene GAPDH (NM_002046.3) were designed and synthesized by NanoString Technologies.

RESULTS

Histology and DAB IHC staining

H&E staining (data not shown) demonstrated the presence of MM in all ten samples that stained positively for the melanoma marker Melan-A (data not shown). The endothelium of the microvessels expressed

Figure 2. Representative IF IHC-stained sections of metastatic melanoma to the brain demonstrating cytoplasmic expression and some nuclear expression of PRR (A, red) on the OCT4⁺ (A, green) cells. ACE (B, green) was expressed by the ERG⁺ (B, red) endothelium of the microvessels. Some NANOG⁺ (C, red) cells expressed ATIIR1 (C, green). ATIIR2 (D, red) was expressed in the cytoplasm of the OCT4⁺ (D, green) cells. Cell nuclei were counterstained with 4', 6'-diamidino-2-phenylindole (A-D, blue). Scale bars: 20 μ m. IF: immunofluorescence; IHC: immunohistochemical; PRR: pro-renin receptor; ATIIR1: angiotensin II receptor 1; ATIIR2: angiotensin II receptor 2; ACE: angiotensin converting enzyme

ACE [Figure 1A]. The tumor tissue widely expressed PRR [Figure 1B], ATIIR1 [Figure 1C] and ATIIR2 [Figure 1D], mostly in the cytoplasm.

Human tissues used for positive controls: placenta for PRR, liver for ATIIR1, and kidney for ATIIR2 and ACE demonstrated the expected staining patterns [Supplementary Figure 1]. The omission of the primary antibody provided a control for the secondary antibody (data not shown).

IF IHC staining

IF IHC staining showed cytoplasmic expression of PRR [Figure 2A, red] on the OCT4⁺ [Figure 2A, green] CSCs within MM to the brain. ACE [Figure 2B, green] was expressed only on the ERG⁺ [Figure 2B, red] endothelium of the microvessels. ATIIR1 [Figure 2C, green] was expressed by the NANOG⁺ [Figure 2C, red] CSCs, while ATIIR2 [Figure 2D, red] was expressed on the OCT4⁺ [Figure 2D, green] CSCs in MM to the brain.

Supplementary Figure 2A-H displays individual IF IHC stains shown in Figure 2. Supplemental Figure 2I shows the appropriate negative control on a section of MM to the brain by the omission of the primary antibody.

WB

PRR, at a molecular weight of 40 kDa, was present in all five samples of MM to the brain [Figure 3A]. The negative control of mouse kidney also showed a comparatively faint band. ACE, at 190 kDa, was detected in all five samples, with multiple smaller molecular weight bands detected in all the samples [Figure 3B], possibly due to degraded protein. ATIIR1 was seen in two of the five samples at 45 kDa, with a 28-kDa

Figure 3. Representative images of Western blots performed on five samples of metastatic melanoma to the brain. PRR was detected in all five samples at 40 kDa (A). ACE was detected in all five samples at 190 kDa, with multiple lower bands consistent with protein degradation (B). ATIIR1 was detected at 45 kDa in two samples and at 28 kDa in all five samples (C). ATIIR2 was present at 50 kDa in all five samples (H). Positive controls were mouse brain extract for PRR (A), mouse lung protein extract for ACE (B), mouse brain for ATIIR1 (C), PC3 cell lysate for ATIIR2 (D). Negative controls were mouse kidney for PRR (A), human tonsil for ACE (B), mouse kidney for ATIIR1 (C), and NTERA2 for ATIIR2 (D). PRR: pro-renin receptor; ATIIR1: angiotensin II receptor 1; ATIIR2: angiotensin II receptor 2; ACE: angiotensin converting enzyme

band was also present in all five samples and the positive control [Figure 3C], possibly due to degradation. ATIIR2 was seen in all five samples at 50 kDa [Figure 3D].

NanoString mRNA analysis

NanoString mRNA analysis revealed very high levels of mRNA expression for PRR, moderate levels of ACE and low levels of ATIIR1 mRNA expression, while ATIIR2 was below detectable levels [Figure 4].

DISCUSSION

We have recently identified three CSC subpopulations within MM to the brain: a Melan-A⁺ subpopulation and a Melan-A⁻ subpopulations that express the ESC markers OCT4, SALL4, SOX2 and NANOG, and a pSTAT3⁺ subpopulation localized to the CD34⁺ endothelium of the microvessels within the tumor^[21]. This study demonstrated the expression of PRR, ATIIR1 and ATIIR2 by these CSCs subpopulations we have identified. The demonstration of widespread expression of these cell surface receptors by DAB IHC staining, may be due to their relatively abundant expression within the samples we have examined. Using

Figure 4. Relative expression of mRNA transcripts of PRR, ACE, ATIIR1 and ATIIR2 by NanoString mRNA analysis of four samples of metastatic melanoma to the brain showing high levels of expression of PRR, moderate levels for ACE, low levels for ATIIR1 and undetectable levels for ATIIR2, relative to the housekeeping gene GAPDH. PRR: pro-renin receptor; ATIIR1: angiotensin II receptor 1; ATIIR2: angiotensin II receptor 2; ACE: angiotensin converting enzyme

OCT4 and NANOG as surrogate markers, IF IHC staining revealed localization of PRR, ATIIR1 and ATIIR2 to the OCT4⁺/OCT4⁺/SALL4⁺/SOX2⁺/NANOG⁺ CSC subpopulations while ACE was localized the CSC subpopulation on ERG⁺ endothelium of the microvessels which we have shown to express pSTAT3 previously. The expression of PRR, ACE, ATIIR1 and ATIIR2 was confirmed by WB. NanoString mRNA analysis showed high levels of expression of PRR, lower expression levels of ACE and ATIIR1. ATIIR2 was below detectable levels which may be due to mRNA degradation or its transient presence during transcription within the samples examined.

We have previously reported expression of PRR, ATIIR1 and ATIIR2 by the SOX2⁺ CSC subpopulation, and exclusive expression of ACE by the subpopulation on the endothelium of the microvessels, in human isocitrate dehydrogenase-wildtype GB^[26] and OCSCE affecting different subsites^[27-29]. mRNA expression of renin, ACE, ATIIR1 and ATIIR2 has been demonstrated on primary cultured human keratinocytes, melanocytes, dermal fibroblasts and dermal capillary endothelial cells, but ATIIR2 is not detected in melanocytes^[31].

Cellular proliferation associated with ATI-treated and ATII-treated infantile hemangioma cell culture has shown to be diminished by ACE inhibitor ramipril and the ATIIR2 antagonist PD123319, and is enhanced by ATIIR2 agonist CGP42112^[32], implying a role for the RAS peptides in stem cell proliferation.

Blockade of the RAS leads to inhibited growth of colorectal cancer liver metastases in the regenerating liver^[33] and recent reports of increased overall survival of GB patients treated with angiotensin receptor blockers^[34], support the role of the RAS in cancer. It is exciting to speculate that CSCs in MM to the brain maybe a novel therapeutic target by modulating the RAS, although more work including a larger sample size, control tissue samples and *in vitro* and *in vivo* functional work is needed to determine the precise role of the RAS in this aggressive cancer.

In conclusion, in this study we have demonstrated the expression and localization of components of the RAS: PRR, ACE, ATIIR1 and ATIIR2 in MM to the brain. PRR, ATIIR1 and ATIIR2 are localized to the CSC subpopulations within the tumor while ACE is expressed by the CSC subpopulation on the endothelium of the microvessels. Targeting the CSCs using modulators of the RAS may be a novel therapeutic approach for MM to the brain.

DECLARATIONS

Acknowledgements

We thank Ms Liz Jones, Ms Alice Chibnall and Dr Jonathan Dunne of the Gillies McIndoe Research Institute for their assistance in IHC staining, tissue processing for NanoString mRNA analysis, and WB, respectively.

Abstract

Aim: Hypersensitivity reactions to carboplatin are not an infrequent adverse event in ovarian cancer patients. However, reintroduction of platinum-containing schedules is the standard of care in platinum-sensitive recurrent ovarian cancer. Rapid desensitization is a procedure for gradual reintroduction of drug. It allows a safe administration of medications that are beneficial for the management of patients after certain types of hypersensitivity reactions. It is indicated in cases in which there are no reasonable therapeutic alternatives.

Methods: We performed a descriptive retrospective study of high-grade ovarian cancer patients with known carboplatin hypersensitivity reactions that were treated with a 13-steps rapid desensitization protocol with 3 different solutions and infusion rates. The procedure followed a mathematic model (gradual increases with a relationship between doses following a geometric series) which is called logarithmic rapid desensitization protocol (LRDP). The aim was to describe the safety of the LRDP in terms of number and severity of infusion reactions and the effectiveness in the rate of cycles completely administered.

Results: Four different patients diagnosed with recurrent platinum-sensitive ovarian cancer with a previous infusion reaction were included. LRDP was administered in 19 different cycles. LRDP was administered safely in all 19 cycles, only 2 patients had a mild cutaneous reaction in 4 different cycles during LRDP (21.05%). The foreseen dose of carboplatin was fully administered in all cycles.

Conclusion: LRDP with carboplatin is a feasible and safe protocol in patients with previous infusion reaction to carboplatin. The protocol might allow a safe administration of drugs, that are beneficial for the management of patients, after certain types of hypersensitivity reactions, and it is indicated in cases in which there are no reasonable therapeutic alternatives.

INTRODUCTION

Platinum-based chemotherapeutic agents have been used for the treatment of numerous solid tumors affecting several locations (such as breast, ovarian, endometrial, lung, and gastrointestinal tract). As a result of its extended use, platinum compounds have produced an increased number of reactions^[1,2]. Hypersensitivity reactions are much more frequent with platins than with other drugs. Reactions to carboplatin are a frequent adverse event with an overall incidence of 1%-44% supposing a challenge in the management of ovarian cancer.

In ovarian cancer, platinum-responsiveness have been a classical prognostic factor. Reintroduction of platinum-containing schedules in patients with platinum-responsiveness relapse (> 6 months of interval) is widely recommended^[3-4]. Carboplatin has shown in a randomized trial similar survival than cisplatin but with better safety profile and quality of life^[5]. Since then carboplatin-containing chemotherapy has been considered standard and, as a consequence, relapsed ovarian cancer patients are frequently exposed to an important number of carboplatin infusions.

Positive carboplatin skin tests and the presentation pattern of these reactions suggest that type I pathway immunological mechanisms are involved. Moreover, platinum-specific IgE can be also found in serum among exposed refinery workers and it supports the theory of type IgE-mediated reaction. Furthermore, clinical symptoms related to a reaction to carboplatin range from a mild rash to severe anaphylaxis; thus, different types of immunologic hypersensitivity seem to be implicated^[1].

The fact that the reintroduction of platinum is a major issue in platinum-sensitive patients has prompted the development of desensitization protocols. Rapid desensitization is a procedure for gradual reintroduction of drug at a low dose by dissolving it at a low and intermediate concentration, until reaching the target dose. It allows a safe administration of medications that are beneficial for the management of patients after certain types of hypersensitivity reactions, and it is indicated in cases in which there are no reasonable therapeutic alternatives.

We have performed a retrospective study with the aim of assessing the effectiveness and safety of a logarithm (geometric series) rapid desensitization protocol (LRDP) of carboplatin in patients with platinum-sensitive ovarian relapse that had a previous allergic reaction during carboplatin infusion.

METHODS

Design

This is a pivotal study with the objective of assessing effectiveness and safety of LRDP, in terms of number and severity of infusion reactions, in patients with previous reactions to carboplatin exposure and proportion of completely administered carboplatin-containing schedules. A retrospective review of the clinical chart of patients diagnosed with ovarian cancer in our institution since January 2007 was performed. Data extracted from the clinical chart included: (1) diagnosis, pathological variables and demographic data; (2) data from initial infusion reaction; (3) skin tests; and (4) data from the outcome during LPRD and type of reactions occurring during this protocol.

Classification of the initial reaction bore three aspects: characteristics, severity and timing (time interval between drug administration and the reaction).

Characteristics of clinical symptoms associated with the initial hypersensitivity reactions were categorized by organ system involvement. Cutaneous symptoms (oedema of the face and hands, flushing, pruritus, urticaria or angioedema), respiratory symptoms (dyspnea or wheezing or oxygen desaturation, coughing, nasal congestion), abdominal symptoms (nausea, emesis/vomiting, diarrhea, or abdominal pain), laryngeal angioedema/throat tightness, or cardiovascular symptoms (chest pain, hypotension, hypertension, or tachycardia), neurological/muscular (vision disturbances, weakness, unusual taste, hallucinations, or neurological compromise) according to previous publications^[1,2].

Hypersensitivity severity: A mild rash may be the first manifestation of reactions. Hypersensitivity reactions were classified as mild (reactions limited to the skin), moderate (features suggesting respiratory - dyspnea, wheeze -, cardiovascular - dizziness, diaphoresis, chest tightness - or gastrointestinal involvement - nausea, vomiting, abdominal pain -) or severe (hypoxia, hypotension and neurological compromise - confusion, collapse or incontinence -) according to the scale proposed by Brown^[6].

As for the timing of reaction, hypersensitivity reactions were categorized as immediate or delayed. Immediate reactions were turned up usually during drug administration while delaying reactions were presented after drug administration.

This retrospective study was approved by the local Ethics Committee of Hospital Clinico Universitario of Valencia (resolution number 320) in November 2016.

Patients

Patients included had a histological diagnosis of high-grade ovarian carcinoma and a platinum-sensitive relapsed defined as recurrence after at least 6 months of platinum-free interval. Being considered candidates for the LRDP, patients must have presented a hypersensitivity reaction during carboplatin infusion in a previous cycle. Carboplatin hypersensitivity is a late event^[7]. Consistent with these studies, all reactions in our population occurred after re-exposure to at least seven previous cycles of carboplatin.

In all cases, the initial infusion reaction had been evaluated and managed by emergency staff of the outpatient Oncology department.

Exclusion criteria were an impossibility to understand or to sign informed consent or lack of expected benefit with the reintroduction of carboplatin according to the clinician's opinion.

All patients with a previous type I reaction underwent a skin test with carboplatin before LRDP. Skin testing was performed at least 4 weeks after the initial reaction to minimize the likelihood of false negative results. Drug was diluted further in water with 5% dextrose for testing. For prick test, a drop of carboplatin (10 mg/mL) was applied to the volar surface of the forearm followed by pricking. For intradermal injections 0.03 mL (of a 1:100 dilution followed, if the result was negative, by an 1:10 dilution). A positive reaction was defined as a wheal with a diameter at least 3 mm large that produced by a negative control. Histamine prick (10 mg/mL) was used as a positive control^[1,2].

Informed consent was obtained from each patient before skin testing and desensitization procedures.

Treatment

Before (24-72 h previous) administration of LRDP, a blood test including creatinine and hemogram was performed. Patients were then seen in the outpatient unit of Medical Oncology. Treatment was only

administered if neutrophils count was ≥ 1500 and platelet count $\geq 100,000$. A total dose of carboplatin was always calculated according to the most recent creatinine levels.

According to the severity of the previous reaction and the results of the skin test, the first cycle of the LRDP was administered under an intensive monitoring in an Intensive Care Unit or under a lighter monitoring surveillance in beds of the Oncology Department inpatient area.

A standard premedication with corticosteroids and antagonists of histamine receptors was administered before desensitization to all patients. Metoclopramide hydrochloride 10 mg and dexamethasone 8 mg were given intravenously before initiation of LRDP as standard emesis prophylaxis. Histamine blockade (H1/H2) was performed with 5 mg of parenteral dexchlorpheniramine (5 mg/mL amp) and ranitidine (50 mg i.v.).

The management of reaction during desensitization was intended to block the effects of mast cell mediators, including histamine, prostaglandins and leukotrienes. If symptoms of a hypersensitivity reaction was developed during the desensitization procedure, the infusion was stopped.

In case of a mild reaction, 50 mg of parenteral dexchlorpheniramine (5 mg/mL) was administered. For severe or recurrent reactions, 40 mg of parenteral methylprednisolone (sodium succinate 0.5 mg/kg intravenously) and epinephrine 0.3 mL (1 mg/mL) were also added. Bronchoespasm and throat tightness was treated with inhaled B-agonists. Flushing was treated with aspirin and montelukast. Once symptoms have resolved, the protocol was resumed and the infusion was restarted at the point where the reaction occurred. All desensitization procedures were prescribed and supervised by the allergy and oncology departments and were conducted under physician supervision.

This 13-step LRDP combined gradual increases in the rate of infusion and concentration of carboplatin, administering the total dose over 5 h [Table 1].

The total target dose of carboplatin was calculated using the Cockcroft-Gault's formulation based on the area under the curve with a creatinine level obtained in no more than 24 h previous to the LRDP. Three different solutions A, B and C were employed with a total volume of 50 mL, 100 mL and 500 mL of water with 5% dextrose respectively and delivered in 13 consecutive steps. The concentrations of the solutions were 0.1 mg/mL for infusion A, 1 mg/mL for infusion B and 2 mg/mL for infusion C. Solution A was used for steps 1 to 7, solution B for steps 8 to 11 and solution C for steps 12 and 13. The total dose of carboplatin administered in the last step was calculated by subtracting the cumulative dose given in the steps 1-12 from the total target dose.

The initial dose was approximately in the order of a 10^{-4} times lower (in a rank of $0.2-3 \times 10^{-4}$) that the target dose and each step deliver twice the dose of the previous step. All step concentrations are arranged in a geometric series with a factor two. The first term of the series is 1/32 and the common ratio is 2 (1/32, 1/16, 1/8, 1/4, 1/2, 1, 2,). The rate of the infusion was adjusted every 15 min. The final step 13 maintained a constant rate of infusion in order to deliver the remainder of the total carboplatin dose.

RESULTS

From February 2011 to November 2014, 4 patients with platinum-sensitive recurrence of ovarian cancer that had presented a documented hypersensitivity reaction to the latest carboplatin infusion were treated with LRDP.

Patients characteristics and type of infusion reaction are shown in Table 2. Cutaneous reaction was the most frequent type of reaction to standard carboplatin administration in our series. All patients presented

any type of cutaneous reaction. According to severity, the half of patients, 2 out of 4, experienced a mild reaction (either pruritus, urticaria or angioedema).

One patient (1/5) developed a moderate reaction to standard infusion of carboplatin with cutaneous symptoms (palmar rash, pruritus, urticaria), respiratory symptoms (dyspnea) and cardiovascular symptoms (dizziness and diaphoresis).

Another patient (1/5) presented a severe reaction, including cutaneous (edema of the face and hands/flushing with palmar erythema, pruritus, urticaria), respiratory (dyspnea and oxygen desaturation) and cardiovascular symptoms (hypotension).

All 4 patients included had developed a reaction to standard carboplatin after at least 7 previous cycles of carboplatin (range 8th-14th cycle of carboplatin).

Regarding skin test results, only one patient had positive skin tests to carboplatin cutaneous exposure at their initial evaluation and the remaining 3 patients were negative. The patient who had specific-IgE (in skin) showed a moderate reaction in relation to the initial reaction and only a cutaneous reaction during the desensitization.

In total, 19 cycles of LRDP carboplatin were administered (in all cases successfully) under the LRDP. The rate of reactions during desensitization procedure was 21.05% (4 reactions out of 19 cycles), of whom all 4 reactions were considered as mild (palmar and/or facial erythema with pruritus). Despite these reactions, once symptoms have resolved, the foreseen carboplatin dose was fully administered after the protocol was resumed.

DISCUSSION

This report describes our experience with 19 rapid desensitizations with carboplatin in 4 patients that had a previous hypersensitivity reaction during standard carboplatin infusion. The procedure is successful, and we have been able to complete all the desensitizations undertaken.

Table 2. Characteristics of patients: type and severity of initial infusion reactions and during LRDP

Patient	Type of reaction	Timing	Severity	Skin test	Number of cycles of carboplatin inducing reaction	Schedule that induced reaction	Number of cycles with LRDP	Schedule during LRDP	Reaction during LRDP
Patient 1	Cutaneous	Immediate	Mild	-	8th (2nd line)	Carboplatin Paclitaxel	6	Carboplatin DLP	None
Patient 2	Cutaneous	Immediate	Mild	-	9th (2nd line)	Carboplatin Gemcitabine	2	Carboplatin Gemcitabine	None
Patient 2 (II)							4	Carboplatin DLP	None
Patient 3	Cutaneous Respiratory Cardiovascular	Immediate	Moderate	+	14th (3th line)	Carboplatin Gemcitabine	2	Carboplatin Gemcitabine	Cutaneous (2/2)
Patient 4	Cutaneous Respiratory Cardiovascular	Immediate	Severe	-	11th (3th line)	Carboplatin Gemcitabine Bevacizumab	5	Carboplatin monotherapy	Cutaneous (2/5)

LRDP: logarithmic rapid desensitization protocol

Carboplatin has had an increasing use and there has been an increase incidence of reactions. When a reaction occurs, options are desensitizing or substituting with a different agent. Successful replacement of carboplatin by cisplatin has been shown in patients with gynecological malignancies^[8,9]. However, the possibility of developing a reaction to the substituting platinum agent may be as high as 25%^[10] and cases of fatal cisplatin reactions have been reported^[11]. In this context, substitution of carboplatin must be considered with caution. Because of, desensitization protocols have been successfully used to manage hypersensitivity reactions^[1,2,12,13].

Goldberg *et al.*^[14] reported a desensitization regimen in two patients based in serial dilutions, with administration of increasing concentrations of carboplatin. Patients subsequently received infusions of 10^{-3} , 10^{-2} , and 10^{-1} of the total of the carboplatin dose. The final infusion contained 90% of the total drug dose.

Castells has developed a successful protocol of desensitization which would be supported by a basic biochemical mechanism: hypo-responsiveness in mast cells associated to suboptimal and increasing doses delivered at fixed time intervals (15 min). Therefore, specific mast cell and basophils tolerance could be due to the molecular stabilization of membrane, that would permit surpass a threshold antigen concentration required to activate these cells^[15]. Based on these dates, a 12-step protocol with a standardized three-resolution was generated which allows, for gradual increases in the infusion rate, to administer the target dose over 5-8 h. Doses of antigen must be delivered at fixed time intervals. Steps 1-11 last 15 min, and step 12 was prolonged to complete the target dose. The rate of the infusion was changed every 15 min, which each step delivering approximately twice (2 or 2.5) the dose of the previous step. The final step 12 maintained a constant role of infusion to deliver the remainder of the total dose. According to the description of the own authors, bag A contains a 100-fold lower amount of final target dose diluted in 250 mL (water with dextrose 5%); bag B contains a 10-fold lower amount of final target dose diluted in 250 mL and bag C contains final target minus a cumulative dose of previous steps, diluted in 250 mL^[1,2,12,13].

We have chosen a different path to calculate drug concentration of each bag, not giving importance to the concentration of each solution in relation to the target dose as other models. In order to facilitate the calculations, we selected a concentration based on mathematic concepts on the unit. The solution A had a concentration of 10^{-1} mg/mL (0.1 mg/mL) of the drug, the solution B had a concentration of 1 mg/mL and solution C (one only step) was calculated with a concentration of 2 mg/mL and including the total remaining dose of the drug in order to be administered at a faster speed. The initial dose of protocol had not a direct relationship with the target dose even though was approximately in order of 10^{-4} (approximately in a rank of $0.2-3 \times 10^{-4}$) lower than the target dose (if this dose is in the rank of 1-1000 mg) and this allowed us to apply the protocol in a simpler way. The procedure followed a mathematic model (gradual

increases with a relationship between doses following a geometric series) which is called LRDP. We have implemented this protocol consisting of 13 doses delivery stages, underlining the accurately relationship between doses in a geometric series. Progression of the doses occurred logarithmically. Each step delivered exactly twice the dose of previous step, in such a way that all step concentrations arranged in a geometric series with a factor two. The first term of the series is 1/32 and the common ratio is 2 (1/32, 1/16, 1/8, 1/4, 1/2, 1, 2,). The total quantity of volume in each of the three bags with each of the solutions is not very different from the volume to administer. Therefore, in case of a potential mistake in the schedule, the risk for the patient is minimized.

To enhance patient safety, administration of LRDP was performed by a multidisciplinary team including physicians and nursing staff from the Departments of Allergy, Medical Oncology and Pharmacy. LRDP with carboplatin is a feasible and safe protocol in patients with previous infusion reaction to carboplatin.

CONCLUSION

We have performed a retrospective study with the aim of assessing the effectiveness and safety of a LRDP with carboplatin in patients with a previous reaction. It is a promised protocol for administration of carboplatin after an infusion reaction.

The protocol might allow a safe administration of drugs (it can be applied to other drugs because the therapeutic dose of the majority of drugs is in a range between 1-1000 mg), that are beneficial for the management of patients, after certain types of hypersensitivity reactions, and it is indicated in cases in which there are no reasonable therapeutic alternatives.

DECLARATIONS

Authors' contributions

Designed the study and wrote the manuscript: Burches E, Pérez-Fidalgo JA

Abstract

Excess adiposity, a worldwide-growing pathological condition, is now recognized as a main risk factor for most chronic diseases including colorectal cancer (CRC). Obese subjects show an increased cancer incidence with obesity representing an important indicator of survival, prognosis, recurrence and response to therapy. A low-grade chronic inflammation of metabolically active tissues including the adipose tissue (AT), defined as meta-inflammation, is a main feature of obesity. Fatty acids (FA), the main AT components, are important modulators of inflammation, and the type of FA stored in AT critically affects tissue functions. Their profile within AT mirrors FA dietary intake but also depends on a metabolic control. Obesity, changes in the habitual diet, weight loss or pathological conditions like CRC influence FA profile of AT pointing to these molecules as important actors in AT dysfunction and meta-inflammation, that characterize metabolic diseases and may favor cancer development. Worth of note, diet is receiving growing attention as a main determinant in cancer prevention due to its capacity to modulate immune response and inflammation. Alterations in the balance between different families of FA may contribute to generate a pro-inflammatory profile with deleterious effects on metabolic and immune homeostasis at both local and systemic levels. This review focuses on FA as regulators of human AT inflammation discussing the role of obesity-, diet-, and weight loss-associated changes in FA profile in this process. The relevance of FA composition of AT in linking diet, obesity and CRC will be also reviewed.

Keywords: Obesity, adipose tissue, inflammation, diet, weight loss, fatty acids, colorectal cancer

INTRODUCTION

The overweight and obesity epidemic represents a rapidly growing health threat in several countries. Excess adiposity is associated with increased incidence of several cancers and represents an important indicator of survival, prognosis, recurrence and response to therapy in many tumors, including colorectal cancer (CRC). The risk of developing CRC is significantly increased in obese subjects, with abdominal obesity being more predictive than overall obesity, and is highly modifiable by diet^[1]. Dietary habits and excessive adiposity can not only influence cancer growth but also shape host immune response^[2]. White adipose tissue (AT), now recognized as the largest endocrine organ, plays a key role in metabolic and immune homeostasis^[3]. This tissue influences many local and systemic physiological and pathological processes by virtue of its capacity to secrete a large number of hormones, cytokines/chemokines/adipokines, extracellular matrix proteins, lipid metabolites and growth factors^[4]. In condition of chronic positive energy balance, AT undergoes profound modifications including adipocyte expansion, induction of hypoxia, and mitochondrial function alterations that lead to tissue remodeling, inflammation and metabolic dysfunction^[5]. These events tightly couple with dramatic changes in the immune cell repertoire and functions^[6,7] shifting the balance of cell subsets and soluble mediators toward a pro-inflammatory profile. Indeed, growing evidence indicates that meta-inflammation - a chronic low-grade inflammatory state occurring in metabolically active tissues including the AT - characterizes obesity and contributes to the impairment of immune functions, thus representing a key determinant in the development of obesity-related morbidities, including cancer^[8].

Evidence suggests that lipids, especially fatty acids (FA), the main components of AT, play an important role not only in obesity development but also in the interplay between excessive adiposity and development of associated diseases^[9]. Dietary lipids derived from plants and animals encompass FA (saturated, SFA, monounsaturated, MUFA, and polyunsaturated, PUFA), their derivatives including mono-, di-, and triglycerides and phospholipids, as well as sterols such as cholesterol. Among FA, SFA are mainly found in animal food, but a few plant food is also high in saturated fats, such as coconut, coconut oil, palm oil, and palm kernel oil. MUFA can come from both various plant-based (e.g., vegetable oils and nuts) and animal-based sources (e.g., red meats and high-fat dairy products). PUFA are essential FA as they cannot be synthesized from precursors in the diet, and derive primarily from plant-based sources. However, ω 3 PUFA can also be found in fish oils^[10,11].

The type of FA stored in AT, besides adipocyte fat overload, critically affects tissue functions. FA can directly or indirectly modify immune and inflammatory responses by several mechanisms, acting on cell surface and intracellular receptors that control cell signaling and gene expression^[12,13]. Recent studies have indicated that dietary FA quality rather than quantity has major implications in meta-inflammation development. In fact, FA exhibit either pro- or anti-inflammatory activity depending on their chemical structure^[11,13]. In general, long-chain SFA have been associated with inflammation while short-chain FA show anti-inflammatory effects^[14]. On the other hand ω 3 PUFA favor anti-inflammatory profiles, while ω 6 PUFA, with a few exceptions, are endowed with pro-inflammatory activity^[10]. Lastly, the effect of MUFA is more debated, with evidence for either anti-inflammatory or weak pro-inflammatory responses^[11,13].

The FA composition of AT is widely considered a marker of medium- and long-term dietary fat intake, with a general agreement that FA content in AT mirrors their relative abundance in the diet^[15]. However, FA profile in AT also depends on, at a certain extent, a metabolic control. Indeed, different AT sites exhibit different FA compositions^[16,17] as well as different rates of FA turnover^[18] and active remodeling^[19]. Furthermore, while some ω 3 PUFA such as docosahexaenoic acid are preferentially stored, others like

eicosapentaenoic acid are preferentially released or turned over during lipolysis^[19]. More recently, evidence points to a relevant role of enzymes involved in FA metabolism in defining plasma and tissue FA profiles. Human studies indicate that inter-individual variation in desaturase genes is due to both genetic and lifestyle factors, highlighting that the function of these enzymes may influence disease risk^[20].

In the following sections we will overview obesity-, diet-, and weight loss-associated changes of FA profiles by focusing on human AT. The role of FA as potential regulators of inflammation in metabolically active tissues, in particular AT, and as a link between obesity and CRC development will be discussed.

OBESITY-ASSOCIATED FATTY ACID PROFILES OF ADIPOSE TISSUE AND THEIR RELATIONSHIP WITH DIETARY INTAKE

Subcutaneous (SAT) and visceral (VAT) white AT depots constitute AT bulk. Their body distribution shows person-to-person variations and depends on several factors such as age, nutrition, sex, and energy homeostasis of the individual AT^[21]. VAT and SAT show significant variations in anatomical, cellular, molecular, and physiological characteristics^[22] and play different roles in metabolic syndrome development^[21]. In fact, excessive VAT accumulation is commonly associated with insulin resistance, markers of oxidative stress and inflammation, high risk of type 2 diabetes (T2D), dyslipidemia, and high mortality^[23-25]. Conversely, SAT accumulation is associated with improved insulin sensitivity and lower risk of T2D. Furthermore, metabolically beneficial adipokines (i.e., leptin and adiponectin) are secreted in higher amounts by SAT, whereas pro-inflammatory mediators are more abundantly secreted by VAT, regardless the body weight^[22]. Interestingly, in obese subjects, SAT exhibits a higher content of SFA with respect to VAT that instead shows a higher accumulation of MUFA as well as a higher activity of stearoyl-coenzyme A desaturase 16 (SCD16) and SCD18. Conversely, a similar PUFA composition has been reported for both fat depots^[16,17].

Some studies investigated obesity-associated FA profile of AT that can be modified by specific diets, weight loss or in pathological conditions like CRC. However, the patterns of FA accumulation distinguishing lean with respect to obese subjects are poorly known. A summary of the main differences in FA profiles of AT related to fat depot, obesity, weight loss and cancer, are shown in Table 1.

Despite any difference in SFA, MUFA and PUFA ($\omega 3$ and $\omega 6$) total content in the VAT of lean with respect to obese subjects, a clear-cut decrease in the $\omega 3/\omega 6$ ratio was detected in the latter^[26]. Furthermore, analysis of individual members of the $\omega 6$ PUFA family unraveled that arachidonic acid content increases in obese subjects with respect to lean while γ linolenic acid, the only member of the $\omega 6$ PUFA family endowed with anti-inflammatory activity, decreases in the same subjects^[27]. Moreover, a higher palmitoleic acid content and SCD1 index have been reported in SAT of obese *vs.* lean subjects^[28]. Likewise, our study demonstrated that higher levels of palmitoleic and stearic acids together with a higher desaturation index (i.e., SCD1 $\Delta 9$ -18) are found in the VAT of obese subjects^[29].

The FA composition of AT reflects not only the dietary intake but also endogenous fat processing. Thus, changing the nature of the fat consumed has a profound influence on the type of FA available to the body and may alter AT composition^[30]. In this regard, our most recent data show a higher arachidonic acid dietary intake in obese subjects as well as a higher arachidonic acid content of VAT^[27,29]. The relative proportion of some PUFA (i.e., linoleic, α linolenic, eicosapentaenoic and docosahexaenoic acids) as well as of SFA (i.e., palmitic acid) and MUFA (i.e., palmitoleic acid) in SAT was also found to mainly reflect their dietary intake in a large Swedish cohort study of adult men^[31]. Likewise higher levels of oleic acid in SAT were observed when overweight subjects received a MUFA- rather than a SFA-rich diet^[32]. The association between dietary FA and their composition in specific AT was studied in a cohort of obese subjects from the

Table 1. Fat depot-, obesity-, weight loss- and cancer-related differences in fatty acid profile of visceral and subcutaneous adipose tissue

Comparison	AT localization	FA profile and lipid metabolism enzymes	Ref.

Mediterranean area. Significant correlations were found for oleic, linoleic and α linolenic acids and for total $\omega 6$ PUFA between the subjects' habitual diet and AT composition. Interestingly, VAT accumulation was positively associated with $\omega 6$ PUFA and inversely associated with MUFA and $\omega 3$ PUFA^[17]. The subsequent assessment of the dietary pattern, AT composition and degree of obesity showed that despite a similar dietary pattern among the groups, overweight and morbidly obese individuals ($\text{BMI} \geq 40 \text{ kg/m}^2$) have a higher MUFA content than obese subjects ($\text{BMI} \leq 40 \text{ kg/m}^2$), probably due to differences in SCD1 activity, slightly higher in morbidly obese than in obese subjects^[33].

WEIGHT LOSS AND DIET-INDUCED MODIFICATIONS OF ADIPOSE TISSUE FATTY ACID PROFILES

The association between individual FA content and body weight is rather complex due to the fact that distinct FA share dietary sources and metabolic pathways. Furthermore, a complex interplay among lifestyle, bulk intake of nutrients together with the genetic background influences FA composition of AT in addition to their dietary intake. Likely due to this complexity, only few studies investigated the association between specific FA or FA profile of AT with dietary intake, and assessed the effects of changes in FA composition of AT on the health status. Nevertheless, beneficial changes in FA profiles of AT have been observed in response to weight loss, that can potentially contribute to weight maintenance, as well as to modifications of the dietary pattern. Some rather old studies, carried out in small cohorts of subjects, first observed that weight loss, promoted in obese subjects by different low calorie diets (LCD), results in a reduced accumulation of α linolenic acid in SAT while the content of other FA remained unchanged^[34,35]. This preferential reduction also occurred when LCD were supplemented with canola or linseed oils^[36]. These findings strongly suggest that the relative amount of individual FA in AT depends, not only, on

the dietary intake but also on the different rates of metabolic reaction that utilize FA as substrates. Subsequent analysis of FA composition after LCD-induced weight loss and 6-month weight maintenance showed a reduction in total SFA, palmitic and palmitoleic acid content that paralleled a concomitant increase of stearic and oleic acids^[37]. Likewise a significant increase in some $\omega 3$ (i.e., eicosapentaenoic and docosahexaenoic acids) and $\omega 6$ (i.e., linoleic, dihomo- γ -linolenic, arachidonic and docosatetraenoic acids) PUFA was also observed. Furthermore, a specific role of MUFA in weight management and as predictors of weight change was suggested. In fact lower baseline content of MUFA in SAT predicts a better weight maintenance while lower oleic acid accumulation predicts lower weight decrease^[37]. Potentially beneficial modifications in FA composition of SAT have also been observed in a Finnish study upon obesity surgery - a procedure that leads to changes in gut anatomy and diet as well as to weight loss - in combination with rapeseed oil- and fatty fish-enriched diet^[38]. The main findings were a decreased content in SFA, mainly due to palmitic acid decrease, paralleling an increased accumulation of oleic acid in SAT. The metabolic improvement observed after surgery has been attributed not only to weight loss but also to diet-induced changes of endogenous lipid metabolism enzymes. In fact the increased activity of elongase 5 and delta 6 desaturase (D6D), as well as the decreased activity of SCD1 and D5D were strongly associated with weight loss^[38]. Interestingly, with the exception of $\omega 3$ PUFA, comparable modifications in FA content were induced by weight loss or lifestyle intervention without surgery^[38].

DIETARY FATTY ACIDS AS MODULATORS OF ADIPOSE TISSUE INFLAMMATION

The primary event in the sequence leading to chronic inflammation in AT is metabolic dysfunction of adipocytes, that promotes inflammation via the expression of inflammatory response genes. In spite of the well-known capacity of FA to modulate inflammatory processes and of the observation that specific FA profiles in the AT are associated with a pro-inflammatory condition, only few studies investigated the effects of direct exposure of adipocytes rather than of other cell types within the stromovascular fraction, to different FA on AT inflammation. Contrasting results were some time achieved likely reflecting differences in AT microenvironment, as the stromovascular fraction of AT strongly contributes to shape inflammation being a major source of immune mediators. Nevertheless, these studies shed light on the molecular pathways triggered specifically in adipocytes underlying the pro- or anti-inflammatory effects of FA^[4,6].

In vitro studies have reported that SFA stimulate an inflammatory response by the activation of Toll-like receptor (TLR)/NF- κ B pathways. Abdominal SAT and VAT adipocytes from obese subjects exposed to free FA (i.e., oleic, linoleic, arachidonic, lauric and myristic acids or palmitic and stearic acid mixtures) show an increased expression of pro-inflammatory cytokines (TNF- α , IL-6 and CCL2)^[39,40]. Interestingly the extent of SFA response does not differ greatly between AT explants and isolated adipocytes, highlighting the capacity of the latter to mount an autonomous inflammatory response to environmental factors^[40]. However, the reported activation of TLR pathways by dietary SFA (lauric and palmitic acids) was not confirmed in other studies in SAT explants and adipocytes under different experimental conditions (i.e., FA concentration or degree of endotoxin contamination)^[41].

While SFA were found to stimulate pro-inflammatory responses, $\omega 3$ PUFA, in particular docosahexaenoic and eicosapentaenoic acids, have been reported to exert an anti-inflammatory action in whole SAT and VAT as well as in isolated adipocytes from obese subjects by down-regulating the expression of pro-inflammatory mediators (IL-18, CASP-1, IL-1 β , CX3CL1, CCL2, TNF- α and IL-6)^[41-43]. Likewise, our studies demonstrated that docosahexaenoic acid attenuates the VAT adipocyte inflammatory status by reducing STAT3 activation and IL-6 secretion, and up-regulating adiponectin expression, regardless the body weight^[26,27]. Conversely, exposure of VAT adipocytes from lean and obese subjects to arachidonic acid results in a significant up-regulation of phospho-STAT3 and concomitant down-regulation of PPAR γ expression as compared to the untreated paired individuals^[26,27]. The observation that obesity-associated FA profile of VAT parallels alterations of the immune cell repertoire in the tissue microenvironment suggests

a role for VAT PUFA composition in shaping immune phenotypes^[44]. $\omega 3$ and $\omega 6$ PUFA, in particular decosahexaenoic and arachidonic acids, have also been reported to differently influence adipocyte transcriptional program in lean and obese subjects^[42,43,45]. Among the genes modulated by decosahexaenoic acid are those involved in AT inflammation and metabolism such as *FADS1* and *FADS2* genes that code for D5D and D6D, respectively, and thus control AT PUFA metabolism^[45,46]. The regulatory action of dietary PUFA on adipocyte genomics adds further evidence for a role of diet in the modulation of obesity-associated AT inflammation.

The role of FA in the modulation of obesity-associated AT inflammation has also been investigated in several clinical trials aimed at assessing the effect of consumption of different FA on the expression of inflammation-related genes in AT. However, some conflicting results have been reported probably due to the large variability in concentration and type of FA used in each intervention, differences among the specific populations investigated, variability in intestinal microbiota among individuals. Moreover, recent studies suggest that the AT response to FA is more complex than originally anticipated, and that the gene expression in AT is site specific suggesting that not all fat depots in the body are controlled in the same manner. The analysis of inflammatory responses in different sites (SAT or VAT, whole AT or isolated adipocytes) may therefore have generated discordant results.

As described for the *in vitro* studies, the consumption of a SFA-rich diet results in a pro-inflammatory gene expression profile in SAT (i.e., CD16a, IL-1 β , IL-6, IL-6R and TNF- α), while MUFA-rich diet or acute post-prandial MUFA intervention lead to different profiles depending on the category of subjects. Indeed in abdominally obese^[32] or healthy subjects the majority of regulated genes show anti-inflammatory features, whereas in subjects at higher risk of T2D the post-prandial consumption of MUFA-containing macadamia nut oil evokes an inflammatory response with up-regulation of several inflammatory genes (CCL2, IL-1 β , IL-6, IL-6R, TNF- α and TNFRSF1A)^[47]. These results indicate that MUFA can also exert a pro-inflammatory response, which is greater among subjects with obesity-related diseases as compared to healthy individuals. In line with this evidence, an exacerbated AT post-prandial inflammatory response (NF- κ Bp65, CCL2, IL-6 and IL-1 β) occurs in SAT of metabolic syndrome patients^[48].

The potential benefits of $\omega 3$ PUFA consumption on a wide range of AT inflammatory responses have been highlighted in recent studies^[49]. In a randomized controlled trial involving severely obese patients (≥ 40 kg/m²), $\omega 3$ PUFA supplementation over an eight-week period results in down-regulation of inflammatory genes (CCL2, CCL3, HIF1A, CD40 and IL-6), and up-modulation of the anti-inflammatory adiponectin in SAT, but not in VAT, in comparison with the control group^[50]. Additionally, consumption of different sources of fatty fish reduces the expression of AT inflammatory genes including inflammasome-associated IL-18, IL-1 β and IL1RN or impairs fasting glucose in obese subjects^[43,51]. Moreover, in a clinical trial (FFAME) involving healthy volunteers and based on eicosapentaenoic and decosahexaenoic acid supplementation, $\omega 3$ PUFA showed immune-modulatory and anti-inflammatory capability through the modulation of several inflammatory and specific immune genes during evoked AT inflammation induced by experimental endotoxemia^[52,53]. In contrast to these results, no effect on SAT inflammation was observed neither in overweight to moderately obese adults consuming a diet rich in $\omega 3$ PUFA^[54], nor in obese postmenopausal women after decosahexaenoic acid supplementation^[55]. Finally, $\omega 3$ PUFA (i.e., eicosapentaenoic acid and/or α -lipoic acid) dietary supplementation in addition to weight loss and dietary interventions unravels differences in the expression of genes related to inflammation and immune response in SAT from overweight/obese women^[56]. Other clinical evidence demonstrates that weight loss, known to improve obesity-associated low grade inflammation, is linked to changes in AT FA composition, suggesting a specific role of different FA in weight management and control of inflammation^[57].

A strong association between SFA and MUFA AT profiles and AT inflammation was demonstrated by the KOBS study. The results achieved showed that surgery-induced weight loss of obese individuals

reduces the expression of IL-1 β and NF- κ B pathway and unravels a positive/negative association between inflammation and SFA and MUFA content, respectively, in both SAT and VAT^[16]. These correlations were modified by the FADS1/FADS2 genotype, both in KOBS and DIOGENES studies, indicating that variants in this gene cluster may influence the interaction between AT FA and tissue inflammation^[16,58]. In the same KOBS cohort, Walle *et al.*^[38] measured serum and AT FA composition and AT expression of genes regulating FA metabolism before and one year after obesity surgery, combined with dietary counseling. Interestingly, some of the changes observed in AT FA profile are associated with the expression of elongases and desaturases, key enzymes in FA metabolism^[38]. According to these results, weight loss after bariatric surgery in morbidly obese women^[59] or after LCD in obese premenopausal women^[60] significantly improves the SAT inflammatory and immune profile by decreasing the expression of pro-inflammatory factors while increasing that of anti-inflammatory molecules as well as of genes involved in the regulation of lipid metabolism. Furthermore, the effects of two different LCD among obese women, within the NUGENOB study trial, were determined on SAT mRNA expression level, according to energy deficit and fat to carbohydrate ratio^[61]. Among the transcripts deregulated during the diets are genes involved in lipid, carbohydrate and energy metabolism^[61,62]. In contrast to these results, no changes in adipocyte gene related to inflammation and metabolism were reported in SAT in two cohorts of obese pre- and post-menopausal women after energy-restricted diets^[63,64], although inflammation related biomarkers were reduced systemically^[63].

ADIPOSE TISSUE INFLAMMATION, FATTY ACID PROFILE AND COLORECTAL CANCER

AT-associated inflammation promoted by incorrect dietary habits and obesity, under the influence of signals derived from the gut microbial flora, is a main mechanism that may favor CRC development and progression^[65]. Inflamed AT may contribute to tumorigenesis by releasing pro-inflammatory mediators and by modifying the lipid metabolism, which is part of the reprogrammed energy metabolism that characterizes cancer^[66]. In turn, cancer cells have the ability to induce metabolic changes in neighboring adipocytes and to use AT released FA as substrates for their proliferation^[67,68].

A number of studies have analyzed the profiles of FA in AT of CRC patients, in association or not with dietary intake, or have correlated specific FA profiles with CRC risk^[69,70]. Some old studies reported a similar FA profile in healthy and CRC affected subjects^[71,72]. However, despite a comparable consumption of the major dietary components and fat intake between the study groups, an age-associated decrease in unsaturated fat intake was observed only in the CRC group. Conversely, correlation between dietary and AT PUFA:SFA ratio was found in the control but not in the cancer group^[72].

More recently, a general agreement has been achieved on the increased accumulation of pro-inflammatory ω 6 PUFA (mostly dihomo- γ -linolenic and arachidonic acids) as well as on the unbalanced ω 3/ ω 6 PUFA ratio in the AT of CRC patients, regardless of tumor subsite, even though differences were reported among studies on the relative abundance of individual PUFA and type of AT involved^[27,73-75]. In particular, a comparison of VAT and SAT FA profiles in colon cancer (CC) patients highlights a decrease of the ω 3 PUFA α linolenic and stearidonic acid content, coupled to increased dihomo- γ -linolenic and arachidonic acid content in VAT of CC patients as compared to controls. Conversely, FA composition of SAT in CC subjects is only marginally altered, with increased γ linolenic acid levels^[74]. Although no dietary information was available for the study population, the low ω 3/ ω 6 PUFA ratio generally observed in AT likely reflects Western dietary habits^[74]. Changes in the ω 3/ ω 6 PUFA profile (higher dihomo- γ -linolenic and docosapentaenoic acids, *vs.* lower α linolenic acid) were also reported in SAT from CRC patients, in association with markers of systemic inflammation^[75]. The altered ω 3/ ω 6 PUFA balance in cancer patients can markedly affect tissue composition and function as a result of the reduced protective effect of ω 3 PUFA. Moreover, a CRC-associated increase of total SFA and MUFA content in VAT and SAT, respectively, was also described in some studies^[74].

Although the influence of BMI on the FA changes in CRC-affected subjects was not considered in the above studies, its relevance emerged in our subsequent studies in which the VAT FA composition was analyzed in newly diagnosed CRC patients, sub-grouped in lean and obese according to BMI^[26,27,29]. A reduced $\omega 3/\omega 6$ PUFA ratio as well as an increased content of dihomo- γ -linolenic and docosatetraenoic acids, coupled with STAT3 activation characterize CRC subjects, irrespective of BMI^[26,27]. However, compared to healthy individuals, obese CRC patients show a selective accumulation of arachidonic acid in VAT, whereas a lower SFA content is specific of lean CRC subjects despite a higher dietary intake^[27,29]. The lack of correspondence between SFA intake and storage in the latter subjects could in part rely on an accelerated SFA to MUFA conversion as suggested by the increased estimated activity of SCD1 $\Delta 9$ -18^[29]. Interestingly, the increased content of pro-inflammatory FA in AT from CRC-affected individuals is associated to an enhanced adipocyte release of inflammatory cytokines and chemokines (IL-6, CCL2, CXCL8) and with the establishment of an immunosuppressive VAT microenvironment^[27].

AT and its FA content have also been related to tumor progression by Mosconi *et al.*^[76], who analyzed VAT peri-tumoral fat composition in CRC patients at different tumor stages. The total content of MUFA in close proximity of, but not far from the tumor lesion, was found significantly increased in patients at higher tumor stage, especially stage IV. Comparable levels of SFA and PUFA were instead found in the same patients, irrespective of the tumor stage, suggesting a selective involvement of MUFA in cancer progression^[76]. Some food processing techniques (industrial hydrogenation of fats) and cooking methods (heating and frying at temperatures > 220 °C) convert FA, naturally present in food in the *cis* form, into their *trans* form, and the latter configuration has been associated with increased risk of cancer and cardiovascular diseases^[77]. In the EURAMIC epidemiological study the FA composition of SAT samples was used as a measure of FA intake and associated with CC risk^[78]. Statistically significant inverse correlations were found between *cis*-MUFA concentration and the incidence of CC. Conversely, CC incidence positively correlates with the content of *trans*-MUFA^[78]. As it stems from these results, the same category of FA (e.g., MUFA) can exert a protective or promoting effect on CRC onset/progression, depending on their configuration, the fat depot in which they are enriched, and the tumor stage^[76,78].

As stated above, AT FA profiles are influenced also by the activity of enzymes driving FA synthesis and/or conversion. The expression/activity of these enzymes have been found dysregulated in tumor and AT from cancer patients. In particular, FA synthase (FASN), a key anabolic enzyme, increases in the intestinal mucosa of subjects with CRC or with pre-cancerous lesions according to the increased metabolic demand of cancer cells^[79]. In contrast, FASN expression and activity are significantly reduced in VAT adjacent to the tumor lesion, resulting in impairment of FA synthesis and AT storage^[80]. The inflammatory VAT microenvironment might account for this reduction as a comparable FASN downregulation was described in obese and CRC-affected individuals^[27,45,81].

Altogether, the alterations of FA metabolism and profiles in different fat depots, in proximity or far from the tumor lesions, contribute to maintain a pro-inflammatory microenvironment in CRC patients, and strongly support a role for both unbalanced dietary intake and changes in FA metabolism and storage in colon and rectal carcinogenesis.

CONCLUSION

The type of daily consumed dietary fat together with metabolic activities influence the FA profile in AT and can alter its functionality thus contributing to the onset of meta-inflammation that characterizes obesity and metabolic diseases [Figure 1]. The promotion of inflammatory processes within AT determines an inflamed microenvironment that can represent a trigger for the development of a number of obesity-related pathologies including CRC. All together these findings highlight the relevance of maintaining healthy dietary habits and the central role of AT in preserving health and well-being. However, the studies,

Figure 1. A schematic representation of the interplay between diet and metabolism in determining the fatty acid profile of adipose tissue. The consequences of adipose tissue dysfunction in the pathogenesis of obesity-related morbidities including cancer are depicted

especially the clinical trials, carried out until now provide often contrasting results. This should drive to implement new researches specifically addressed to clarify the relationship among the various molecular pathways involved in FA metabolism and inflammation establishment. The improvement of knowledge on the real role that dietary habits play in modulating key metabolic processes, will allow to provide personalized nutritional advices that take in account the inter-individual differences, including those gender-related, in the response to diet.

Abstract

Cancer exacts a heavy socioeconomic cost. Earlier detection and treatment are likely to mitigate this cost. Unfortunately, conventional tissue biopsy, the gold standard in cancer diagnosis cannot fulfill the goal of earlier detection. While liquid biopsy is a promising alternative to tissue biopsy, it has its challenges and limitations. A major challenge is the isolation of bona fide lipid membrane vesicles from biological fluids. In this review, we presented a new perspective of isolating different types of extracellular vesicles (EVs) by their affinity for membrane lipid binding ligands for liquid biopsy. EVs are lipid membrane particles naturally released by almost all cells and are found in almost all biological fluids suitable for liquid biopsy. They carry materials from the secreting cells that could affect the biology of the recipient cells and could thus inform on the state and progress of the disease. However, isolating bona fide EVs is a technical challenge as biological fluids have a complex composition and contain particles or aggregates that are physically similar to EVs. Here we review the use of membrane lipid-binding ligands to isolate different bona fide EV subtypes, and to circumvent the problem of co-isolating physically similar non-EV complexes in current EV isolation protocols. We will discuss the advantages of this technique and its potential for accelerated biomarker discovery and validation through examples of pre-clinical studies. We propose that isolating EV subtypes is a technically viable and robust strategy to overcome the current bottleneck of isolating EVs for liquid biopsy.

INTRODUCTION

Cancer is the second leading cause of death in the world according to WHO (<https://www.who.int/news-room/fact-sheets/detail/cancer>). In 2018, there was an estimated 18.1 million new cancer cases and 9.6 million cancer deaths worldwide with 70% occurring in low and middle-income countries^[1]. This creates a devastating socioeconomic burden. To reduce this cancer burden, WHO has recommended cancer prevention through avoidance of risk factors and implementation of existing evidence-based prevention strategies. In addition, this burden can be reduced through early detection of cancer as many cancers could be cured if diagnosed early and treated adequately.

The gold standard in cancer diagnosis is tissue biopsy. However as this is an invasive procedure, it is often done when cancer is suspected and when the cancer is usually at an advanced stage. Also, the suspected cancer may be in tissues that are hard to access such as the brain and tissue biopsy will be difficult with significant clinical risks such as bleeding or infection. As such, surrogate methods for detecting the presence of cancer such as liquid biopsy are being aggressively developed. Liquid biopsy was originally defined by the US. National Cancer Institute as “a test done on a sample of blood to look for cancer cells from a tumor that are circulating in the blood or for pieces of DNA from tumor cells that are in the blood” (<https://www.cancer.gov/publications/dictionaries/cancer-terms/def/liquid-biopsy>). Although tissue biopsy remains the gold standard for cancer diagnosis, liquid biopsy is gaining traction as it is less invasive and could be used to screen for cancer prior to disease manifestation when the cancer is in its early stage. Biomarkers used in liquid biopsy have also expanded beyond circulating tumor cells or DNA to include circulating exosomes and miRNAs.

This review will focus primarily on the use of exosomes or more precisely, extracellular vesicles (EVs) in liquid biopsy. As recommended by Minimal Information for Studies of EVs (MISEV2014)^[2] and the recently updated and expanded MISEV2018^[3], the term “Exosomes” is presently used to describe small (50-200 nm) extracellular vesicle that has an endosomal biogenesis while the term “EV” is a more generic term to describe membrane vesicles secreted by cells. Since the EV types and biogenesis of most EVs in bodily fluids are presently not known, the term EV is, therefore, more appropriate when referring to secreted membrane vesicles in liquid biopsy.

EVS AS SOURCES OF BIOMARKERS

MISEV2018 defines EVs as “particles naturally released from the cell that are delimited by a lipid bilayer and cannot replicate, i.e., do not contain a functional nucleus”^[3]. They are produced by nearly all cell types from bacteria to yeast, plants and animals. EVs are known to carry a complex cargo of proteins, lipids, RNA, DNA and other metabolites. As the cargo is derived from the secreting cell, the cargo reflects the type and biology of the cells and could potentially inform on the state of health in the cells. Furthermore, as EVs are generally thought to mediate intercellular communication through the conveyance of biological materials from one cell to another, EVs could potentially propagate disease or modulate host response. Hence the cargo of EVs could also predict the progress or resolution of the disease. Together, these EV features provide a strong rationale for the use of EVs in bodily fluids such as blood, urine, saliva, tears or sweat in liquid biopsy assays. The reader is referred to several recent comprehensive reviews in this area^[4-8].

ADVANTAGE OF PLASMA EV OVER WHOLE PLASMA FOR BIOMARKER DISCOVERY AND ANALYSIS

EV-based liquid biopsy is essentially a transformation of the traditional assay for biomarkers in plasma or other bodily fluids into an assay for biomarkers in EVs isolated from either plasma or other bodily fluids. This transformation is critical as using EVs from bodily fluids as the source of biomarkers as opposed to unfractionated bodily fluids could greatly enhance the signal to noise ratio in detecting a biomarker. For example, plasma, a commonly used bodily fluid in diagnosis has a wide dynamic concentration range of at least 10 orders of magnitude between the most abundant plasma protein, albumin and rare biomarker proteins^[9]. In fact, > 95% of the protein mass in human plasma is dominated by a dozen proteins with albumin and the globulins constituting about 50% and 25%, respectively^[10]. As such, disease-associated protein biomarkers are likely to be rare and masked by the highly abundant proteins, making plasma biomarker discovery and detection challenging. Specific methods to Isolate EVs from plasma could potentially remove the highly abundant proteins from the plasma and enhances the discovery and detection of rare disease-associated biomarkers.

TECHNOLOGIES FOR ISOLATING EVS FROM BODILY FLUIDS

As extensively discussed in the MISEV2018^[3], EVs could be isolated from different bodily fluids such as serum/plasma, urine, tears, milk, spinal fluids using a large variety of techniques. As each of the fluids have unique features that could interfere with EV purification and analysis, MISEV emphasized the need for these fluids to be appropriately processed prior to EV isolation and analysis. For example, blood plasma is routinely treated with anti-clotting agents such as EDTA, citrate or heparin to prevent clotting while the urine is often depleted of Tamm-Horsfall protein, a major urinary protein. However, MISEV2018 does not specifically recognise any method as the gold standard for EV isolation but noted that the choice is dependent on the end use of the EVs. Presently, the most commonly used methods for EV isolation as described in MISEV2018 are generally based on biophysical parameters such as size (e.g., filtration, size exclusion chromatography, precipitation), density (e.g., differential ultracentrifugation, sucrose gradient ultracentrifugation) and charges (e.g., electrophoresis, ion exchange chromatography). EVs are also isolated according to surface proteins (e.g., immunoaffinity chromatography). Combination of these technologies, e.g., filtration with density ultracentrifugation are also being used or developed to improve the efficiency, specificity and purity of the EV preparation.

As noted by several groups, the desired end use of the purified EVs is greatly affected by the choice of isolation techniques or combination of techniques. For example, precipitation or filtration techniques could process large volumes of fluids and while this is critical in preparing sufficient therapeutic EVs, these methods may not be as stringent as size exclusion chromatography in isolating highly enriched EV preparation^[11,12]. As many of the current EV isolation techniques require specialized equipment and many procedural steps, microfluidic chips are increasingly being used in the isolation of EVs as a means to reduce the hands-on time and the number of procedural steps. Most of the microfluidic chips to isolate EVs are also based on the same fractionation parameters as the conventional EV isolation techniques namely immune-capture by antibodies against surface proteins of EVs^[13], size fractionation by membranes^[14,15], ciliated micropillars^[16], acoustics^[17] or viscoelasticity^[18].

Generally, most EV isolation technologies enriched for EVs on the basis of size or densities. Hence most EV preparations, especially those from biological fluids, are also significantly enriched in similar sized non-EV complexes such as HDL and LDL lipoprotein complexes and/or protein aggregates, and two or more isolation techniques often have to be used in tandem to reduce non-EV components^[19-23]. In addition, most of the current EV isolation technologies require relatively large volume of sample fluid, typically 250 μ L to 1 mL or long preparation time to isolate sufficient EVs for diagnostic applications.

Hence, development of EV-based liquid biopsy is hampered by two technical challenges, isolation of bona fide lipid membrane vesicles and EV isolation from small sample volumes.

ISOLATING EVS THROUGH THEIR UNIQUE DEFINING FEATURE, LIPID MEMBRANE

The unique defining feature that differentiates EVs from other secreted cellular products is their lipid membrane. Therefore, isolating EVs via their lipid membrane would enhance the specific enrichment of EVs.

Although the lipid membrane of EVs originates from the secreting cells, the EV membrane is not representative of the outer or inner cell membranes per se but rather of specific microdomains in cellular membranes. For example, the membrane of exosomes derived from Daudi cells is enriched in lipid rafts as evidenced by the presence of GM1 gangliosides which are enriched in lipid rafts^[24]. It was further reported using annexin V (AV) binding studies that phosphatidylserines are exposed on the outer surface of exosomes^[25]. However, it is not clear if exosomes with exposed phosphatidylserines are exosomes or apoptotic bodies as membrane vesicles from healthy cell populations are likely to contain apoptotic bodies from apoptotic cells that are inevitably present in a healthy cell population^[26]. In addition, it was also observed that in platelets, AV binding activity was restricted mainly to microvesicles, and not exosomes^[27]. Finally, we observed that small EVs produced by mesenchymal stem/stromal cells (MSCs) consist of at least 3 sub-types that are distinguished by their mutually exclusive binding affinity for cholera toxin B (CTB) chain, AV and shiga toxin B (ST) chain^[28]. The latter three proteins bind membrane lipids, GM1 gangliosides, phosphatidylserines and globotriaosylceramides, respectively. The extraction of small EVs by these three proteins was confirmed by scanning electron microscopy images of nanosized, spherical structures of approximately 100-200 nm. Protein analysis of the three EVs revealed an enrichment of exosome-associated proteins such as Alix, Tsg 101, CD9, CD81 in the CTB-binding EVs which were much reduced in the AV-binding EVs and not detectable in the ST-binding EVs. RNA was detectable only in the ST-binding EVs^[28]. It was also established through pulse-chase studies that the CTB-binding EVs have an endosomal biogenesis, i.e., exosomes while the biogenesis of the AV- and ST-binding EVs is not known^[28,29]. In the pulse-chase studies, the MSCs were pulse-fed with either biotinylated transferrin or biotinylated CTB and the biotinylated proteins was then “chased” to determine if the biotinylated proteins re-appear in the culture medium as EVs.

CTB, AV and ST are multi-meric with at least five lipid-binding monomers per molecule. It was reported that these monomers bind their lipid targets in a positive co-operative manner such that the lipid-bound ligand is thermodynamically most stable when all the lipid-binding monomers are bound by the target lipids^[30-32]. Therefore, the binding of an EV type by any of the three ligands implies that the targeted lipids for the ligands are exposed on the EV membrane surface and are also present in high localized concentration to enable multimeric binding^[28]. This thermodynamic preference of each ligand to bind multiple lipid molecules ensures that the ligand binds lipid-rich macromolecules or complexes such as EVs.

As a consequence of this preference, the lipid-binding ligand cannot be immobilized on a solid support and must be in solution to minimize steric hindrance and facilitate ligand binding to multiple lipids (unpublished observation, SKL). This thus minimizes the versatility in designing the procedural protocol for isolation.

Together, the above observations suggest that EVs could be isolated through their lipid membrane via specific membrane lipid-binding ligands as shown [Figure 1].

Figure 1. Isolation of CTB/AV/ST-binding EVs from liquid biopsy. Biotinylated-CTB, AV or ST is added to the liquid biopsy. These ligands, CTB, AV or ST will bind exposed membrane lipids, GM1 gangliosides, phosphatidylserines or globotriaosylceramides on the EV membrane, respectively. After binding, the ligand-bound EVs can be readily extracted using either streptavidin-coated magnetic beads and magnets, or streptavidin-coated polystyrene and membrane filtration. These extracted CTB/AV/ST-binding EVs can be used directly for biomarker discovery or assay. CTB: cholera toxin B; EVs: extracellular vesicles; AV: annexin V; ST: shiga toxin

ISOLATING PLASMA EVS THROUGH THEIR AFFINITY FOR MEMBRANE LIPID-BINDING

LIGANDS

The binding affinity of EVs for CTB and AV in conditioned medium from cell cultures has also been observed in EVs in biological fluids such as plasma and ascites fluid^[33,34]. However, it was observed that less than 1% EVs in the plasma have exposed phosphatidylserines^[35]. Furthermore, the CTB chain- and AV-binding EVs in the plasma and ascites fluid are distinct populations of EVs with each subtype having a cargo of proteins that is unique to EV subtype and pathological state of the patient^[33,34].

DIFFERENTIAL DISTRIBUTION OF DISEASE BIOMARKERS IN EV SUBTYPES OF BIOLOGICAL FLUIDS

When plasma EVs were isolated according to their affinity for lipid-binding ligands, it was observed that the distribution of a protein across the different EV subtypes is variable and the level of some proteins in one EV subtype but not the other EV types or the bodily fluid correlate with the disease state of the patient. This was evident even when the proteome of plasma and plasma EV sub-types from normal healthy pregnant woman and pre-eclampsia pregnant women were analyzed in low-resolution 2D protein gels^[33]. When analyzed by more sensitive mass spectrometry and compared, there were differences within and between the healthy and pre-eclampsia populations of patients in each of the three fractions, namely plasma, CTB- and AV-binding plasma EVs. These differences may occur in only one or two of the fractions, and the differences could be an elevation in one fraction and a reduction in another. As such, a single source of biological fluid could yield many candidate biomarkers.

In addition, we also discovered that known proteins with weak or no correlation to a disease exhibited a strong correlation to disease when associated with a specific EV type of the biological fluid. Therefore, to facilitate the discovery of candidate biomarkers and their subsequent validation in population, we routinely screened known and well-characterized proteins for candidacy as biomarkers using antibody arrays or ELISAs^[33]. The rationale for this strategy was two-fold. Firstly, the candidate biomarker would have a well characterised ELISA. Secondly, the isolation technique could be readily coupled to the standard 96 well ELISA platform leading to a semi-automated and moderately high throughput procedure^[33].

As a proof of concept, we tested our strategy in a study to identify predictive biomarkers for pre-eclampsia using a prospective biobank^[36]. Known and well-characterised proteins were first screened as potential pre-eclampsia biomarkers in plasma, plasma CTB-binding EV and plasma AV-binding EV from patients. Three different candidate biomarkers were identified, namely placental growth factor (PlGF), Tissue inhibitor of metalloproteinase & Plasminogen activator inhibitor-1 in plasma (plasma PlGF), plasma CTB-binding EV (CTB-TIMP1) and plasma AV-binding EV (AV-PAI1), respectively^[36]. These three biomarkers were tested in a prospective biobank of 843 pregnant women. Pre-eclampsia was predicted about 7.3 (\pm 2.9) weeks before clinical diagnosis with a combined AUC of 0.96, sensitivity of 100%, specificity of 78.6%, and PPV of 9.9%. The cut-off concentration for predicting PE was at < 1235 , ≤ 300 or > 1300 and $< 10,550$ pg/mL plasma for plasma PlGF, CTB-TIMP1 & AV-PAI1 respectively.

Differences in the proteome of the different EV types were also observed in cancer patients. Using a similar strategy as in the pre-eclampsia study, it was observed that MMP9 was elevated in AV-, but not detectable in CTB- or ST-binding EVs from the ascites fluid of serous ovarian cancer patients. However, this MMP9 elevation was not observed in AV-binding EVs from ascites fluid of liver cirrhosis patients^[34]. More recently, a preliminary screen of plasma, plasma CTB-binding EV and plasma AV-binding EV revealed the presence of potential biomarkers that could prospectively predict the outcome of chemoradiation therapy in patients with head and neck squamous-cell carcinoma^[37].

The presence of EVs in biological fluids with different affinities for membrane lipid-binding ligands demonstrated that the presence of concentrated, exposed domains of specific membrane lipids in some EV types are not unique to EVs from cell cultures. Importantly, this is a physiological phenomenon and not a consequence of the unique nutrient composition of the culture medium. It is also notable that each EV subtypes have different proteomes and that the proteome of these EV subtypes is differentially enriched in disease biomarkers.

ADVANTAGES AND DISADVANTAGES OF USING MEMBRANE LIPID BINDING MOLECULES IN EV ISOLATION FOR DIAGNOSIS

There are several advantages of using membrane lipid binding molecules to isolate EVs for diagnosis. The most important advantage is that the principle for this isolation technique is based on the defining feature of EVs, namely the presence of a lipid membrane. Membrane lipids are generally amphiphilic, i.e., having both hydrophobic and hydrophilic ends, and in aqueous solution, they will form micelles or liposomes, i.e., vesicles. Therefore, it is likely that these membrane lipids especially when present in localized high concentrations in aqueous biological fluids, are likely to be minimally in a micelle configuration, and most possibly, a vesicular structure. The presence of membrane or cytosolic proteins will strongly corroborate the presence of membrane vesicles.

Based on affinity for membrane lipid-binding ligands, it is obvious that biological fluids contain several EV types with EV type-specific proteome. Importantly from the diagnostic perspective, this EV type-specific proteome is also dependent on the pathophysiological state of the donor and this pathophysiology-

associated change in EV proteome varies with the EV type. Practically, it transforms a biological fluid as a single source of biomarkers into multiple independent sources of biomarkers.

A third advantage is that as the different EV types are novel sources of biomarkers, the distribution of known and well-characterized biomarkers and proteins in these EVs are not known. As we have shown, examining their distribution in the different EV types as a function of the pathophysiological state is a viable strategy to identify candidate biomarkers. Furthermore, it is easier to validate these known and characterized biomarkers and proteins as the necessary assay reagents such as antibodies are available.

A fourth advantage is that the technique for EV isolation by lipid-binding ligands is akin to the commonly used antibody capture techniques, and can be easily adapted for direct coupling to an ELISA for biomarker assay. Hence isolating EV from biological fluids and assaying for biomarkers by ELISA can be readily adapted for the standard automated 96 well ELISA platform used in routine clinical laboratory settings. It is also amenable to the recent developments in nano-plasmonic technology^[38].

Finally, the volume of plasma required for extracting EVs by their affinity for membrane lipid binding ligands in sufficient quantity for a typical ELISA ranges from 10-30 μL biological fluids per assay^[34,36]. As each of the EV types identified so far are unique EVs^[28,33], the volume of biological fluid could be reduced further by using multiplexed EV isolation system where the different membrane lipid-binding ligands are added to the same sample and the bound EVs are then extracted according to the ligands bound to the EVs.

Despite the advantages of lipid binding ligands for isolation of EVs, there are significant limitations with this approach. The avidity of the ligands for the different lipids has turned out to be a double-edged sword. The dissociation constants (K_D) of CTB to GM1 is between 4.6×10^{-12} ^[39] and 7.3×10^{-10} ^[40], K_D of AV to phosphatidylserine is 5×10^{-10} M^[41,42] and K_D of ST to GB3 is $5-30 \times 10^{-10}$ M^[32]. These dissociation constants which are comparable to the median K_D of antibody to antigen is $5-30 \times 10^{-11}$ M^[43] illustrate the difficulty in dissociating the EVs from the ligands for subsequent characterisation. While this poses significant challenge for biological studies of the different EV types, biomarker discovery and assay can be readily performed on the ligand-bound EVs.

Another drawback of this approach is the limited number of suitable lipid binding ligands to isolate EVs. Also, it is highly conceivable that many other EV types may not exhibit sufficiently distinctive lipid molecules for EV stratification by this method. Also, the lipid binding characteristics of an EV is not likely to be a characteristic of a specific cell type and is thus not likely to provide information on the cell source of the EVs. Nevertheless, lipid binding ligands represent an additional tool to isolate and stratify EV types that could increase the yield and specificity of EV types when complemented with present EV isolation tools such as size exclusion fractionation or immunoaffinity isolation technology.

CONCLUSION

We propose that the use of membrane lipid binding ligands in EV isolation for liquid biopsy is a viable and robust strategy to circumvent the present technical limitations in isolating bona fide EVs from biological fluids for liquid biopsy. In addition, this isolation technique is versatile can be easily integrated into the current clinical analysis platforms using 96 well assay plates and even newer analytical platforms such as nano-plasmonics^[44] which uses the interaction of light and electronic oscillations in metallic substrates in a nanometer-dimension to detect the presence of single EV.

Abstract

Patients with glioblastoma (GBM), a malignant brain tumor, exhibit a mean survival of less than 1.5 years. Despite treatment, the disease eventually develops resistance, resulting in disease relapse. Autophagy is a process of degradation and clearance that is activated to maintain cellular homeostasis. Its roles in cancer disease course and the treatment response, however, are controversial. In GBM, accumulating evidence has indicated that autophagy can protect cells, especially those with stemness features, causing the development of cell resistance. In this review, we discuss the impact of the cell reaction to currently active treatments, including temozolomide, radiation, tumor treating fields, bevacizumab (Avastin), etoposide (VP-16), cisplatin (CDDP), and carmustine (BCNU). Most of these induce the up-regulation of autophagy through signaling pathways of DNA damage response, reactive oxygen species, hypoxia, retinoblastoma, AMP-activated protein kinase, AKT/mTOR and MST4 kinase affecting cell fate by altering cell metabolism, cell death, and DNA repair. Treatment-related autophagy may be modulated by combining autophagy inhibitors such as chloroquine or antioxidants to prevent the development of resistance, thus improving cancer treatment.

INTRODUCTION

The term autophagy is derived from Greek words, “auto” and “phagy”, meaning self-eating^[1], representing a process of degradation and clearance that is activated in response to aggregated protein and dysfunctional organelles to maintain cellular homeostasis^[2]. The autophagy pathway is initiated by a series of active proteins, such as autophagy-related (ATG) proteins, UVRAG, Beclin 1, PIK3C3, LC3 and p62^[3]. Together, they contribute to the formation of double-membrane autophagosomes, and eventually, fusion with lysosomes for degradation of inner substances [Figure 1]. Hence, autophagy has been implicated in several diseases including cancer^[4]. In the past, autophagy was believed to be related to apoptosis^[5]. Recently, an opposite impact of autophagy, i.e., promoting cell survival, has been widely studied^[6]. This “double-edged sword” effect in tumorigenesis varies depending on the cellular reaction to specific stimulation as well as in different cancer types. High levels of autophagy in the tumor environment (with limited nutrient and oxygen conditions) allow cancer cells to survive, resuming proliferation and initiation^[7].

Glioblastoma (GBM) is a disease composed of extremely varied tumor microenvironments and heterogeneous cancer cells. It is a fatal disease known to have a poor prognosis, and is not considered curable. Despite advanced treatment strategies, a notable improvement was not observed in terms of the outcome. Hence, it is not surprising that the tumor cells in the apex of the hierarchy, or those that are capable of self-renewal and differentiation, display highly-activated autophagy signaling to survive and thrive from the given treatment, such as temozolomide (TMZ)^[8]. Moreover, the molecular characters of GBM involved in the growth and survival via intracellular pathways are distinct genetic aberrations in epidermal growth factor receptor (EGFR), PTEN, TP53, IDH1 and so on^[9]. Among these frequently reported genes in clinical disease, EGFR is well-known as a driving receptor tyrosine kinase (RTK) in GBM that dictates multiple oncogenic signaling^[10]. The signaling amplification of EGFR accounts for approximately 60% of GBM cases. The mutant form EGFRvIII receptor, which is constitutively active that is independent of the ligand binding condition, is also common. In association with EGFR signaling pathway, it was found that levels of MDA-9, a protein related to tumor cell behavior and stemness, were increased in glioma stem-like cells to regulate the protective autophagy^[11] [Figure 1]. Moreover, it was found that STAT3 levels were related to beclin 1 expression via EGFR amplification^[12,13] [Figure 1]. Other RTKs in GBM, such as vascular endothelial growth factor receptor (VEGFR)^[14], platelet-derived growth factor receptor (PDGFR)^[15] and discoidin domain RTK 1 (DDR1)^[16], also contributes to modulating the autophagy formation through AKT/mTOR^[16,17], RAF/MEK^[18] and HIF-1/BCL2 Interacting Protein 3^[19-21] signalings [Figure 1]. As thus, therapeutic agents targeting these factors, for example bevacizumab^[14] and PDGF neutralizing antibody^[15], has been reported to enhance autophagy signaling [Figure 1]. Despite of the implications by disease- or treatment-related autophagic alterations, clinical trials with autophagy inhibitors, such as chloroquine (CQ) or its analogs, showed only limiting benefits^[22]. So far, the exact role of autophagy in GBM remains ambiguous, especially regarding treatment resistance^[23].

The effect of autophagy on tumors is not universal. On one hand, autophagy protects cells by clearing damaged organelles, thereby promoting cell survival. On the other hand, it achieves damage control by eliciting self-eating, leading to the process of autophagic cell death. The pros and cons of this biologic reaction does not have a clear boundary and may be dynamic. Regarding drug treatment, the appearance of autophagy also had divergent effect. For example, in a study of PI3K/mTOR inhibitor BGT226, application of the drug led to autophagic cell death in head and neck cancer cell lines^[24]. In contrast, application of PI3K/AKT/mTOR inhibitors sensitized cells to radiotherapy as well as reduced autophagy formation^[25]. Various effects of autophagy in the cancer treatment have been demonstrated, making the reaction complicated in each circumstance. However, in the case of GBM, the appearance of autophagy during specific treatment seems to support the development of resistance^[26]. In this article, we will discuss the molecular significance of autophagy in the current treatment of GBM. We will also discuss the formation of the reaction and the potential benefit of inhibiting autophagy along with the treatment.

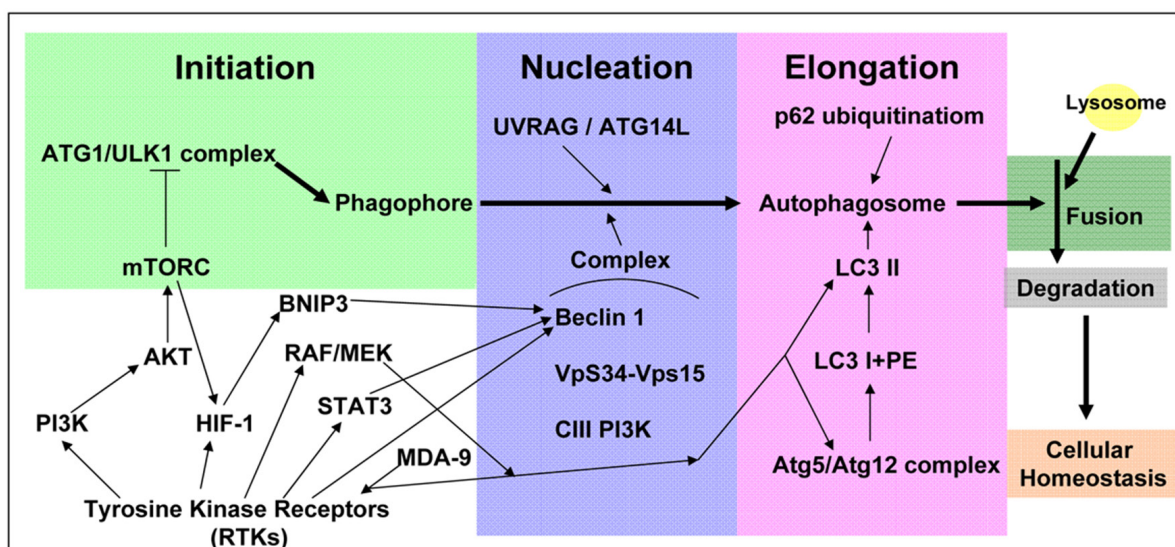

Figure 1. The schematic figure of the principal cell signaling pathways associated with the autophagic process. The process of autophagy pathway begins from the initiation step to the nucleation step, the elongation step, and to the formation of mature autophagosome which subsequently fuses with lysosome to perform the degradation process. The commonly activated pathways related to aberrant RTKs in GBM are also shown. Their roles to affect the individual steps of the autophagic process are indicated. RTKs: receptor tyrosine kinases; GBM: glioblastoma; HIF-1: hypoxia-inducible factor-1

TMZ

Being the most standard chemotherapy for GBM, it is mandatory to understand how autophagy is induced by TMZ. The first-line drug acts by inducing lethal DNA damage and subsequent reactive oxygen species (ROS) production^[27]. The effect is, however, mostly only transient and resistance is almost inevitable, with up to 90% of the patients experiencing early disease recurrence^[28]. Development of TMZ resistance in GBM is complicated and less understood, but till date, clear factors leading to resistance are still limited to pre-existing O⁶-methylguanine-DNA methyltransferase (MGMT)^[29]. According to previous studies, the DNA damage response (DDR) can induce autophagy in a yeast system^[30] and the enhanced autophagy can increase DNA repair ability to cause chemo-resistance^[31]. In GBM, TMZ-induced autophagy in glioma cell lines is dependent on MGMT expression, mismatch repair system and Rad51-mediated homologous recombination^[32]. The glioma cell lines resistant to TMZ cotreated with O⁶-benzylguanine, an O⁶-alkylguanine-DNA alkyltransferase (a DNA repair enzyme) inhibitor, can be re-susceptible to TMZ via autophagy regulation^[33]. The cascades of TMZ-induced autophagy showed that the phosphorylation of H2AFX at Ser139 following TMZ treatment initiates DDR [Figure 2], sequentially, leading to phosphorylation of PRKAA (Thr172), ULK1 (Ser555/575), MAPK14 (Thr180/Tyr182), RPTOR (Ser792) and suppressive phosphorylation of AKT (Ser473) and mTOR (Ser2448) to induce autophagy and inhibit apoptosis^[34]. However, further investigation is needed to examine whether there are other signaling pathways involved between autophagy and DDR.

In addition to MGMT that contributes to naïve TMZ resistance, the mechanism for tumor acquiring resistance is more complicated. In our previous studies, we identified transcriptional binding factor specific protein 1 and its downstream modulator, superoxide dismutase 2 (SOD2), as the critical factors in the tolerance of TMZ-induced ROS in models of resistance^[35,36]. In fact, it has also been reported that TMZ can induce autophagy via ROS signaling^[37] [Figure 2]. The detailed mechanism between autophagy and ROS, however, needs further investigation. SOD2 is known to specifically function in mitochondria to regulate oxidative stress and energy metabolism^[38]. Altered metabolic reprogramming by mitochondrial control in cancer may play a role in chemotherapy resistance^[39]. For instance, increased autophagy derived from

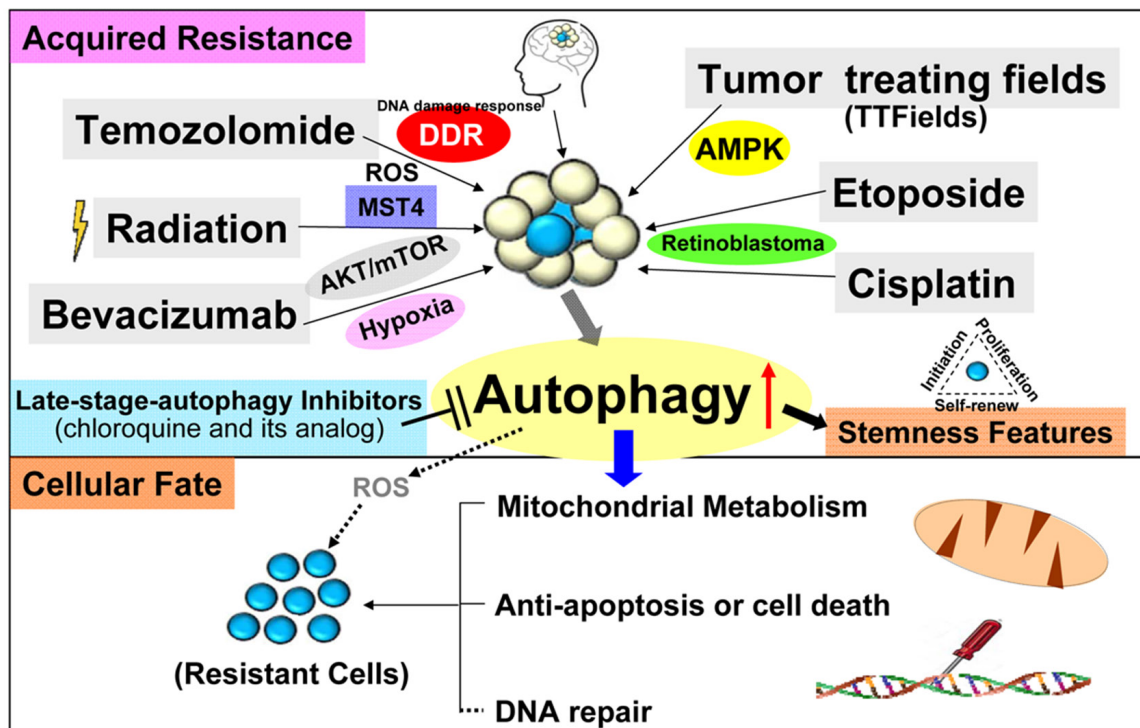

Figure 2. The schematic diagram demonstrates that in primary or recurrent GBM patients, the standard regimens consists of TMZ, radiation, TTFields, bevacizumab, etoposide and cisplatin, which enhance cell stemness, metabolism (energy), anti-apoptosis and DNA repair to acquire therapeutic resistance through the signaling pathways of DDR, ROS, hypoxia, AKT/mTOR, MST4 kinase, AMPK and RB. Nowadays, the inhibitors of late-stage autophagy, such as CQ or its analogs, have been tested in clinical trials of GBM patients. TMZ: temozolomide; GBM: glioblastoma; TTFields: tumor treating fields; ROS: reactive oxygen species; DDR: DNA damage response; AMPK: AMP-activated protein kinase; RB: retinoblastoma; CQ: chloroquine

glucose starvation condition causes GBM cell quiescence, survival and chemoresistance^[40] and complex I linked oxidative phosphorylation is required to maintain mitochondrial respiration (electron transfer system) through autophagy regulation^[41]. Furthermore, presence of glioma stem-like cells may have crucial role in acquiring resistance^[42]. An emerging concept in cancer biology suggests these specific subgroups with stemness features are responsible for acquisition of resistance^[42]. The stem cells are characterized by self-renewal and multipotent abilities^[43]. These allow cells to be resistant to standard therapy, and are associated with the treatment outcome^[42]. In glioma stem-like cells, autophagy-associated proteins, i.e., DNA Damage Regulated Autophagy Modulator 1 and p62, can regulate the cell migration and invasion by modulating energy metabolism (ATP) and affect mitochondrial morphology by regulating mitochondrial fusion^[44]. Some studies have indicated that autophagy can regulate epithelial-to-mesenchymal transition^[45] and the capabilities of migration and invasion in those cells under nutrient deprivation are damaged when autophagy is activated through regulation of ATG proteins or beclin 1^[46]. However, it was found that TMZ treatment plus autophagy inhibitor could suppress cell migration and invasion^[47], suggesting further investigation was needed to determine the role of TMZ-induced autophagy in this aspect. Moreover, stemness features in the glioma stem-like cells are reduced by autophagy inhibition and apoptosis is enhanced by blockage of autophagy^[48]. Recently, it is found that the blockage of autophagy up-regulates the TMZ-sensitivity in these stem-like cells through metabolic dysfunction-related ferroptosis^[49] in the stem-like cells, demonstrating the close correlation between autophagy and metabolism. In summary, application of these the explains how the disease is capable of surviving TMZ toxicity regardless of MGMT status.

RADIATION

Radiation can cause similar treatment response to TMZ. Radiation treatment in GBM cells can induce autophagy through the PI3K/AKT/mTOR pathway, ROS^[50,51] and MST4 kinase-ATG4B signaling^[52] [Figure 2]. Inhibition of autophagy makes these cells susceptible to stimulation^[53,54]. Moreover, it is reported that GBM cells are susceptible to radiation following inhibition of MDA-9 expression^[55]. Radiation has various effect to autophagy. Studies have indicated that the relatively radio-sensitive cells or small radiotherapy fraction (2 Gy) displays enhanced autophagic flux, while more radio-resistant cells or larger radiotherapy fraction exhibited an inhibition of autophagic flux^[56]. Regarding the glioma stem-like cells, it was reported the subsets were enhanced for autophagy after radiation to promote metabolism, anti-apoptosis and stemness^[57], while the other reports showed that CD133⁺ cells or sphere cells from one patient have a lower level of autophagy^[58,59]. Notably, it is also found that CD133⁺ glioma stem-like cells can be resensitized to radiation treatment by using autophagy inhibitors (bafilomycin) or down-regulation of ATG protein levels^[60]. Though the exact effect remains unclear, the association between autophagy, radiation, and the stemness features is intriguing.

Whether targeting autophagy will benefit radiotherapy effect is also controversial. On one hand, a study has found that autophagy in malignant glioma cells is a transition status promoting apoptotic cell death following radiation, which can be reversed by suppressing autophagy function^[61]. On the other hand, from the aspect of PI3K/AKT/mTOR signaling (it is active in most GBM patients^[62]), Cerniglia *et al.*^[63] and Gil del Alcazar *et al.*^[64] have indicated that NVP-BE235, a dual PI3K/mTOR inhibitor, can promote GBM cells sensitive to radiation and up-regulate autophagy by directly affecting the function of DNA damage repair (DNA-dependent protein kinase catalytic subunit and ATM kinase) and autophagy related proteins (ATG5 and Beclin1), respectively. The results demonstrated that there are different responses after administrating the inhibitor and radiation leading to cell death. Furthermore, Zhuang *et al.*^[65] also reported that rapamycin can lead to the differentiation of glioma stem-like cells, up-regulating the cell radiosensitivity and reducing tumorigenesis through activation of autophagy. However, the application of the autophagy inducers on mice experiment or clinical seems to be rare and limited in information^[62,66]. In addition, most clinical trials nowadays prefer the combination of autophagy inhibitors with radiochemotherapy but not radiotherapy only^[67]. Therefore, the directions of future research must focus on further exploration of how radiation induces autophagy (time point, tumor suppress genes, DNA damage repair and so on) and how the affected autophagy changes the cell fate.

TUMOR TREATING FIELDS

Optune, a tumor treating fields (TTFields) device, is used as an advanced GBM treatment with only minor side effects noted in newly diagnosed or recurrent GBM patients. The device in combination with TMZ increased the median overall survival by almost 5 months compared to the TMZ alone group^[68]. At 200 kHz frequency, TTFields treatment has been reported to cause damaged mitosis and up-regulation of autophagy^[69]. It is also found that the enhancement of autophagy is induced by TTFields treatment through AMP-activated protein kinase (AMPK) signaling^[70] [Figure 2] and down-regulation of the pathway inhibits the protective autophagy to reduce TTFields-induced acquired resistance. By combining with sorafenib, a multi-kinase inhibitor that can induce autophagy in prostate cancer cells through increased levels of LC3^[71], the device exhibited enhanced autophagy and more inhibited tumor behavior to promote a better therapeutic strategy^[72]. Regarding the mechanism, it was reported that TTFields can suppress DDR in non-small cell lung cancer cell lines^[73] and the combination of radiation can inhibit DNA damage repair in glioma cell lines^[74]. Furthermore, it is found that TTFields can cause ROS production to promote apoptosis in the cell line study^[72]. This may have impact in inducing the clearance of damaged mitochondria (mitophagy)^[75]. It is not clear, however, whether TTFields-increased autophagy is associated with inhibition of DNA damage repair. Further explorative experiments are thus needed to elucidate the mechanism and the role of autophagy in the disease-controlling mechanism of the device.

BEVACIZUMAB

Bevacizumab can directly promote apoptosis and antiangiogenesis by regulating the associated proteins in GBM cells^[19,76]. This drug has been reported to cause resistance in the cells through suppressing AKT-mTOR signaling^[76] or through inducing hypoxia-inducible factor-1 α /AMPK pathway^[19] to increase autophagy influx [Figure 2]. It was also reported that bevacizumab could cause a hypoxia microenvironment, which in turn, was related to enhanced autophagy^[77,78]. Thus, inhibition of the autophagy process was postulated to resensitize bevacizumab to GBM cells.

Up-regulation of glucose metabolism before autophagy induction was observed in bevacizumab-treated GBM cell lines^[79]. Further investigation is needed to link the mechanism between autophagy and the cell metabolism after the treatment. It was also noted that bevacizumab can induce autophagy in glioma stem-like cells by enhancing VEGF-independent angiogenesis (vasculogenic mimicry, an alternative vasculature) through KDR/VEGFR-2 phosphorylation, which the formation is closely related with GBM resistance^[80]. This highlights the therapeutic value of autophagy-inhibiting strategies in regard with the anti-angiogenesis therapy.

ETOPOSIDE

Etoposide (VP-16) treatment has been reported to induce autophagy, thereby increasing the therapeutic resistance in GBM cells^[81,82]. The drug is a topoisomerase II inhibitor that also enhances autophagy by modulating though retinoblastoma protein (RB)^[81] [Figure 2]. Down-regulation of RB can inhibit autophagy by preventing autophagosomes fusion from lysosome and promoting cell death in GBM cells and glioma stem-like cells^[81]. Furthermore, knockdown of RB can enhance apoptotic cell death and up-regulate the immunostaining intensity of γ -H2AX (a DNA double-strand break marker) induced by etoposide^[81]. Earlier studies have demonstrated a close link between etoposide-induced autophagy, RB, and DNA damage.

CISPLATIN

Cisplatin (CDDP) is a DNA alkylating agent that is widely used for human malignant tumors including GBM^[83]. CDDP-associated resistance often develops through autophagy induction in multiple cancer cell types^[84-87]. In cervical cancer cells, it is found that blockage of autophagy can increase CDDP-induced cytotoxicity via endoplasmic reticulum stress^[88]. One study indicated that autophagy was associated with CDDP resistance in GBM and down-regulation of RB suppressed autophagy induced by CDDP^[87] [Figure 2]. Moreover, it was found that CDDP could induce long non-coding RNA to suppress CDDP-induced autophagy, which promoted apoptosis in GBM cells^[89]. CDDP could also enhance the level of death receptor (DR5), directing glioma stem-like cells to tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) apoptotic pathway^[90]. TRAIL, on the other hand, was reported to enhance the expression of autophagy leading to resistance of breast cancer cells, and blockage of autophagy could reduce the resistance^[91]. The association between autophagy and TRAIL in GBM has thus been inferred. In addition, the mechanism of DNA repair induced by CDDP could promote resistance of GBM cells via the Jun kinase/stress-activated protein kinase signaling pathway^[92]. Further experiments are required to verify whether autophagy is related to the DNA repair induced by CDDP.

CARMUSTINE

Another DNA damaging nitrosoureas agent carmustine (BCNU) is reported to promote ROS-mediated autophagic cell death in solid tumor cells in combination with arsenic trioxide^[93]. In terms of the role of ROS in the drug reaction, it was supportively reported that in human glioma cell line U98MG, the overexpression of Nrf 2, an anti-oxidant transcriptional factor, could reduce the carmustine-induced

cytotoxicity^[94]. How autophagy was utilized in carmustine-related oxidative stress and anti-oxidant reaction remains to be elucidated.

AUTOPHAGY INHIBITORS IN CLINICAL TRIAL

Traditionally, CQ is used for malaria treatment. Due to the basic property of CQ, it stays in lysosomes leading to enhanced lysosomal pH and inhibition of autophagy^[95,96]. Hence, CQ has been investigated in clinical trials for cancer therapy including GBM. An early clinical trial of CQ in a small population of GBM patients (NCT00224978) showed that the median survival increased in patients receiving CQ in combination with standard regimens^[97]. Currently, there are 3 ongoing clinical trials involving CQ in GBM or astrocytoma patients (NCT02378532 (Phase 1), NCT02432417 (Phase 2) and NCT03243461 (Phase 3)). In addition to CQ, more candidate autophagy modulators are expected with or without the standard drugs to be investigated in clinical trials.

CONCLUSION

The current standard treatments of primary or recurrent GBM can cause autophagy induction and the enhanced autophagy through DDR, ROS, hypoxia, AKT/mTOR, AMPK and RB pathways may result in cell resistance, resulting in enhancement of stemness features, increased abilities of metabolism, anti-apoptosis, and DNA repair. Therefore, in order to reduce the resistance caused by treatments, the usage of standard treatment plus autophagy inhibitors and signaling inhibitors may be a potential strategy for GBM therapy.

Abstract

Liquid biopsy consists in a simple blood sampling that allows to analyze cell free DNA (cfDNA), containing specific genomic clues released by the tumor into the bloodstream. In this review, we shall focus on the analysis of cfDNA in lymphoma and, in particular, on its application in the genotyping and monitoring of two common types of B-cell lymphoma, i.e., diffuse large B-cell lymphoma (DLBCL) and classical Hodgkin lymphoma (cHL). From a diagnostic standpoint and based upon the current international guidelines, lymphoma diagnosis has so far relied on the analysis of the tissue biopsy. From a molecular viewpoint, though, the tissue biopsy does not reflect the entire molecular heterogeneity of lymphomas. In fact, in an individual patient, lymph nodes at different anatomical sites, as well as different areas of the same lymph node, may show different genetic profiles. Consequently, molecular analysis of genomic DNA extracted from a single lymph node biopsy may not recapitulate the whole mutational landscape of the disease. Liquid biopsy may overcome this hurdle, since cfDNA is released by all tumoral cells and can reveal the entire molecular complexity of lymphomas. From a translational perspective, liquid biopsy may also be used to evaluate clonal evolution, response to therapy and minimal residual disease. Consistently, in DLBCL as well in cHL, the drop of the mutational burden during the treatment course provides complementary information to conventional imaging techniques. The integration of liquid biopsy with imaging techniques may prove useful for a better prediction of patients' outcome and for a better treatment tailoring.

GENERAL CONCEPT ON CIRCULATING CELL FREE DNA

Liquid biopsy consists in a simple and easy sampling of peripheral blood, that can be subjected to the molecular analysis of specific genomic clues released by the tumor^[1,2]. Because circulating tumor cells are very rare or absent in many types of lymphomas, liquid biopsy approaches have been focused on circulating tumoral DNA (ctDNA) released by lymphoma cells into the bloodstream^[3-5]. However, the ctDNA represents only a fraction of the total amount of cell free DNA (cfDNA), that is derived also from healthy cells. The cfDNA circulates in plasma at a low concentration as double-stranded DNA fragments with a dimension < 200 base pairs^[6]. In individuals without malignancies, plasma cfDNA derives mainly from the apoptosis of normal hematopoietic cells. cfDNA levels may also rise in para-physiological conditions, such as trauma, burns or high exercise. In healthy subjects, the cfDNA concentration ranges between 1 and 10 ng/mL and can reach 30ng/mL in lymphoma patients^[7].

CFDNA ISOLATION

It is possible to selectively isolate cfDNA from plasma in order to proceed with subsequent molecular analysis^[8]. To isolate cfDNA, a few very important technical precautions need to be observed in order to avoid white blood cell lysis that may contaminate the cfDNA with genomic DNA (gDNA)^[9]. If using standard collecting tubes containing ethylenediaminetetraacetic-acid (EDTA) as anticoagulant, plasma extraction is recommended within 3 h from the collection of peripheral blood^[9]. EDTA tubes, however, are not able to preserve the integrity of cfDNA and are not able to prevent the lysis of nucleated cells for more than 3 h. Therefore, in order to allow the shipment of biological material, specific tubes, namely cfDNA BCT Streck tubes (Streck), can stabilize cfDNA and can prevent the contamination by gDNA from white blood cells for up to 14 days at a temperature between 6 and 37 °C^[10]. After collection, plasma is separated from the corpuscular blood by centrifugation of blood samples at 800 rpm at 4 °C for 10 min. A second centrifugation at 13,000 rpm at 4 °C for 10 min allows to pellet and remove any remaining cells. Plasma samples are then stored in 1 mL aliquots at -80 °C until cfDNA extraction^[8].

cfDNA can be selectively extracted using two different methods. The first method, named QIAamp Circulating Nucleic Acid (Qiagen), relies on the use of ion-exchange resins that bind the plasma cfDNA^[11]. The second approach relies on an automatic method that utilizes the Maxwell RSC Instrument coupled with Maxwell RSC cfDNA Plasma Kit (Promega). This method consists in an automated nucleic acid purification platform that processes up to 16 samples simultaneously and allows to obtain high quality cfDNA starting from 1 mL of plasma^[12]. After extraction, cfDNA is usually quantified by a fluorometric assay. Approximately 30-40 ng of cfDNA are needed for subsequent molecular analysis^[8].

CAPP-SEQ ANALYSIS AS FOR DEFINING THE LYMPHOMA GENOTYPE ON CFDNA

Since lymphoid malignancies harbor a unique molecular marker, namely the immunoglobulin (Ig) gene rearrangement, the identification of presence of this biomarker in the cfDNA may be used to track minimal residual disease (MRD) during the course of treatment. Once the Ig gene rearrangement has been identified on the lymph node biopsy, it is possible to evaluate the amount of this rearrangement in the cfDNA using Next-Generation-Sequencing (NGS) or polymerase chain reaction based methods^[13,14]. Pivotal studies have shown that the proportion of cfDNA carrying the lymphoma-specific Ig rearrangement decreases rapidly in patients who respond to therapy and tends to remain negative in those who maintain the response^[13,14]. Conversely, the Ig rearrangement remains high in patients who do not respond to treatment^[13,14]. As expected, these patients experience both a worse progression-free survival and a worse overall survival compared to patients with undetectable Ig gene rearrangement^[13,14]. This method is very effective in monitoring MRD but has some pitfalls. First, this method does not work in a biopsy free manner since it requires, at the time of diagnosis, the identification of the individual patient's specific Ig

rearrangement on the lymph node tissue biopsy. Once the patient's unique Ig rearrangement has been identified on the tissue biopsy, it is then possible to track it on the liquid biopsy to evaluate MRD. Second, this method does not allow a comprehensive disease genotyping on the liquid biopsy^[15].

To overcome these limits, the use of Cancer Personalized Profiling by Deep Sequencing (CAPP-Seq) has been established as a reliable tool to genotype cancer patients^[16]. This molecular strategy utilizes disease specific probes that selectively capture a set of exonic and intronic regions known to be recurrently affected in a particular cancer type. The selected targets are then amplified and sequenced by NGS allowing the detection of the specific tumor mutational profile of a patient. This method, linked to a stringent bio-informatic analysis, allows to detect mutations in cfDNA with a high sensitivity, identifying mutations with allelic frequency as low as 0.02%. In addition, CAPP-Seq allows the identification of single nucleotide variants, as well as insertion/deletions, copy number alterations and rearrangements, thus covering a large variety of genomic alterations of human cancers^[16].

APPLICATION OF LIQUID BIOPSY IN LYMPHOMA

Lymph node biopsy is the gold standard for the diagnosis of lymphoma, but genetic lesions identified in the tissue biopsy may not reflect the entire molecular complexity of every single patient with lymphoma^[17,18]. Consistently, in an individual patient, lymph nodes at different anatomical sites, as well as different areas of the same lymph node, may show different genetic profiles^[19]. However, outside of clinical studies aimed at investigating the clonal heterogeneity of lymphomas, multiple biopsies are not routinely performed in lymphoma patients for both practical and ethical concerns. On these grounds, once a diagnosis of lymphoma is performed on a tissue biopsy, liquid biopsy may be used to explore the entire mutational landscape of lymphoma, since this approach has the potential to collect the tumor cfDNA deriving from most, or potentially all, of the different sites of tumor involvement in the body [Figure 1]^[15]. In particular, a liquid biopsy CAPP-Seq approach may be used to: (1) genotype lymphoma patients; and to (2) evaluate treatment response [Figure 2].

LIQUID BIOPSY AS A TOOL FOR GENOTYPING LYMPHOMA PATIENTS

In DLBCL, liquid biopsy allows to identify at least one somatic non-synonymous mutation per patient in over 70% of cases^[20,21]. The mutational profile identified by liquid biopsy reflects that revealed by DLBCL genomic studies performed on the lymph node biopsies^[22]. More precisely, the most common genetic lesions found by liquid biopsy reflect those detected on the tissue biopsy, and comprise alterations of *KMT2D*, followed by *TP53*, *CREBBP*, and *PIM1*. In addition, *EZH2* and *BCL2* mutations, as expected, are more frequently found in germinal center (GC) DLBCL, whereas *TNFAIP3* and *PIM1* mutations are more frequent in non-GC DLBCL^[20]. In addition, by comparing the mutations identified in cfDNA with those identified in gDNA extracted from the tissue biopsy, cfDNA appears to be representative of most of the mutations that occur in > 20% of the alleles of the tumor biopsy, with a sensitivity > 90% and a specificity of ~100%. Furthermore, a fraction of mutations has been found exclusively in cfDNA, conceivably because, due to spatial tumor heterogeneity, they are restricted to clones that are anatomically distant from the biopsy site^[20].

Regarding cHL, the rarity of neoplastic Hodgkin and Reed-Sternberg (HRS) cells in the biopsy has limited the assessments of the genetic landscape of the disease^[23]. In this context, liquid biopsy may be a reliable tool to overcome this limit. Analogous to DLBCL, it has been demonstrated that cfDNA analysis in cHL mirrors the genetics of HRS cells micro-dissected from the tissue biopsy. Consistently, most of cHL mutations are identified in the tissue biopsy as well as in the cfDNA and some more mutations are identified only in cfDNA, conceivably because they are derived from different anatomical sites^[23]. Genotyping of cHL on the liquid biopsy has allowed to refine the current knowledge of cHL genetics.

Figure 1. Liquid biopsy may recapitulate the entire mutational complexity of diffuse large B-cell lymphoma (DLBCL) patients. In every single DLBCL patient, the mutational profile of the lymphoma may vary in different anatomical sites. For instance, a DLBCL patient may harbor a *EP300* and *KMT2D* mutation in the left axillary lymph node (in brown), a *EP300*, *KMT2D* and *CD79b* mutation in the right axillary lymph node (in red), a *KMT2D* and *CD79b* mutation in the right inguinal lymph node (in blue), and a *KMT2D* and *TP53* mutation in a lymph node deep in the abdomen (in green). Consistently, if the biopsy targets a superficial lymph node (e.g., the left axillary lymph node; in brown), in order to avoid unnecessary surgical risks, a certain number of mutations (i.e., *CD79b* and *TP53* mutation) present in the lymphoma genome would go undetected. Importantly, those mutations, if detected, might serve as predictive biomarkers as well as molecular markers allowing the monitoring of the disease during treatment. Conversely, cfDNA analysis on the liquid biopsy may overcome these limitations, since it is representative of all the different anatomical sites of the disease

STAT6, not previously reported in exome sequencing studies of this lymphoma, has been identified as the most frequently mutated gene in cHL, underlying the importance of cytokine signaling in the biology of this tumor^[23]. Also, liquid biopsy has documented that different histologic subtypes of cHL are biologically distinct. *STAT6* and *TNFAIP3* mutations are enriched in nodular sclerosis cHL compared with mixed cellularity cases. Also, NF- κ B, PI3K-AKT, cytokine and NOTCH signaling pathways, are frequently deregulated by gene mutations, and might be relevant for the biology of the disease and for the identification of potential therapeutic targets^[23].

LIQUID BIOPSY AS A TOOL TO EVALUATE TREATMENT RESPONSE

In cHL, imaging techniques, such as interim positron emission tomography/computer tomography (PET/CT) scan after 2 cycles of chemotherapy, provide a powerful tool to predict cHL outcome before completion of chemotherapy^[24-26]. However, interim PET/CT results are inconsistent with the final outcome in 20% to 30% of patients^[24-26]. This lack of specificity and/or sensibility may be corrected, at least in part, by monitoring ctDNA concentration during the course of treatment. A recent study prospectively analyzed ctDNA during treatment in a cohort of 24 cHL patients homogeneously treated with adriamycin, bleomycin, vinblastine, dacarbazine (ABVD)^[23]. The study showed that ctDNA analysis may complement interim PET/CT in predicting patients' outcome^[23]. More precisely, patients achieving a complete response had a larger drop in the ctDNA load after 2 ABVD courses compared to refractory patients. Also, a 2-log drop

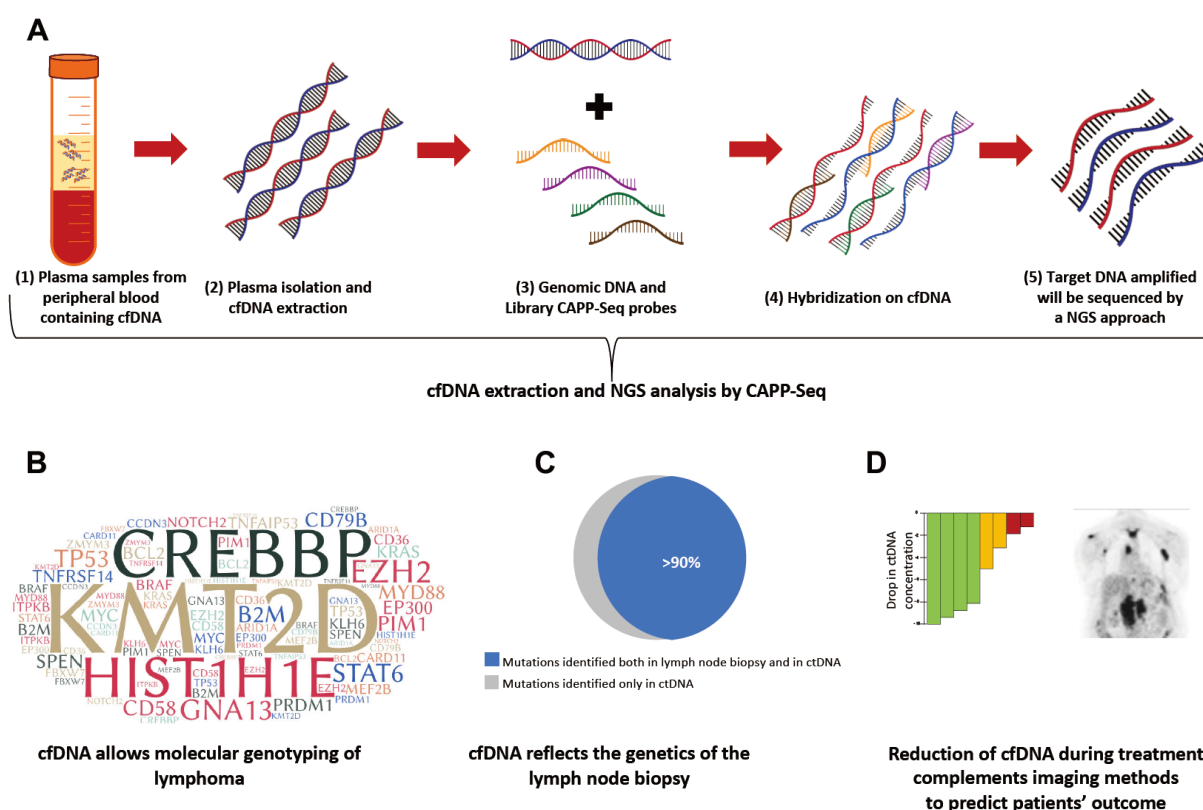

Figure 2. Applications of liquid biopsy in lymphomas. A: cell free DNA (cfDNA) can be selectively isolated and extracted from plasma samples. cfDNA may be analysed with the Cancer Personalized Profiling by Deep Sequencing (CAPP-Seq) method, that exploits magnetic probes that selectively capture and isolate specific genomic regions of interests, namely the target region. The target region is then subsequently sequenced by a Next-Generation-Sequencing (NGS) approach; B: consistently, cfDNA analysis on the liquid biopsy allows the genotyping of lymphomas and allows a better understanding of lymphoma pathogenesis; C: liquid biopsy mirrors the mutational landscape of the lymph node biopsy in most of cases and, in addition, allows the identification of mutations not identified in the tissue biopsy; D: the integration of imaging methods with the monitoring of the kinetics of the mutations identified by liquid biopsy on cfDNA may allow a more sensitive and specific prediction of patients' outcome. The colored bars indicate the various levels of cfDNA drop during therapy. A higher drop in the cfDNA concentration (in green) may predict a favorable response to therapy, whereas a smaller drop may predict resistance to therapy

in ctDNA after 2 chemotherapy courses sorted out as the best cutoff to predict progression. Indeed, cured patients who were inconsistently judged as interim PET/CT-positive achieved more than a 2-log drop in ctDNA, whereas relapsing patients who were inconsistently judged as interim PET/CT negative achieved less than a 2-log drop in ctDNA^[23].

Similarly, ctDNA analysis by CAPP-Seq methodology also allows to evaluate treatment response in DLBCL patients. ctDNA has been analyzed at baseline and during the course of treatment in a multicenter cohort of 217 patients with DLBCL treated with rituximab, cyclophosphamide, doxorubicin, vincristine, prednisone (R-CHOP) or R-CHOP-like chemo-immunotherapy^[21]. Two different thresholds have been identified to optimally predict patients' outcome, namely early molecular response (EMR) and major molecular response (MMR). These thresholds, including a 2-log drop in ctDNA after one cycle (EMR) and a 2.5-log drop after two cycles (MMR), predict event free survival after front-line therapy in the training cohort and in two validation sets^[21]. Interestingly, the prognostic value of molecular response maintained an independent association with an increased risk of progression and death also in multivariate analyses^[21]. Recently, a new prediction tool for DLBCL patients, namely Continuous Individualized Risk Index (CIRI), has been documented to dynamically determine outcome probabilities for individual patients utilizing risk predictors acquired over time, including clinical, radiological and molecular markers identified with a liquid biopsy approach^[27].

CONCLUSIONS AND FUTURE PERSPECTIVES

In conclusion, liquid biopsy is a non-invasive method that may be used in lymphomas to achieve several objectives: (1) better characterize the biology and pathogenesis of the lymphoma through the analysis of biological markers that reflect the entire molecular heterogeneity of the disease in its different anatomical sites; (2) identify new prognostic and predictive markers; and (3) prospectively evaluate the dynamics of ctDNA during treatment in order to predict the probability of response to treatment in a more sensitive and specific manner and, if necessary, the need for an early switch to a more efficacious treatment. In order to validate these initial results, several ongoing clinical trials aim at assessing whether cfDNA genotyping can improve outcome prediction in lymphoid malignancies and whether it might identify mutations predisposing to treatment resistance (NCT03280394^[28], NCT02883517^[29], NCT03702309^[30]).

In addition to the previously mentioned application of liquid biopsy in lymphoma, preliminary evidence also suggests that cfDNA analysis might reflect the methylation profile identified in the tissue biopsy^[31,32]. More precisely, global hypomethylation of the genome, as well as aberrant methylation of specific regions of interest detected on the liquid biopsy, namely DAPK1 promoter hypermethylation, might represent potential prognostic biomarkers in lymphomas^[31,32].

The liquid biopsy of lymphoma, as described in this review, aims at analysing mutations of somatic origin, and therefore does not pose major ethical issues beyond the conventional ethical requirements. If the patient plasma is stored in a biobank for subsequent analysis, the conventional guidelines for biobanking should be followed^[33,34].

Abstract

Cachexia affects the majority of patients with advanced cancer. It leads to poor surgical and oncological outcomes, and negatively affects quality of life. It has long been reported that components of the host immune system, including pro-inflammatory cytokines such as IL-1 α , IL-6, TNF- α and INF- γ , participate in the syndrome of cachexia. Yet therapeutic targeting of these pro-inflammatory factors has not yielded meaningful improvements in cachexia management. More recently, the impact of immune cells in the tumour mass (tumour-associated macrophages) and host circulation (myeloid suppressor cells) has garnered much interest with regards to their role in immune tolerance in cancer. However, their role in the generation of systemic inflammation and cancer cachexia is underexplored and outstanding questions remain. This review summarises the key mediators and targets of immune dysfunction in cancer cachexia. Here we describe the host response including skeletal muscle wasting; highlight the current knowledge gap areas; and report the results of previously trialled immunotherapies. A greater understanding of complex interaction between the tumour, immune system and peripheral tissues in the genesis and maintenance of cancer cachexia is a key step in identifying future therapeutic targets.

Keywords: Cancer cachexia, interleukins, macrophages, immunotherapy

INTRODUCTION

Cachexia is “a multifactorial syndrome defined by an ongoing loss of skeletal muscle mass (with or without loss of fat mass) that cannot be fully reversed by conventional nutritional support and leads to progressive

functional impairment”^[1]. Cachexia has a negative impact on a large proportion of patients with advanced cancer with it contributing to high levels of morbidity and mortality^[2]. Although there still remains some debate over the formal definition of cancer cachexia, it is characterized by unintentional weight loss, muscle wasting, anorexia and fatigue^[3]. Systemic inflammation is a key driver of cancer cachexia and has been advocated as a core nutritional assessment in patients with cancer^[4,5]. Pro-inflammatory cytokines are activated by the tumour mass, and act both centrally (through anorexia) and peripherally (by skeletal muscle wasting) to result in host nutritional depletion^[6]. Tumour and host-derived factors thus lead to a chronic inflammatory and impaired immune state^[7]. Immunosuppression is a large problem in cachectic cancer patients contributing to reduced responses to surgical and oncological outcomes^[8]. The dysfunction of the immune system is complex and involves multiple mechanisms characterised by a reduction in monocyte, macrophage, dendritic and natural killer (NK) cell function, ultimately leading to susceptibility to infections, and therefore, an overall increase in morbidity^[9].

In short, it has long been apparent that systemic inflammation plays a role in the pathogenesis of cancer cachexia. The successful therapeutic targeting of systemic inflammation requires a better understanding of the involved mediators and the link between tumour and immune tissues. This review aims to describe some of the key elements of immune dysfunction in cachexia and give an overview of previously trialled immunotherapies.

PRO-CACHECTIC CYTOKINES

TNF- α

TNF- α (previously known as “cachectin”^[10]) was initially held responsible for causing most of the metabolic derangements and clinical features of cachexia. TNF- α is released by many types of cell, including activated macrophages, CD4+, neutrophils, mast cells, eosinophils and neurons. In particular, it can be produced by tumour, immune and stromal cells to induce growth and survival advantage in the tumour microenvironment^[11]. Its expression can ultimately lead to anorexia, muscle and adipose wasting, loss of appetite, increased energy expenditure and insulin resistance in both patients with various types of cancer, and the Colon-26 carcinoma mouse model of cancer cachexia (C26)^[12]. Many of the effects of TNF- α arise through activation of NF κ B, which in turn leads to activation of the ubiquitin-proteasome pathway and skeletal muscle degradation^[13]. It also acts to induce oxidative stress and nitric oxide species (NOS). Experimental evidence suggests TNF- α can induce adipose wasting in white adipose tissue through inhibition of lipoprotein lipase (LPL), suppression of transcription and promotion of lipolysis^[14,15] as well as stimulation of thermogenesis through increased expression of UCP2 and UCP3 in skeletal muscle.

The role of TNF- α in mediating many of the effects of cancer cachexia was initially supported by evidence that intraperitoneal injection of soluble recombinant human TNF-receptor antagonist was able to improve food intake and thus lead to weight gain in tumour-bearing rats^[16]. Lewis lung carcinoma (LLC) mice deficient in TNF- α receptor protein type 1 showed a reduction in muscle wasting compared with LLC wild-type mice despite similar levels of TNF- α being detected in the serum^[17]. Treatment with antioxidants or NOS inhibitors was shown to increase body weight and prevent muscle wasting in mice^[18]. Despite this, TNF inhibition alone in animals has not been shown to be sufficient to reduce or reverse the cachectic process indicating that, although it is involved in the pathogenesis of cancer cachexia, it is not solely responsible^[19].

Studies in patients with cancer, have also not been successful. In particular adipocytes taken from cancer patients, showed no decrease in LPL messenger RNA (mRNA) or LPL enzyme activity^[20]. Some studies have shown raised TNF- α levels in the serum of patients with pancreatic cancer associated with weight loss, whereas other studies in patients with terminal cancer showed no association between TNF- α and weight loss^[21,22]. Others have shown that TNF- α correlates with stage of disease or tumour size rather than degree

of weight loss^[23]. These discrepancies between studies may be due to differences in measuring techniques, possible auto or paracrine roles for TNF- α in adipose tissue, or heterogeneity between patients, sexes and tumours.

In summary, TNF- α is involved in systemic inflammation, but as cachexia is likely to be multifactorial, it is difficult to implicate TNF- α as the sole cause. More clinical studies are required to fully isolate its effects in patients.

Interferon gamma

Interferons are multifunctional cytokines that block viral infections and affect cell proliferation and differentiation^[24]. Interferon gamma (IFN γ) is produced by activated T and NK cells, and is arguably the most potent monocyte-macrophage activating factor^[25]. In the context of cancer, tumour-infiltrating lymphocytes (TILs), which have shown to be of particular importance in tumour immunosurveillance, are the main source of IFN γ ^[26]. There is an overwhelming body of evidence for both beneficial and detrimental roles of IFN γ in a range of diseases, including cancer. However, its role in patients with cachexia is a relatively underexplored area.

Several animal studies have indicated a central role for IFN γ in the pathogenesis of cachexia. Central administration of rat interferon resulted in decreased food intake whereas peripheral administration failed to do so^[27]. Mice overexpressing IFN γ producing tumour cells developed loss of body weight, atrophy of adipose tissue, and reduced appetite, all of which were then reversed by pre-treatment of the mice with anti-IFN γ antibodies^[28]. Mice with LLC also demonstrated a reduction in weight loss after treatment with anti-IFN γ antibody, significantly reducing fat wasting in particular^[29]. In rats that had received transplants of MCG 101 sarcoma, anti-IFN γ antibody reduced weight loss, but the effect of treatment was short-lived^[30]. Similarly to TNF- α , IFN γ has been shown to inhibit LPL activity in adipocyte cells *in vitro*, as well as that of glycerol phosphate dehydrogenase in cultures of rat adipocytes^[31].

IL-1 α

Levels of IL-1 α have been shown to be increased in animal models of cachexia. It is thought to cause similar effects to that of TNF- α ^[32]. IL-1 α is a pro-inflammatory cytokine produced mainly by macrophages and endothelial cells and is known for being a trigger of the acute phase response, thus playing a role in cancer pathogenesis, as well as shock and autoimmune disorders^[33]. In a similar fashion to other cytokines discussed, it is also able to inhibit LPL activity and stimulate lipolysis in cultured adipocytes^[34]. The ability of IL-1 to induce anorexia is thought to be due to a central effect on appetite suppression^[35] involving blockade of neuropeptide Y. It also increases plasma concentrations of tryptophan and serotonin leading to early satiety and suppression of hunger^[36].

Again, there is evidence for the role of IL-1 α in animal models of cachexia, but little in humans. IL-1 α can induce cachexia and anorexia in rats. IL-1 α treated rats showed loss of body weight. Administration of IL-1 α receptor antagonist (IL-1 α) to tumourbearing rats however, did not result in any improvement in body weight^[37]. Following direct tumour injection with IL-1 α , C26 mice demonstrated significantly reduced weight loss (without an effect on tumour burden) compared with mice who had systemic injection^[38]. Cultures of C26 cells also demonstrated raised levels of IL-6 after stimulation with IL-1 α , which were suppressed by monoclonal antibody to IL-6^[38]. In tumour samples from patients undergoing surgical resection for upper gastrointestinal malignancy, IL-1 β and IL-6 were also significantly overexpressed in the cancer specimens, at both mRNA and protein levels, compared with control mucosa. Protein levels were seen to correlate with CRP, indicating that tumour may be the source of IL-1 β ^[39].

IL-1 β

IL-1 β is a proinflammatory cytokine released by macrophages. It regulates the expression of other cytokines including IL-6 and IL-12. Recently, the loss of p53 in cancer cells from breast cancer mouse models have been shown to induce the secretion of WNT ligands that stimulate tumour associated macrophages (TAMs) to produce IL-1 β , therefore helping to drive systemic inflammation. Macrophages were prevented from secreting IL-1 β by pharmacological and genetic blockade of WNT secretion in p53 null cancer cells. This blockade also resulted in decreased neutrophilic inflammation and metastasis formation^[40]. These findings therefore suggest an important potential future role for personalised immune therapy in patients with cancer cachexia.

IL-1 β has also been better associated with the clinical features of cachexia such as anorexia, weight loss and sarcopenia than other cytokines such as IL-6 in a study of 83 advanced cancer patients^[41]. Patients with gastric cancer cachexia have also been shown to have a higher prevalence of IL-1B+3954 T allele than those without indicating that patient genotype plays a role on immunological regulation of cancer cachexia^[42].

IL-6

IL-6 can target adipose tissue, skeletal muscle, gut, and liver tissue, which can all affect cachectic patient body composition. It signals through the membrane bound receptor gp130 found in most tissues in the body^[43]. Once bound to its receptor, it activates JAK tyrosine kinase leading to phosphorylation of tyrosines and the binding of STAT proteins. STAT proteins can translocate to the nucleus and increase the transcription of genes involved in immune function, cell proliferation, differentiation and apoptosis^[43].

Several mouse cancer models have clearly demonstrated that blocking IL-6 and associated signalling can attenuate cachexia progression. Deletion of the *IL-6* gene in the APCMin/+ mouse prevented the development of cachexia^[44]. IL-6 when secreted by tumour cells can also increase autophagy in myotubes when joined with soluble IL-6 receptor^[45]. IL-6 trans-signalling through the soluble IL-6R has the potential to amplify IL-6 signalling in the cachectic patient and has been shown to be involved in cross-talk between tumour, muscle and adipose tissue in genetic mouse models of pancreatic cancer cachexia^[46]. Autophagy and increasing IL-6 levels have been associated with poor prognosis and weight loss in lung cancer patients^[45]. It has also been shown to be the key cytokine that regulates the hepatic acute phase response in patients with pancreatic cancer cachexia^[47]. IL-6 remains a promising therapeutic target in cancer cachexia but a better understanding of its direct and indirect effects, as well as tissue specific actions, is required.

CYTOKINE GENOTYPE

The presence and concentration of (potentially) pro-cachectic cytokines in cancer patients appear to be dependent not only on the type of tumour, but also on the burden of disease present, and patient specific factors such as age, sex and genotype. It is still not fully understood why patients with the same histological disease may vary with regards to the presence and severity of cachexia. Genetic variation in immunity is one possible reason. Specific single nucleotide polymorphisms in the *IL-1*, *IL-6* and *IL-10* genes have been associated with cachexia in gastrointestinal cancers^[48]. The 1082G allele in the IL-10 promoter was validated in an independent cohort. This was shown to be more prevalent in Myc/mTOR-driven mouse models of cachexia as well as cachectic colorectal cancer patients^[48]. The C allele of the rs6136 polymorphism in the P-selectin gene has also been associated with weight loss and low CT muscularity in a large group of cancer patients^[49]. These results suggest a role for the immune system in the complex presentation of cachexia.

CELLS

Myeloid derived suppressor cells

Many studies have now suggested that tumour infiltrating immune cells (those which are mainly of myeloid origin) are able to differentiate into cells which then promote tumour growth and metastasis

through their ability to induce systemic inflammation^[50]. Tumours can grow through myelopoiesis and the successful evasion of tumour cells from both the innate and adaptive immune systems^[51]. However, the progression of cancers appears dependent on tumour-associated myeloid cells through their ability to promote angiogenesis and tissue remodelling^[52]. This apparent immunosuppression has been linked to the development of cachexia in very few studies, despite tumour-induced immunosuppression being well documented in the literature^[53].

Myeloid derived suppressor cells (MDSC) may play a role in tumour-related immunosuppression. Tumour-induced amplification of the myeloid compartment leads to the expansion of myeloid-derived suppressor cells. MDSCs are immature myeloid cells in various stages of differentiation, but are not fully differentiated neutrophils, monocytes/macrophages or dendritic cells. They are found in the bone marrow, spleen, lymph nodes and tumours^[50]. Their mechanisms of action are not fully understood but they are thought to be immunosuppressive and to play a role in the over production of cytokines and inflammatory mediators, which may contribute to cachexia.

MDSC expansion in 4T1 breast carcinoma-bearing mice is associated with the induction of the hepatic acute phase protein response and altered fat metabolism^[53]. This response is also seen in the C26 and LLC mouse models. The pro-cachectic acute phase response is not seen, however, in 66C4 subclone of 4T1 mice in which MDSC expansion does not occur^[53]. Defects in myeloid cell-mediated inflammation has also been shown to result in reduced expression of pro-inflammatory cytokines in the serum of mice with hepatocellular carcinoma^[54]. Interestingly, this led to enhanced loss of adipose tissue and decreased macrophage number in visceral adipose tissue, suggesting a possible local role for macrophages in the regulation of cancer-induced fat loss^[54]. These findings imply that myeloid cell-mediated inflammation confers a beneficial function in these rodents, and may provide a potential explanation for the failure of several anti-inflammatory drugs in treating cachexia. Although a direct link between the development of cachexia and MDSCs has not been proven, the above studies have suggested that the development of cancer cachexia is partly explained by the expansion of immature myeloid populations associated with the tumour.

TAMs

TAMs increase tumour progression and metastasis and suppress anti-tumour immune functions^[55]. Monocytes from blood infiltrate the tumour and are primed by the tumour microenvironment to exert these effects^[55]. The immune cells within the tumour's microenvironment consist of myeloid-derived suppressor cells, NK cells, dendritic cells, T cells and macrophages^[56]. It is this infiltrate that contributes to tumour growth and the release of cytokines that promote the pro-cachectic environment. TAMs are recruited via cytokines and chemokines and suppress the activity of cytotoxic T-lymphocytes via programmed cell death 1 ligand 1 (PD-L1) or B7-H4 and other receptors^[57]. Activated macrophages also secrete cytokines leading to the activation of several complex cascades, thereby increasing inflammatory status^[58]. The chemokine monocyte chemoattractant protein-1 is possibly responsible for the migration of monocytes to adipose tissue in chronic inflammation^[59]. The mechanisms by which macrophages modulate adipocyte function in cachexia are still unclear.

TILs

TILs are often found in tumours and are thought to reflect an immune response against the tumour. Many studies report a survival benefit associated with the presence of TIL, suggesting they may delay tumour progression. CD3+ and CD8+ TILs in particular have been identified as having a positive effect on prognosis^[60].

IMMUNE SYSTEM BIOMARKERS

The Neutrophil: Lymphocyte ratio is a prognostic indicator in cancer. Neutrophils increase the inflammatory reaction to pathogens but also interact with cancer cells to produce cytokines and effector

molecules (e.g., VEGF) that are able to stimulate angiogenesis and promote tumour growth^[61]. Activated neutrophils can move from the circulation to the tumour site to release reactive oxygen species that in turn can lead to further DNA damage. They also have anti-tumour roles through antibody-mediated cytotoxicity of tumour cells^[62].

C-reactive protein is an acute phase non-specific inflammatory marker that can be elevated in response to infection, surgery or malignancy. It is produced by the liver in response to increased levels of IL-6 released by activated macrophages, as well as IL-1 and TNF- α ^[63]. The Glasgow Prognostic Score utilises raised CRP and hypalbuminaemia to predict those patients with systemic inflammation as part of cancer cachexia and who have a poor outcome. It has been examined in more than 60,000 patients and has been shown to have independent prognostic value^[64].

IMMUNOTHERAPEUTIC AGENTS FOR CANCER CACHEXIA

Immunotherapeutic agents for cancer cachexia have yielded mixed results. The different forms of immunotherapy are discussed in detail below.

TNF α inhibitors

There are currently several TNF inhibitors in use for the management of diseases such as rheumatoid arthritis (RA), psoriasis and inflammatory bowel disease, namely etanercept, infliximab and adalimumab^[65]. These drugs have revolutionised the treatment of RA but have also offered insights into the role that TNF- α plays in cachexia. In RA patients, they attenuate the hepatic acute phase response and, importantly, improve patients quality of life^[65,66]. They have also been shown recently to prevent worsening of the disease and restore fat free mass^[67]. These drugs are now used to treat many thousands of patients and have been shown to be effective at blocking TNF- α , but are not effective in treating cancer-induced cachexia^[62-64]. The feature common to all of these diseases is chronic inflammation due to exaggerated production of pro-inflammatory cytokines. Etanercept has showed some promising results in improving fatigue in a small cohort of cancer patients^[68]. A phase I/II study was conducted on pancreatic cancer patients comparing etanercept and gemcitabine with gemcitabine alone. A small increase in progression free survival was seen associated with higher plasma IL-10 levels, but there was no significant improvement in 6 month progression-free survival compared with gemcitabine alone^[68]. A placebo-controlled double-blind trial was also undertaken in 63 patients with incurable malignancy and weight loss of > 2.27 kg over 2 months or daily intake of < 20 calories/kg body weight. Weight gain was found to be minimal in both arms with comparable survival times. Treatment was associated with higher neurotoxicity^[69]. In this trial, therefore, etanercept was not effective in the treatment of cachexia in patients with advanced disease.

Infliximab has been used in a phase II placebo controlled randomised study in patients with stage II-IV pancreatic cancer^[70]. Patients were given either 3 mg/kg or 5 mg/kg infliximab with gemcitabine or placebo with gemcitabine. The mean change in lean body mass was + 0.4 kg for those on placebo, + 0.3 kg for those receiving 3 mg/kg of infliximab, and + 1.7 kg for those receiving 5 mg/kg of infliximab. No statistically significant differences were seen, however^[70].

Another agent with anti-inflammatory activity is OHR/AVR118, a broad-spectrum peptide-nucleic acid immune modulator that targets both TNF- α and IL-6^[71]. A phase II study involving patients with advanced cancer and cachexia showed an improvement in anorexia, dyspepsia, strength, and depression^[71].

Anti-IFN γ treatments

Anti IFN γ treatments have been effective in reverting cachexia in the LLC mouse model^[29]. There have been no trials undertaken in cancer patients, mainly due to the fact that this type of therapy requires a dose to completely block the action of IFN γ , and at present, such a treatment programme would be very expensive. The only trial conducted in patients with cachexia due to sepsis showed no benefit^[72].

IL-1/6 inhibitors

The IL-1 pathway has been previously targeted in humans with the recombinant human IL-1 receptor antagonist Anakinra and the neutralising monoclonal anti-IL-1 antibody Canakinumab. Anakinra, as previously discussed, has had success in rheumatoid patients but has yet to be trialled in patients with cancer^[65]. However, a more specific IL-1a human monoclonal antibody, MABp1, has shown promising results in cancer. An initial dose escalation and expansion study was designed using MABp1^[73]. The first dose escalation study was performed in patients with refractory cancer to assess its safety and tolerability. It identified an optimal intravenous dose which was then used in the following phase II study of forty-two patients^[73]. Median plasma IL-6 concentrations decreased from baseline to week 8 ($P = 0.08$). Of those 30 patients who had an assessment of body composition, lean mass increased significantly by 1.02 ± 2.24 kg ($P = 0.02$)^[73]. It was then compared to megestrol acetate in patients with advanced colorectal cancer and > 5% weight loss. Those in the MABp1 treatment arm showed a trend towards increased survival^[74]. A placebo-controlled, double blind phase III study in 333 patients with advanced colorectal cancer was then undertaken which resulted in increased lean body mass as well as symptom relief (pain, anorexia, fatigue)^[75].

IP1510 is a synthetic peptide IL-1 receptor antagonist. Pre-clinical studies found it to have low toxicity, and to be a potential effective treatment for cachexia. It was then trialled in advanced gynaecological cancer patients where it was well tolerated, and it significantly improved patient anorexia, depression and physical performance. Weight stabilisation or gain was seen in 17 of the 26 enrolled patients^[76]. Interpretation of the current data is limited because the study was neither randomised nor controlled. However, further larger trials are to be initiated targeting IL1 in cancer cachexia^[74].

Studies involving IL-6 antibodies have been undertaken in patients with advanced non-small cell lung cancer. The humanised monoclonal IL-6 antibody Clazakizumab [ALD518] has shown beneficial results in increasing haemoglobin levels and preventing loss of lean body mass. Fatigue scores were also improved compared with controls^[77]. There are, however, no phase III trials underway.

Immunotherapeutic agents continue to be a promising treatment for cancer cachexia and may be added to the multi-modal management approach for this complex syndrome.

Standard cancer immunotherapy

Anti-cancer immunotherapy including pembrolizumab above has been shown to improve outcomes in a range of tumour types, including melanoma, lung and bladder cancers, many of which respond poorly to traditional agents. Some of these therapies are, however, poorly understood. Patients with cancer cachexia have been shown to respond poorly to some immunotherapies such as immune check point inhibitor therapy, likely due to elevated clearance or the establishment of primary resistance^[78]. In two large clinical trials involving patients with melanoma and non-small cell lung cancer, there was a paradoxical association between plasma clearance of Pembrolizumab [a programmed cell death protein inhibitor (PD-1)] and poor overall survival. Those patients who responded poorly were noted to have reduced body weight and low albumin, suggesting that the presence of cachexia rendered these patients unable to respond to Pembrolizumab^[76]. The hypoalbuminaemia was hypothesised to explain the elevated plasma clearance, and therefore the dose was increased in these patients to counteract this apparent resistance, but it did not result in improved outcomes. Studies in lung cancer patients treated with immunotherapy have shown that decreases in pre-treatment BMI, weight loss and high neutrophil:lymphocyte ratio were associated with significantly shorter progression-free survival^[79]. However, other studies in lung cancer patients have also shown that two thirds of those receiving PD-1 and PD-L1 immune check point inhibitors experienced stability or an increase in their skeletal muscle index^[80]. Thus, although at first glance immunotherapy would seem to be a natural antidote to cancer cachexia, it is difficult to unravel the clinical impact of immunotherapy from the known adverse outcomes of any cancer patients with poor nutritional status.

These studies therefore raise the possibility that immunotherapies could represent effective anti-cachexia agents but that synchronous multimodal and nutritional anti-cancer treatments may be required to establish or enhance their overall effectiveness.

A key consideration in using immunotherapy may be the inflammatory status of the host. It has been demonstrated that the host inflammatory status influences the efficacy of therapy with inflamed patients most likely to benefit from therapies with an anti-inflammatory mode of action^[81]. Similar to the call to “stage the tumor, stage the host”^[82] it is now key that treatment stratification is based on the inflammatory status of the patient and this is now being used as a mandatory measure in clinical trials in some tumour groups^[83]. It is clear that whilst immunotherapies as a treatment for cancer cachexia, there is a necessity to ensure patients who receive these are those who are most likely to benefit.

CONCLUSION

The pathogenesis of cancer cachexia is highly dependent on the patient's immune response. The interplay between inflammatory cytokines (such as TNF- α , IFN γ and interleukins) and pro-cachectic factors contributes to the complex aetiology. These cytokines are produced by the host in response to the tumour, as well as by the tumour itself. Many treatments have tried to regulate the immune response in cachexia but have largely been unsuccessful, perhaps in part due to the multifactorial nature of cachexia, and the observed heterogeneity of patient factors. Large-scale clinical studies are needed to prove whether neutralisation of deleterious cytokines or direct receptor antagonism in combinatorial treatment regimens is an effective therapeutic approach to improve patient outcomes or to reverse muscle loss in cancer cachexia.

Abstract

While we made great strides in the early detection of a handful of cancers, many other cancers are still detected at fairly later stages, thus hindering the deployment of effective surgical or therapeutic intervention to change their dismal clinical outcomes. The arduous journey of cancer cells from the primary tumor to colonize distant secondary organs or tissues begins with their ability to activate or deactivate various cellular processes at will, including the autophagy machinery. In this review, we discuss how circulatory cancer cells from primary tumors could selectively mobilize different subsets of microRNAs (miRNAs) to enable autophagic recycling of nutrients during their search for secondary sites to colonize and to disable such cell survival programs once they have successfully established at distant organs or tissues. We also discuss how this new miRNA-autophagy-metastasis axis can be targeted by the emerging RNA Medicine toolkit.

Keywords: Autophagy, miRNAs, cancer, metastasis

CANCER METASTASIS: KNOWING TOO LITTLE, TOO LATE

Metastasis remains one of the key reasons for the poor prognosis of cancer patients. The one-year survival of patients with stage 1 localized lung cancers is 87.3%, but plummets to merely 18.7% for stage 4 metastatic lung cancers^[1]. Similar trend is observed for colorectal cancer, where one-year survival is 97.7% if detected at stage 1 and rapidly decline to 43.9% if detected at stage 4. These depressing statistics underscores our

current knowledge gap in understanding the metastatic process, which impacts our ability to offer curative treatment options to cancer patients.

In the early stages of cancer, tumors are typically benign and remain confined within the normal boundaries of a tissue. As tumors grow and become malignant, however, they acquire the capacity to break through these boundaries and invade adjoining tissues. Notably, dissemination of tumor cells can occur relatively early in cancer progression^[2]. During the process of metastasis, only a rare population of invasive cancer cells escape the primary tumor, survive the treacherous transit through the circulatory system, and subsequently establish secondary tumors in distant organs/tissues^[3]. These invasive cancer cells, which exhibit extensive cytoskeletal remodeling, secrete proteases like extracellular-matrix-degrading metalloproteinases and cathepsins to drive their invasion and migration through the stroma, a network of supportive, connective tissue cells at the basement membrane^[4,5]. Furthermore, the stroma can actively promote the initiation of metastasis by releasing transforming growth factor- β and other cell-signalling proteins to trigger cancer cells to undergo epithelial-to-mesenchymal transition (EMT) - a reversible phenotypic change in which cells lose intercellular adhesion and epithelial polarization and gain motility and invasiveness^[6]. Transition into a mesenchymal cancer cell state allows for efficient intravasation of the lymphovascular system and acquisition of a stem-cell phenotype to promote survival during transit. These circulatory cancer cells can be arrested at distant organs/tissues, where they extravasate into the parenchyma of target organs to commence colonization. After extravasation, the invading cancer cells undergo mesenchymal-to-epithelial transition (MET) at the new settlement sites. The conduciveness of these niches for colonization can dictate the period of dormancy of these micrometastatic cancer cells. Long period of latency often exists between the development of a primary tumor and clinical manifestations of metastasis, indicating that metastatic colonization is a highly inefficient process in which most of these disseminated tumor cells (DTCs) die. To survive and establish macrometastases at distant organs/tissues, the minor subset of DTCs must overcome immune surveillance and other host-tissue defenses to achieve overt colonization at secondary sites^[7]. Although breast-to-lung metastases have been shown to arise mainly from cells that have not undergone EMT in mouse models of breast cancer^[8], it could be interpreted as rapid conversion into the epithelial cell state of DTCs, via MET, as soon as they arrive at supportive niches in the lung. Notably, the breast cancer cells that have undergone EMT are found to be resistant to chemotherapy and this could be attributed to their acquisition of a stem cell-like phenotype^[9].

AUTOPHAGY: A CRUCIAL CANCER CELL SURVIVAL MECHANISM DURING METASTASIS

Autophagy is a cellular housekeeping mechanism which degrades and recycles bulks of cytoplasmic materials for the synthesis of essential cellular components^[10]. Highly conserved from yeast to mammals, autophagy acts as an adaptive response to environmental stresses such as nutrient deprivation. The autophagy machinery has multiple distinct stages: initiation, nucleation, elongation, fusion and cargo recycling^[10]. During stress, shifts in nutrient availability can be detected by proteins involved in energy homeostasis, such as the 5' AMP-activated protein kinase (AMPK)^[11] and the target of rapamycin complex 1 (TORC1). The activation of AMPK and the corresponding inhibition of TORC1 will lead to the assembly of the Atg1/ULK complex, thereby kickstarting autophagy.

During autophagy, cytoplasmic cargoes are encapsulated by double-membrane vesicles known as autophagosomes and thereafter sent to the lysosomes to be degraded^[12]. The intricate, multistep processes of autophagy are facilitated by numerous autophagy-related proteins (Atg). Detailed characterization of these proteins can be found in the review by Feng *et al.*^[13]. At the initiation stage, the Atg1/ULK complex is assembled. This complex consists of Atg1/ULK, the regulatory subunit Atg13 and the scaffold complex Atg7-Atg31-Atg29 [Figure 1]. Importantly, the assembly of the Atg1/ULK complex is critical for the

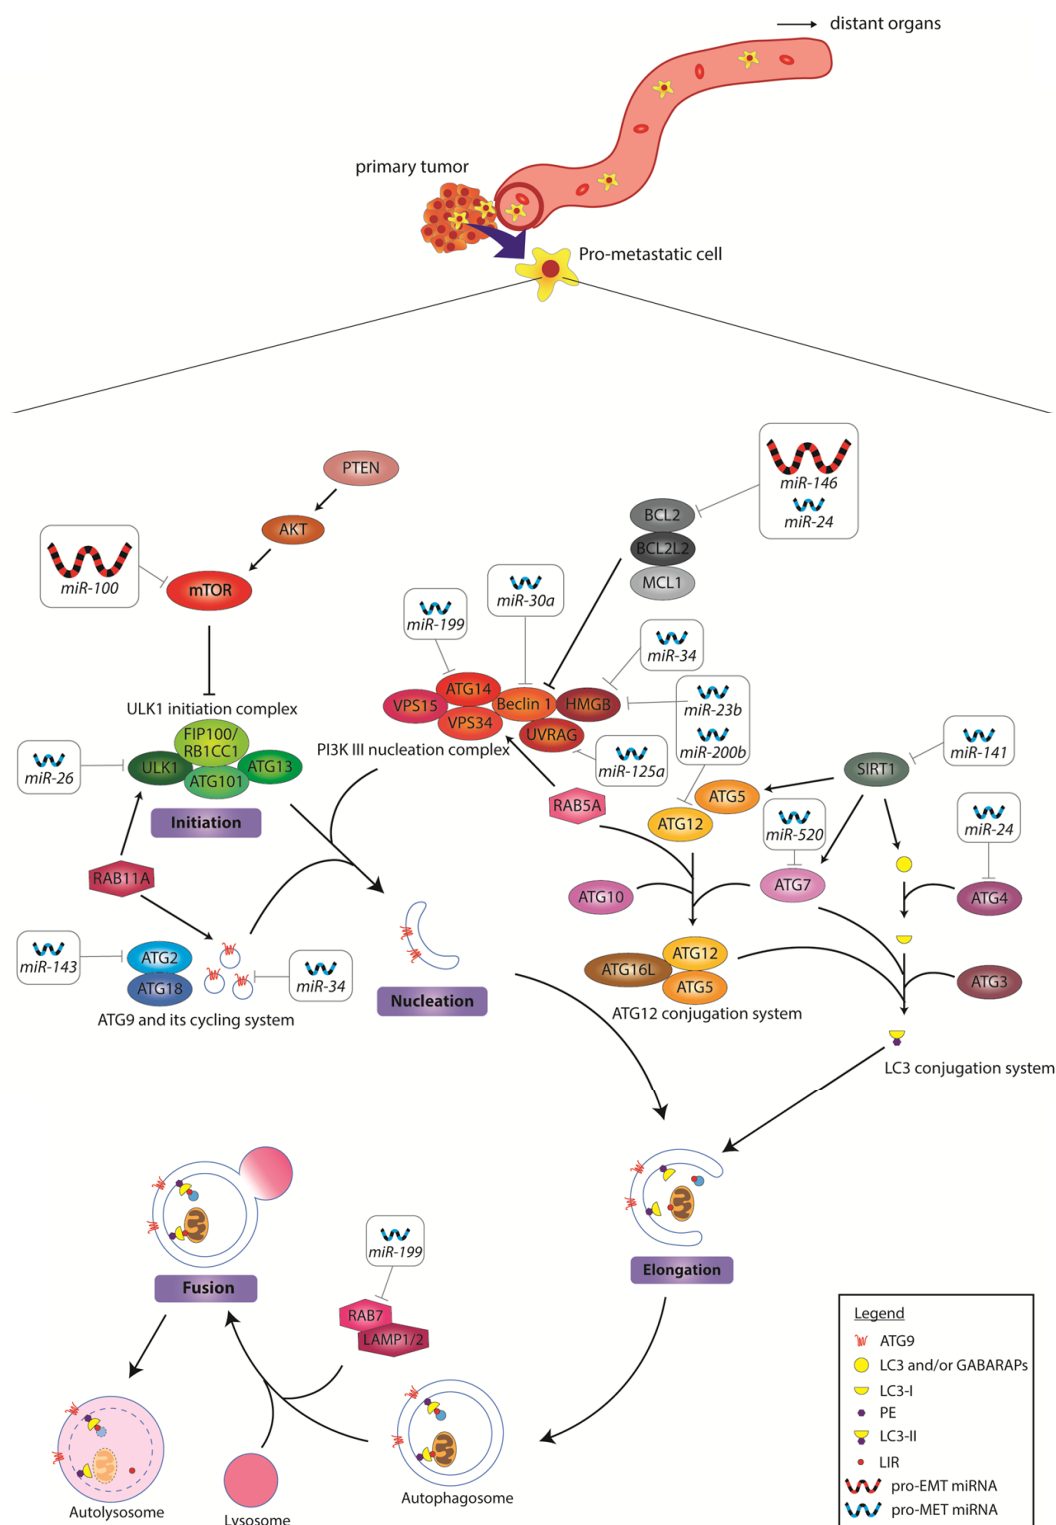

Figure 1. MiRNA regulation of autophagy during cancer invasion. The key components of macroautophagy is shown in this diagram. In the invading pro-metastatic cancer cell, autophagy is upregulated by gain of oncomiRs and loss of tumor-suppressive miRNAs. The oncomiRs target the inhibitors of autophagy to increase autophagic flux. The downregulated miRNAs on the other hand, are required for the activation of autophagy. Upregulated pro-EMT miRNAs are depicted as large red icons, while downregulated pro-MET miRNAs are depicted as small blue icons. The miRNA targets and mechanisms of actions are summarized in Table 1. EMT: epithelial-to-mesenchymal transition; oncomiRs: oncogenic miRNAs; MET: mesenchymal-to-epithelial transition

recruitment of downstream proteins to the phagophore assembly site. Next, Atg9 and its cycling system (Atg2, Atg18) are activated to facilitate membrane delivery to the expanding phagophore. This is followed by the assembly of the PI3K complex consisting of Vps34, Vps15, Vps30/Atg6, Atg14, and Atg38 [Figure 1], a process responsible for recruiting more proteins that are required for further phagophore expansion. Subsequently, two ubiquitin-like conjugation systems are activated for phagophore expansion, namely the Atg12 and the Atg8 conjugation systems. A detailed mechanism in which these conjugation systems function has been reported by Yin *et al.*^[10]. The human homologs of Atg8 are categorized into two families - LC3 and GABARAP. Importantly, LC3 is employed during the phagophore elongation stage, whereas GABARAP proteins are only activated at a later stage of maturation. Upon induction of phagophore elongation, LC3 is cleaved at the C-terminal by ATG4B protease to form cytosolic LC3-I. This is followed by its subsequent conjugation and recruitment to the membrane to form LC3-II^[13]. The level of LC3-II is often known to correlate with the number of autophagosomes due to its association with autophagosome maturation^[14].

Fundamentally, LC3-II acts as an adaptor protein that selectively recruits cargoes to the autophagosome to be degraded^[14]. Following cargo recruitment and closure of the autophagosome, the autophagosome directly fuses with a lysosome to form an autolysosome^[12]. The cytosolic cargoes within the autolysosome are then broken down by lysosomal hydrolases, liberating building blocks for future synthesis of other macromolecules.

The importance of autophagy as a cellular homeostatic mechanism is underscored by the prevalence of autophagic defects in a myriad of diseases. Besides being a protein and organelle quality control mechanism that prevents the accumulation of aggregated and dysfunctional proteins, basal autophagy is also a highly regulated catabolic process that supports cellular metabolic and biosynthetic programs in response to nutrient deprivation and other forms of stress. In cancer pathogenesis, however, autophagy is hijacked by rapidly proliferating cancer cells as they adapt to the perturbations of the cancer microenvironment^[15].

Autophagy is finely regulated in response to the specific energy demands or stress cues emitted throughout the different stages of metastasis - local invasion, intravasation, dissemination, extravasation and colonization at distant sites. Several studies suggested that autophagy is associated with EMT in cancer and activation of autophagy promotes metastasis^[16]. This is corroborated by the high levels of autophagy detected in EMT-activated cancer cells, hence strongly supporting its role in promoting early metastasis^[17]. Additionally, cell detachment from the extracellular matrix typically has been shown to induce anoikis, a self-defense strategy that eliminates misplaced cells through apoptosis^[18,19]. It then becomes crucial for cancer cells to evade anoikis so as to survive while traversing to distant organs/tissues. Importantly, several studies have postulated the pro-metastatic role of autophagy in overcoming anoikis^[20-22]. Although the underlying mechanisms remain largely unknown, anoikis resistance conferred by autophagy has been shown to enhance the survival of cancer cells when they disseminate into the lymphovascular system, leading to their successful metastasis to distant organs.

Given that autophagy is a key cellular process that confers stress tolerance under adverse conditions, its activation in cancer cells that intravasate into the blood or lymphatic vessels enables them to withstand extreme metabolic stress induced by the changing environment^[23]. To compensate for the sudden change in energy demands of the circulating DTCs, autophagy is activated to retain pools of functional mitochondria to sustain viability of the DTCs. In addition, autophagy-mediated degradation of proteins provides a sustainable source of nutrients for the DTCs to fuel ATP production and biosynthesis of other macromolecules that are essential for growth and survival^[23,24].

Successful metastatic colonization is not only limited to the ability of DTCs to overcome stress that they are exposed to during circulation. Following extravasation from the blood vessel, the DTCs have been shown

to switch from EMT to MET with concurrent inactivation of autophagy in supportive niches^[25]. However, if the new environment is not permissive in situations such as cellular stress or a lack of available growth factors, the DTCs could exist in a dormant state, possibly by retaining elevated autophagic functions and delaying MET. Notably, autophagy inhibition in the neoadjuvant setting has also been shown to reduce pro-metastasis stromal cells at the premetastatic niche^[26]. Future work could be performed to determine whether inactivation of autophagy is necessary to drive MET of invading tumor cells at distant organs/tissues, thus providing new impetus for the development of anti-metastasis autophagy inhibitors.

MIRNAS: NONCODING REGULATORS OF AUTOPHAGY AND CANCER METASTASIS

MicroRNAs (miRNAs) are endogenously expressed small non-coding RNAs of 19-25 nucleotides in length, which negatively regulate gene expression post-transcriptionally. They regulate multiple cellular processes including proliferation, differentiation and apoptosis. They have been implicated in a growing list of human diseases, such as diabetes and cancer^[27].

In the canonical miRNA biogenesis pathway, the primary transcript (pri-miRNA) in the nucleus forms a characteristic stem loop structure, which is recognized and cleaved by the Drosha/DGCR8 heterodimer into pre-miRNA. The pre-miRNA hairpin loop is transported into the cytoplasm by Exportin-5, where its terminal loop is further cleaved by RNA endonuclease III Dicer to generate the mature duplex miRNA. Either strand can be processed into the final mature single-stranded miRNA, with the strand originating from the 5' end of the transcript known as 5p, while the strand originating from the 3' end is known as 3p. Association of the mature miRNA duplex with Argonaute proteins (Ago) forms the RNA-induced silencing complex (RISC), where the guide strand of ~22 nt remains in Ago while the passenger strand gets degraded^[28,29]. Due to the short sequence length of miRNAs, and the fact that their partial complementary binding to multiple regions of target messenger RNAs (mRNAs) is sufficient to guide the RISC to its target genes, miRNAs are able to regulate the expression of a myriad of genes that play critical roles in controlling cellular processes, including autophagy and cancer metastasis.

AUTOPHAGY-REGULATING MIRNAS IN CANCER METASTASIS

Owing to the complexity and dynamic nature of autophagy, past literature that implicated a role of miRNAs in the regulation of autophagy have been highly discordant even in the same cell type. To reconcile and put things into perspective, we examined and discuss the opposing roles of miRNA-regulated autophagy during the invasion phase versus the distant organ/tissue colonization phase of cancer metastasis.

At the onset of metastasis, cancer cells in the primary tumor first undergo EMT to enable the attached cancer cells to gain motile traits for invasion of the lymphovascular system. The role of autophagy in cancer cell motility and invasion was comprehensively reviewed by Mowers *et al.*^[23]. Suffice to say that many reports have now demonstrated the elevation in autophagy in cancer cells drives tumor dissemination, and this may in part be regulated by miRNAs. miRNAs that have been shown to regulate autophagy and cell migration/invasion in the context of cancer have been summarized in [Table 1](#).

Upregulation in oncogenic miRNAs (oncomiRs) is known to promote tumorigenesis^[29] via modulation of gene expression of a variety of growth and survival pathways in cancer cells. For instance, elevated levels of miR-100 and miR-146 are found in cancer cells. Notably, these oncomiRs have been shown to be critical for the activation of pro-survival autophagy via suppression of the expression of autophagy inhibitory effectors like the mammalian target of rapamycin (mTOR) and Bcl2, respectively [\[Figure 1\]](#)^[30,32,33]. miR-100 and miR-146 have also been shown to be key EMT effectors that promote metastasis^[31,34], with miR-100 proposed to act through HOXA inhibition^[83], and miR-146 via Notch2 inhibition^[84]. Overexpression of

Table 1. MiRNAs and their effects on autophagy and metastasis

miRNA	Action	Gene target	Effect in Autophagy		Effect in metastasis
			Mechanism of action	Expression status in cancer	
<i>miR-100</i>	Activator ^[30]	<i>mTOR</i>	Activates ULK1 initiation	Upregulated ^[30]	Activator ^[30,31]
<i>miR-146a</i>	Activator ^[32]	<i>BCL2</i>	Activates PI3K III nucleation	Upregulated ^[33]	Activator ^[33,34]
<i>miR-23b</i>	Inhibitor ^[35]	<i>HMGB2</i> <i>ATG12</i>	Inhibits PI3K III nucleation Inhibits ATG12 conjugation	Downregulated ^[35,36]	Inhibitor ^[36]
<i>miR-24</i>	Inhibitor ^[37]	<i>BCL2</i> <i>ATG4</i>	Inhibits PI3K III nucleation Inhibits LC3 conjugation	Downregulated ^[38]	Inhibitor ^[38]
<i>miR-26a/b</i>	Inhibitor ^[39]	<i>ULK1</i>	Inhibits ULK1 initiation	Downregulated ^[39,40]	Inhibitor ^[40]
<i>miR-30a</i>	Inhibitor ^[41]	<i>Beclin1</i>	Inhibits PI3K III nucleation	Downregulated ^[42]	Inhibitor ^[42]
<i>miR-34</i>	Inhibitor ^[43,44]	<i>HMGB1</i> <i>ATG9a</i>	Inhibits PI3K III nucleation Inhibits ATG9 cycling	Downregulated ^[45]	Inhibitor ^[46]
<i>miR-125a</i>	Inhibitor ^[47]	<i>UVRAG</i>	Inhibits PI3K III nucleation	Downregulated ^[48]	Inhibitor ^[48]
<i>miR-141</i>	Inhibitor ^[49]	<i>SIRT1</i>	Inhibits ATG12 and LC3 conjugation	Downregulated ^[50]	Inhibitor ^[50,51]
<i>miR-143</i>	Inhibitor ^[52]	<i>ATG2B</i>	Inhibits ATG9 cycling	Downregulated ^[53]	Inhibitor ^[53]
<i>miR-199</i>	Inhibitor ^[54,55]	<i>ATG14</i> <i>Rab7A</i>	Inhibits PI3K III nucleation Inhibits autophagosome and lysosome fusion	Downregulated ^[56]	Inhibitor ^[56]
<i>miR-200</i>	Inhibitor ^[57]	<i>ATG12</i>	Inhibits ATG12 conjugation	Downregulated ^[58]	Inhibitor ^[58,59]
<i>miR-520</i>	Inhibitor ^[60]	<i>ATG7</i>	Inhibits ATG12 and LC3 conjugation	Downregulated ^[60]	Inhibitor ^[61]
<i>miR-21</i>	Inhibitor ^[62,63]	<i>Rab11A</i> <i>PTEN</i>	Inhibits ULK1 initiation and ATG9 cycling	Upregulated ^[64]	Activator ^[64]
<i>miR-29a</i>	Inhibitor ^[65]	<i>ATG9A</i>	Inhibits ATG9 and its cycling	Upregulated ^[66]	Activator ^[66]
<i>miR-93</i>	Inhibitor ^[67,68]	<i>PTEN</i> <i>ATG16L1</i>	Inhibits ULK1 initiation Inhibits ATG12 conjugation	Upregulated ^[67]	Activator ^[67,69]
<i>miR-214</i>	Inhibitor ^[70]	<i>PTEN</i> <i>ATG12</i>	Inhibits ULK1 initiation Inhibits ATG12 conjugation	Upregulated ^[71]	Activator ^[71]
<i>miR-221/222</i>	Inhibitor ^[72]	<i>ATG12</i>	Inhibits ATG12 conjugation	Upregulated ^[72,73]	Activator ^[73]
<i>let-7</i>	Activator ^[74]	<i>mTOR</i>	Activate ULK1 initiation	Downregulated ^[75]	Inhibitor ^[75]
<i>miR-7</i>	Activator ^[76]	<i>mTOR</i>	Activates ULK1 initiation	Downregulated ^[77]	Inhibitor ^[77]
<i>miR-16</i>	Activator ^[78]	<i>mTOR</i>	Activates ULK1 initiation	Downregulated ^[79]	Inhibitor ^[79]
<i>iR-205</i>	Activator ^[80,81]	<i>PTEN</i>	Activates ULK1 initiation	Downregulated ^[82]	Inhibitor ^[82]

these oncomiRs provides several advantages to the invading cancer cells. Firstly, an increase in autophagy flux helps DTCs to resist anoikis following detachment from the primary tumor as well as to enable DTCs to gain access to nutrients to survive the arduous journey of traversing to distant organs/tissues. In addition, they concurrently change gene expression patterns in the cancer cells to allow these cells to become mesenchymal and thus more motile to invade distant sites.

Apart from oncomiRs, the loss of tumor-suppressive miRNAs has also been shown to drive cell invasion and migration [Figure 1]. Several autophagy-inhibiting miRNAs, namely, miR-23b, miR-24, miR-26, miR-30a, miR-34, miR-125a, miR-141, miR-143, miR-199, miR-200 and miR-520 are found to be downregulated in cancer. Notably, these miRNAs are also known MET effectors^[35-43,45-61,85,86]. As opposed to the primary role(s) of oncomiRs, we speculate that the loss of these miRNAs allows for higher autophagy flux and suppression of MET in the DTCs to help them adapt to unfavorable settlement sites.

Intriguingly, there exists a group of miRNAs that appear to block autophagy and yet promote EMT. These include oncogenic miR-21, miR-29a, miR-93, miR-214 and the miR-221/222 cluster that are highly expressed in cancer [Figure 2]^[62-73,87]. It seems counter-intuitive that successful distant organ/tissue invasion can be achieved for cancer cells without autophagy, but it remains plausible that the effects of these miRNAs might be context-dependent. For example, overexpression of miR-21 and miR-93 have been shown to induce metastasis by targeting PTEN^[64,69], which in turn may promote the blockade of autophagy via activating the PI3K-Akt-mTOR signaling cascade. Since one miRNA can target many different genes, the biological

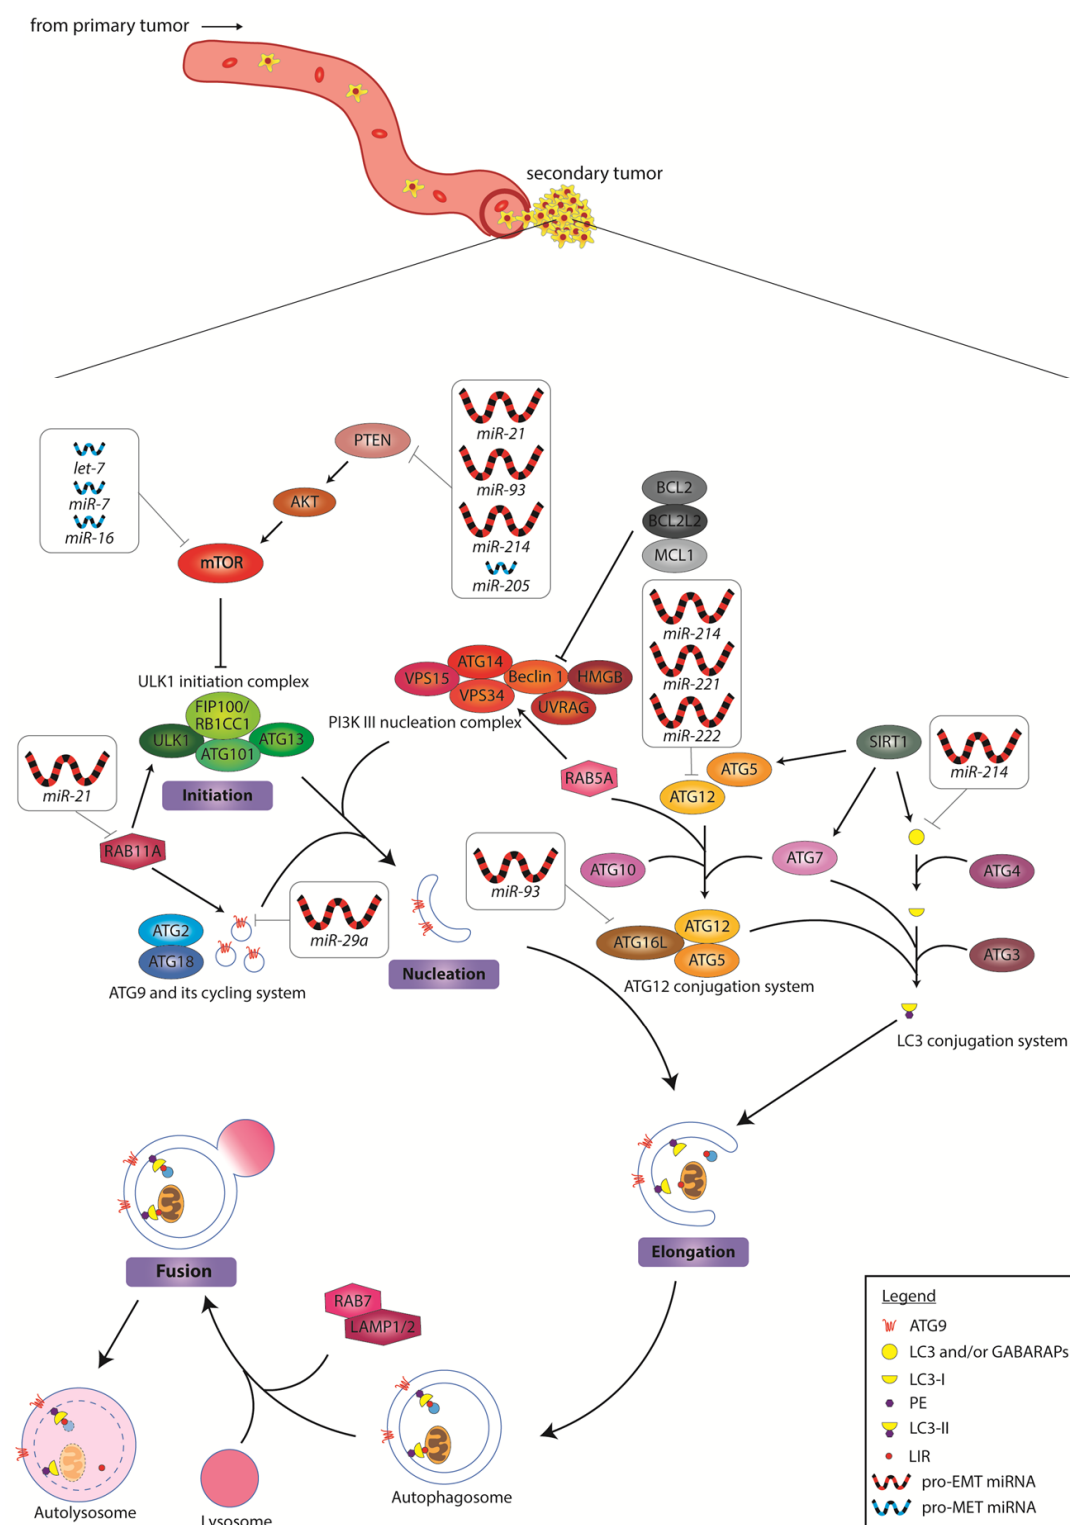

Figure 2. MiRNA inhibition of autophagy during secondary tumor formation. In the colonization process, autophagy is inhibited either by upregulation of anti-autophagy miRNAs, or the downregulation of the pro-autophagy miRNAs. This process promotes the re-establishment of an epithelial cell state for developing into macrometastasis. Upregulated pro-EMT miRNAs are depicted as large red icons, while downregulated pro-MET miRNAs are depicted as small blue icons. EMT: epithelial-to-mesenchymal transition; MET: mesenchymal-to-epithelial transition

context should also be taken into consideration in reconciling the opposing EMT-promoting and anti-autophagy effects of miRNA-dependent loss of PTEN. Could miR-21 and miR-93 also regulate other targets concurrently to yield the phenotype observed? We also noted that several of these studies demonstrate induction of cell migration/invasion by overexpressing miR-21 or miR-93 in cancer cells grown in the tissue culture setting^[64,67]. Unlike the circulating DTCs in a living organism, cancer cells cultured *in vitro* are never short of nutrient supply. It is perhaps not surprising that the need to trigger pro-survival autophagy in these cancer cells might be over-written by external culture conditions *in vitro*. Alternatively, miRNAs like miR-21 and miR-93 may serve as sensors of favorable distant niches. As the DTCs extravasate at their destination sites, these miRNAs could respond to the new environment that provides nutrients to fuel the transition from micro- to macro-metastasis. Similarly, there exists tumor suppressive miRNAs that have been implicated in autophagy activation but yet inhibit cancer growth and metastasis. These miRNAs, including let-7, miR-7, miR-16 and miR-205, have been shown to be less abundant in tumors^[74-82]. Their absence in DTCs at micrometastasis sites might be crucial to cell survival, as autophagy genes will remain activated to ensure nutrient supply until conditions of the new environment turn favorable for macrometastasis.

PRECISION TARGETING OF MIRNA-AUTOPHAGY SIGNALING NODES BY SMALL MOLECULE AND RNA-BASED THERAPEUTICS

To date, cytotoxic chemotherapy remains the most widely used neoadjuvant or adjuvant treatment modality against cancers despite its association with a host of unpredictable side effects^[88]. In addition, a recent study demonstrates that cytotoxic chemotherapeutics broadly used in neoadjuvant cancer therapy elicit tumour-derived extracellular vesicles with enhanced pro-metastatic capacity^[89]. Hence, precise targeting of metastasis-enabling cellular processes, such as autophagy, is warranted and could synergize with chemotherapy to maximize therapeutic efficacy. For instance, small molecule inhibitor targeting of focal adhesion kinase (commonly known as FAK) activates the SRC kinase and thereby inhibits autophagy, which in turn, prevents the migration of SRC-driven metastatic tumor cells^[90,91]. Given the complexity of signaling pathways driving metastasis, a systematic framework for the development of effective anti-metastatic drugs has recently been proposed^[92].

Of late, RNA-based therapies (antisense, siRNAs, aptamers, miRNA mimics/anti-miRs and synthetic mRNA) have shown great promise as powerful adjuncts to the drug developer's existing toolbox of small molecules and biologics^[93]. Notably, miRNA-based therapeutics gained much attention in translational medicine and are currently tested in various Phase I and II clinical trials. miRNA-based therapeutics is broadly categorized as miRNA mimics and inhibitors of miRNAs (also known as anti-miRs or antagomiRs). miRNA mimics, in the form of synthetic double-stranded small RNA molecules that match the corresponding miRNA sequence, are aimed at replenishing the lost miRNA expression in diseases. Most of the commercial miRNA mimics are often modified by methylation of the passenger strand to increase their stability. AntagomiRs, on the other hand, are antisense oligonucleotides that are single-stranded and can be chemically-modified (with locked nucleic acids or with 2'-O-methoxyethylribose nucleoside) to increase affinity for their miRNA targets to block their functions^[94]. To prevent degradation by RNases in biofluids or in the endocytic compartment of cells, these miRNA therapeutics are frequently stabilized by oligonucleotide chemistry (as mentioned above or by adding phosphorothioate-like groups) or encapsulated in delivery vehicles, such as poly(lactide-co-glycolide) particles, neutral lipid emulsions, synthetic polyethylenimine, cyclodextrin, chitosan, etc.,^[95]. For instance, epidermal growth factor (EGFR)-targeted, EnGeneIC delivery vehicle-packaged miR-16 mimics have been tested in a Phase I clinical trial (NCT02369198) in which acceptable safety profile and on-target activity of these miR-16 mimics have been demonstrated in patients with malignant pleural mesothelioma^[96]. In addition, two other clinical trials (NCT02862145 and NCT01829971), involving the use of miR-34a mimics to treat primary liver cancer, small

cell lung cancer (SCLC), lymphoma, multiple myeloma, renal cell carcinoma and melanoma, also showed promising anti-cancer results^[97]. Given that a subset of miRNAs mediate the crosstalk between autophagy and metastatic states of cancer cells, we postulate that the miRNA-autophagy-metastasis axis of cancer could be effectively targeted by the precise *in vivo* delivery of specific combinations of miRNA therapeutics (involving miRNAs depicted in [Figures 1 and 2](#)), which could improve the clinical trajectory of late stage cancers. Alternatively, blockade of the biogenesis of oncomiRs via small-molecule RNA ligands has also been reported to be a feasible anti-cancer approach^[98]. These small molecules consist of high affinity RNA binding motives, including the aminoglycoside neomycin and different natural and artificial nucleobases, that target pri-miRNAs of oncogenic miR-372/miR-373 and inhibit Dicer-mediated maturation of these miRNAs to elicit anti-proliferative effects on gastric cancer cells.

Apart from miRNA therapeutics, siRNA therapeutics that target a number of driver oncogenes like *c-Myc*, *PD-L1/2*, mutant *KRAS*, *PKN3*, *EphA2*, *LMP2/7*, *MECL1*, *APN401* and *PLK1* have also been shown to exhibit on-target anti-cancer effects and elicit little or no overt toxicities in humans in a number of Phase I clinical trials (NCT00306904, NCT02314052, NCT02528682, NCT01676259, NCT01808638, NCT01591356, NCT00672542, NCT02166255 and NCT01437007). We envisage that delivery of siRNAs targeting genes that are important for autophagy and metastasis of cancer cells could also be a viable therapeutic route to combat late stage cancers.

CONCLUSION

Alterations in key cellular processes, including cell adhesive properties and autophagy, promote tumor cell dissemination and colonization at distant organs/tissues. These processes are mediated by a vast network of miRNAs that has the propensity to crosstalk with each other. Striking this Achilles heel of cancer precisely via specific combinations of miRNA therapeutics could dramatically improve the survival outcomes of cancer patients. Future work should be focused on tissue-specific targeting delivery vehicles, which carry miRNA therapeutics or other payloads, so as to avoid potential toxicities and off-target effects.

DECLARATIONS

Abstract

Multiple myeloma (MM) is a plasma cell cancer characterized by sustained endoplasmic reticulum (ER) stress and unfolded protein response activation in the setting of high rates of immunoglobulin synthesis. Consequently, MM cells rely heavily on protein quality control pathways for survival as evidenced by the clinical efficacy of proteasome inhibitors (PI). Autophagy is an intracellular self-digestion mechanism that plays a role in the ER protein quality control process. Unsurprisingly then, basal levels of autophagy were recently found to confer a survival and drug-resistance benefit to MM cells. However, excessive induction of autophagy in MM cells leads to autophagic cell death, highlighting the double-edged nature of autophagy modulation in MM. This review provides an overview of the role that autophagy plays in MM pathogenesis, survival, and drug-resistance. We highlight the potential utility of therapeutically targeting autophagy in MM, focusing on preclinical data of autophagic modulators in combination with alkylators, anthracyclines, PI, and immunomodulatory drugs.

MULTIPLE MYELOMA

Multiple myeloma (MM) is a neoplastic disorder characterized by the dysregulated proliferation of a plasma cell clone that typically produces a monoclonal immunoglobulin, ultimately resulting in end-organ damage^[1-3]. Clinical suspicion for active MM is often based on the presence of one or more laboratory/imaging abnormalities, termed the CRAB criteria [hypercalcaemia (C), renal impairment (R), anaemia (A), and osteolytic bone lesions (B)], particularly if occurring in a patient with a precursor plasma cell disorder such as monoclonal gammopathy of undetermined significance (MGUS) or smoldering MM (SMM)^[4]. A diagnosis of active MM requires the presence of greater than 10% clonal bone marrow (BM) plasma cells in association with either one or more of the CRAB features or a biomarker of malignancy (BM plasmacytosis equal or greater than 60%, ratio of involved vs. uninvolved light chain equal or greater than 100 or the presence of more than 1 focal lesion on magnetic resonance imaging)^[5,6]. MM is generally preceded by the asymptomatic precursor conditions MGUS and/or SMM^[6]. MGUS is characterized by low levels of monoclonal protein (< 3 g/dL) and less than 10% clonal plasma cells in the BM while SMM is characterized by the presence of > 3 g/dL of monoclonal protein with BM plasmacytosis exceeding 10% but less than 60%^[6]. Evidence of end organ damage related to the plasma cell disorder is an exclusion criteria for MGUS/SMM diagnosis. Patients with MGUS and SMM progress to active MM at a rate of 1% and 10% per year, respectively^[7].

While single driver mutations have not been identified in MM, marked genomic instability is a hallmark of the disease and contributes to elevated proteotoxic stress^[8]. The high frequency of genomic mutations may confer a survival advantage by enabling MM cells to quickly adapt to stresses in the environment. However, this comes at a cost. This deregulation of gene expression results in the accumulation of toxic misfolded proteins that exerts additional stress on MM cells^[9-13]. Furthermore, MM are highly secretory cells, characterized by staggering rate of synthesis of clonal immunoglobulins which further contributes to baseline ER stress. Therefore, protein quality control pathways are essential for MM survival^[8].

AUTOPHAGY

Autophagy is a tightly regulated self-digestion mechanism that promotes the lysosomal degradation of organelles, intracellular pathogens, and misfolded proteins. It is a key cellular mechanism to maintain homeostasis and guarantee energy supply as products of autophagic digestion can be re-utilized in anabolic processes^[14-16]. Therefore, nutrient and energy deprivation, ER stress, and hypoxia can all induce autophagy as a means to enable cell survival^[17]. In mammalian cells, there are three main types of autophagy, namely macroautophagy, microautophagy, and chaperone-mediated autophagy^[15].

Macroautophagy

Macroautophagy is a type of autophagy that delivers cellular contents to the lysosome via the formation of double-membrane structures called autophagosomes which then fuse with lysosomes to form autolysosomes^[18,19]. Macroautophagy can be subdivided into non-selective (bulk) and selective autophagy^[16]. During non-selective autophagy, bulk cytoplasm is randomly engulfed by a phagophore [Figure 1]. Notably, the mammalian target of rapamycin (mTOR) pathway is a key inhibitor of autophagy^[20]. Subsequently, the phagophore matures into an autophagosome and this process is mediated by autophagy-related protein 7 (ATG7), ATG8 (LC3), and ATG12^[21,22]. ATG7 functions as an E1-like enzyme by binding and activating ATG12 and ATG8 to facilitate the transfer of ATG12 to ATG5 via the E2 enzyme ATG10^[23-27]. The resultant ATG12-ATG5 conjugate forms a large multimeric complex together with ATG16 (ATG12-ATG5-ATG16) which acts as an E3 ligase to facilitate phosphatidylethanolamine (PE) and LC3 conjugation and conversion of LC3-I to LC3-II. LC3-II stably associates with the autophagosome membrane and regulates autophagic membrane expansion, recognition of autophagic cargo, and autolysosome formation^[21,22]. Finally, autophagosome and lysosome fusion occurs and the autophagic cargo is degraded by lysosomal hydrolases^[21,22]. Selective

Figure 1. Autophagy. There are three types of autophagy: macroautophagy, microautophagy, and chaperone-mediated autophagy. Macroautophagy is a type of autophagy that delivers cellular contents to the lysosome via the formation of double-membrane structures called autophagosomes which then fuse with lysosomes to form autolysosomes. Macroautophagy takes place in five main steps. Initiation of autophagy occurs in response to metabolic or therapeutic stress and is mediated by ULK1, ATG13, FIP200, and ATG101. During the nucleation step regulated by BECLIN-1, ATG14L, VPS15, and VPS34, the formation of the phagophore occurs. Expansion results in the sequestration of cytosolic contents within the autophagosome and is facilitated by ATG5, ATG12, ATG16L, and LC3-PE. Degradation is the breakdown of autophagosomal contents upon formation of the autolysosome (fusion of autophagosome and lysosome). Microautophagy is a largely non-selective process that facilitates the direct uptake and breakdown of cytosolic cargo by lysosomes. Chaperone-mediated autophagy refers to the chaperone-dependent targeting of specific cytosolic proteins to lysosomes for proteolysis. HSC70 binds to the consensus motif of specific proteins to target them to the lysosome-associated membrane protein type 2A (LAMP-2A) receptor on the lysosomal membrane. Once internalized by the lysosome, these cytosolic proteins are degraded

macroautophagy, on the other hand, specifically targets damaged or redundant organelles such as mitochondria (mitophagy), peroxisomes (pexophagy), ribosomes (ribophagy), aggresomes (aggrephagy), etc.^[28]. Specifically, mitophagy is the selective degradation of mitochondria by macroautophagy in a PTEN-induced kinase 1 (PINK1)- and Parkin-dependent fashion^[29,30]. Type 1 mitophagy sequesters and removes mitochondria in response to nutrient deprivation, whereas type 2 mitophagy removes damaged mitochondria^[31]. Type 3 mitophagy (micromitophagy), on the other hand, eradicates damaged mitochondrial components through the formation of mitochondria-derived vesicles that are subsequently degraded by lysosomes^[31].

Microautophagy

In eukaryotic cells, microautophagy is a largely non-selective process that facilitates the direct uptake and breakdown of cytosolic cargo by lysosomes. Specifically, cytosolic material is sequestered by direct invagination of the vacuolar/lysosomal membrane, forming autophagic tubes that pinch off into the lysosomal lumen^[32-34].

Chaperone-mediated autophagy

Chaperone-mediated autophagy (CMA) refers to the chaperone-dependent targeting of specific cytosolic proteins to lysosomes for proteolysis^[35-37]. This is a mechanistically distinct process that occurs only in mammalian cells. Unlike the other types of autophagy, CMA does not require the formation of vesicles^[37]. Instead, HSC70 binds to the consensus motif of specific proteins to target them to the lysosome-associated membrane protein type 2A receptor on the lysosomal membrane^[35-37]. Once bound, the targeted proteins start to unfold as they are internalized into the lysosomal lumen and then degraded^[35-37].

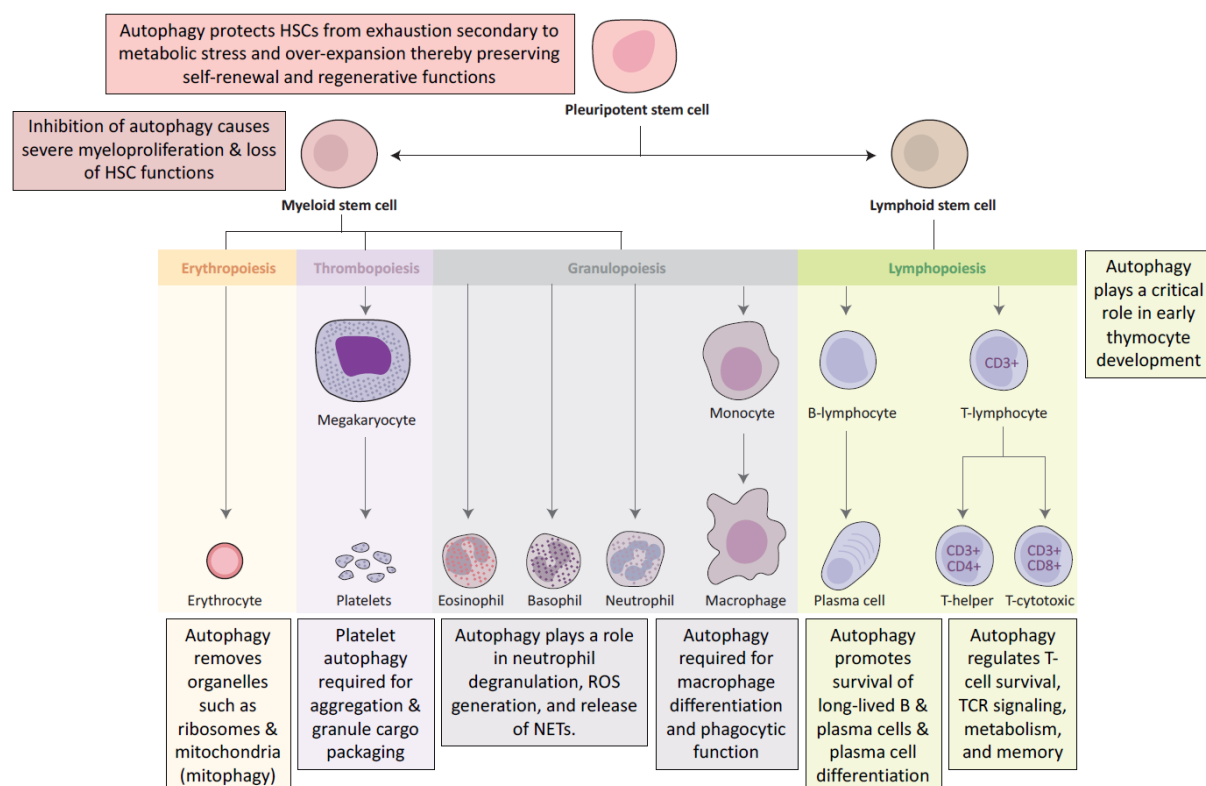

Figure 2. Examples of key functions that autophagy plays in the maintenance and differentiation of hematopoietic stem cells. Image adapted from First Aid for the USMLE Step 1^[63]

IMMUNE FUNCTIONS OF AUTOPHAGY

Autophagy as an immune effector

Autophagy plays a key role in eukaryotic cells as a stress response mechanism activated to recycle intracellular organelles in the face of nutrient deprivation^[38]. However, advances in our understanding of autophagy reveal also an intricate reciprocal relationship between autophagy and immunity^[38]. Specifically, autophagy acts as an immune effector by: (1) facilitating the direct elimination of microbes through xenophagy and LC3-associated phagocytosis^[39]; (2) modulating the inflammatory response by amplifying PAMP-TLR signaling whilst inhibiting type I IFN signaling and inflammasome activation^[40]; (3) enhancing MHC class II-mediated antigen presentation and cross-presentation^[39,40]; and (4) contributing to secretion of pro-inflammatory cytokines such as IL-6, which could be relevant to MM pathogenesis^[39].

Autophagy in the maintenance of hematopoiesis

Apart from regulating immune effector functions, autophagy is a key adaptive mechanism critical to the maintenance of hematopoietic hemostasis [Figure 2]^[41]. Hematopoietic stem cells (HSCs) thread a tight, but dynamic and demand-adapted, balance between quiescence and proliferation throughout the entire life of the organism^[41]. Studies have shown that autophagy protects HSCs from exhaustion secondary to metabolic stress^[41-43]. Firstly, basal autophagy removes activated mitochondria, regulates the metabolism, and maintains the self-renewal and regenerative capabilities of HSCs^[44]. Research shows that conditional deletion of ATG12 in transplanted murine HSCs severely impairs their ability for BM engraftment and self-renewal^[45]. Secondly, when subjected to *ex vivo* cytokine withdrawal or *in vivo* nutrient deprivation, HSCs robustly upregulate autophagy to circumvent an energy crisis to ensure HSC longevity^[43].

Deletion of ATG7, a critical component of autophagosome formation, in murine HSCs results in accumulation of dysfunctional mitochondria, upregulation of oxidative stress and DNA damage, and ultimately cell death^[46]. Interestingly, aged HSCs were found to maintain a low metabolic state by upregulating autophagy in order to sustain robust long-term self-renewal potential comparable to young HSCs^[44]. Downstream of HSCs, autophagy also plays a key role in the development, differentiation, and function of erythrocytes, platelets, granulocytes, macrophages, and T cells as summarized in [Figure 2](#)^[41].

Since malignant transformation of HSCs or early progenitors results in leukemia, homeostatic mechanisms; such as autophagy, that protect HSCs from metabolic, oxidative, and genotoxic stress; are crucial to prevent hematopoietic malignancies^[47]. Indeed, ATG7 deletion in myeloid cells results in dysregulated and invasive myeloproliferation resembling acute myeloid leukemia^[42].

Autophagy in plasma cell ontogeny

Autophagy plays a key role in plasma cell (1) differentiation; (2) survival; and (3) protein quality control.

Autophagy in plasma cell differentiation and survival

B lymphocyte to plasma cell differentiation is controlled by a complex genetic reprogramming system leading to downregulation of genes involved in the maintenance of B-cell identity [e.g., paired box protein 5 (PAX5), transcription regulator protein BACH2 (BACH2), B-cell lymphoma protein 6 (BCL6)] and upregulation of genes involved in terminal differentiation of Ig-secreting plasma cells [e.g., B-lymphocyte-induced maturation protein 1 (BLIMP-1), interferon regulatory factor 4 (IRF4), and X-box binding protein 1 (XBP1)]^[48]. Specifically, BLIMP-1 acts as a molecular switch to repress PAX5 and BCL6, and induces XBP1 to promote antibody production and plasma cell differentiation^[49,50]. Interestingly, while BLIMP-1 and IRF4 are essential for plasma cell differentiation, only IRF4 is essential for plasma cell survival^[51]. Consistent with this, BLIMP-1 deficient plasma cells remained viable and retained their transcriptional identity but lose the ability to secrete Ig^[51].

Beyond epigenetics, autophagy also plays an essential role in plasma cell differentiation and survival [\[Figure 3\]](#). Studies have found increased expression of autophagic genes in differentiating plasma cells. Conditional deletion of ATG5 in murine B cells results in reduced IgM and IgG responses in the setting of both T-cell dependent and independent immunizations; further suggesting that autophagy is required for B lymphocyte to plasma cell differentiation^[52]. Notably, ATG5 was also essential for the homing and/or survival of long-lived plasma cells in the BM^[52]. Consistent with this, long-lived plasma cells were found to highly express autophagic genes and display high basal levels of autophagy^[53].

Autophagy as a mechanism of protein quality control

Plasma cells are professional antibody secreting cells (ASCs) uniquely optimized towards large-scale immunoglobulin synthesis, folding, assembly, and secretion^[54]. Not unique to plasma cells, however, is the fact that the protein synthesis process is intrinsically error prone. In fact, up to 30% of newly-synthesized proteins are defective and need to be degraded^[47,54]. Thus, an intricate balance between protein synthesis, folding, and clearance must be maintained to prevent the accumulation of potentially toxic misfolded proteins^[47,54]. This is especially crucial for ASCs that cope with increased Ig synthesis by upregulating folding capacity through the induction of unfolded protein response (UPR)-driven ER expansion^[11]. However, when Ig synthesis exceeds folding capacity, the integrity of the proteome is preserved through an interconnected network of protein quality control pathways which include the proteasome, autophagy, aggresome, and UPR pathways^[47]. These pathways are so important to plasma cells that the amount of newly-synthesized proteins degraded by the proteasome is 15-folds higher in plasma cells compared to resting B-cells^[55]. Perhaps not surprisingly then, that MM, a cancer of plasma cells, exhibits the same reliance on the protein quality control as evidenced by the clinical efficacy of proteasome inhibitors (PI).

Figure 3. Role of autophagy in plasma cell ontogeny and malignancy. Differentiating plasma cells and MM cells induce autophagy to restrict the ER and downregulate BLIMP-1 expression to decrease immunoglobulin synthesis and deal with excessive proteotoxic stress. Autophagy is also essential for the survival and maintenance of memory B cells and BM long-lived plasma cells. In MM, induction of autophagy has been linked with bortezomib resistance. Image adapted from Milan *et al.*^[60]

Indeed, sensitivity of MM to PI is determined by a combination of Ig secretory load, protein degradation capacity, and commitment to plasma cell maturation; which, taken together, suggests that being an ASC confers this unique susceptibility to MM^[56-59].

While autophagy does not directly dispose of misfolded immunoglobulins, plasma cells deficient in autophagy had greater energy imbalance, enhanced immunoglobulin synthesis, reduced intracellular ATP, and elevated ER stress^[52]. Consistent with this, autophagy-deficient plasma cells displayed higher expression of BLIMP-1 and XBP1 with corresponding increase in ER size [Figure 3]^[52]. These findings suggest that autophagy not only facilitates the acquisition of an Ig-secretory phenotype in the in pre-plasma cells, but also serves to limit the overproduction of Ig and maintain cellular ATP levels to ensure survival in differentiated plasma cells [Figure 3]^[60]. Autophagy also plays an important role in the removal of misfolded protein aggregates which, due to steric hindrance, are unable to be efficiently degraded by the proteasome^[61]. Failure to dispose of misfolded protein aggregates results in proteotoxic stress and induction of terminal ER stress^[62].

AUTOPHAGY IN MM

Autophagy is necessary for the differentiation and maintenance of antigen-specific long-lived plasma cells, the physiologic counterpart to MM cells. As MM cells retain many characteristics of the original plasma cell clone such as Ig secretion and an enlarged cytoplasm and ER, it is reasonable to hypothesize that autophagy might also play a role in MM proteostasis and survival.

Indeed, MM cells exhibit higher levels of basal autophagy compared to other tumors, including lymphoma derived from earlier B-cell progenitors, and autophagy is necessary for the survival of MM cells^[64]. Disruption of autophagy through BECLIN-1 knockdown or pharmacologic inhibition (with 3-methyladenine and/or chloroquine) causes MM cell apoptosis^[65,66]. Basal autophagy is hypothesized to

alleviate proteotoxic stress and promote MM survival by (1) limiting the secretion of immunoglobulins and (2) providing an alternative proteolytic pathway for the clearance of ubiquitinated proteins through a p62-dependent mechanism^[60]. Despite this, concomitant inhibition of the proteasome and autophagy in pre-clinical studies have reported inconsistent results, ranging from synergism to antagonism^[60]. This may partly be explained by the observation that while basal autophagy is protective, persistent and uncontrolled autophagy results in autophagic cell death^[67,68]. Autophagic cell death in MM can be induced by caspase-10 or caspase-8 inhibition^[67,68]. Specifically, caspase-10 cleaves and inhibits BCL2 associated transcription factor 1, a BECLIN-1 activator, to temper the autophagic response and avoid cell death^[67]. MM cells therefore need to tightly regulate autophagy to maintain viability as dysregulation either way leads to deleterious effects in MM.

Mitophagy has been reported to play conflicting roles in carcinogenesis, survival, and drug-resistance. Some studies report that mitophagy protects untransformed cells from excessive reactive oxidative species damage and genetic instability, and that suppression of mitophagy favors carcinogenesis^[69,70]. Conversely, other studies suggest that mitophagy promotes cancer cell survival and drug resistance by protecting cells from apoptosis^[71,72]. In MM, while the suppression of mitophagy is associated with bortezomib resistance; doxorubicin, a widely used anti-MM chemotherapy, is a classical inhibitor of mitophagy^[73]. This dichotomy highlights the need for a better understanding of the role mitophagy plays in MM.

DNA damage and autophagy

Apart from ongoing proteotoxic stress, other hallmarks of MM are genetic instability and abnormalities (e.g., aneuploidy, translocations), and oxidative stress which lead to replicative stress and constitutive DNA damage^[74,75]. Recent studies have shown that DNA damage can activate autophagy through a number of interconnected pathways^[76]. Examples of DNA damage repair (DDR) pathway proteins that regulate autophagy are ataxia telangiectasia-mutated (ATM), poly (ADP-ribose) polymerase 1 (PARP1), c-Jun N-terminal kinase (JNK), and p53^[76]. Specifically, autophagy can be induced by ATM-mediated phosphorylation of AMP-activated protein kinase (AMPK)^[77,78]. AMPK in turn activates both tuberous sclerosis complex 2 (TSC2), to remove the inhibitory effect of mTOR complex 1 (mTORC1) on autophagy, and unc-51 like autophagy activating kinase 1 (ULK1) to promote autophagosome formation^[77-79]. ATM also phosphorylates and activates CHE-1 which in turn upregulates the transcription of two mTOR inhibitor genes [regulated in development and DNA damage responses 1 (REDD1) and DEP domain-containing mTOR-interacting protein (DEPTOR)]^[80]. Nuclear factor-kappa B, a well-known pro-myeloma transcription factor, can be activated by ATM and as a result, upregulate BECLIN-1^[81]. Induction of PARP1 promotes autophagy via AMPK activation on the background of ATP depletion and elevated AMP levels^[82]. DNA damage-induced JNK phosphorylates BCL-2 resulting in BCL-2 dissociation, relief of BECLIN-1 inhibition, and induction of autophagy^[83]. Nuclear p53 activates autophagy through a number of distinct signaling pathways. Firstly, p53 upregulates phosphatase and tensin homolog (PTEN) which leads to PI3K-Akt-mTORC1 inhibition and autophagy induction^[84,85]. Secondly, p53 influences AMPK activity (1) directly through transcriptional upregulation, and (2) indirectly by activating Sestrin1 and Sestrin2 which in turn activate AMPK^[85,86]. Thirdly, death-associated protein kinase (DAPK) is transcriptionally upregulated by p53 and triggers autophagy by phosphorylating BECLIN-1 to facilitate its dissociation from BCL-2 and BCL-X_L^[87-89]. DAPK also phosphorylates protein kinase D which activates the VPS34 class III PI3K complex leading to induction of autophagy^[87-89]. Lastly, p53 also upregulates damage-regulated autophagy modulator, a lysosomal protein involved in the degradation step of autophagy^[90]. However, unlike nuclear p53, cytoplasmic p53 can also activate mTOR to inhibit autophagy^[91]. Functionally, autophagy is essential for homologous recombination and nucleotide excision repair and cells deficient in autophagy rely chiefly on the error-prone non-homologous end joining repair pathway, which may explain the genomic instability observed in autophagy-deficient cells^[92-98].

EXPLOITING AUTOPHAGY IN MM

Preclinical studies of autophagy modulators in MM

HDAC6 inhibitors

Histone deacetylases (HDACs) catalyze the removal of acetyl groups on lysine residues in target proteins^[99]. Furthermore, HDACs also deacetylate non-histone proteins, thereby providing an additional layer of control over protein function, stability, and protein-protein interaction^[99]. HDAC6 is a class IIb HDAC that is mainly localized to the cytoplasm, unlike class I and IIa HDACs which shuttle between the cytoplasm and nucleus, suggesting that HDAC6 functions mainly to regulate non-histone proteins^[99]. Indeed, HDAC6 possess intrinsic ubiquitin-binding activity and co-localizes with the microtubule network to transport misfolded polyubiquitinated proteins to aggresomes/autophagosomes for subsequent lysosomal degradation^[99-101]. HDAC6 therefore promotes ubiquitin-dependent or ubiquitin-independent aggresome formation and while HDAC6 is not required for the initiation of autophagy per se, it is necessary for the targeted delivery of the autophagy machinery to aggresomes^[62,100-105]. Importantly, HDAC6 also promotes the formation of an F-actin network essential for autophagosome-lysosome fusion^[105]. The development of HDAC6 inhibitors therefore presents an opportunity to exploit autophagy to destabilize protein homeostasis in MM.

Preclinical studies have shown that the HDAC6-selective inhibitors WT161 and Tubacin trigger the accumulation of acetylated tubulin of and inhibits MM cell growth *in vitro*^[106,107]. Additionally, combinatory treatment using WT161 or Tubacin with the PI bortezomib not only induces synergistic cytotoxicity but was also able to overcome bortezomib resistance^[106,107]. Mechanistically, the addition of WT161 to bortezomib resulted in further accumulation of polyubiquitinated proteins which led to a further increase in ER stress signaling and the UPR, evidenced by the upregulation of ATF4 and the pro-apoptotic protein CHOP^[106]. Interestingly, the ER stress sensor proteins inositol-requiring enzyme 1 (IRE1 α) and PERK-like endoplasmic reticulum kinase (PERK) were found to be downregulated by WT161, suggesting that HDAC6 inhibition also suppresses the UPR, preventing it from functioning as an ER stress mitigator^[106].

Another HDAC6-selective inhibitor, ACY-1215, demonstrated synergistic cytotoxicity when used in combination with carfilzomib, an irreversible second generation PI^[108]. The addition of ACY-1215 resulted in increased LC3-II consistent with the disruption of autophagic flux secondary to HDAC6 inhibition^[108]. Mechanistically, the addition of ACY-1215 to carfilzomib inhibited both aggresome formation and autophagosome-aggresome association^[108]. Consistently, a novel HDAC6 inhibitor MPToG413 was shown to both disrupt bortezomib-induced aggresome formation and exhibit synergism with bortezomib^[109]. The combination of MPToG413 and bortezomib could also overcome cell adhesion-mediated drug resistance in the MM-BMSC co-culture setting^[109]. MPToG413 was further found to decrease MM-BMSC adhesion and downregulate the pro-myeloma cytokines VEGF and IL-6 in the context of the MM BM microenvironment^[109].

Autophagy inhibitors + DNA-damaging chemotherapy

DNA damaging agents such as melphalan are highly cytotoxic to MM cells and are a mainstay of treatment in MM, particularly as a conditioning regimen ahead of autologous hematopoietic stem-cell transplantation^[110]. Consistent with the aforementioned link between DDR and autophagy, a recent study found that melphalan and doxorubicin induce cytoprotective autophagy as a pro-survival mechanism in MM cells through the upregulation of BECLIN-1-dependent autophagosomes^[111]. knockdown of autophagy genes (BECLIN-1 and ATG5) and pharmacologic inhibition of autophagy (via hydroxychloroquine and 3-methyladenine) significantly enhanced the cytotoxicity of melphalan and doxorubicin *in vitro* and *in vivo*^[111].

High mobility group protein B1 (HMGB1) is a critical regulator of autophagy that is often upregulated in MM^[112,113]. Specifically, HMGB1 binds competitively to BECLIN-1 causing BCL-2 displacement and

autophagy induction^[112]. A study found that HMGB1 overexpression in MM was associated with mTOR inhibition, autophagy induction, and reduced sensitivity to dexamethasone^[113]. Conversely, knockdown of HMGB1 increased apoptosis in MM cells exposed to dexamethasone^[113].

HMGB1 has also been recognized a marker of induction of immunogenic cell death (ICD). ICD is triggered by exposure to certain cytotoxic agents (e.g., anthracyclines, oxaliplatin, bortezomib)^[114,115]. ICD involves the release of soluble mediators along with alterations in the cancer cell surface composition in a way that converts dying cancer cells into therapeutic vaccines that are phagocytosed by antigen presenting cells (APCs) for the cross-priming of CD8⁺ T-cells to stimulate anti-tumor specific T-cell immune responses^[114,115]. HMGB1 is a nuclear nonhistone chromatin-binding protein secreted by dying tumor cells exposed to cytotoxic agents that binds to toll-like receptor 4 on APCs to increase the rate of antigen processing and presentation by APCs to T cells^[116]. Interestingly, studies have shown that autophagy in tumor cells regulates HMGB1 secretion and that inhibition of autophagy leads to intracellular sequestration of HMGB1 and the induction of caspase-mediated cell death^[117]. Macroautophagy therefore enhances antigen cross-priming after ICD which results in the following conundrum. From a cytotoxicity point of view, it makes sense to combine DNA-damaging agents with autophagy inhibitors. However, from an ICD perspective, the addition of autophagy inhibitors to DNA-damaging agents may be counterproductive to antigen cross-priming.

Autophagy modulators + PI

Bortezomib, a first-in-class PI, was approved for use in MM by the FDA in 2003 and has become a mainstay of therapy at every disease stage ever since. Despite significant clinical efficacy in most naïve patients, most of the patients ultimately become refractory to bortezomib therapy^[118-120]. This has prompted the development of second-generation PIs (e.g., carfilzomib and ixazomib) currently in clinical use for relapsed or refractory MM; and next-generation PIs (e.g., marizomib and oprozomib) currently in advanced clinical trials^[121]. Based on evidence that susceptibility to PI depends on the ability of MM cells to remove misfolded proteins through protein quality control pathways, novel therapeutic approaches targeting alternative pathways in protein homeostasis are also actively being studied^[122].

Research has shown that crosstalk exists between the proteasome, UPR, and autophagy^[65,123,124]. Specifically, whenever the proteasome is overwhelmed and/or inhibited, polyubiquitinated and misfolded proteins co-aggregate in the cytosol to form aggresomes which are then degraded through macroautophagy^[101,125,126]. Mechanistically, proteasome inhibition induces ER stress and PERK-eIF2 α and IRE1-JNK activation, leading to the induction of autophagy^[127,128]. Other mechanisms of bortezomib resistance, in the context of autophagy, include the upregulation of PROFILIN-1 which enhances autophagy through BECLIN-1 interaction and increased expression of CIC5, a chloride channel that enhances bortezomib-induced autophagy via AKT-mTOR inhibition^[129]. PIs also rapidly induce the expression of SQSMT1/p62 to upregulate p62-dependent autophagy to compensate for proteasome insufficiency^[64].

Along the same line, preclinical studies have reported synergistic cytotoxicity with dual blockade of the proteasome and autophagy in MM. MG132, a PI, induced cytoprotective autophagy that can be inhibited, by 3-methyladenine, to enhance apoptotic cell death^[128]. Notably, 3-methyladenine resulted in the accumulation of polyubiquitinated proteins and exacerbation of ER stress in cells treated with MG132^[128]. Autophagy inhibitors that have demonstrated synergy and enhanced MM cytotoxicity with bortezomib *in vitro* include Elaiphyllin (macrolide antibiotic) and Metformin^[130,131]. Elaiphyllin, in particular, had significant cytotoxic activity even when used alone in mutant p53 MM^[130]. Metformin, on the other hand, inhibits GRP78 which is crucial mediator of bortezomib-induced protective autophagy^[131].

However, other conflicting studies have also shown that Metformin inhibits MM proliferation by inducing autophagy (and cell cycle arrest) through AMPK activation and dual repression of mTORC1 and

mTORC2^[132,133]. In line with this, it has been reported that when used in combination with bortezomib, the autophagy inhibitors 3-methyladenine or chloroquine can also have an antagonistic effect^[65]. One potential explanation could be that bortezomib induces apoptosis partially through autophagic cell death. Consistent with a role for autophagic cell death in MM cells treated with bortezomib, a novel SCF (Skp2) inhibitor CpdA stabilizes p27 to induce caspase-independent autophagic cell death in MM cells resistant to bortezomib; and also synergized with bortezomib^[134]. Another compound, betulinic acid (BetA), activates protein phosphatase 2A (PP2A) to trigger DAPK-dependent autophagic cell death in MM cells with high BCL-2 expression^[135].

Autophagy inhibitors have also shown potency in bortezomib and carfilzomib-resistant MM cells^[136]. The non-selective HDAC inhibitor SBHA upregulates the BH3-only protein BIM, which in turn sequesters BECLIN-1 to inhibit cytoprotective autophagy, thereby overcoming acquired bortezomib resistance^[136]. Chloroquine potentiated carfilzomib cytotoxicity and was able to overcome carfilzomib resistance *in vitro*^[137]. Lastly, pharmacologic inhibition of thioredoxin with PX12 upregulates mitophagy to re-sensitize bortezomib-resistant cells to bortezomib^[73]. Combination treatment of MM cells with PX12 and bortezomib led to synergistic toxicity and inhibition of ERK1/2 and mTOR signaling, suggesting the involvement of ERK1/2 and mTOR in mitophagy suppression^[73].

PI3K-AKT-mTOR inhibitors

While activating mutations in PI3K and AKT have not been reported in MM, the PI3K-AKT-mTOR pathway is commonly activated in MM through juxtacrine and paracrine signaling within the MM tumor microenvironment^[138,139]. Interactions between MM and the stromal and endothelial compartments result in the secretion of IL-6, VEGF, and IGF-1, which in turn activate pro-survival and proliferative pathways such as PI3K-AKT-mTOR, JAK/STAT3, NFκB, and MEK/ERK^[139]. In line with this, efforts to inhibit PI3K-AKT-mTOR signaling have led to the study of mTORC1 inhibitors (e.g., rapamycin) in MM. However, results from preclinical studies were disappointing as rapamycin and the other rapalogs demonstrated a cytostatic, but not cytotoxic, response in MM^[140]. This lack of potency could be due, in part, to the activation of cytoprotective autophagy. Nonetheless, mTORC1 inhibitors have shown synergistic activity in other cancers when used in combination with clinically approved anti-MM agents such as dexamethasone, lenalidomide, and panobinostat, and pre-clinical agents such as sorafenib (tyrosine kinase inhibitor), 17-AAG (HSP90 inhibitor), NVP-AEW541 (IGF1R inhibitor), and MK2206 (AKT inhibitor)^[141-148].

Upstream of mTOR, AKT inhibitors have also been studied in MM. In preclinical studies, perifosine, an AKT inhibitor, was cytotoxic to MM cells as a single-agent and also synergized with bortezomib, dexamethasone, doxorubicin, melphalan, and U0126 (MEK1/2 inhibitor)^[149]. Another AKT inhibitor TAS-117 enhanced ER stress and MM apoptosis when added to bortezomib or carfilzomib^[150]. These studies once again highlight the duality of autophagy in MM, suggesting that excessive induction of autophagy, rather than protecting cells from excessive ER stress, pushes cells towards autophagic cell death.

The next class of PI3K-AKT-mTOR pathway inhibitors are the dual PI3K-mTOR inhibitors. One such inhibitor, BEZ235, demonstrated good preclinical single-agent activity in MM and also synergized with bortezomib, doxorubicin, and melphalan^[151,152]. Another study reported a pro-survival function of autophagy in MM cells treated with PI-103, a competitive dual PI3K and mTOR inhibitor, which inhibits the proteasome, induces UPR, and upregulates autophagy^[153]. Importantly, Bafilomycin-A, an autophagy inhibitor, enhanced apoptosis in cells treated with PI-103^[153].

Heat-shock protein inhibitors

Heat shock proteins are molecular chaperones that play indispensable roles in protein folding/unfolding, multiprotein complex assembly, and protein sorting^[154]. As a function of protein sorting, HSP70 and HSP90

also participate in chaperone-mediated autophagy^[155-157]. Heat-shock proteins (HSPs) therefore help alleviate proteotoxic stress to prevent apoptosis in MM^[158]. Consistent with this, HSP70 and/or HSP90 inhibition induces UPR and apoptosis in MM^[159-161]. In preclinical studies, combination of HSP90 inhibitors KW-2478, Retaspimycin, and 17-AAG with bortezomib demonstrated synergistic cytotoxicity^[162-164]. Another HSP90 inhibitor, NVP-HSP990, displayed potent, *in vitro* anti-myeloma activity and synergism with melphalan, HDAC inhibitors, and PI3K/mTOR inhibitors^[165,166]. Other HSP90 inhibitors such as PU-H71, SNX5422, and NVP-AUY922 have also shown promising pre-clinical results in MM^[158,167-169]. Apart from HSP90, HSP70 has recently emerged as a promising therapeutic target in MM and a number of HSP70 inhibitors (e.g., PET-16, Ver-155008, MAL3-101) have shown good pre-clinical anti-myeloma activity^[160,161,170,171].

Interestingly, treatment of MM cells with HSP90 inhibitors (e.g., 17-AAG, NVP-AUY922), bortezomib, or dexamethasone results in compensatory upregulation of HSP70 which confers a degree of drug-resistance and protects MM cells from apoptosis^[172,173]. HSP70 is a molecular chaperone of HSP90. Consequently, inhibition of HSP70 leads to the downregulation of HSP90 while inhibition of HSP90 results in upregulation of HSP70^[160,171,174]. It has been shown however, that simultaneous inhibition of both HSP70 and HSP90 leads to greater MM cytotoxicity compared to inhibiting HSP90 alone^[160,171,174]. To this end, there has been increasing interest in developing inhibitors against heat shock factor 1 (HSF), the “master regulator” of the heat shock response that controls the expression of both HSP90 and HSP70^[158]. In preclinical studies, several novel HSF1 inhibitors (e.g., CCT251236, KRIBB11) were found to induce MM cell death that was associated with the induction of the UPR^[175].

Autophagy modulators currently in clinical trials

Several clinical trials have highlighted the potential role of autophagy modulators in the treatment of MM. For the purpose of consistency while discussing these trials, overall response rate (ORR) is defined as a partial response (PR) or better, and clinical benefit rate (CBR) is defined as stable disease (SD) or better.

Hydroxychloroquine/Chloroquine

Hydroxychloroquine (HCQ)/Chloroquine (CQ) have been clinically studied for their potential role in inhibiting autophagy. Although the exact mechanism of HCQ/CQ has not been elucidated, it is thought to function by alkalinizing intracellular compartments which disrupts the autophagic proteolytic process^[176]. HCQ/CQ have been extensively studied in myeloma to potentiate the effects of other anti-myeloma drugs, particularly PI.

A phase I clinical trial assessed the efficacy of HCQ in combination with bortezomib in patients with relapsed or refractory MM^[177]. Patients were given a 2-week run in with HCQ alone, followed by combination therapy with bortezomib. The combination of HCQ and bortezomib was well tolerated, with no adverse events meeting the criteria of a dose-limiting toxicity. Of the 22 patients assessed at the end of the study, 13.6% had a very good partial response (VGPR), 13.6% had minimal response (MR), and 45.5% had stable disease (SD). Interestingly, all of the patients who had a VGPR were bortezomib-naïve. Twenty-seven percent of patients in the study had progressive disease (PD). Of these, two thirds were bortezomib-refractory. This study also found a therapy-associated increase in autophagic vesicles in BM plasma cells. However, due to the small sample size, the authors were unable to correlate number of autophagic vesicles with clinical response.

A smaller phase II trial looked at CQ in combination with bortezomib and cyclophosphamide in refractory MM^[178]. Of the 11 patients enrolled, 8 completed at least 2 cycles and were assessed for clinical response. The most common side effects included fatigue, constipation, myalgia, anorexia, anemia and thrombocytopenia, but was generally well tolerated. 37.5% of patients achieved a PR with a median duration of response of 4 months. One patient (12.5%) had SD, and 50% of patients experienced PD, with

an overall clinical benefit rate of 40%. These studies demonstrate that HCQ/CQ are well tolerated in combinations with PI and may help potentiate the effects of existing myeloma therapies.

A recent study looked at dual autophagic inhibition via HCQ and rapamycin with cyclophosphamide and dexamethasone in patients with relapsed or refractory MM based on their preclinical, synergistic anti-tumor activity^[179,180]. The quadruple therapy was generally well-tolerated with one case of hematologic dose limiting toxicity (thrombocytopenia) occurring at a HCQ dose of 800 mg, which was then established as the maximum tolerated dose. Of the 18 patients enrolled in the trial, 1 had a VGPR and 3 had a PR, for an ORR of 22%. Seven patients had MR, and 5 had SD, for a CBR of 89%. Median duration of a response was 4.5 months, and median time to best response was 1.9 months. Two patients had immediate progression of disease. Unfortunately, correlative studies were unable to predict the depth of treatment response based on the number of autophagic vesicles in BM-derived MM cells. The promising results of this study warrant further investigation of dual autophagy modulation in MM.

HDAC6 inhibitors

HDAC inhibitors represent an important new group of anti-cancer drugs. There are 18 different isoforms of HDACs in human cells that are subdivided into 4 classes based on subcellular localization and non-cell-based enzymatic activity^[181]. Clinical studies with pan-HDAC inhibitors vorinostat and panobinostat outlined a narrow therapeutic window due to frequent and often severe hematologic and non-hematologic (particularly gastrointestinal/GI) toxicities, eliciting clinical interest in isoform-specific HDAC inhibition^[182].

Ricolinostat is an oral, selective HDAC6 inhibitor that has been extensively studied in MM. A phase 1b multicenter trial of escalating doses of ricolinostat with lenalidomide and dexamethasone in patients with relapsed or refractory MM showed 55% ORR^[182]. In lenalidomide-naïve and lenalidomide-sensitive patients, the ORR was 69%, compared to 25% in lenalidomide-refractory patients. In patients that responded, the median time to response was 7 weeks with a median duration of response of 24 months. Treatment with ricolinostat was overall well tolerated with 2 patients experiencing a dose-limiting toxicity at the highest tested dose which included syncope and myalgia.

Similarly promising results emerged from a phase 1/2 clinical trial assessing the safety and efficacy of ricolinostat with bortezomib and dexamethasone in patients with MM relapsed or refractory to PI, immunomodulatory drugs, or stem cell transplant^[183]. In this study, 15 patients were recruited for dose escalation monotherapy with ricolinostat, and 57 patients were given combination therapy. Monotherapy with ricolinostat was well tolerated with no dose-limiting toxicities up to 360 mg Q.D. Patients on combination therapy did not have any dose-limiting toxicities during escalation studies. Most common side effects associated with combination therapy were gastrointestinal toxicities, cytopenia, and fatigue. Of the patients treated with monotherapy, 6 patients (6/15, 40%) had stable disease with a median response duration of response of 11 weeks. Patients on combination therapy had an ORR of 29%, and a clinical response rate of 39%. Interestingly, patients on combination therapy who were previously refractory to bortezomib had an ORR of 14%. The response seen in patients with bortezomib-refractory MM suggests that HDAC6 inhibitors can overcome resistance to PI.

Taken together, these results demonstrate a promising role for HDAC6 inhibitors in the treatment of relapsed and/or refractory MM. There are currently ongoing trials assessing the role of HDAC6 inhibitors in combination with anti-myeloma treatments such as pomalidomide and dexamethasone (NCT01997840, NCT02189343).

HSP90 inhibitors

A phase 2 clinical trial looked at the HSP90 inhibitor tanespimycin in combination with bortezomib in patients with relapsed and/or refractory MM^[184]. All patients enrolled in the study experienced at least one side effect, with most common grade 3/4 toxicities being fatigue, thrombocytopenia, neutropenia, and abdominal pain. Four patients had significant liver toxicity with higher doses of tanespimycin, however this was manageable and reversible. The best responses observed to treatment were 1 MR in the 340 mg/m² group, and 2 PRs in the 175 mg/m² group. An additional 10 patients across all treatment groups had stable disease. A later phase 3 study evaluating tanespimycin and bortezomib has been completed, however results are not yet available.

KW-278 is a novel, non-anisomycin, non-purine based HSP90 inhibitor that has a more favorable pharmacokinetic and safety profile compared to tanespimycin^[185]. A phase 1 trial examined the safety and efficacy of KW-278 in B-cell malignancies, including 22 MM patients^[186]. The most common side effects included diarrhea, headache, rhinitis, and fatigue. Ten patients experienced grade 3 and 4 toxicities such as lethargy, syncope, QT prolongation, and neutropenia. Six patients experienced eye disorders (decreased visual acuity, blurry vision, dry eyes) that were deemed related to KW-278. All of the eye disorders were reversible with the exception of dry eyes. Two patients died during the trial and both deaths were determined to be unrelated to the study medication. Of the 21 MM patients evaluated, 20 patients (95%) had stable disease, and 1 patient had progressive disease.

A subsequent phase 1/2 study evaluated KW-278 with bortezomib in patients with relapsed or refractory MM who had failed at least 1 previous treatment^[187]. The most common side effects were fatigue and gastrointestinal toxicity, while the most common grade 3-4 side toxicities were cytopenias. There was no sign of significant ophthalmologic side effects in the 95 patients enrolled in this study. There were 28 serious treatment-related adverse events such as lung infections, GI toxicity, anemia, hematuria, syndrome of inappropriate diuretic hormone, pancreatitis, and transient ischemic attack. Efficacy of the treatment was based on a KW-278 dose of 175 mg/m² with bortezomib at the standard concentration. The ORR was 39%, the CBR was 92%. Median progression-free survival was 6.8 months, and median duration of response was 5.6 months. Patients who were lenalidomide-naïve had an ORR of 45.5 as compared to 25% for patients previously exposed to lenalidomide. Bortezomib-naïve patients had an ORR of 44% vs. 33% in patients previously exposed to bortezomib. These findings suggest a potential therapeutic benefit of KW-278 with bortezomib in the treatment of relapsed or refractory MM.

PI3K-AKT-mTOR inhibitors

The PI3K-AKT-mTOR inhibitor everolimus was tested as a single agent in a phase 1 trial in patients with relapsed and/or refractory MM^[188]. Most side effects were mild to moderate with gastrointestinal upset, elevated muscle and liver enzymes, and cytopenias being the most common. One patient developed an atypical pneumonia that was thought to be drug-related. Of the 15 patients assessed, 10 (67%) experienced clinical benefit with one patient achieving a partial remission after 4 cycles.

A phase I trial assessed the safety and efficacy of everolimus in combination with lenalidomide in patients with relapsed or refractory MM^[189]. Most common side effects were fatigue, cytopenia, diarrhea and neuropathy. One patient discontinued treatment due to non-infectious pneumonitis that was related to everolimus, and another discontinued due to grade 3 myalgia. Of the 23 patients that completed 2 cycles of treatment, the CBR was 74% with 1 CR and 4 PR. In patients who were lenalidomide-naïve, the ORR was 90%, compared to 37.5% for patients who had previously received lenalidomide. Median progression-free survival was 5.5 months, and median overall survival was 29.5 months. Promising results from these studies demonstrate the potential for mTOR inhibitors to be used the treatment of relapsed or refractory MM. A clinical trial looking at the role of mTOR inhibitors in combination with pomalidomide and dexamethasone is currently enrolling (NCT03657420).

Repurposing of FDA-approved drugs for use in MM

Metformin, the oral biguanide drug used in the treatment of diabetes, has been shown to exert anti-MM effects both *in vitro* and *in vivo*. The exact mechanism of metformin's anti-tumour activity has not been elucidated, but it is hypothesized to induce autophagy through the inhibition of STAT3 and BCL-2^[132]. The anti-retroviral drug nelfinavir has also shown anti-MM effects *in vivo* by triggering the UPR, and has been studied extensively clinical trials for relapsed MM^[190,191]. A new phase 1 clinical trial is assessing the safety and efficacy of metformin, nelfinavir and bortezomib in with relapsed or refractory MM (NCT03829020). This is only one example of the potential utility of drug repurposing strategies in cancer, rationally designed based on theoretical synergistic mechanisms of activity.

CONCLUSION

Autophagy plays a crucial pro-survival role in MM. Increased protein synthesis and proteotoxic stress are hallmarks of cancer, and MM is the prototypic cancer with impaired protein homeostasis based on its staggering rate of immunoglobulin synthesis and baseline level of proteotoxicity. Importantly, autophagy protects MM cells from excessive ER stress by limiting the secretion of immunoglobulins and providing an alternative proteolytic pathway for the clearance of ubiquitinated proteins. Consistent with a therapeutic role in targeting protein homeostasis, PI are highly effective anti-MM agents that are FDA approved for the treatment of MM in all its stages. However, clinical resistance to PI is inevitable, leading to research interest in targeting alternative pathways contributing to protein quality control such as autophagy, alone or in combination with PI. As with other mechanisms of protein homeostasis, such as the UPR; while a basal level of autophagy is cytoprotective and inhibiting autophagy to blunt non- proteasomal proteolysis has also been shown to have therapeutic benefit, sustained autophagy as in the setting of persistent proteasome inhibition, may result in autophagic cell death. This highlights the “Janus-faced” role of autophagy in MM. Autophagy therefore represents an opportunity to therapeutically exploit MM's unique “Achilles' heel”: its dependence on protein quality control. With a better understanding of the molecular sequelae of autophagy inhibition/induction in MM, we are eagerly awaiting the development or repurposing of drugs to target autophagy in an effort to overcome PI resistance and improve outcome for our patients with MM.

Abstract

Hyponatremia is the most frequently encountered electrolyte disorder in cancer patients and is usually multifactorial in its origin. In this review, we discuss the predisposing factors, pathophysiology, clinical symptomatology, and currently available diagnostic and therapeutic options for the management of hyponatremia. In addition to paraneoplastic syndromes, concurrent chemotherapy and comorbidities predispose oncology patients to the risk of hyponatremia. Initial symptoms and signs can be subtle and the prompt evaluation and initiation of treatment is of paramount importance to prevent neurocognitive and other complications. The syndrome of inappropriate antidiuresis (SIAD) is the most common cause of hyponatremia, and the use of serum and urine parameters that distinguish SIAD from other etiologies is discussed. Individualized treatment is preferred depending on the underlying cause and severity of hyponatremia. The treatment of hyponatremia is reviewed and the importance of avoiding rapid overcorrection of the sodium level to reduce the risk of osmotic demyelination syndrome is emphasized. Vasopressin receptor antagonists (vaptans) offer a direct approach to the management of euvoletic and hypervolemic hyponatremia, but the indications for their use and long-term safety need to be clarified. The treatment of hyponatremia is likely to reduce complications and improve survival in cancer patients.

INTRODUCTION

Dysnatremias are common electrolyte imbalances in cancer patients^[1]. Hyponatremia (serum sodium < 135 mEq/L) is the most common electrolyte abnormality encountered in clinical practice. Oncology patients are particularly at risk of developing hyponatremia due to their underlying cancer (including associated paraneoplastic syndromes), predisposition to infections, antibiotic use, concurrent chemotherapy, and nausea and pain. Hyponatremia in cancer patients is a predictor of outcome, hospital length and cost of stay, and an independent predictor of mortality in the intensive care unit^[2-5]. The syndrome of inappropriate antidiuresis (SIAD) is a frequent cause of cancer related hyponatremia^[6]. Hyponatremia due to ectopic arginine vasopressin (AVP; also known as antidiuretic hormone or ADH) production has been identified in 24.6% of small cell lung cancer patients and is associated with shorter survival^[7]. After brain metastasis, hyponatremia is the second leading cause of neurologic disorders in patients with small cell lung cancer^[8]. Other malignancies with a high prevalence of hyponatremia include gastrointestinal, hematological, breast and urological malignancies^[9]. Many chemotherapeutic agents coupled with hydration protocols can cause hyponatremia. Concomitant use of thiazide diuretics^[10] and opioid derivatives used for the management of cancer-related pain increase AVP release and contribute to hyponatremia^[5]. Vincristine and vinblastine have neurotoxic effects on the hypothalamic-pituitary-thyroid axis and cause hyponatremia while cyclophosphamide enhances the effect of AVP on the kidneys. Furthermore, cisplatin and carboplatin stimulate production of AVP and inhibit absorption of sodium by renal tubules. Treatment strategies with targeted therapies (inhibitors of angiogenesis, anti-epithelial growth factor tyrosine kinase receptor inhibitors and monoclonal antibodies) in cancer patients increases the incidence of hyponatremia (25.5%) in the treatment group. Higher incidence of hyponatremia is observed with a treatment combination of cetuximab and brivanib (63.4%) as well as with pazopanib (31.7%)^[11]. Patients receiving chemotherapy generally increase their free water intake. In small cell lung cancer patients receiving chemotherapy, tumor lysis syndrome increases the risk of hyponatremia due to increased release of AVP. In this clinical situation hyponatremia could be prevented by water restriction before the start of chemotherapy.

In cases of symptomatic hyponatremia, pharmacologic intervention may be necessary to increase serum sodium levels^[8]. The management of hyponatremia is becoming increasingly important in oncology due to the negative correlation of hyponatremia with performance status and the prognosis of cancer^[7,11]. Treatment of hyponatremia in small cell lung cancer patients is associated with improved survival^[12]. Sodium normalization is an independent prognostic factor for improved overall survival and progression free survival in patients with advanced non-small cell cancer with hyponatremia treated with first line chemotherapy or targeted therapy^[11]. Failure to identify the potential cause of hyponatremia and delay in appropriate treatment plan places the patient at risk of an adverse outcome. In this review, we discuss the initial evaluation, diagnostic algorithm and treatment of hyponatremia in cancer patients.

CLINICAL PRESENTATION

Symptoms of hyponatremia have variable clinical presentations, can be nonspecific and confounded by other comorbidities, and can range from mild cognitive deficits to severe neurologic symptoms. Symptoms of mild hyponatremia are nonspecific and may manifest as malaise, anorexia, muscle cramps, nausea, confusion, lethargy, and headache. More severe neurologic manifestations such as vomiting, somnolence, seizures, respiratory arrest, coma, and death are due to cerebral edema. Symptoms are often subtle, if present at all, in patients with chronic hyponatremia in which the brain has had time to adapt to the hypotonic state. Chronic hyponatremia is associated with falls and increased risk of fracture^[13]. A rapid decrease in serum sodium induces symptoms at a higher sodium level and the severity of symptoms reflect the degree of brain edema and guide the urgency of management. Patients with acute hyponatremia are at risk of permanent neurologic impairment.

PATHOPHYSIOLOGY OF HYPONATREMIA

Hyponatremia denotes a state of relative excess free water in relation to sodium in conjunction with impaired free water excretion. AVP regulates water balance in the body. AVP release is regulated by changes in effective osmolality or hypotonicity. Sodium is the major determinant of serum osmolality. Osmoreceptors, located in the anterior hypothalamus, detect changes in effective serum osmolality and regulate the release of vasopressin and thirst. An increase in serum osmolality activates osmoreceptors leading to secretion of vasopressin from the posterior pituitary. The threshold for releasing vasopressin is lower than for triggering thirst to avoid persistent thirst^[10]. Hyponatremia is a state of low effective serum osmolality or hypotonicity. Effective serum osmolality refers to the number of osmoles that contribute water movement between intracellular and extracellular compartments determined by the relative solute permeability properties of the membranes separating the compartments. Total osmolality reflects the concentration of all solutes in a given weight of water (mOsm/kg) regardless of the permeability properties of the separating membrane. A calculated serum osmolality [calculated serum osmolality (mOsm/kg) = $2 \times \text{Na (mEq/L)} + \text{glucose (mg/dL)}/18 + \text{urea (mg/dL)}/2.8$] < 275 mOsm/kg could refer to isotonic, hypotonic or hypertonic hyponatremia, depending on which osmoles are included in the formula, whereas a measured serum osmolality < 275 mOsm/kg always indicates hypotonic hyponatremia.

Clarification of tonicity is important because isotonic hyponatremia does not cause cerebral edema. The basolateral membrane of the renal collecting duct is permeable to water (aquaporin-3 and aquaporin-4 water channels). Vasopressin acts at the vasopressin-2 receptor on the cells of the renal collecting duct leading to fusion of aquaporin-2 in the apical membrane allowing water to enter into the cells of the collecting duct and ultimately to the circulation. Reabsorption of water from the collecting duct increases the concentration of sodium and other electrolytes in the urine, and concentrates urine. Low serum osmolality (normal range 285-295 mOsm/kg) decreases vasopressin release leading to excretion of free water from renal tubules. Patients with a reset osmostat, as seen in hypovolemia (baroreceptor stimulation), quadriplegia, and psychosis, have mild hyponatremia that is unresponsive to changes in fluid and water intake. Patients with a reset osmostat excrete 80% of a water load (10-15 mL/kg given orally or intravenously) within four hours, while patients with SIAD have impaired water excretion. Fractional excretion of urate [FEurate (%) = $(\text{urine urate} \times \text{serum Cr})/(\text{serum urate} \times \text{urine Cr}) \times 100$] is also normal (4%-11%) in patients with a reset osmostat while patients with SIAD have elevated FEurate (> 11%)^[14]. Identification of a reset osmostat is important because the risk of severe hyponatremia is low. In addition, treatment is not necessary and likely to be ineffective, since bringing sodium to the normal range will increase thirst^[15]. Since AVP release is controlled by hemodynamic and nonhemodynamic stimuli, cancer patients are at risk of hyponatremia due to hemodynamic (hypovolemia, hypotension, congestive heart failure, and nephrotic syndrome) and non-hemodynamic stimuli (pain, stress, nausea, vomiting, hypoxemia, hypercapnia, perioperative state and infections)^[16].

Pseudohyponatremia (a lab artifact) is due to an inaccurate measurement of sodium in the presence of abnormally high concentration of proteins and lipids in the blood. Larger relative proportion of plasma is occupied by excessive lipids and proteins. In this situation, serum osmolality is actually in the normal range since total number of solutes in the plasma remain the same. Monoclonal gammopathies can also cause pseudohyponatremia^[10]. Patients undergoing urological and gynecological surgery can have high serum osmolality due to mannitol and glycine absorbed in the circulation during irrigation. Effective osmoles, e.g., mannitol, glycine and glucose (seen in uncontrolled diabetes), increase serum osmolality by shifting water from intracellular compartments.

CLASSIFICATION OF HYPONATREMIA

Hyponatremia is classified on the basis of biochemical severity, rapidity of onset, development of symptoms, measured serum osmolality, and volume status. Acute hyponatremia is defined as hyponatremia that is

documented to exist < 48 h. The risk of cerebral edema increases in patients with acute hyponatremia since brain cells have less time to adapt to a hypotonic environment. Conditions predisposing cancer patients to acute hyponatremia include a postoperative state (especially after prostate and uterine surgery), polydipsia, thiazide diuretics, and infusion of cyclophosphamide. Brain cells adapt to hyponatremia by extruding sodium, chloride, and organic osmoles from cells. After adaptation, a rapid increase in serum sodium, as potentially seen after hypertonic saline administration, can cause damage to the myelin sheath leading to osmotic demyelination. In most clinical situations in which the duration of hyponatremia is less clear, hyponatremia should be considered chronic and managed accordingly to avoid the risk of osmotic demyelination^[10]. Mild hyponatremia refers to serum sodium levels ranging from 130 mEq/L to 135 mEq/L; moderate hyponatremia refers to serum sodium levels ranging from 125 mEq/L to 129 mEq/L; profound hyponatremia refers to serum sodium levels < 125 mEq/L. Assessment of volume status in hyponatremia is challenging because of the variability in individual clinical assessment. Furthermore, in this context it should be clarified whether volume status refers to effective circulating volume, total body water or extracellular fluid^[10]. In addition to absolute serum sodium levels, other factors that guide treatment of hyponatremia include symptoms and the rate of development of hyponatremia.

EUVOLEMIC HYPONATREMIA

Euvolemic hyponatremia results from low solute intake or SIAD and is a major cause of hyponatremia in cancer patients. Several malignancies are associated with SIAD. SIAD results from the abnormal production (increased release from the neurohypophysis or ectopic production) or action of AVP resulting in an excess of total body free water relative to sodium. SIAD is defined by hyponatremia (serum Na < 135 mEq/L) and an inappropriately concentrated urine (urine osmolality > 100 mOsm/kg, usually > 300 mOsm/kg) in the presence of low serum osmolality (< 275 mOsm/kg), euvolemia, and normal renal function. Renal sodium excretion is increased (usually > 30 mEq/L in a random urine sample) due to decreased aldosterone production and possibly increased secretion of natriuretic peptides^[17,18], which helps to distinguish SIAD from hypovolemic and hypervolemic hyponatremia. Urine sodium is typically < 30 mEq/L in hypovolemic and hypervolemic hyponatremia, unless there is an underlying process contributing to renal sodium loss such as diuretic use^[19]. Additional criteria that help to diagnose SIAD include serum osmolality less than the urine osmolality, low serum uric acid < 4 mg/dL and serum blood urea nitrogen (BUN) < 21.6 mg/dL, elevated fractional sodium excretion > 0.5%, fractional urea excretion > 55%, and fractional uric acid excretion > 11%.

Causes of SIAD are outlined in Table 1. SIAD is a diagnosis of exclusion. Other causes of euvolemic hyponatremia include adrenal insufficiency and hypothyroidism. Hematocrit levels and serum concentrations of uric acid and BUN may be decreased in SIAD^[20] due to hemodilution. These analytes could be elevated in hypovolemic hyponatremia^[21]. In the diagnosis of SIAD, diagnostic tools that are less useful, and potentially dangerous in the latter case, include AVP levels and water loading tests [Table 2]. Cancer patients can have a combination of SIAD and other processes that contribute to hyponatremia. Therefore, the management of these patients is often complicated and relies on the recognition of such comorbidities. Hyponatremia could be a marker of occult malignancy^[22]. Patients with an unidentifiable cause of SIAD should have a chest X-ray. Furthermore, a chest CT should be considered in patients with a history of smoking and a MRI of the brain in patients with persistent neurologic symptoms and signs despite correction of hyponatremia^[23].

HYPERVOLEMIC HYPONATREMIA

Patients with congestive heart failure, nephrotic syndrome, liver and kidney disease can have hypotonic hyponatremia with increased extracellular fluid volume due to reduced effective arterial volume that activates baroreceptor-mediated neurohormonal release of vasopressin. Concomitant use of diuretics,

Table 1. Causes of syndrome of inappropriate antidiuresis

Tumors	Infections	Drugs	Other
Extrapulmonary small cell carcinoma	AIDS	Chemotherapy agents	Postoperative state (major abdominal or thoracic surgery; pituitary surgery or other neurosurgery)
Lymphoma	Encephalitis	Cisplatin	Hydrocephalus
Meningeal carcinomatosis	Hydrocephalus	Cyclophosphamide	Cavernous sinus Thrombosis
Metastatic brain and spine tumors	Idiopathic, particularly in the elderly	Ifosfamide	Multiple sclerosis
Olfactory neuroblastoma	Meningitis	Vinristine	Guillain-Barre Syndrome
Ovarian teratoma	Pneumonia (bacterial and viral)	Vinblastine	Delirium Tremens
Endometrial carcinoma	Pulmonary abscess	Melphalan	Acute intermittent porphyria
Pancreatic carcinoma	Aspergillosis	Methotrexate	Acute respiratory failure
Primary brain tumors	Tuberculosis	Targeted Therapies:	Acute Psychosis
Prostate carcinoma	Brain abscess	Afatinib	Stroke
Bladder carcinoma	Rocky mountain spotted fever	Brivanib	Subarachnoid hemorrhage and other intracranial hemorrhages
Small cell lung carcinoma and other pulmonary tumors	Malaria	Cetuximab	Traumatic brain injury
Thymic tumors		Geftinib	General anesthesia
Sarcomas		Linifanib	Nausea
		Pazopanib	Pain
		Sorafenib	Stress
		Vorinostat	
		Non-chemotherapy agents	
		Desmopressin/Vasopressin	
		Methylenedioxymethamphetamine	
		NSAIDs	
		Opiates	
		Oxytocin	
		Phenothiazines	
		Prostaglandin-synthesis inhibitors	
		Rosiglitazone	
		Selective serotonin reuptake inhibitors (SSRIs)	
		Selective norepinephrine reuptake inhibitors (SNRIs)	
		Thiazide diuretics	
		Ciprofloxacin	
		Tricyclic antidepressants	
		Chlorpropamide	

e.g., thiazides, loop diuretics and spironolactone, may also contribute to hyponatremia. Reduced oncotic pressure in nephrotic syndrome has a similar effect due to baroreceptor-mediated neurohormonal activation. Chemotherapy induced tubulopathy decreases the ability of the kidney to excrete free water. Increased free water intake in the presence of kidney disease causes hypervolemic hyponatremia^[10].

HYPOVOLEMIC HYPONATREMIA

Reduced effective circulatory volume (as seen in pancreatitis, bowel obstruction, sepsis, diarrhea, and sweating) increases vasopressin release leading to increase water retention and hyponatremia that worsens with hypotonic volume repletion^[10].

CEREBRAL SALT WASTING SYNDROME

Cerebral salt wasting (CSW) syndrome is a clinical entity primarily but not exclusively associated with intracranial disease that leads to hyponatremia and decreased extracellular fluid volume^[24]. Although most commonly described in neurosurgical patients with subarachnoid hemorrhage, CSW is also seen in cerebral neoplastic dissemination in brain metastasis^[8]. However, CSW syndrome remains controversial and incompletely understood.

CSW is associated with primary overproduction of atrial natriuretic peptide and brain natriuretic peptide resulting in a decrease in sodium and water reabsorption in the kidney while reduced sympathetic outflow in intracranial disease reduces activity of renin-angiotensin system and increases natriuresis^[25-27]. CSW syndrome may lead to a clinical picture similar to SIAD^[28]. Laboratory findings common to SIAD and CSW syndrome include hypotonic hyponatremia, increased fractional excretion of urate (FEurate > 11%), high urine osmolality (> 100 mOsm/kg), and urine sodium (> 30 mEq/L) in the presence of normal thyroid,

Table 2. Criteria for diagnosis syndrome of inappropriate antidiuresis^[10,19]

Essential criteria	Supplemental criteria
Serum osmolality < 275 mOsm/kg	Blood urea nitrogen < 10 mg/dL
Urine osmolality > 100 mOsm/Kg	Serum uric acid < 4 mg/dL
Clinical euolemia:	FEurate [‡] > 11%
Absence of signs of hypovolemia* and hypervolemia**	FENa [‡] > 1%
Central venous pressure 6-10 cm H ₂ O	FEurea [‡] > 55%
Urine sodium > 30 mEq/L	Correction of hyponatremia through fluid restriction
No evidence of hypothyroidism, adrenal insufficiency	Failure to correct hyponatremia after 0.9% saline infusion
No diuretic use	
No renal insufficiency	

*Signs of hypovolemia (decreased skin turgor, orthostasis, dry mucus membranes, tachycardia). **Signs of hypervolemia (edema, ascites). adrenal, and renal function. After normalization of hyponatremia, FEurate normalizes in patients with SIAD (FEurate 4%-11%) but remains persistently elevated in CSW (FEurate > 11%)^[14]. Clinical symptoms and signs of hypovolemia (decreased skin turgor, orthostasis, dry mucus membranes, tachycardia) and low central venous pressure in the setting of normal kidney function denote CSW. Serum AVP levels are elevated as seen in patients with hypovolemia^[21]. Identification of CSW from SIAD is of paramount importance to guide appropriate therapy; aggressive volume and salt repletion in CSW versus fluid restriction in SIAD.

After correction of hypovolemia, sodium loss is repleted with sodium chloride tablets and fludrocortisone with close monitoring of serum electrolytes^[29]. Rarely, hypertonic saline is required to correct hyponatremia^[29].

APPROACH TO THE DIAGNOSTIC EVALUATION OF HYPONATREMIA

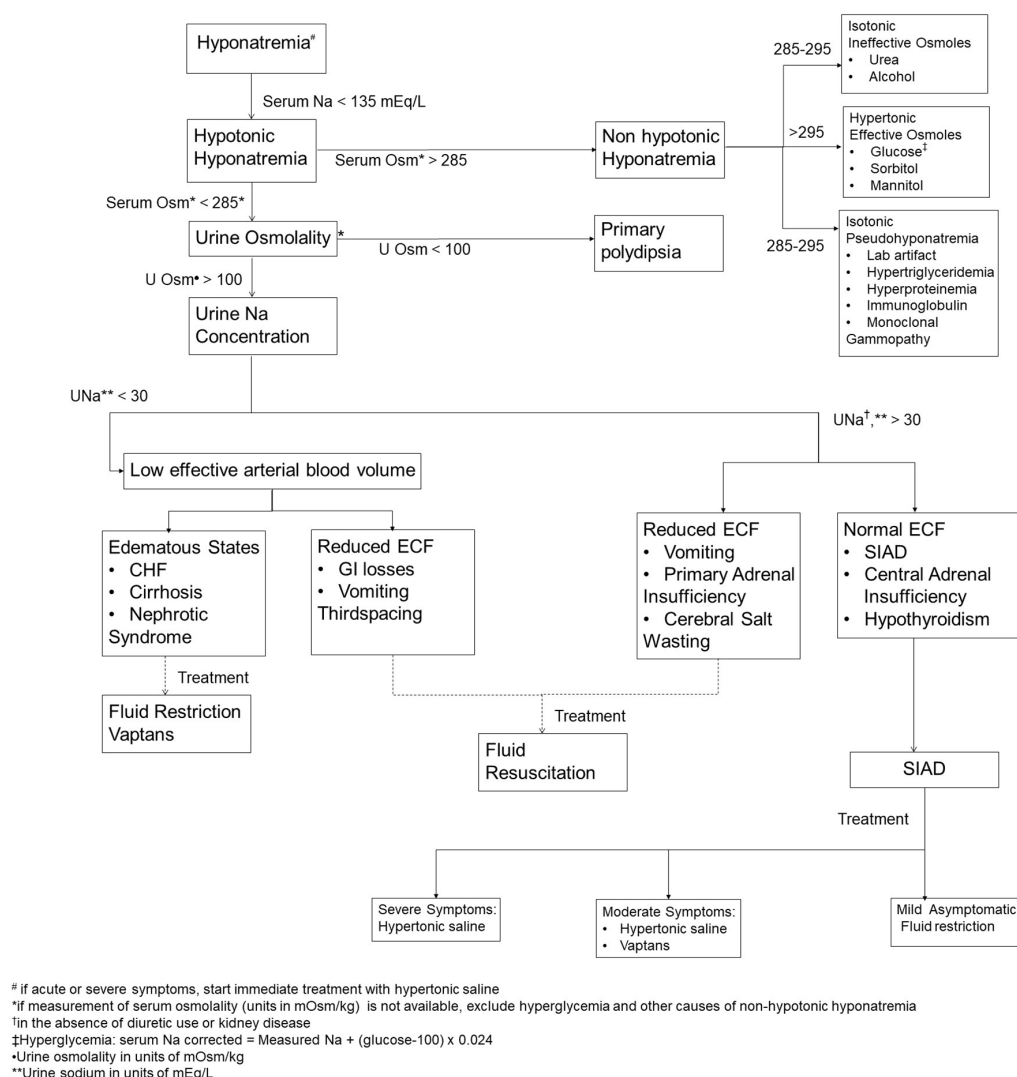

The initial step in the evaluation of hyponatremia is to measure serum osmolality. If hyponatremia is associated with hypoosmolality, the next step will be to measure urine osmolality and urine sodium. SIAD is a diagnosis of exclusion after ruling out other causes of euolemic hyponatremia such as hypothyroidism (free T₄, thyrotropin stimulating hormone) and adrenal insufficiency (total cortisol, adrenocorticotrophic hormone). Other causes that could be excluded in cases of hypotonic hyponatremia are decreased effective circulating blood volume and renal insufficiency^[16] [Figure 1].

Copeptin is secreted from the posterior pituitary along with AVP. There is a strong correlation between plasma AVP levels and copeptin levels. Although copeptin levels tend to be highest in small cell lung cancer, evaluation of copeptin levels between cancer-related versus non cancer-related SIAD show no significant difference. Multiple other factors (e.g., pain, nausea, stress, medications) contribute to elevated copeptin levels. Copeptin levels > 84 pmol/L indicate hypovolemic hyponatremia whereas low levels of copeptin < 3.9 pmol/L indicate primary polydipsia^[30].

CLINICAL MANAGEMENT/TREATMENT OPTIONS

Definitive treatment for hyponatremia involves treating the underlying cause. Medical therapy [Table 3] improves the serum sodium level and prevents potential neurologic complications. In patients with severe symptomatic hyponatremia, a 5 mEq/L increase of serum sodium is likely to improve clinical symptoms^[10]. The serum sodium should be acutely increased 1-2 mEq/L/h over 3-4 h using hypertonic saline (3% NaCl). To avoid the risk of over correction, current guidelines recommend i.v. infusion of 150 mL of 3% hypertonic saline over 20 min, rechecking serum sodium concentration and then, if necessary, repeating the 150 mL of 3% hypertonic saline infusion^[31]. Frequent monitoring of serum sodium along with 150 mL of hypertonic saline avoids rapid increase in serum sodium. Hypertonic saline can be administered at an

Treatment of hyponatremia in small cell lung cancer patients is associated with improved survival [10].

**Figure 1.** Evaluation of hyponatremia^[10,19,46]

initial rate of 1-2 mL/kg/h, although patients with seizure or coma may require a higher initial infusion rate of 2-4 mL/kg/h. A total volume of 500 mL hypertonic saline is sufficient to increase serum sodium 5 mEq/L. Hypertonic saline infusion is stopped when symptoms improve, serum sodium concentration increases by 10 mEq/L in total, or the serum sodium concentration reaches 130 mEq/L. If symptoms do not improve despite an increase of serum sodium by 10 mEq/L, or a serum sodium level of 130 mEq/L, other etiologies for these symptoms should be explored^[10]. In patients with mild symptoms, 3% saline can initially be administered at 0.5 mL/kg/h^[32]. Furosemide in combination with hypertonic saline infusion promotes electrolyte-free water excretion^[33]. The use of normal saline in the treatment of SIAD should be avoided due to the concern of net free water retention and worsening hyponatremia^[33].

In the asymptomatic patient, SIAD is initially treated with fluid restriction to 500-1000 mL daily (1 L/m²/day or 2/3 maintenance in children) so that free water intake is below the capacity for kidney water excretion plus insensible losses. Intake and output should be monitored closely to ensure compliance with fluid restriction and to maintain an oral intake of at least 500 mL/day below the average urine volume (in adults). In patients with mild asymptomatic hyponatremia fluid restriction could be started at 1200-1500 mL. A commonly

Table 3. Management of hyponatremia^[10,19,46]

Medical therapy	Indication	Dose	Adverse effects
Demeclocycline	Euvolemic and hypervolemic hyponatremia	300-600 mg bid	Slow onset of action, acute kidney injury
Lithium	Euvolemic hyponatremia	600-1800 mg/day	Narrow therapeutic window, confusion and somnolence
Fludrocortisone	Cerebral salt wasting SIAD	0.1-0.3 mg/day	Hypokalemia, hypertension
NaCl tab	Cerebral salt wasting SIAD	1-3 g/day in divided doses	Non-adherence to therapy for chronic use
Urea	Euvolemic hyponatremia	30 g/day	Lack of palatability, slow onset of action
Vaptans	SIAD hypervolemic hyponatremia	Conivaptan 20 mg i.v. bolus over 30 min and then 20 mg i.v. infusion over 24 h. Infusion rate can be increased to 40 mg daily; maximum duration of treatment is 4 days. Tolvaptan 15 and 30 mg tab for oral use. Maximum dose 60 mg. Therapy should be initiated in the hospital with monitoring of serum sodium	Dry mouth, increased thirst and polyuria; risk of rapid increase in serum sodium; liver injury associated with higher doses; concern for increase in mortality
Hypertonic saline 3%	Euvolemic hyponatremia and hypervolemic hyponatremia	Hypertonic saline 3% 150 mL i.v. bolus over 20 min × 3. Check serum sodium after every bolus. Hypertonic saline 3% continuous infusion 1-2 mL/kg/h*	Osmotic demyelination syndrome
Fluid restriction	Euvolemic and hypervolemic hyponatremia	Fluid restriction (500-1000 mL) includes all fluids including intravenous fluids. Degree of fluid restriction depends on serum sodium level, urine output and insensible fluid losses. Fluid restriction to < 500 mL/day of 24 h urine output is recommended	Rapid correction in case of primary polydipsia. Less likely to be effective if 24 h urine output is < 1500 mL
Isotonic saline	Hypovolemic hyponatremia	Fluid resuscitation with 0.9% normal saline	Ineffective and potentially dangerous in euvolemic hyponatremia. Should not be used in hypervolemic hyponatremia
Electrolyte free water	Management of overcorrection	Electrolyte free water 10 mL/kg over one hour. Desmopressin 2 mcg i.v. every 8 h	Hyponatremia

*Total amount of 3% NaCl to infuse (mL) = (desired change in serum Na × 1000)/ΔNa[†]. [†]ΔNa (change in serum sodium per liter infused) = (513[#] - serum sodium)/[TBW (L)** + 1]. [#]Amount of sodium (mEq) in 1 L of 3% NaCl. **TBW (L) = weight (kg) × 0.6 (children, nonelderly men); 0.5 (nonelderly women, elderly men); or 0.45 (elderly women). SIAD: syndrome of inappropriate antidiuresis; TBW: total body water

used medication to treat SIAD, especially chronic disease, is the tetracycline antibiotic demeclocycline, which has the side effect of causing nephrogenic diabetes insipidus^[34]. A few of the other side effects of demeclocycline include GI intolerance, renal toxicity, and photosensitivity. One should note, however, that its onset of action is delayed (typically 5 days or more), so it is not appropriate for the acute management of severe SIAD. Urea (available as prescription and over the counter) at a dose of 30-60 g/day has been used to induce osmotic diuresis in chronic hyponatremia. Side effects of urea include headache and GI irritation. Combining urea with NaHCO₃, sucrose and citric acid (urea 10 g + NaHCO₃ 2 g + citric acid 1.5 g + sucrose 200 mg) improves the taste and makes it palatable. Addition of urea to orange juice could also help reduce the bitter taste. Fludrocortisone can increase serum sodium up to 5 mEq/L and salt supplementation (NaCl 1 g po TID) can also be considered^[35].

Fluid restriction is preferred in patients with expanded extracellular volume. Intake and output of urine should be monitored closely. Free water intake should be 500 mL less than the urine output. Patients with reduced extracellular volume and hemodynamic instability require rapid fluid restoration. Extracellular volume is restored with i.v. infusion of 0.9% saline or a balanced crystalloid solution. As volume repletion suppresses vasopressin release in hypovolemia, close monitoring of serum sodium and urine output is required to avoid hypernatremia in the presence of increased free water clearance^[10]. Potassium deficiency should be replaced. Since potassium is osmotically active and can be exchanged with sodium, overcorrection of sodium is a concern in case of potassium repletion.

CENTRAL PONTINE MYELINOLYSIS

The rapid correction of hyponatremia by any means can cause central pontine myelinolysis, also known as osmotic demyelination syndrome^[36]. It is characterized by severe and often irreversible neurologic sequelae such as dysarthria, dysphagia, psychiatric disturbances, spastic paraplegia or quadriplegia, seizures, pseudobulbar palsy, and altered mental status. Symptoms of osmotic demyelination occur 4-6 days after rapid overcorrection^[37]. Therefore, the overall goal of treatment should be to avoid increasing the serum sodium levels by more than 0.5 mEq/L/h (or 10 mEq/L/day) and 8 mEq per subsequent day^[10,38]. However, some experts recommend an even more conservative therapeutic goal of an increase of no more than 8 mEq/day^[33,39]. Serum sodium levels should be assessed every 2-4 h during the initial stages of treatment for severe symptomatic hyponatremia. Desmopressin, 1-2 µg parenterally every 6-8 h, has been used along with hypertonic saline to reduce the risk of rapid correction, although further studies are needed to confirm the effectiveness of this approach^[40]. In addition to the degree of hyponatremia and rate of hyponatremia development, factors that also increase the risk of osmotic demyelination syndrome include liver disease, concurrent use of thiazide diuretics, and antidepressants. Suppression of AVP release with volume repletion in patients with reduced extracellular volume increases the risk of rapid correction of sodium due to increase free water clearance. In addition to close monitoring of urine output, serum sodium should be monitored every 2 h^[10].

VAPTANS: MECHANISM OF ACTION, CLINICAL IMPLICATIONS AND FUTURE PERSPECTIVES

Vaptans are AVP receptor antagonists that are FDA-approved for clinical use in patients with euvolemic and hypervolemic hyponatremia. AVP antagonists block vasopressin receptors on principal cells in the renal collecting tubules. Inhibition of AVP receptors blocks increase in cAMP and protein kinase A that leads to reduced translocation of aquaporin 2 (water channels) to the luminal membrane. Binding of vaptans decreases the permeability of the apical membrane to water. Vaptans are aquaretic agents because they enhance electrolyte free-water clearance without associated natriuresis^[13]. Vaptans are utilized to reduce fluid restriction in patients with symptomatic mild to moderate chronic hyponatremia due to SIAD and heart failure^[39]. Conivaptan is a non-peptide dual V1A/V2 AVP receptor antagonist. Conivaptan, given as an initial i.v. bolus followed by a continuous infusion, increases serum sodium up to 6 mEq/L as compared with placebo. Use of i.v. conivaptan can be associated with rapid correction of hyponatremia, transient symptomatic hypotension, and peripheral i.v. site reaction. Patients receiving conivaptan through a central venous catheter did not have any adverse reactions^[41]. The most common reason for discontinuation of conivaptan is infusion site reaction^[42]. Tolvaptan is an oral V2-receptor antagonist also approved for use in euvolemic or hypervolemic hyponatremia. The most common adverse effects reported during tolvaptan use are thirst and dry mouth. Although it is an oral medication, the use of tolvaptan should be limited to the inpatient setting to monitor for overcorrection of serum sodium following administration.

Vaptan use has been associated with alanine aminotransferase elevation and hepatotoxicity with long term use. During treatment with vaptans, in addition to close monitoring of serum sodium, urine osmolality should be monitored. The dose of vaptan should be increased if the urine osmolality remains high. If urine osmolality is low, fluid intake should be restricted^[13]. The clinical trials evaluating these agents did not include patients with serum sodium less than 115 mEq/L^[43]. Caution is advised in patients with acute symptomatic hyponatremia, underlying liver disease, and volume depletion^[39]. Post hoc analysis from the trial ACTIVE showed a reduction in mortality ~50% in patients with congestive heart failure after the correction of hyponatremia with the use of tolvaptan. The EVERST trial evaluated the role of tolvaptan (30 mg Po QD) in cardiac failure patients for 2 years. There was no difference in all cause mortality in tolvaptan treated patients versus placebo^[41].

In the SALT WATER trial, long term use of tolvaptan (2 years) was evaluated for safety and efficacy in patients with euvolemic and hypervolemic hyponatremia. Hypernatremia was reported in only one patient.

As compared with fluid restriction, lithium and urea, vaptans offer a therapeutic option that is pathophysiologically focused, potent and effective^[41]. Despite efficacy of vaptans in improving serum sodium, clinical practice guideline on the diagnosis and treatment of hyponatremia do not recommend the use of vaptans due to concern for overcorrection of sodium and lack of mortality benefit^[23]. The safety and efficacy of tolvaptan was evaluated in a post hoc subgroup analysis of the patients with cancer in SALT-1 (study of ascending levels of tolvaptan in hyponatremia) and SALT-2 clinical trials. Baseline sodium in the cohort of the SALT trials was 130 mEq/L. A 15 mg dose of tolvaptan was titrated up to 30 or 60 mg over 4 days if the increase in serum sodium was < 5 mEq/L in the prior 24 h. Tolvaptan was withheld or reduced and fluid intake was increased if serum sodium was > 145 mEq/L. Serum sodium normalized to > 135 mEq/L in 66.6% of the patients by day 30. Serum sodium exceeded the desired rate of correction (> 8 mEq/L over the first 8 h of therapy or > 12 mEq/L over 24 h) in 1.8% of patients. None of these patients developed any symptoms of osmotic demyelination syndrome^[6].

In our experience, vaptans are well tolerated by cancer patients and offer a therapeutic option in patients with euvoletic and hypervolemic hyponatremia when fluid restriction alone is insufficient to increase serum sodium levels or to avoid the discomfort associated with fluid restriction. Although the vaptans are well tolerated and effective, their high cost continues to be a limitation for routine use. In a post hoc analysis, economic models from SALT-1, SALT-2 and EVERST reported decrease in length of stay in the hospital and hospital cost savings with tolvaptan use^[44]. To reduce the risk of hyponatremia all i.v. medications should be concentrated and hypotonic i.v. fluids should be avoided in hospitalized patients, e.g., perioperatively, during cancer chemotherapy, bronchitis, pneumonia or lung disease^[45].

CONCLUSION

Oncology patients with hyponatremia need close monitoring of fluid intake and output to prevent derangements in salt and volume balance. Hyponatremia in cancer patients is associated with advanced disease and poor prognosis. Improvement in serum sodium correlates with improved survival^[9]. Whether the treatment of hyponatremia improves overall survival needs to be investigated. Proposed algorithms for the management of hyponatremia could be utilized in patients with cancer, recognizing that hyponatremia is of diverse etiology in this population. Use of therapeutic agents such as the vaptans offer a convenient, effective, and targeted approach to the management of hyponatremia. Further studies are likely to clarify cost effectiveness and safety concerns related to vaptan use in cancer patients.

Abstract

As with many types of cancer, immunotherapy is changing the management of squamous cell carcinoma of the head and neck (HNSCC). In a locally advanced or metastatic setting, treatment options have long been curtailed, but this paradigm is currently changing. Checkpoint inhibitors were the first to be validated in second-line treatment with PD-1 and PD-L1 inhibitors and these treatments are available in USA for first-line use. In addition, many studies are underway to use its molecules earlier in the care or try to increase their effectiveness with associations. The issues of patient selection that would benefit the most from immunotherapy and the evaluation of the response to these treatments are not completely solved. The goal is here to update the possibilities of current treatment by immunotherapy in HNSCC as well as on various development pathways in progress.

Keywords: Head and neck squamous cell carcinoma, checkpoint inhibitors, immunotherapy, clinical trial

INTRODUCTION

Head and neck cancers are currently responsible for more than 700,000 cases and more than 350,000 deaths per year^[1]. After a heavy treatment combining surgery, radiotherapy and chemotherapy, more than half of the patients relapse locoregional or metastatic^[2]. With chemotherapy and anti-epidermal growth factor receptor, advanced treatment was relatively limited before the arrival of immunotherapy in

the therapeutic arsenal. Head and neck cancers are cancers inducing immunosuppression and therefore particularly likely to respond well to immunotherapy. The purpose of this article is to review studies validating the use of first-line and second-line checkpoint inhibitors (CPIs) in HNSCC, as well as studies evaluating new indications. The aim is also to evaluate the new immunotherapy modalities under evaluation and to discuss the difficulties of using these new treatment.

VALIDATED TREATMENT IN SECOND LINE

Nivolumab was the first molecule to be approved by the Food and Drug Administration with the Checkmate 141. This showed an overall survival improvement of 7.7 months *vs.* 5.1 months (HR = 0.68, 95%CI: 0.54-0.86) compared with monotherapy with docetaxel, methotrexate or cetuximab in HNSCC progressing after a first platinum-based line. This difference was greater in PD-L1 patients > 1% with an OS of 8.2 months *vs.* 4.7 months, but the curves were also separated for PD-L1 negative patients (< 1%). Nivolumab was therefore approved regardless of PD-L1 expression^[3].

Pembrolizumab was studied in the same situation with the Keynote 0-40 Phase III study, but this time docetaxel was given every 3 weeks at a dose of 75 mg/m². While the first analysis was not significant, the discount reached statistical significance with a median overall median survival of 8.4 months (95%CI: 6.4-9.4) *vs.* 6.9 months (95%CI: 5.9-8.0), HR = 0.80 (95%CI: 0.65-0.98, *P* = 0.0161). The reduction in HR relative to nivolumab can be explained by several factors. First, a cross-over effect in the chemotherapy group with many patients receiving immunotherapy secondarily, secondly because a majority of patients received docetaxel, which is the most effective chemotherapy and also by the use of docetaxel every three weeks used in this study which is probably more effective than the weekly rhythm used with nivolumab. In the subgroup analyzes, survival was significantly increased from 7.9 to 11.6 months in favor of pembrolizumab in patients with PD-L1 > 50%. There was no difference in the PD-L1 population < 50%. These results led to the approval in Europe of pembrolizumab in PD-L1 patients > 50%^[4].

A third phase 3 trial, the EAGLE study, compared an anti-PD-L1 (durvalumab) alone or with an anti-CTLA4 (Tremelimumab) to a standard chemotherapy. This study was negative for the overall survival, but the durvalumab arm as monotherapy was consistent with nivolumab and pembrolizumab with a median overall survival at 7.6 months and a response rate of 17.9%. In addition, the control arm was superior to what was expected because weekly paclitaxel was predominantly used (which is probably the best treatment option for these patients) and there was an important crossover with control arm patients receiving immunotherapy^[5].

FIRST LINE TREATMENT

The Keynote 048 trial is an open-label, randomized, phase 3 trial comparing 887 patients in first line with pembrolizumab to the extreme protocol [cisplatin or carboplatin, 5-fluorouracile (5FU) and cetuximab]^[6]. Pembrolizumab was administered at a fixed dose of 200 mg every 3 weeks alone or in combination with cisplatin and 5FU chemotherapy. The stratification factors were the expression of PD-L1 by tumor proportion score (TPS: expression of PD-L1 by tumor cells ≥ 50% *vs.* < 50%), p16 status for oropharyngeal tumors (positive *vs.* negative) and Eastern Cooperative Oncology Group status (0 *vs.* 1). Pembrolizumab showed a benefit in overall survival over chemotherapy and cetuximab in the combined positive score (CPS) population ≥ 20 (a score that studies expression on both tumor cells and immune cells in the microenvironment) with a median of 14, 8 months *vs.* 11 months; HR 0.58 (95%CI: 0.44-0.78). This advantage was found in the group of CPS ≥ 1 with a median of 12.3 months *vs.* 10.4 months; HR 0.74 (95%CI: 0.61-0.90). But it is important to note that if survival is better with pembrolizumab, at the beginning immunotherapy is deleterious for some patients with more deaths in the first six months. In terms of tolerance, treatment-related adverse event levels of Gr 3-5 were 17% with pembrolizumab against 69% with

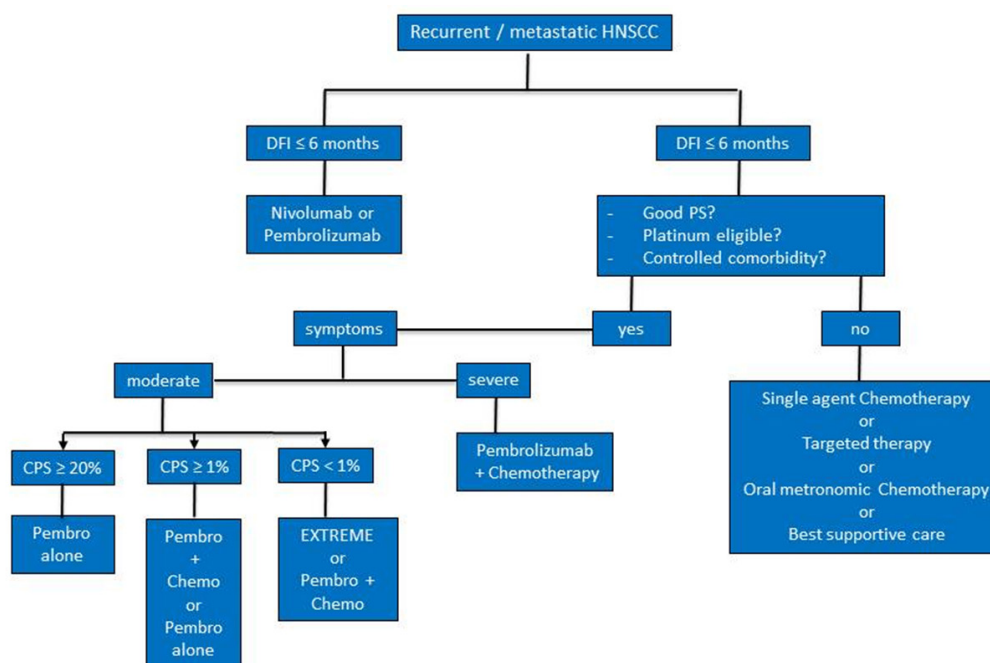

Figure 1. Proposed therapeutic decision tree in the recurrent/metastatic head and neck squamous cell carcinoma (HNSCC)

the Extreme protocol. The update during the American Society of Clinical Oncology (ASCO) 2019 also showed a benefit in overall survival in the pembrolizumab group associated with chemotherapy compared with the Extreme group, regardless of the subgroup of patients. The median OS was 14.7 months vs. 11 months, respectively; HR 0.60 (95%CI: 0.45-0.82) for the CPS group ≥ 20 , 13.6 months vs. 10.4 months; HR 0.65 (95%CI: 0.53-0.80) for the CPS group ≥ 1 and 13 vs. 10.7; HR 0.72 (95%CI: 0.60-0.87) months in total population.

It is therefore the first randomized trial that demonstrates an improvement in overall survival compared to standard platinum and cetuximab treatment in the first line. This trial also establishes the CPS as a valid marker for selecting patients most likely to benefit from pembrolizumab monotherapy. In CPS ≥ 20 , the toxicity profile favors treatment with pembrolizumab monotherapy, whereas the combination of pembrolizumab with chemotherapy seems the best alternative for CPS < 20 that can benefit. Pembrolizumab in monotherapy may also be discussed in slowly progressive patients with CPS < 20 . Be that as it may, it is likely that this study will upset the frontline management of HNSCC cancers in the front line.

There are currently two other studies currently underway evaluating first-line CPIs. Durvalumab alone or in combination with tremelimumab is compared to the EXTREME protocol in the KETREL trial and the nivolumab and ipilimumab combination is still compared to the same protocol in the CA609-651 trial.

Finally, these new studies will change the management of HNSCC cancers. We propose in [Figure 1](#) a decisional tree for the treatment of recurrent or metastatic HNSCC.

IMMUNOTHERAPY MORE PRECOCIOUS

Because of the improvement in overall survival provided by the inhibitors of checkpoint, the question arises of introducing these treatments earlier in curative intent for localized disease, in neoadjuvant or adjuvant treatment.

Table 1. Recent immunotherapy approaches in head and neck squamous cell carcinoma

Immunotherapy	Mecanism of action	Stage of clinical development	Setting
M7824	Bispecific anti-PD-L1 and anti-TGF- β antibody	Phase I	Recurrent/metastatic HNSCC in second therapeutic line
Monalizumab with cetuximab	New checkpoint inhibitor targeting NKG2A + anti EGFR	Phase II	Recurrent/metastatic HNSCC
Danvatirsen with durvalumab	Inhibitory antisense oligonucleotide of STAT3 + anti-PD-L1	Phase Ib/II	Metastatic HNSCC naive of anti-PD-L1
SD101 with pembrolizumab	TLR9 agonist + anti-PD-1	Phase I/II	Recurrent/metastatic HNSCC, anti-PD1 naive
Epacadostat	Oral IDO1 inhibitor	Phase III failures	Recurrent/metastatic HNSCC
Lenvatinib	Broad-spectrum TKI	Phase Ib/II	Metastatic HNSCC, after at least one line of chemotherapy
MEDI6974 with durvalumab	Ox40 agonist antibody + anti-PD-L1	Phase Ib	Before surgery with stage III-IVA HNSCC
Dendritic cell vaccination with conventional chemotherapy	Mature CD loaded with WT1 peptides + OK-432 (TLR-4 ligand)	Phase I/II	Recurrent/metastatic HNSCC

HNSCC: head and neck squamous cell carcinoma; EGFR: epidermal growth factor receptor; TGF: transforming growth factor

In adjuvant, trials are in progress with comparative immunotherapies or added to cisplatin or cetuximab during radiotherapy, but there is currently no efficacy data. There is no sign of toxicity so we expect a better tolerance than current treatments. A randomized Phase II trial compared potentiated radiotherapy with cetuximab or pembrolizumab in inoperable patients not eligible for cisplatin. Tolerance was better in the pembrolizumab group with a 3-4 grade toxicity of 69% vs. 88% with cetuximab. There was particularly less mucositis and radiodermatitis with pembrolizumab^[7].

In neoadjuvant, a phase I is in progress that combines durvalumab with TPF (cisplatin docetaxel 5FU) to potentiate induction chemotherapy.

A phase 2 study also studied still in neoadjuvant 23 patients with high-risk HNSCC cancer (probable R1 resection or capsular rupture) who received pembrolizumab 1 to 3 weeks before surgery. There was 47% response with an anti-tumor effect on more than 10% of the surface, including 32% major response on more than 70% of the surface and 1 complete response^[8]. Similar results have been observed with nivolumab^[9].

It is also possible that immunotherapy may make subsequent chemotherapy more effective, which would favor earlier administration of immunotherapy.

NEWS IMMUNOTHERAPY

Many immunotherapy molecules with different mechanisms of action are currently under development. A review of the 2016 literature presented the latest insights into the field of immunotherapy for HNSCC^[10]. Many immunotherapy associations were already being tested. The goal here is to present some of these innovations with a promising future to show the diversity of this one. Table 1 summarizes the molecules presented.

A phase 1 study showed promising results with a bispecific anti-PD-L1 and anti-transforming growth factor- β (TGF- β) antibody (M7824). The goal is to inhibit TGF- β , which increases tumor immunodepression. In addition, inhibition of the TGF- β pathway could increase the activity of anti-PD-L1. Among 32 patients, 7 had partial response, 6 had tumor stability, and grade III was found among 10 patients (31.3%). Further development will be interesting to follow^[11].

Monalizumab is a new CPI targeting NKG2A. This is expressed on CD8+ lymphocytes and on NK lymphocytes. The ligand of NKG2A, human leucocyte antigens (HLA)-E, is overexpressed in HNSCC.

Blocking this interaction stimulate CD8+ and NK lymphocytes and increase antibody-dependent cell-mediated cytotoxicity (ADCC). Since Cetuximab acts mainly via an ADCC mechanism, it could be potentiated by Monalizumab. A phase II study included 40 patients to receive weekly cetuximab combined to monalizumab every two weeks after failure of platin. The response rate, which was the primary endpoint, was 27.8%, or 11 out of 40 patients (compared to 13% with cetuximab alone according to historical data). The tolerance was particularly good, making this association a promising issue^[12]. It is interesting to note that monalizumab seems to be effective after failure of an anti-PD-1.

Another phase Ib/II study investigated the combination of danvatirsen with durvalumab among patients with metastatic HNSCC naive of anti-PD-L1. Danvatirsen is an inhibitory antisense oligonucleotide of STAT3 (that stimulates the immunosuppressive function of the microenvironment). Among 44 treated patients, 23% of responses (higher than those found with durvalumab monotherapy) were found with 3 complete responses. An increase of transaminases and transient thrombocytopenia were the major toxicities and it seems there is no additive toxicity of the two treatments^[13].

SD101 is a TLR9 agonist stimulating the activity of dendritic cells. This later became antigen-presenting cells to activate an anti-tumor response via T lymphocytes. A phase I/II study investigated the combination with pembrolizumab. Patients received pembrolizumab every 3 weeks and SD-101 injected into a single tumor site each week for 4 injections and then every 3 weeks up to 7 injections. Among the 26 patients included, the median injections of SD-101 administered were 5. Patients experienced injection site reactions and influenza-like illness with 28% of toxicities \geq grade 3. The immune-induced effects of pembrolizumab do not appear to have increased. The response rate in mITT (that is to say, among the 23 patients who had reached at least the first tumor evaluation) was 30.4% with 7 partial responses, 3 stabilities, 10 progressions in imaging and 3 clinical progressions before the scan. Tumor size reductions \geq 30% were observed in injected lesions (8/18 or 44.4%) as well as in non-injected lesions (8/14 or 57.1%). At the time of the analysis, 5 of the 7 responses were ongoing (1 to 27 weeks). Therefore, stimulation of dendritic cells seems promising with activity in the injected site, but also at a distance, at the cost however of a significant toxicity^[14].

Epacadostat is an oral IDO1 inhibitor (indoleamine 2,3-dioxygenase) showing good phase I and II in combination with pembrolizumab^[15]. IDO1 is an enzyme expressed in the tumor microenvironment that has an immunosuppressive effect by decreasing tumor infiltration by cytotoxic T lymphocytes (TILs). But in the face of phase III failures in melanoma, development has unfortunately been halted^[15].

Associations with tyrosine kinase inhibitors (TKIs) have also been studied in a phase Ib/II study. Lenvatinib, a broad-spectrum TKI, has been associated with pembrolizumab in 22 progressive metastatic patients after at least one line of chemotherapy. The 24-week response rate was 36% with a median response time of 8.2 months, a progression-free survival (PFS) of 8.2 months, and one year progression-free survival rate of 37%. But the toxicity is important with 91% of side effect, of which 14% of grade 4 and 18% of patients who had to stop the treatment. The main symptoms were fatigue, loss of appetite, hypertension and digestive disorders. Associations with other less toxic tyrosine kinase inhibitors may be considered^[16].

Another trial associated durvalumab with an activating agonist of the immune response, MEDI6974 (Ox40 agonist antibody). The treatments were administered for a short time before surgery. An increase and activation of cytotoxic lymphocytes within the tumor has been demonstrated. This association could potentially be interesting^[17].

A phase I/II study investigated dendritic cell vaccination with conventional chemotherapy in patients with head and neck cancer^[18]. Eleven patients with relapsed or refractory disease were recruited (with HLA-A2 or HLA-A24 positive as well as WT1 expression, a tumor antigen). Mature dendritic cell (DC) loaded

with WT1 peptides were injected intradermally approximately every 2-3 weeks. OK-432 (TLR-4 ligand) was administered subcutaneously near the vaccination sites to activate the DCs. Treatment was generally well tolerated with none of the patients with grade 2 adverse events except for hematologic adverse events with leucocytopenia and grade 2 anemia. Non-hematologic adverse events were consistent with the classic adverse effects of chemotherapy (discomfort, nausea, anorexia, and constipation except transient erythema at injection sites and low-grade fever). 5 patients presented a stabilization of the disease and 6 patients a progression of the disease. The median PFS and OS were 6.4 months and 12.1 months, respectively. But the median duration of PFS and OS of patients with stable disease was significantly longer than that of patients with progressive disease. The median PFS was 13.0 months *vs.* 2.8 months ($P = 0.00136$) and the median OS was 30.3 months *vs.* 8.1 months ($P = 0.0126$). Two patients had a long-term survival of 30.3 m and 44.4 m. Furthermore, all patients with stable disease showed improvement of WT1-specific immune responses after vaccination in all tests performed [HLA tetramer, interferon gamma (IFN γ) ELISPOT and mobilization CD107a] as well as an increased Th1/Th2 ratio of 1.36 times on average. Dendritic cell vaccination is therefore an interesting research path because of its efficacy in some patients and its good tolerance^[18].

In conclusion, many promising new immunotherapies are being developed with different mechanism of action. Some may be used alone and other combined with CPIs or other conventional therapy.

DIFFICULTY OF ASSESSING IMMUNOTHERAPY

Evaluation of immunotherapies may be different and more difficult than conventional anti-tumor treatments. In fact, patients treated with CPI observed phenomena of pseudo-progression (tumor response after an initial progression) and, on the contrary, hyperprogression phenomena with a rapid and significant increase in tumor volume.

These pseudo progression are probably due to infiltration of immune and inflammatory cells and/or a delayed clinical response. These phenomena are relatively rare but may explain the benefit of immunotherapy treatment beyond progression. For example, in the Checkmate 141 study, of 240 patients randomized to receive nivolumab, 146 showed progression according to RECIST. Sixty-two of these patients continued nivolumab and 84 discontinued treatment. Of the 60 patients who continued nivolumab evaluable for the response, 15 (25%) had not changed their tumor burden and 15 (25%) had a reduction in the size of the target lesion (3% of patients had responded by RECIST after progression). This attests the interest to continue the treatment beyond the progression if the general state remains correct and in the absence of rapid progression. Note that the expression of PDL1 does not seem to differentiate patients who will be treated or not beyond progression^[19].

This pseudo progression can in part explain the possible increase of efficacy of subsequent chemotherapy after failure of anti-PD-1. Indeed a French retrospective study in 82 patients receiving chemotherapy (45% monotherapy and 55% combination therapy) after failure of immunotherapy showed a 30% responses and a 57% disease control, higher than those usually observed in the 3rd line. Chemotherapy could also activate the immune system by releasing tumor antigens, with check point inhibitors known to remain in the body for a long time.

Hyperprogressions are associated with poorer survival. A French retrospective study suggested that hyperprogression can be observed in 29% of patients treated by immunotherapy^[20]. This controversial phenomenon could be induced by an excessive immune reaction, a paradoxical action of anti-PD-1/PD-L1 promoting tumor development, or ultimately only the natural history of advanced phase cancer.

Finally, unlike conventional chemotherapy, the occurrence of autoimmune adverse events seems to correlate with the effectiveness of the CPIs. In an analysis of 114 patients treated with anti-PD-1: 43% exhibited

immunological toxicity. These patients had higher response rates (30.6% *vs.* 12.3%), better progression-free survival (6.9 months *vs.* 2.1 months) and improved overall survival (12.5 months *vs.* 6.8 months). This analysis may of course be biased since patients who benefit from immunotherapy pursue it longer and are therefore more likely to develop immunological toxicity^[21].

PREDICTIVE FACTOR OF EFFICACY OF IMMUNOTHERAPY

One of the major challenges of immunotherapy is to select patients responding to immunotherapies with predictive biomarkers of effectiveness. Currently, the only one used is the expression of PDL1 but it is very imperfect, especially with excellent results in PDL1 negative patients.

The expression of PD-L2 and the signature IFN γ have been explored, but do not seem particularly convincing.

HNSCC have been classified into 6 groups: immunoreactive, inflammatory, Human Papilloma Virus (HPV)-like, classical, hypoxemic and mesenchymal^[22]. The inflammatory and immunoreactive profiles are probably more sensitive to immunotherapies because they are strongly infiltrated by cells of the immune system. The important tumoral infiltration by the CD8 lymphocytes could characterize this inflammatory type.

In a cohort of 34 patients with significant CD8+ lymphocyte infiltration and a high PD-1/TIM3 expression ratio (regardless of HPV status and smoking status) showed an increase in overall survival (84 months *vs.* 13 months) with anti-PD-1 treatment, compared with non-inflammatory tumors^[23].

The estimation of the mutational load (TMB) in the primary tumor, but also from the circulating DNA could also become a predictive biomarker^[24].

There is also evidence that HPV-positive tumors may be better able to respond to anti-PD1. There is indeed a biological rationale for better efficacy of anti-PD1 in HPV + tumors since they show more immune infiltrates and more markers of activated T cells. A retrospective analysis of 54 patients treated after platinum failure with pembrolizumab (32 patients) or nivolumab (22) overall survival was significantly better for HPV positive patients: 17 months *vs.* 4.5 months. Similarly, the duration of anti-PD1 treatment was significantly increased in positive HPV: 7 months *vs.* 3 months^[25].

Much simpler, a study presented at ASCO 2018 has recently been shown to have a high lymphocyte neutrophil count associated with tumor inflammation and poor prognosis^[26]. The 114 patients were treated with anti-PD1 classified in 4 quartiles according to this ratio. Patients with the lowest ratio had an overall survival well above 12.5 months compared to those with the highest ratio (4.1 months, $P < 0.0001$). In this cohort, PD-L1 expression did not discriminate patients. Thus, a very simple and clinical marker proves to be a powerful prognostic factor for the efficacy of immunotherapies.

CONCLUSION

Squamous cell carcinoma of the head and neck has not been spared by the revolution of immunotherapy. Indeed, the CPIs are now an integral part of the therapeutic arsenal and new indications are emerging either as monotherapy or in combination. In addition, many other classes of molecules are currently under development. The selection of patients who will benefit most from immunotherapy with new biomarkers remains an important challenge in the use of these new therapies. The question of the optimal duration and determination of the best combinations of these immunotherapy treatments remains unresolved. The therapeutic management of HNSCC cancers will continue to be disrupted in the coming years.

Abstract

Persistent high-risk human papillomavirus (HR-HPV) infection is associated with anogenital and head & neck squamous epithelial (HNSCC) tumors, which altogether cause about 550,000 new cases every year. Several evidences suggest that the microbiota could have a role on the inflammatory, epithelial mesenchymal transition and tumorigenesis processes promoted by HR-HPV infection, yet the mechanisms involved remain to be clarified. In this review we report the state of the art on this topic and on the most promising *in vitro* developed models for studying the host-pathogen interactions. Using MEDLINE, several terms were searched and combined to select the most pertinent papers. The investigation was limited to the international indexed articles published in PubMed in the last 10 years. This review reports the latest knowledge in the field of the microbial-associated anogenital tumors and HNSCC. In addition, we also discuss the *in vitro* epithelial culture systems that reproduce the pathophysiological features of the tumoral microenvironment and the *in vivo* response to microbial agents, thus representing a useful tool for analyzing at cellular and molecular levels the role played by infective agents in tumorigenesis.

Keywords: High risk human papillomavirus, microbiota, *Fusobacterium nucleatum*, epithelial-mesenchymal transition, anogenital cancer, head & neck squamous cell carcinoma, colorectal cancer, transepithelial electrical resistance

INTRODUCTION

As referred in the last human papillomavirus (HPV) cancer report of the HPV Information Centre^[1], unremitting HPV infection, mainly promoted by high-risk HPV (HR-HPV) 16 and 18 E6 and E7 oncoproteins, is the main microbial etiological factor till now recognized that is necessary, yet not sufficient, for the development of anogenital and of head & neck cancers (namely of the tonsil, tongue and oropharynx).

Despite the progresses in vaccination and screening prevention led to the reduction of cases number^[2,3], these tumors are still diffuse among the general population, with the highest mortality rate in countries with a low socio-economic level^[3].

Cervical cancer is the 3rd most frequent female tumor in the world (2nd in the age range 15-44) with about 600,000 new cases/year and a 50% mortality rate^[4,5].

In the last three decades oropharyngeal tumors, which include some 450,000 new cases/year (mostly affecting older tobacco and alcohol users worldwide), have increased also in young people, due to sexual habits changes predisposing to HR-HPV infection^[6].

It has been reported that oncogenic HPV-related oropharyngeal tumors have a better prognosis than those HPV negative^[7,8]. On the other hand, it is known that HR-HPV-mediated cervical oncogenesis generally develops after a long latency (about 10-30 years from infection). Thus, it remains a conundrum the fact that tumor latency and prognosis differ in the two populations of patients, regardless of the treatment and of the fact that both types of cancer share a common infective cause^[9]. Seemingly, HR-HPV infection is not *per se* enough to cause these cancers, though viruses are classified as Class 1 carcinogens by the International Agency for Research on Cancer^[4]. Recent evidences suggest that the microbiota of the cervical and oropharyngeal niches (that includes bacteria, protozoa, viruses and fungi, although sometimes the term specifically refers only to bacterial communities) can have both a harmful and a protective role. Further, the microbiota can influence persistent HPV-mediated inflammation, epithelial mesenchymal transition (EMT) and tumorigenesis, although the mechanisms involved are still largely unknown and controversial^[10]. In fact, just as a balanced bacteriota may be constituted by both pathogens and commensals, the human virota can include, among the others, both low risk and HR-HPVs, without inducing morbidity for its host if the immune surveillance and the whole microbiota itself are able to control its load and persistence^[11].

Therefore, an open question is if commensal HPV types, belonging to the human virota, play a protective role against the oncogenic ones or not^[12-15]. What is sure is that cancer often arises from a metabolic imbalance. Given this assumption, the metabolic profile of the microenvironment, in which host cells directly cooperate with viruses and bacteria, could reveal a snapshot of their functional and complex interactions that are at the basis of HPV infection, persistence susceptibility, inflammation, EMT, uncontrolled cell proliferation and cancer progression.

To learn more about it, researchers have developed several *in vitro* co-culture systems that could mimic the physiological appearance of the tumoral microenvironment^[16].

On this basis, the purpose of this study was to show the state of the art on epithelial carcinogenesis and on the most suitable *in vitro* 3D models till now developed for the study of host-pathogens interactions.

By using MEDLINE, terms such as “microbiota”, “virota”, “virus”, “epitheliotropic virus”, “HPV”, “bacteriota”, “bacteria”, “*Fusobacterium nucleatum*”, “*Porphyromonas gingivalis*”, “EMT”, “eukaryotic cells”, “keratinocytes”, “epithelial cells” “epithelial infection”, “epithelial cancer”, “anogenital cancer”, “head and neck squamous cell carcinoma (HNSCC)”, “epithelial models”, “2D”, “3D”, “3D epithelial cultures”, “rafts”, “spheroids”, “reconstructed tissues”, both in single and mutually combined, were searched in titles and abstracts in order to find PubMed indexed most pertinent articles; only original research articles published in peer review journal were considered. Papers including EBV or other epitheliotropic viruses other than HPV were excluded.

The literature search was limited to the most recent scientific publications (10 years); six thousand and five hundred nine appropriate abstracts and full papers were carefully read and reviewed; those relevant (216) were reconsidered based on the above described inclusion and exclusion criteria and then 70 were reported in detail and included in the text.

Overall, our findings highlight the most recent advances in the field of host-pathogens interactions. We focused on the *in vitro* 3D modeling for the study of the microbial induced epithelial carcinogenesis and emphasized its ability in mimicking at best the role of bacteria and viruses within an *in vivo* microenvironment.

MICROBIOTA, IMMUNE RESPONSE AND EPITHELIAL CANCER

Several studies, among which that conducted by Kyrgiou *et al.*^[10], underlined that vaginal microbiota may drastically influence host innate immune response, infection susceptibility and cervical cancer development, but without proving causality and thus making necessary further longitudinal studies. In this direction, Ilhan *et al.*^[17], through a triple approach based on liquid chromatography mass spectrometry, 16S rRNA gene sequencing and immunoassay, evaluated and integrated the metabolic signature of the vaginal microbiota and the inflammatory status changes of 78 women, including HPV-negative/positive controls, low-/high-grade cervical-dysplasia or -cancer affected females. These authors found that unique cervicovaginal metabolites and microbes allow to discriminate clearly the affected patients from healthy subjects, thus providing novel cancer hallmarks. For example, the lipidic three-hydroxy-butyrate, eicosenoate, and oleate/vaccenate are distinctive of cancer patients, while sphingolipids, plasmalogens and linoleate positively correlate with cervicovaginal inflammation.

Regarding this niche, the absence of dysbiosis and a dominance of peculiar gram-positive bacteria belonging to the *Lactobacillus* genus may inhibit several pathogens, preserve aminoacidic and nucleotide metabolisms and avoid the inflammatory state. Conversely, *Fusobacterium* spp., *F. nucleatum* in primis, promotes cell survival, proliferation, dysregulated carcinogenesis and cervical cancer through the induction of the WNT/ Beta catenin signaling pathway, as emerged by research in colorectal cancer (CRC)^[12,18,19].

Since it has been demonstrated a significant correlation between bacteria belonging to the *Fusobacteria* genus, mainly *Sneathia sanguinegens*, and high-grade squamous intraepithelial lesions, they could be hired as microbiological markers of clinically significant cervical diseases^[10].

This evidence has also been observed in another study by Mitra *et al.*^[12], who found that a relative abundance of *Fusobacterium* spp. associates with higher levels of cytokines such as IL-4 and TGF- β , which have been shown to generate local immunosuppression, HPV immune evasion and cancer development.

Moreover *F. nucleatum* inversely correlates with CD3⁺-T cell counts, whose aberrant signaling and function is typical in cervical carcinogenesis.

Al-Hebshi *et al.*^[15] have reported an abundance of the periodontal pathogen *F. nucleatum*, selected by the tumor environment, followed to a lesser extent by *Campylobacter*, *Parvimonas* and *Prevotella* spp. in oral squamous cell carcinoma, while the *Streptococci* are frequently associated with a healthy status.

Although the results obtained from clinical studies vary in the oral cancer associated microbiota composition, partially due to differences in the methodological approaches, the functional data consistently show an enrichment of a virulent, chronic inflammatory bacteriota that, as a passenger within the tumor environment, contributes to the worsening of the tumoral disease.

HIGH-RISK HPVS, MICROBIOTA, EPITHELIAL MESENCHYMAL TRANSITION AND CANCER PROGRESSION

As known, EMT associates with cell migration, invasion, resistance to chemotherapy and anoikis. During this process, several signaling pathways, such as those involving TGF- β , Wnt, Hedgehog, β -catenin, Notch, Nanog, STAT3 and ERK, are activated in the cell leading to a pro-metastatic behavior^[20,21]. In this context, EMT can be also regulated by HR-HPVs^[22,23].

Despite anogenital and oropharyngeal squamous cell carcinomas (OPSCC) promoted by these viruses have a more favorable prognosis respect to HPV negative ones, EMT usually associates with an aggressive tumoral behavior, making HPV role an open issue. In a study on a cohort of 296 OPSCC-patients, EMT was confirmed as an adverse marker of evolution of HPV related carcinomas^[24].

In another research, the expression of five EMT markers was assessed in normal and tumoral cervical tissues, revealing that E-cadherin and β -catenin expression decreases gradually, while that of N-cadherin, vimentin and fibronectin increases during malignant progression^[25]. Moreover, Su *et al.*^[26] studied the role of DNA methylation of the ten-eleven translocation methyl-cytosine dioxygenase 1 (TET1), which oxidizes 5-methylcytosine to 5-hydroxymethylcytosine within cervical lesions. At a precancerous level, TET1 inhibits EMT, interacting with chromatin modifiers and downregulating mesenchymal genes such as *ZEB1* and *VIM*^[26]. *In vitro* culture of cervical cancer cells revealed that p68, an ATP-dependent RNA helicase, induces EMT through the transcriptional activation of the TGF- β 1 pathway, inducing cancer progression^[27].

Finally, Pang *et al.*^[28] reported that HPV18 E6 regulates YB-1 mRNA expression by promoting EMT and cervical lesion progression through the enhanced Snail expression.

Moreover, both HPV and EMT upregulate programmed cell death ligand-1 (PD-L1) expression, an immune checkpoint and therapeutic target in OPSCC, whose efficacy is currently under investigation^[29,30]. Precisely, PD-L1 is overexpressed in about half of OPSCC that seem to have a better response to anti-PD-1 therapy^[31].

Regarding the involvement of bacterial microbiota in EMT, *F. nucleatum* has been frequently found in stools and bioptic specimens of CRC affected patients, and more recently also of OPSCC patients. It has been suggested that this bacterium triggers EMT to malignant transformation by interacting with E-cadherin, as suggested by *in vitro* experiments on NCM460 cells^[32,33]. In a cohort of stage III/IV CRC affected patients, Yan *et al.*^[34] found a significant correlation between the presence of *F. nucleatum* and tumor progression also in relation to chemotherapy efficacy, suggesting its role as a biomarker for a

therapeutic approach improvement. Panebianco *et al.*^[35] also confirmed this link. Moreover, the same authors underlined that not only gut bacteria, but also the intratumor ones, may influence patients' response toward chemo- and immuno-therapeutic drugs and *vice versa*^[36].

More recently, it has emerged that EMT can also be promoted by *Porphyromonas gingivalis*, an anaerobe frequently found in chronic periodontitis. In fact, it has been observed that this bacterium causes an early EMT of chronically infected human oral epithelial cells (OECs) that, through PI3K/Akt activation, ultimately lead to the loss of E-cadherin and to the accumulation of β -catenin, together with an increased expression of Zeb1, vimentin, MMP-2, -7, and -9. Moreover, upon stimulation with this bacterium, OECs migratory capacity increases proportionally^[37-39].

Both *F. nucleatum* and *P. gingivalis* determine an enhanced transcription of mesenchymal markers, an increase of TGF- β 1, TNF- α and EGF and a downregulation of those associated to epithelial layer integrity, as evidenced by transepithelial electrical resistance measures^[40].

Recently, a new tumor metastasis model has been proposed. Till now it was supposed that epithelial-like cancer cells acquire mesenchymal features in order to produce metastasis by exploiting the vascular system, and then switch back to an epithelial phenotype to establish the new tumor. The existence of a stable population of hybrid epithelial/mesenchymal cells, possessing epithelial and mesenchymal characteristics with both tumorigenic and metastatic properties, has been hypothesized^[41,42]. Moreover, in predisposed individuals, with defects in the innate immunity response or with a specific epigenetic background, bacterial or viral infections could lead to EMT, causing a chronic inflammatory state, through the activation NF- κ B and MAPK^[43]. Considering this and the emerging role of the microbiota on EMT and cancer progression, more rational and shared laboratory models should be used to better investigate the microbiota composition^[44] and its relationship with the human host.

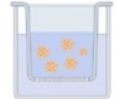

IN VITRO EPITHELIAL MODELS FOR STUDYING THE HOST-PATHOGENS INTERACTIONS

The first studies focused on host-pathogens connections started in the 1970s with Todaro^[45] and Taylor-Robinson^[46], who described the interactions between oncogenic viruses and human cells, and mycoplasma pneumonia and ciliated tracheal epithelium, respectively. Since then, *in vitro* models acquired popularity in the microbiology field, due to their reproducibility, higher versatility and high-throughput data acquisition respect to *in vivo* models^[47] [Table 1]^[5,16,38,45-62]. Undeniably, due to the improvement in imaging and screening techniques and to the *in vitro* models features, nowadays it is possible to directly analyse characteristics such as: specific surface-adhesion processes (i.e., biofilm formation), spreading capabilities, immune system escapes aptitudes, migration in 3D matrices, and host's cell-type-specific interactions in general.

The development of functional co-culture systems mostly depends on their ability to allow the physiological growth of cellular components in optimized culture media inside trans-well devices or microfluidic chambers. In this regard, Di Giulio *et al.*^[50] developed a model in which *Streptococcus mitis* was grown with human gingival fibroblasts in saliva sterilized stocks enriched with 1% sucrose as culture medium. With this system, the authors demonstrated that *S. mitis* can penetrate within fibroblasts, via a FAK-integrin β 1-vinculin-actin mediated process, which is modulated by the saliva and the microenvironment themselves.

Sterilized artificial saliva has also been used in more complex models such as the multi-culture trans-well system developed by Millhouse *et al.*^[51], in which a complex multispecies biofilm, composed by *S. mitis*, *F. nucleatum*, *P. gingivalis* and *Aggregatibacter actinomycetemcomitans*, was grown on a glass slide and co-cultivated in a trans-well together with immortalized oral keratinocytes (OKF6-TERT2). With this system, these authors validated the efficacy of commercially available oral hygiene products.

Table 1. Epithelial study models' overview (images created with BioRender.com)

Epithelial study models	Since	Pros	Cons	Ref.
2D cultures 	1920s	<i>In vitro</i> reproducibility; versatility; high-throughput data acquisition	Inability to reproduce the <i>in vivo</i> context; poor biological complexity; lack of the 3D; poor data reliability; no cell-cell interaction	Todaro <i>et al.</i> ^[45] Bergmann <i>et al.</i> ^[47]
<i>In vivo</i> models 	1980s	Suitability for: (1) new therapies and preventative treatments testing; (2) biological processes understanding	Inability to recapitulate the human tissue context; time-consuming procedures; high costs; requirement of specific manual skills; ethical issues	Taylor-Robinson <i>et al.</i> ^[46] Pasupuleti <i>et al.</i> ^[48]
3D spheroids 	1980s-90s	Fully humanized models; no animal sacrifice required	No tissue organization; unsatisfactory biological complexity; insufficient data reliability; lack of cell-microenvironment interactions	Melissaridou <i>et al.</i> ^[16] Bergmann <i>et al.</i> ^[47] Sawant <i>et al.</i> ^[61]
3D organotypic cultures 	1990s-2000	Fully humanized models; no animal sacrifice required; capacity to mimic the <i>in vivo</i> context: recapitulation of epithelial strata, cytochrome differentiation, EMT markers expression and carcinogenic process; possibility of implementation with the vascular counterpart, macrophages and T-cells; permissiveness to the physiological growth of cellular components; appreciable biological complexity; suitability for the study of pathogen-induced cells modification and host tissue-microbial agents interactions; more reliability and cheaper to antiviral drugs properties study than xenografts; reliability of the data	Model management complexity; inability to mimic long-term conditions	Squarzanti <i>et al.</i> ^[51] Sztukowska <i>et al.</i> ^[38] Riedl <i>et al.</i> ^[49] Di Giulio <i>et al.</i> ^[50] Millhouse <i>et al.</i> ^[51] Bradbury <i>et al.</i> ^[56] Genovese <i>et al.</i> ^[53] Banerjee <i>et al.</i> ^[54] Chow <i>et al.</i> ^[55] Spurgeon <i>et al.</i> ^[52] Hogervorst <i>et al.</i> ^[57] Fuller <i>et al.</i> ^[58] de Carvalho Dias <i>et al.</i> ^[59] Zhang <i>et al.</i> ^[60] Dabija-Wolter <i>et al.</i> ^[62]

EMT: epithelial mesenchymal transition

Despite these findings and the evidences on the cytoskeletal modifications, the impaired proliferation rate and the gene expression changes occurring in cells infected by bacterial or viral pathogens^[50,63-66], some limitations arise when more complex evaluations are required. According to the literature, the microenvironment highly modifies cells behaviour; therefore, the lack of the “3D” in many *in vitro* models reduces the transferability potential of the *in vitro* data^[52]. This is particularly true for epitheliotropic viruses, such as HPVs, for which the intracellular expression of viral proteins is conditioned by the epithelial renewal/stratification process that cannot be detected within 2D cultures.

In fact, most 3D models enable not only viral life cycle, but also virus induced cellular modifications. They are generally constituted by HPV infected keratinocytes, cultivated onto fibroblast repopulated matrices and let to stratify at the air-liquid interface in specific culture media. They can be easily analysed by western blot, histology, high throughput sequencing and protein-protein interaction assays.

These models made possible to identify novel pro-oncogenic co-factors, such as p130^[53] or 53BP1^[5], important for investigating novel antiviral targets.

3D RAFT (real architecture for 3D tissue) cultures also allowed to elucidate the effect of HPV chronic infection onto eukaryotic cells mitosis; as showed by Banerjee *et al.*^[54], HPV DNA amplification occurs during host's cell G2 phase, despite DNA eukaryotic amplification normally occurs in the S phase; in particular, they elucidated the key role of E7 in forcing host cells permanence in the G2 phase via cyclin B1 cytoplasmic accumulation.

Additionally, RAFT cultures are a more reliable and cheaper solution to study antiviral drugs respect to xenografts in SCID mice, since they are more suitable to be analysed by *in situ* hybridization and RT-qPCR techniques^[55].

Moreover, they can allow the study of host-virus interactions in absence of other cell types or tissues that could hide fundamental pathways promoted by the pathogen, especially when the studies require miRNA or EMT analysis.

As previously described, HR-HPVs E6 and E7 proteins interact and inhibit host p53 and pRb onco-suppressors respectively. Recently, the idea that E6 and E7 can also bind host miRNA or miRNA regulators has been evaluated^[67]. Indeed, despite HPV inability to encode for miRNAs, HPV mediated indirect regulation of both onco-suppressive or tumorigenic miRNAs may offer the opportunity to identify novel therapeutic targets.

RAFT CULTRES, DRUG RESISTANCE AND EMT RESEARCH

Regarding drug resistance and EMT markers expression analysis, RAFT cultures can overcome both 2D and spheroid cultures limitations. Melissaridou *et al.*^[16], working with 5 HNSCC-derived cell lines grown in both 2D and spheroids assays, observed that, while 2D eukaryotic cells and spheroid conformation changes the receptor topography and gene expression, and erases the drug resistance pathways that occur *in vivo*, 3D cultures can better mimic what happens during *in vivo* therapies and allow to study EMT expression markers such as CDH1, NANOG, SOX and EGFR.

However, when epithelial models are necessarily to be used, spheroids utility is limited, because of the less reliability of the data they produce respect to those obtained with the organotypic models. In fact, although they are both made up of epithelial cells, spheroids morphology and structure are too much simplified and do not reproduce the mucosal epithelium in such a representative way as the 3D epithelial RAFTs do. Therefore, compared to 3D RAFTs, the spheroids are less performant for studies on the specific interactions that occur in a well-defined *in vivo* environment.

On the other hand, RAFT cultures can be built with both isolated healthy or tumour/cancer associated keratinocytes and fibroblasts, able to better elucidate the interactions between stromal and epithelial compartments that are at the basis of the initial steps of the carcinogenetic process^[56]. Moreover, they recapitulate all the epithelial layers, the physiological cytokeratin differentiation and the carcinogenic process.

By using *in vitro* reconstructed epithelial systems, Hogervorst *et al.*^[57] highlighted the importance of the papillary-reticular fibroblasts switch. In fact, when epithelial cultures are grown in presence of switched fibroblasts, the expression of CAF associated markers (α -SMA and vimentin) and EMT markers (SNAIL2, N-cadherin and ZEB1) increase, thus suggesting that the fibroblasts switch could be considered an indicator of squamous cell carcinoma (SCC) progression. Similarly, Fullar *et al.*^[58] proved that HPV16 induces the modification of connective matrix that, by the action of epithelial Matrix Metalloproteinase MMP-7 and fibroblast-produced MMP-2, loses collagen and fibronectin in favour of laminin, thus facilitating EMT and carcinogenic events. Comparable effects on MMP super-families were also observed in other HR-HPV positive models^[68].

In agreement with the above, the last trend is to reproduce tissue models with the whole organ complexity^[69]; in fact, the models have been implemented with the vascular component, with macrophages and T-cells, thus allowing to further improve the knowledge in the microbiology field^[59-61].

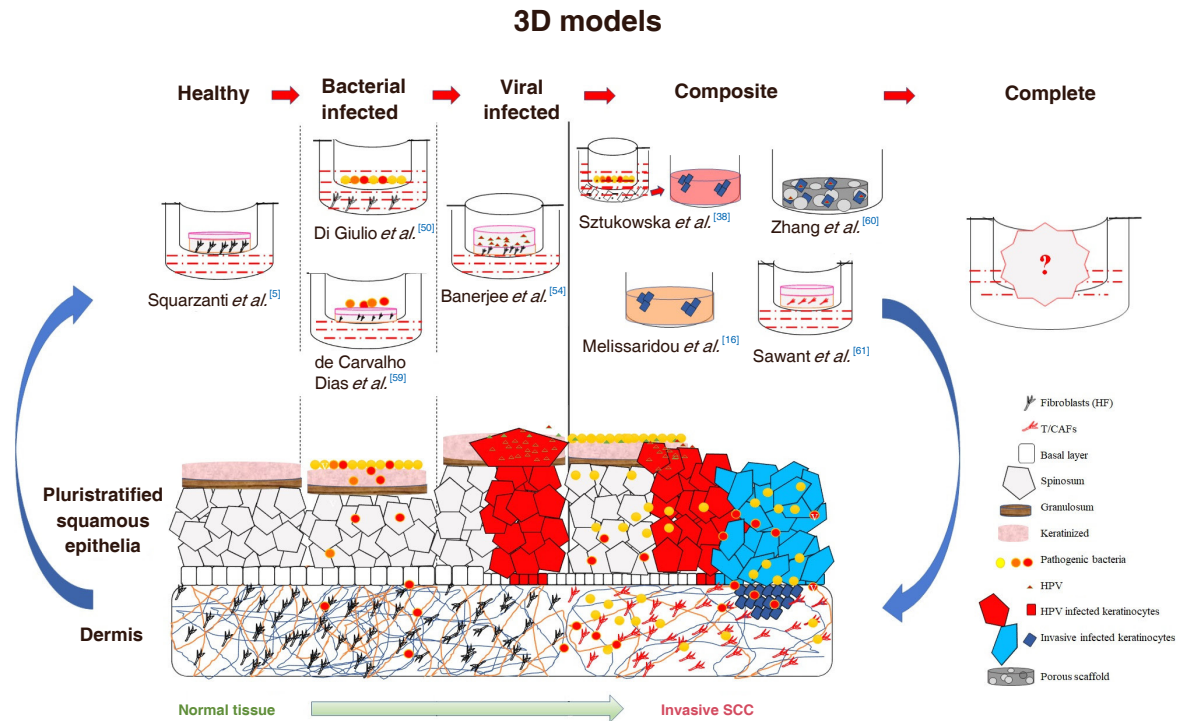

Figure 1. Schematic representation of SCC progression achievable by using *in vitro* 3D infected models. SCC: squamous cell carcinoma; HPV: human papillomavirus

In line with the technological progress, in the last few years several authors have focused their attention on the bacterial-induced EMT. For instance, Sztukowska *et al.*^[38] showed that *P. gingivalis*, associated with OPSCC development, is able in a gingival 3D equivalent to induce the expression and the nuclear re-localization of ZEB1, a well-known EMT transcriptional factor. This effect is reduced by the lack of the bacterial fimbrial FimA protein, while it is enhanced by the co-infection with *F. nucleatum* or *S. gordonii*. A similar study conducted by Lee *et al.*^[37] showed that the carcinogenic properties of *P. gingivalis* are unrelated to the presence of chronic inflammation periodontitis. In this study, the authors showed that in addition to ZEB1, also glycogen synthase kinase-3 beta (p-GSK3 β), Slug, Snail, and vimentin usually increase during EMT under the influence of *P. gingivalis*. Moreover, the co-infection with *F. nucleatum* induces the loss of adhesive molecules such as E-cadherin and β -catenin in cancer-committed cells and the overexpression of MMP-2, -7 and -9 as showed for HPV infection^[69]. These findings confirm those obtained in an established periodontitis-associated oral tumorigenesis murine model used to demonstrate that both *P. gingivalis* and *F. nucleatum* induce tumorigenesis independently from the inflammatory status^[70]. In this latter study, the interaction of bacteria with the keratinocytes Toll-like receptor and the consequent activation of the IL-6-STAT3 axis was possibly involved in the tumorigenesis process.

The above cellular models can be also used to quantify the microorganisms' migration potential, as made by Dabija-Wolter *et al.*^[62] who *in vitro* reconstructed a gingiva to evaluate the migration of *F. nucleatum* through a keratinized squamous epithelium without destroying it, while establishing a chronic infection [Figure 1].

Summarizing, in the last few years, thanks to their suitability to exceed the limitations of monolayer adherent cell cultures, as well as of *in vivo* models and spheroids, 3D epithelial co-cultures have become indispensable tools for investigating the interactions between microbial agents and their hosts.

Although several questions are still open, soon further improvements might help to generate microenvironments that also mimic the bacteria and virus migratory potential.

CONCLUSION

Overall this review highlights the importance of the *in vitro* 3D modeling research field for the study of microbial induced epithelial carcinogenesis. Yet, further improvements are still needed to reach the level of complexity of the real tissue. These models will hopefully help to better understand the respective roles of virus and bacteria in HR-HPV-related cancers.

Abstract

Cell-to-cell communication guarantees homeostasis in a multi-cellular organism. Cancer-to-microenvironment communication sustains malignant growth and dissemination. Whereas the accumulation of mutations is at the origin of malignant cell transformation and neoplasia onset, the interaction between cancer and the surrounding stroma, specifically immune cells, influences the balance between tumour regression and tumour progression. To study how the interaction between cancer and stromal cells is disadvantageous or beneficial for tumour progression, the use of a transparent *in vivo* model bears important research potentials. Zebrafish has been increasingly used as animal model to study tumour biology. The use of transparent zebrafish embryos, with fluorescent endothelial and immune cells, allows the visualization of cell-to-cell interaction, among host cells themselves and between zebrafish stroma and implanted human cancer cells. Here, we summarise our findings on the role of CXCR4 signalling in tumour progression, considering its signature both on cell autonomous and host dependent mechanisms. Finally, we address the translational impact of targeting CXCR4 signalling in cancer and the tumour microenvironment for the treatment of metastatic cancer.

Keywords: CXCR4, cancer, metastasis, neutrophils, zebrafish, immunotherapy

THE TUMOUR MICROENVIRONMENT

Tumours are in constant interaction with the surrounding microenvironment. The tumour microenvironment consists of stromal cells such as cancer-associated fibroblasts (CAFs), endothelial cells, mesenchymal stem cells (MSCs), tumour-associated macrophages (TAMs) and neutrophils (TANs), adaptive immune cells and extracellular matrix (ECM)^[1]. The interaction between cancer and stroma cells results in either tumour promoting or inhibiting effects and the tumour microenvironment differentially contributes to the efficacy of cancer therapies^[2]. Tumour cells engage cells from the microenvironment, either educating resident stromal cells or inducing the recruitment of distal ones to further support malignant growth, motility and dissemination. Along with the angiogenic switch, where endothelial cells are educated by malignant cells to form new vasculature to provide oxygen and nutrients, the immunosuppressive switch phenomenon takes place: the polarization from pro-inflammatory to anti-inflammatory neutrophils and macrophages (N1 to N2 and M1 to M2), where the sub-type 2 associates with a tumour-promoting function, links to immunosuppression, characterized by reduced cytotoxic T cell and enhanced T regulatory (Treg) and myeloid-derived suppressor (MDSCs) cell infiltration^[3]. Interestingly, the cooperation between different subsets of leukocytes and its role in cancer metastases has been recently reported^[4]. The plasticity phenomenon in the microenvironment has been described also for fibroblasts, which respond to a neoplastic lesion in a similar fashion as to a never healing wound^[5]. The interaction between tumour and the microenvironment is controlled by a plethora of signalling molecules, such as chemokines, and their complex networking in cancer requires further understanding to inhibit tumour development.

CXCL12-CXCR4 AXIS IN CANCER AND THE TUMOUR MICROENVIRONMENT

Chemokines are chemotactic cytokines that guide directional cell migration in development and disease and more than 50 chemokine ligands and 18 chemokine receptors have been described in *Homo sapiens*^[5]. Chemokines are classified into four classes, depending on the presence and position of the conserved cysteine residues (CXC, CC, (X)C and CX3C) at the N-terminus, involved in the formation of disulphide bonds between the first and third or second and fourth cysteines^[6]. The chemokines belonging to the CXC subgroup are further classified into angiogenic ELR+ and angiostatic ELR-, whether they are positive or negative for the Glu-Leu-Arg (ELR) motif at the N-terminus^[7,8]. Chemokine ligands can bind multiple chemokine receptors, which possibly work in concert to control signalling activation and inhibition^[8].

CXCR4 is a seven-transmembrane, chemokine, G-protein coupled receptor. The chemokine CXCL12 binds both CXCR4 and CXCR7 receptors in order to guide a directional and collective migration of cell primordia, during the formation of sensory organs in zebrafish^[9-11]. CXCL12 binding to CXCR4 induces the dissociation of the G protein $\alpha\beta\gamma$ trimer and activation of PI3K/AKT/mTOR, MAPK, PKA and PLC/ Ca^{2+} pathways. Moreover, MAPK cascade activation and CXCR4 internalization occur via β -Arrestin, independently from G-proteins [Figure 1A]. In addition, CXCR4 can form homodimers, activating the JAK/STAT pathway and Ca^{2+} release from intracellular storage into the cytoplasm [Figure 1B]. CXCR4 can also form heterodimers with CXCR7. Whereas CXCR4 is internalized and degraded after CXCL12 binding, CXCR7 is internalized and recycled to the plasma membrane. Via β -Arrestin, CXCR7 has either CXCL12 scavenging functions or triggers MAPK signalling activation [Figure 1C]. CXCL12 signalling via CXCR4 and CXCR7 controls cell chemotaxis and migration as well as cell proliferation and survival^[12,13].

In cancer, malignant cells acquire higher CXCR4 levels, compared to normal tissues, and are found to preferentially metastasise in organs where CXCL12 is secreted, in line with the “seed and soil” theory^[14]. Enhanced CXCR4 signalling has been identified in several malignancies such as gastrointestinal tumours^[15], melanoma^[16], basal cell carcinoma^[17], head and neck squamous cell carcinoma^[18], lung cancer^[19], breast^[20] and ovarian^[21] tumours, renal cell carcinoma^[22], prostate cancer^[23], glioblastoma multiforme

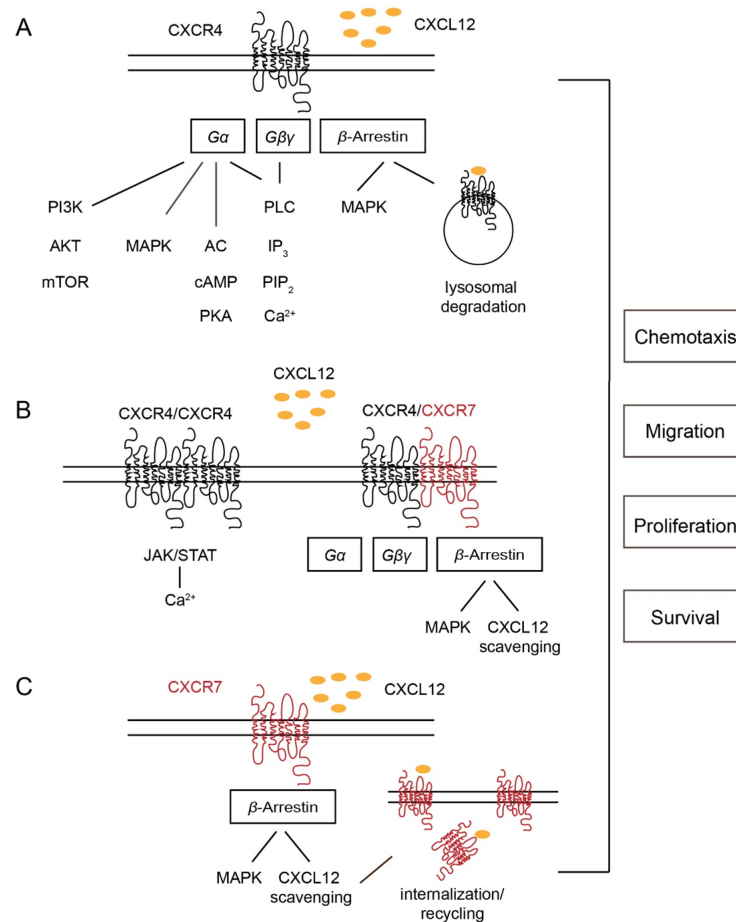

Figure 1. CXCL12-induced signalling via CXCR4 and CXCR7. (A) CXCL12 binds to CXCR4, inducing Gα and Gβγ dissociation and activation of PI3K, MAPK, AC, and PLC signalling pathways. CXCL12 binding to CXCR4 activates β-Arrestin, leading to MAPK signalling pathway activation or receptor internalization. (B) CXCR4 can form homo- and hetero-dimers with CXCR7. (C) CXCL12 binding to CXCR7 induces, via β-Arrestin, MAPK signalling activation, or CXCL12 scavenging, through receptor internalisation and recycling to the plasma membrane. CXCL12-mediated signalling plays a role in cell chemotaxis, migration, proliferation and survival. PI3K: phosphatidylinoside 3-kinase; MAPK: mitogen-activated protein kinases; AC: adenylyl cyclase; PLC: phospholipase C

(GBM)^[24], Ewing sarcoma^[25] and leukemia^[26]. Elevated CXCR4 levels result in increased cell proliferation, dedifferentiation, migration and metastatic spreading of tumour cells, cancer stem cell (CSC) maintenance and it has been associated with the development of tumour resistance towards conventional therapies, leading to poor patient prognosis^[27].

CXCR4 is expressed by both cancer cells and surrounding stromal cells [Figure 2]. The recruitment of stromal cells expressing CXCR4 can be guided by the secretion of CXCL12 by cancer cells themselves or other stromal cells, such as MSCs and CAFs^[28]. Moreover, CXCL12 secreted by CAFs displays effects on tumour cells, enhancing invasive potential^[29] and functioning as a protective shield against T cells, boosting immune escaping mechanisms^[30]. In this context, pharmacological inhibition of CXCR4, resulted in redistribution of CD3+ T cells within the “cancer cell nest”, as defined by the authors, causing reduced cancer cell growth and improved response to check-point inhibitors^[31]. CXCR4 is involved in leukocyte trafficking, hematopoietic stem progenitor cells homing and neutrophil retention in the bone marrow during homeostasis, inflammation, infection and cancer^[12,32-35]. Infiltration of CXCR4hi neutrophils associates with faster tumour growth and angiogenesis in IFNβ deficient mice, injected with melanoma and fibrosarcoma^[36]. CXCR4hi macrophages have been identified in CXCL12-enriched tumour

Figure 2. CXCR4 drives the interaction between cancer and stromal cells. The CXCR4-CXCL12 axis signals in a bi-directional fashion. CXCR4 is expressed by both tumour cells and cells that form the surrounding stroma [fibroblast, T cells, T reg cells, myeloid derived suppressors cells (MDSCs), macrophages and neutrophils], embedded in the extracellular matrix (ECM). The CXCR4 cognate ligand CXCL12 is secreted by both cancer cells and cells in the microenvironment

areas after chemotherapies and are suggested to display pro-angiogenic functions that drive tumour-relapse^[37]. Moreover, CXCL12 expressing glioblastoma cells induce VEGF production and angiogenesis in microvessel enriched areas with high CXCR4 levels^[38]. In addition, CXCR4-expressing peripheral blood monocytes respond to CXCL12-secreting multiple myeloma (MM) tumour cells and acquire M2 associated properties^[39]. Finally, the inhibition of CXCR4 signalling by oncolytic virotherapy limits the infiltration of Treg, decreasing immunosuppression^[40].

Considering the major and intricate role of this chemokine receptor in cancer, its targeting represents an important pharmacological approach that is currently under development, through the use of CXCR4 antagonists, antibodies and CXCL12 binding agents. Importantly, the role of the stromal CXCR4 signalling needs to be considered in drug treatments that target CXCR4 to inhibit cancer spreading.

In 2018, the Nobel prize in Physiology and Medicine was awarded to J.P. Allison and T. Honjo for the development of immune-checkpoint blockade^[41]. This revolutionary discovery clearly underlines the well-known pivotal role of the immune system in cancer. Inhibition of CXCR4 signalling has been found to improve the efficacy of immunotherapies in metastatic breast cancer, by alleviation of desmoplasia and increased T cell infiltration in preclinical *in vivo* models^[42].

Limiting cancer spreading by targeting CXCR4 signalling in the tumour microenvironment is a promising approach that requires further investigations to become an alternative therapeutic form of intervention.

ZEBRAFISH XENOGRAFT AS A MODEL TO STUDY CANCER

Research performed in pre-clinical *in vivo* models is constantly under development to provide further insights into the communication between tumour and the surrounding microenvironment. Zebrafish (*Danio rerio*) is a tropical freshwater teleost, increasingly used to study a range of disease processes^[43] as well as being an excellent tool for the study of development. Several important advances in understanding of cancer and inflammation have arisen from studies in zebrafish^[44-46]. The rapid and external development of transparent embryos^[47], availability of reporter lines with traceable fluorescent cells^[48-50], ease of genetic manipulation^[51,52] and pharmacological approaches^[53] make the zebrafish an excellent *in vivo* model to visualise single cell interactions in real time and to uncover the signalling mechanisms involved, on a whole organism level. Zebrafish is increasingly used as a model organism to study cancer^[54]. There is high conservation of oncogenes and tumour-suppressor genes between zebrafish and human therefore data collected in zebrafish are relevant for humans^[55]. The histology of zebrafish tumours has been shown to be highly similar to tumours found in human cancers^[56]. Moreover, zebrafish is a valuable tool to study drug discovery in the context of cancer research^[57,58]. Zebrafish larvae can absorb small molecular weight compounds from water, which is advantageous when screening for anti-cancer compounds^[59]. The experimental costs are low and procedure are simple and fast. This accounts for the experimental increase in the use of zebrafish in drug discovery during the last two decades in a time- and cost- effective manner. For melanoma, a presently on-going phase I/II clinical trial of Leflunomide combined with vemurafenib is the first to arise from initial screen in zebrafish. To study human cancer metastasis, our group generated a xenotransplantation model of experimental micrometastasis^[60,61]. Human tumour cells engrafted into the blood circulation of 2-day-old zebrafish embryos induce angiogenesis and form micrometastasis sustained by neutrophils and macrophages, nearby hematopoietic sites^[60]. In particular, tumour-induced angiogenesis, metastasis formation and relative chemical approaches to inhibit these processes have been studied using zebrafish as a xenotransplantation model, complementing current knowledge developed through the use of *in vitro* and other *in vivo* models^[62]. Upon localised or haematogenous engraftment of cancer cells, zebrafish xenografts allow qualitative and quantitative assessment of tumour burden and tumour-microenvironment interaction, representing a powerful pre-clinical model to unravel cancer mechanisms and to develop new therapeutic strategies^[61]. In particular, alongside murine models, the use of PDXs in zebrafish has the potential to be used in personalised medicine^[63-66], with the advantage of requiring less tumour material and shorter times for the monitoring of tumour development^[57]. Several studies have shown that the combined use of zebrafish and murine models paves the way towards important insights to elucidate the biology of metastatic cancers and the development of new treatments^[67-71]. Therefore, the zebrafish xenograft model bears the potential to elucidate crucial kinetics and key mechanisms that regulate tumour-microenvironment interaction and ultimately support tumour spreading.

CELL-AUTONOMOUS CXCR4 SIGNALLING: THE CXCR4 ANTAGONIST IT1T IMPAIRS EARLY HUMAN METASTATIC EVENTS, IN A ZEBRAFISH XENOGRAFT MODEL WHERE THE INTERSPECIES CROSS-TALK TAKES PLACE

Chemokines direct tumour and stromal cell bidirectional migration^[72]. CXCR4 plays a physiological role in hematopoiesis^[73,74], leukocyte trafficking^[75-77], cell migration and embryo development^[78], as well as a pathological function in HIV pathogenesis^[79], WHIM syndrome^[80] and cancer^[81,82]. In addition to its cognate ligand CXCL12, CXCR4 can bind ubiquitin^[83], macrophage migration inhibitory factor^[84-86] and CXCL14^[87]. The CXCR4-CXCL12 signalling axis is known to play a critical function in cancer cell spreading, when tumour cells expressing high levels of CXCR4 communicate with CXCL12-secreting stromal cells of distant organs that function as metastatic and secondary growth “soils”^[88].

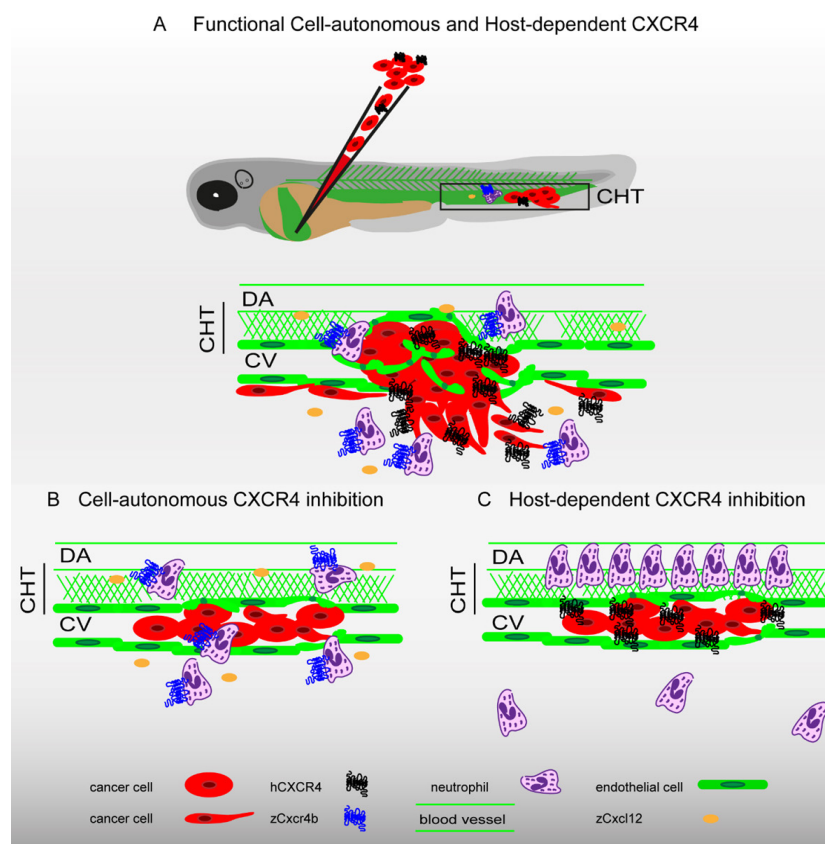

Figure 3. Role of cell-autonomous and host-dependent CXCR4 signalling in experimental metastasis formation in the zebrafish xenograft model. A: inoculation of human tumour cells into the blood circulation of zebrafish embryos results in experimental metastasis formation, characterized by tumour cell aggregates in the blood vessels, and extravasation and invasion in the surrounding tissue, in the region of the caudal hematopoietic tissue (CHT). During early metastatic events, endothelium alteration takes place and neutrophils localize in the surrounding of the tumour. The CHT is a vascular plexus in the tail fin between the DA and the CV and is a hematopoietic site; B: upon disruption of the tumour cell-autonomous CXCR4 signalling, cancer cells are unable to initiate early metastatic events, while surrounded by immune cells; C: the same inhibition of experimental metastasis formation occurs upon disruption of the host-dependent CXCR4 (Cxcr4b) signalling. Neutrophils are preferentially retained in the CHT and their recruitment at the metastatic site is impaired upon Cxcr4 signalling inhibition

We have previously shown that the impairment of the cell autonomous CXCR4 signalling blocks triple-negative breast cancer (TNBC) early metastatic events in the zebrafish xenograft model [Figure 3A and B]. In our model, human triple-negative breast cancer cells, derived from bone metastases developed in a mouse model, were implanted directly into the blood circulation of zebrafish embryos. Using this model, the formation of the primary tumour and the initial steps of metastasis (local invasion and intravasation into the blood circulation) were by-passed. Tumour cells, inoculated into the blood circulation, were found to form early metastases, by adhering to the endothelial wall, forming aggregates and invading the local tail fin tissue. Experimental metastases occurred in proximity of the caudal hematopoietic tissue, an intermediate site of hematopoiesis and a functional analogue of the fetal liver during mammalian development. This observation was in line with breast cancer metastasis formation in the bone^[89,90]. In addition, others have also shown that tumour-derived CXCR4 signalling, in concert with the transcription factor Pit-1, drives tumour growth, in a zebrafish model^[91,92]. Moreover, we demonstrated that the CXCR4 signalling functions across human and zebrafish systems, because CXCR4-expressing human cells respond to zebrafish Cxcl12 ligands and Cxcr4-expressing zebrafish cells migrate towards human CXCL12, showing that the zebrafish xenograft model is a valid approach to study human tumours. Taking advantage of the same *in vivo* model, where the interspecies crosstalk is validated, we propose a recently described CXCR4 antagonist, IT1t, as a possible therapeutic to inhibit early metastasis of TNBC^[93]. In particular, breast

cancer cells pre-treated *in vitro* with the CXCR4 antagonist IT1t displayed reduced metastatic potential in zebrafish. Impaired tumour burden *in vivo* was also observed upon genetic inhibition of tumour-derived CXCR4 or microenvironment-dependent Cxcl12. In conclusion, we showed that the xenograft approach in zebrafish is a valuable model to study human tumours as the CXCR4 signalling functions in human cells upon zebrafish CXCL12 stimulation and vice versa CXCR4-expressing zebrafish cells respond to the human cognate chemokine.

HOST-DEPENDENT CXCR4 SIGNALLING: CXCR4 CONTROLS THE TUMOUR METASTATIC NICHE PREPARATION, BY REGULATING INTRINSIC NEUTROPHIL FUNCTION AND RESPONSE TO CANCER CELLS

Immune cells are programmed to recognise and eliminate transformed cells. However, cancer cells have evolved mechanisms that reprogram the immune defence and make the foe-to-friend switch an important support for survival and progression. The combination of chemotherapy and immunotherapy is a current strategy in the clinic^[94]. Galluzzi *et al.*^[95] have recently reviewed anti-cancer therapies that re-activate the immune system, such as tumour-targeting antibodies, adoptive cell transfer and oncolytic viruses (all classified as passive immunotherapy), dendritic cell-based immunotherapies, anti-cancer vaccines, immune-stimulatory cytokines, immunomodulatory antibodies, inhibitors of immunosuppressive metabolism, pattern recognition receptor agonist, and immunogenic cell death inducers (all classified as active immunotherapy). Antibodies against CXCR4 are included in immunotherapeutic agents that skew the balance between M2/M1 TAMs toward the pro-inflammatory and anti-tumour M1 phenotype^[95].

We have recently shown the role of the host dependent CXCR4 signalling in supporting early metastatic events in the zebrafish xenograft model. Previous work from our group has shown that neutrophils are involved in the metastatic niche preparation by conditioning the ECM during their apparent random walk in the transmigration from the CHT (caudal hematopoietic tissue, transient hematopoietic site) to the tail tissue of zebrafish embryos^[60]. Because CXCR4 is known to regulate the retention of hematopoietic stem progenitor cells (HSPCs) and differentiated leukocytes in the bone marrow in mammals^[96], and is highly expressed in zebrafish myeloid cells^[97], we hypothesised that CXCR4 signalling plays a role in controlling intrinsic neutrophil motility in physiological conditions. We found that neutrophils display altered motility and their number fluctuates during embryo development, leading to the conclusion that CXCR4 regulates neutrophil development in zebrafish. Moreover, a link between CXCR4 signalling and neutrophil response during inflammation has been recently described^[98]. In our model, the neutrophilic response towards cancer cells was also altered in zebrafish mutants with a non-functional *Cxcr4* (*Cxcr4b*). We identified a population of neutrophils that was mainly retained in the CHT and a population of neutrophils that even if moving in the tissue, displayed the inability to infiltrate tumour cell aggregates in the tail fin of *Cxcr4b*-null mutants. In the surrounding of cancer cells, *cxcr4b*-expressing neutrophils reduced their speed in motility, while *Cxcr4b*-null neutrophils maintained similar speeds as in neutrophils that had not been challenged by cancer cells. Therefore, we propose that *Cxcr4* controls neutrophil development and response to tumour cells, initiating early metastatic events [Figure 3A and C]. RNA sequencing performed on sorted neutrophils from wild-type or *cxcr4b*^{-/-} zebrafish larvae supported our conclusion that motility and adhesion are altered when neutrophils lack a functional *Cxcr4* signalling^[99]. In conclusion, we propose that these alterations are responsible for the impaired tumour niche preparation and inhibition of early micrometastasis formation in different types of cancer.

CONCLUSION

Cancer is a complex, multi-step disease and the second leading cause of death worldwide [1 in 6 deaths is due to cancer, 9.6 million cancer-related deaths in 2018 (www.who.int, October 2019)]. Patients diagnosed

with primary tumours are treated, when possible, with surgery. However, metastasis can occur years after surgical intervention^[100]. Metastatic cancer associates with poor patient prognosis and represent a major challenge for clinical research. Chemotherapy is often the pharmacological choice to treat cancer, although side effects alter normal cell physiology and affect patient life quality. Moreover, cancer relapse and therapy resistance associate with poor prognosis. Progress in biomedical research has shown that targeting cancer cells is not the only therapeutic option. The interaction between tumour and surrounding stroma supports cancer survival and spreading, representing therefore a possible new treatment strategy^[101]. Here, we describe the use of the zebrafish xenograft model to study early stages of experimental micrometastasis formation, engrafting fluorescent tumour cells in transparent zebrafish embryos with fluorescent endothelial and immune cells. We propose that targeting CXCR4 signalling on cancer cells or in the tumour microenvironment is a valid approach to inhibit metastatic cancer and suggest that anti-CXCR4 therapy might have double treatment benefits. In addition, therapeutic modulation of the immune system might result in the reinforcement of the immune defence against cancer. However, we suggest that treatments designed to target malignant cells might affect tumour microenvironment intrinsic functions. Specifically, the intrinsic physiological role of myeloid cells can be affected by cancer treatment, resulting in an inability to mount a functional anti-cancer response or, on the other hand, in the ability to mount a tumour-supportive response.

DECLARATIONS

Authors' contributions

Wrote and reviewed the manuscript: Tulotta C, Snaar-Jagalska BE

Availability of data and materials

Not applicable.

Financial support and sponsorship

The work was supported by the Netherlands Organization for Scientific Research (TOP GO Grant: 854.10.012).

Conflicts of interest

Both authors declared that there are no conflicts of interest.

Ethical approval and consent to participate

Abstract

Conventionally, in the pharmacokinetic/pharmacodynamic analysis of small molecule compounds such as cytotoxic anticancer drugs, polymorphism analysis of genes related to absorption, distribution, metabolism, and excretion has been performed in addition to the analyses of blood concentrations of drugs. Such pharmacogenetic factors play an important role in predicting therapeutic effects and adverse events and in the proper use of drugs. With the recent launch of immune checkpoint inhibitors (ICIs) and the rapid development of antibody-drug conjugates (ADCs) currently underway, there is no doubt that antibody drugs, which are large molecule compounds, will become key drugs in anticancer drug treatment. However, the pharmacokinetic and pharmacodynamic analysis of antibody drugs is still not sufficient, and further elucidation of factors and mechanisms affecting their dynamics in the human body is necessary. Moreover, the pharmacogenomic factors of antibody drugs have not yet been fully studied. There are many factors that should be clarified, such as factors that regulate the host immune response in ICI therapy and the effects of ATP-binding cassette transporter and cytochrome P450 on the payload of ADCs. This review provides an outline of antibody drugs in cancer treatment and summarizes the pharmacogenomic factors of antibody drugs known to date.

Keywords: Pharmacogenomics, antibody drug, antibody-dependent cellular cytotoxicity, immune checkpoint inhibitor, antibody-drug conjugate

INTRODUCTION

An antibody is a humoral immunity factor produced by B cells as a biological defense against foreign antigens in the living body. Antibodies, i.e., immunoglobulins, are composed of a light chain and a heavy chain, and there are 2 types of light chains and five types of heavy chains^[1]. Immunoglobulins are classified into IgA, IgD, IgE, IgG, and IgM according to heavy chain subtypes, and in human organisms, IgG accounts for 80%. The IgG family includes IgG1, IgG2, IgG3, and IgG4 according to heavy chain subtypes. On the other hand, immunoglobulin receptors are expressed on neutrophils and macrophages and are composed of glycoproteins called Fc receptors. The Fc receptor has subtypes depending on the immunoglobulin to be bound, IgA binds to Fc α receptor, IgD binds to Fc δ receptor, IgE binds to Fc ϵ receptor, and IgG binds to Fc γ receptor. The structure of the heavy chain of IgG differs in its binding affinity to Fc γ receptors, resulting in specific functional properties for each IgG antibody subtype.

For the immunoglobulin function, four major types of mode of action are known: (1) the neutralizing function by binding of antibody to the antigen; (2) the function of opening the cell membrane by activating complement [complement-derived cellular cytotoxicity (CDC)]; (3) the opsonizing effect taken up by phagocytes through binding of antibody to the antigen; and (4) antibody-dependent cellular cytotoxicity (ADCC) that occurs by binding the antibody to NK cells and releasing cytokines. All currently approved antibody drugs are of the IgG subtype and produce their antitumor effects through these functions.

The application of antibodies to cancer treatment was proposed by the bacteriologist Paul Ehrlich around 1900, but their clinical application became practical since the discovery of monoclonal antibody production technology by the hybridoma of Köhler and Milstein^[2] in 1975. Monoclonal antibodies are characterized by having high antigen specificity, producing almost infinite antibodies by hybridomas, and carrying out the same analysis by producing the same antibodies. They also have advantages for anticancer treatment, such as a long half-life, high potency, and low off-target effect.

As a result, monoclonal antibody therapy has increased hope as a “magic bullet”. However, the initial development of monoclonal antibodies using mice or rats has been abandoned one after another because of their short half-lives and high immunogenicity. With such a background, several techniques for modifying antibody formulations have been developed such as chimeric antibody that genetically substitutes the highly antigenic constant region of mouse antibody, humanized antibody that substitutes human immunoglobulin except for the complementary-determining region (CDR) site, and fully humanized antibody. Currently, about 26 antibody drugs have been approved against cancer, and the monoclonal antibodies for cancer treatment will be reviewed from a pharmacogenomic perspective.

CANCER THERAPEUTIC ANTIBODY

As of August 2019, a total of 26 antibody drugs have been approved for cancer treatment by the US Food and Drug Administration (FDA) [Table 1].

The antitumor efficacy of antibody drugs is brought about by any of the 4 functions mentioned above. Of the 26 FDA-approved drugs, 20 are IgG1, one is IgG2, five are IgG4 isotype, and there are no drugs of IgG3 isotype. This is considered to be due to the fact that IgG1, 2, and 4 have a half-life of about 21 days, while IgG3 has a short 7-day half-life. The main features of each IgG subtype are shown in Table 2. ADCC activity, which is dependent on the avidity of IgG and Fc γ R, is strongest in IgG3, moderate in IgG1, and weak in IgG2 and IgG4^[3]. Therefore, a drug that exerts ADCC activity is composed of an IgG1 isotype and an IgG4 or IgG2 isotype for the purpose of neutralizing action or signal inhibition.

Many of the antibody drugs that have been marketed are made to have ADCC activity or ADCC activity and a neutralizing effect as their main antitumor effects. In the 2010s, development of antibody-drug

Table 1. Therapeutic antibodies for cancer treatment

Class	Generic name	Brand name	Subtype	Target	FDA approval	Major indication
Chimeric Ab	Rituximab	Rituxan	IgG1κ	CD20	1997	CD20+ non-Hodgkin lymphoma
	Brentuximab vedotin	Adcetris	IgG1	CD30	2011	Hodgkin lymphoma
	Cetuximab	Erbitux	IgG1κ	EGFR	2004	Colon cancer
	Dinutuximab	Unituxin	IgG1κ	GD2	2015	Neuroblastoma
Humanized Ab	Trastuzumab	Herceptin	IgG1κ	HER2	1998	HER2+ Breast cancer
	Gemtuzumab ozogamicin	Mylotarg	IgG4κ	CD33	2017	Acute myeloid leukemia
	Bevacizumab	Avastin	IgG1κ	VEGF	2004	Colorectal cancer
	Mogamulizumab	Poteligio	IgG1κ	CCR4	2018	CCR4+ Adult T cell leukemia lymphoma
	Pertuzumab	Perjeta	IgG1κ	HER2	2012	HER2+ Breast cancer
	Trastuzumab emtansine	Kadcyla	IgG1κ	HER2	2013	HER2+ Breast cancer
	Obinutuzumab	Gazyva	IgG1κ	CD20	2013	Chronic lymphatic leukemia
	Pembrolizumab	Keytruda	IgG4κ	PD-1	2014	Non-small cell lung cancer
	Elotuzumab	Empliciti	IgG1κ	SLAMF7	2015	Multiple myeloma
	Atezolizumab	Tecentriq	IgG1κ	PD-L1	2016	Urothelial cancer
	Inotuzumab ozogamicin	Besponsa	IgG4κ	CD22	2017	Acute lymphatic leukemia
Human Ab	Panitumumab	Vectibix	IgG2κ	EGFR	2006	Colorectal cancer
	Ofatumumab	Aezerra	IgG1κ	CD20	2009	Chronic lymphatic leukemia
	Ipilimumab	Yervoy	IgG1κ	CTLA4	2011	Malignant melanoma
	Ramucirumab	Cyramza	IgG1	VEGFR2	2014	Gastric cancer
	Nivolumab	Opdivo	IgG4	PD-1	2015	Malignant melanoma
	Necitumumab	Portrazza	IgG1κ	EGFR	2015	Non-small cell lung cancer
	Daratumumab	Darzalex	IgG1κ	CD38	2015	Multiple myeloma
	Olaratumab	Lartruvo	IgG1	PDGFR	2016	Soft tissue sarcoma
	Avelumab	Bavencio	IgG1λ	PD-L1	2017	Merkel cell carcinoma
	Durvalumab	Imfinzi	IgG1κ	PD-L1	2017	Urothelial cancer
Unclassified Ab	Cemiplimab	Libtayo	IgG4	PD-1	2018	Cutaneous squamous cell carcinoma

conjugates (ADCs), in which cytotoxic anticancer drugs are bound to antibody drugs, and immune checkpoint inhibitors (ICIs) that cause binding inhibition of immune checkpoint molecules has been rapidly advancing.

PHARMACOGENOMICS OF CANCER THERAPEUTIC ANTIBODIES

Antibody drugs show anti-tumor effects by binding to antigens *in vivo*, but because they are proteins with a large molecular weight of about 150 kDa, they have complex pharmacokinetic and metabolic pathways that are completely different from small molecule compounds. Small molecule compounds generally have good membrane permeability and a large distribution volume (Vd) because they are distributed in cells^[4]. Since the effects of metabolism and excretion pathways are large for each drug, many pharmacogenetic studies have been conducted on the effects of polymorphisms of cytochrome P450 and ABC transporter on blood concentration levels of drugs. However, in the case of antibody drugs, the Vd is relatively small, they do not undergo metabolism such as by cytochrome P450, and the main elimination route is the digestion of amino acids in cells. For these reasons, they exhibit very different pharmacokinetics from small molecule compounds, and there are still many unknowns. A detailed description of the pharmacokinetics of antibody drugs was given by the critical review of Liming Liu, and this section outlines pharmacogenomic factors that affect the efficacy and pharmacology of antibody drugs^[5].

Neonatal Fc receptor

The neonatal Fc receptor (FcRn) encoded by *FCGRT* was assumed in the 1960s to be a receptor that protects IgG from catabolism by Roger Brambell^[6,7]. After cloning of FcRn by Simister & Mostov in 1989, analysis of knockout mice by Roopenian & Akilesh proved its function in 2007^[8,9]. The current understanding of FcRn is that blood circulating IgG is taken up by vascular endothelial cells and monocytes by pinocytosis and receptor-mediated endocytosis. Thereafter, IgG binds to FcRn in endosomes in an acidic environment (pH

Table 2. Characteristics of IgG isotypes

Heavy chain subtype	Isotype	ADCC activity	CDC activity	Half-life (days)
$\gamma 1$	IgG1	++	++	21
$\gamma 2$	IgG2	+	+	20
$\gamma 3$	IgG3	+++	+++	7
$\gamma 4$	IgG4	+	-	21

ADCC: antibody-dependent cellular cytotoxicity; CDC: complement-derived cellular cytotoxicity

< 6.0), escapes lysosomal degradation, and is released again into the blood. If the blood IgG concentration is high, binding of FcRn to IgG is saturated, then lysosome-mediated IgG degradation is enhanced, and if the IgG concentration is low, IgG is bound to FcRn and recycled, thereby reducing IgG degradation^[10].

Gene polymorphism of FcRn has been reported to be involved in FcRn expression, with VNTR of 37 bases occurring in the promoter region^[11]. The most common VNTR3/VNTR3 homozygous genotype is reported to have 1.66 times more FcRn expression than the VNTR3/VNTR2 heterozygous genotype^[11]. The levels of anti-TNF- α antibodies infliximab and adalimumab are lower in blood by 14% and 24%, respectively, among heterozygous cases compared to homozygous cases^[12]. On the other hand, as an antibody drug against cancer, in 94 cases that received cetuximab therapy, which is an EGFR antibody for colorectal cancer, a significant difference in distribution clearance and a tendency to a prolonged half-life were observed. There was no change in PK due to copy number variation (CNV) of *FCGRT* gene^[13]. In addition, in 476 patients who received farletuzumab, an anti-folate receptor α antibody against ovarian cancer, there was no difference between PK and the area under the curve (AUC) of VNTR genotype and steady-state, and no change in PK due to CNV^[14]. As described above, there are few reports on blood concentrations of antibody drugs against cancer based on the FcRn genotype, and the relationship with efficacy is unknown. Further evidence is needed.

Antibody-dependent cellular cytotoxicity

An immunoglobulin including an antibody drug binds to an antigen at the Fab region, and the Fc region binds to Fc γ Receptor expressed on immune cells in the body. There are six types of Fc γ R: I, IIA, IIB, IIC, IIIA, and IIIB. Of them, I, IIA, IIC, IIIA, and IIIB are activated forms, and they mainly activate immune cells by phosphorylation of immunoreceptor tyrosine-based activation motif, which transmits activation signals into cells. On the other hand, IIB causes inhibitory functions via phosphorylation of an immunoreceptor tyrosine-based inhibitory motif^[15]. The ADCC activity as a mechanism of action of antibody drugs for cancer is considered to be the apoptosis of target cells by the release of perforin and granzyme from NK cells, mainly by the binding of the antibody drug to Fc γ RIIA of NK cells. The binding strength of the antibody drug and Fc γ RIIA is considered to be correlated with the ADCC activity.

Factors affecting the binding strength to Fc γ R include structural problems with the antibody drug and genetic polymorphisms affecting host immunity. Normally, the Fc region of immunoglobulins is glycosylated, and variations with or without terminal galactose, bisecting N-acetylglucosamine, sialic acid, and fucose at the root have been reported. For the ADCC activity, it has been reported that aglycosylation reduces ADCC activity, and addition of bisecting N-acetylglucosamine and removal of fucose increase ADCC activity. It has been reported that the addition of N-acetylglucosamine to mAb increases ADCC activity by 10-20 times^[16]. Moreover, fucose removal has undergone many technological developments, such as PotelligentTM technology (BioWa, Japan) and GlycomabTM technology (Glycart, Switzerland) based around cell lines engineered with altered glycosylation machinery, that increase ADCC activity by more than 100-fold^[17,18]. In the PotelligentTM cell line, both FUT8 gene alleles, which encode α 1,6-fucosyltransferase, were disrupted by sequential homologous recombination. The GlycomabTM cell lines are stably transfected with the gene encoding 1,4-N-acetylglucosaminyltransferase III (GnIII), resulting in the

Table 3. FcγR polymorphisms and antibody drug efficacies

Drug	Author (year)	Disease treatment (n)	FCGR2A-131 Polymorphism (n)	FCGR3A-158 Polymorphism (n)	Genotyping method	Results
Trastuzumab	Musolino <i>et al.</i> ^[19] (2008)	Metastatic breast cancer (54) Trastuzumab + Taxane	H/H (10) H/R (34) R/R (10)	V/V (11) V/F (26) F/F (17)	Nested PCR-based allele-specific restriction analysis assay	FcγRIIIa-158 V/V genotype was significantly correlated with ORR and PFS. There was a trend to significance in ORR and PFS for the FcγRIIIa-131 H/H genotype
	Tamura <i>et al.</i> ^[20] (2011)	Neoadjuvant breast cancer (15) AC/ PTX+Trastuzumab	H/H (7) H/R (6) R/R (2)	V/V (7) V/F (6) F/F (2)	Goldgate Genotyping	The FcγR2A-131 H/H genotype was significantly correlated with the pCR and the objective response. The FcγR3A-158 V/V genotype exhibited a tendency to be correlated with the objective response
	Tamura <i>et al.</i> ^[20] (2011)	Metastatic breast cancer (35) Trastuzumab	H/H (15) HR (18) R/R (2)	V/V (15) V/F (17) F/F (3)	Goldgate Genotyping	Patients with the FcγR2A-131 H/H genotype had significantly longer PFS
	Hurvitz <i>et al.</i> ^[21] (2012)	Adjuvant breast cancer (1286) Trastuzumab combination	H/H (323) HR (597) R/R (298)	V/V (169) V/F (471) F/F (549)	Nested PCR plus Sanger sequencing	No correlation between DFS and FCGR3A/2A genotypes was seen for trastuzumab-treated patients
	Musolino <i>et al.</i> ^[22] (2016)	Neoadjuvant breast cancer (73) Chemotherapy, Trastuzumab, Lapatinib.	H/H (101) HR (143) R/R (56)	V/V (43) V/F (150) F/F (107)	PCR plus Sanger sequencing	FcγRIIIa V allele correlated with pCR in patients treated with chemotherapy plus trastuzumab plus lapatinib. No significant associations were observed between pCR and FcγRIIIa polymorphism
Rituximab	Cartron <i>et al.</i> ^[23] (2002)	Caucasian FL (49) Rituximab	H/H (13) HR (23) R/R (9)	V/V (10) V/F (22) F/F (17)	PCR followed by an allele-specific restriction enzyme digestion	An association between the FCGR3A genotype and clinical and molecular responses to rituximab
	Weng <i>et al.</i> ^[24] (2003)	Caucasian FL (87) Rituximab	H/H (20) HR (43) R/R (24)	V/V (13) V/F (40) F/F (34)	Nested PCR followed by allele-specific restriction enzyme digestion	FcγRIIIa 158 valine/valine and the FcγRIIIa 131 Histidine/histidine genotypes were found to be independently associated with the response rate and freedom from progression
	Kim <i>et al.</i> ^[25] (2006)	Asian DLBCL (113) R-CHOP	H/H (60) HR (40) R/R (8)	V/V (53) V/F (54) F/F (6)	Nested PCR followed by allele-specific restriction enzyme digestion	No difference was found in OS or EFS according to FCGR3A or FCGR2A alleles. The FCGR3A SNP is predictive of response to R-CHOP, but does not correlate with survival
	Carlotti <i>et al.</i> ^[26] (2007)	Caucasian DLBCL (94) R-CHOP	H/H (30) HR (46) R/R (18)	V/V (18) V/F (46) F/F (30)	PCR with fluorescent labeled probes followed by melt curve analysis	No correlation between FcγRIIIa-158V/V/VF and FcγRIIIa-131HH/HR polymorphisms and the OS, response, and the EFS
	Mitrović <i>et al.</i> ^[27] (2007)	Caucasian DLBCL (58) R-CHOP	H/H (23) HR (27) R/R (8)	V/V (16) V/F (32) F/F (10)	PCR followed by allele-specific restriction enzyme digestion	FcγRIIIa and FcγRIIIa polymorphisms had no impact on EFS and OS
	Dornan <i>et al.</i> ^[28] (2010)	Caucasian CLL (419) Chemotherapy +/- Rituximab	H/H (110) HR (218) R/R (91)	V/V (49) V/F (202) F/F (168)	Allele-specific PCR with SYBR Green	FCGR2A and FCGR3A polymorphisms do not significantly influence the outcomes of CLL patients treated with chemotherapy +/- rituximab
	Zhang <i>et al.</i> ^[29] (2010)	Asian DLBCL (34) R-CHOP	NA	V/V (11) V/F (18) F/F (5)	Allele-specific PCR	FcγRIIIA polymorphisms do not predict prognosis independently
	Prochazka <i>et al.</i> ^[32] (2011)	Caucasian FL (102) Rituximab combination chemotherapy	NA	V/V (8) V/F (51) F/F (43)	Nested PCR followed by allele-specific restriction enzyme digestion	FcγRIIIA polymorphisms have no effect on the outcomes of patients treated with risk-adapted chemotherapy with or without rituximab

Ahlgrimm <i>et al.</i> ^[30] (2011)	Caucasian DLBCL (263)	H/H (105) HR (235) R/R (64)	V/V (76) V/F (140) F/F (47)	TaqMAN SNP Assay	in patients treated with R-CHOP, the EFS and PFS, but not the OS, curves for FcγRIIIa 158 F/F showed a trend to be lower than of 158 V/F and 158 V/V
Fabisiewicz <i>et al.</i> ^[31] (2011)	Caucasian DLBCL (87) R-CHOP	H/H (27) HR (40) R/R (20)	V/V (15) V/F (35) F/F (37)	TaqMAN SNP Assay	Neither FcγRIIIa nor FcγRIIIA allele was statistically significantly related to OS and PFS
Varoczy <i>et al.</i> ^[35] (2012)	Caucasian DLBCL (51) R-CHOP	NA	V/V (12) V/F (29) F/F (10)	TaqMAN SNP Assay	The EFS data were less favorable in the F-allele carriers than in V/V homozygous patients, but not significantly, and OS was almost the same
Ghesquieres <i>et al.</i> ^[33] (2012)	Caucasian FL (460) Rituximab combination chemotherapy	H/H (127) HR (226) R/R (102)	V/V (68) V/F (215) F/F (177)	TaqMAN SNP Assay	FCGR3A and FCGR2A polymorphisms do not affect response rate and outcome when rituximab is combined with chemotherapy or used as maintenance treatment
Persky <i>et al.</i> ^[34] (2012)	Caucasian FL (142) Chemotherapy or Chemotherapy plus CD20 mAb	H/H (17) HR (40) R/R (9)	V/V (5) V/F (29) F/F (20)	TaqMAN SNP Assay	FcγRIIIa polymorphism status may be predictive of survival in FL patients receiving treatments containing an anti-CD20 antibody but not treatment with chemotherapy alone
Liu ^[37] (2014)	Asian DLBCL (164) R-CHOP		V/V (14) V/F (59) F/F (91)	Nested PCR	FcγRIIIa V/V allele was borderline significantly correlated with PFS, but it was not correlated with better OS
Ghesquieres <i>et al.</i> ^[36] (2017)	Caucasian DLBCL (1134) Rituximab combination chemotherapy	H/H (289) HR (579) R/R (266)	V/V (144) V/F (513) F/F (449)	TaqMAN SNP Assay Illumina Infinium array Pyrosequencing	Meta-analysis of two prospective studies. FCGR3A was not associated with EFS and OS. FCGR2A (per R allele) was associated with a better EFS and OS

DLBCL: diffuse large B-cell lymphoma; PFS: progression-free survival

expressed antibodies bearing bisecting N-acetylglucosamine. Now, the Potelligent™ technology is used for the development of mogamulizumab, and the Glycomab™ technology is used for obinutuzumab.

On the other hand, there are gene polymorphisms of *FcGR* as a host factor, and among them, polymorphisms of *FCGR2A* and *FCGR3A* are reported to be related to ADCC activity. A coding polymorphism in the extracellular domain of *FCGR2A* has been described where a C>T substitution (rs1801274) changes the amino acid at position 131 from histidine to arginine (H131R). A second important *FcGR* coding polymorphism occurs in extracellular domain 2 of *FCGR3A*; a T>G substitution changes valine to phenylalanine at position 158 (V158F, rs396991).

Although many studies have been conducted on trastuzumab and rituximab as to whether these gene polymorphisms affect the efficacy of antibody drugs, many conflicting reports have been published [Table 3]. For trastuzumab, FcGR2A H/H and FcGR3A V/V are reported to be correlated with prolongation of progression-free survival (PFS) in metastatic breast cancer, FcGR2A H/H and FcGR3A V/V were reported to be correlated with pathological complete remission in the neo-adjuvant setting, and no obvious correlation was found between FcGR and overall survival in the adjuvant setting; thus, there is still no unified view^[19-22]. Similarly, rituximab has been investigated for its effect on drug efficacy against follicular lymphoma and diffuse large B cell lymphoma (DLBCL), but there are no reports of statistically significant effects, except in the early 2000s^[23-37]. As described above, *FcGR* SNPs and the ADCC activity of antibody drugs are clear *in vitro*, but their relationship with clinical efficacy is not clear. The reasons for this include the validity of the SNP verification method, the possibility that the number of cases needed to verify the effect of SNP

on ADCC activity has not been collected, and the possibility that there are individual differences in the number or function of host immune cells that exert ADCC activity. The search for further mechanisms and factors involved in ADCC is desirable.

Immune-checkpoint inhibitors

In recent years, ICIs that activate the exhausted immune cells by inhibiting immune checkpoint molecules typified by CTLA4 and PD-1/PD-L1 pathways with antibody drugs have been key drugs for the treatment of malignant melanoma and non-small cell lung cancer. To date, 1 anti-CTLA4 antibody (ipilimumab), 2 anti-PD-1 antibodies (nivolumab and pembrolizumab), and 3 anti-PD-L1 antibodies (atezolizumab, durvalumab, and avelumab) have been marketed. Anti-PD-1 antibodies have IgG1 isoforms, and the other ICIs have IgG4 isoforms. All drugs have anti-tumor effects, mainly due to neutralization or signal inhibition, with dramatic therapeutic effects in many cancer types such as malignant melanoma, NSCLC, and merkel cell carcinoma^[38]. However, ICIs have unclear drug efficacy biomarkers, and they cause immune-related adverse events (irAEs) that are different from the adverse events of conventional anticancer drugs. IrAEs occur due to the activation of host immunity by ICIs, causing immune response disorders and hormonal abnormalities in organs such as the thyroid, lungs, and pancreas. Although myelotoxicity and gastrointestinal toxicity are less likely than with cytotoxic chemotherapy, irAEs can sometimes be life threatening. Moreover, various biomarker searches for PD-1 inhibitors, which are frequently used in clinical practice, have been investigated. Tumor PD-L1 expression, tumor mutation burden (TMB), T cell receptor (TCR) repertoire, human leukocyte antigen (HLA), microbiome, etc. are attracting attention^[39]. ICIs activate host immunity by blocking the co-stimulatory/inhibitory pathway with antibody drugs, but the major signaling pathway of antigen-presenting cells and T cells is the binding of major histocompatibility complex (MHC) and TCR. Antigen-presenting cells present peptides produced from tumors as antigens, which are recognized by TCRs. From the above, peptides presented as antigens are factors on the tumor side, and MHC and TCR are factors on the host side.

Tumor antigen peptides that are factors on the tumor side include cancer testis antigens such as the melanoma-associated antigens (MAGEAs) and New York esophageal squamous cell carcinoma 1 that are expressed in tumors regardless of gene mutations, and tumor antigen peptides generated by tumor gene mutations. The number of tumor non-synonymous mutations is called the TMB, and it is attracting attention as an index of tumor immunogenicity, especially in melanoma and NSCLC that typically have high mutation burdens due to the mutagenic effects of ultraviolet light and cigarette smoking, respectively^[40]. In 2014, Snyder *et al.*^[41] performed 64 whole-exome sequencing of melanoma patients treated with CTLA-4 antibody and showed significantly higher TMB in patients with stable or responsive disease for more than 6 months, and TMB more than 100 was associated with better overall survival^[41]. This result was confirmed by examination of CTLA-4 antibody against other malignant melanoma cohorts, and it was shown that the higher the TMB of non-small cell lung cancer, the better the response rate and PFS of PD-1 antibody^[42,43]. Since then, many cancer types have been shown to have a linear response rate with TMB, and it has become clear that TMB can help predict certain therapeutic effects^[44]. However, some cancer types do not follow this linear response. For example, merkel cell carcinoma and renal cell carcinoma are more sensitive than expected to TMB, whereas mismatch-repair (MMR)-proficient colorectal cancer is less sensitive than expected. That is, although TMB has some degree of correlation with the therapeutic effect, other factors are also assumed to be related to the therapeutic effect of ICIs. In addition, technical issues still remain, such as the fact that TMB does not have a confirmed calculation method and cut-off criteria, and whether analysis samples are performed with tumor samples or cell-free DNA.

Like TMB, DNA MMR defects (MMRds) are considered biomarkers of ICIs by causing somatic mutations. Le *et al.*^[45,46] showed that pembrolizumab had a response rate of 53% in 86 cases with 12 cancer types of

tumors with MMRds exhibiting micro-satellite instability (MSI), showing a robust efficacy regardless of the type of cancer^[45,46]. From these results, nivolumab and pembrolizumab were first approved by the FDA in 2017 with the genotype MSI-positive regardless of cancer type.

The HLA genotype is important as a host element. HLA class I is rich in sequence diversity of peptide binding sites. The HLA-I allele is encoded by three genes on chromosome 6 (HLA A, HLA B, and HLA C), and each of these variants constitutes a slightly different peptide. Chowell *et al.*^[47] examined the genotype of HLA-I in 1535 patients treated with ICIs. They found that patients with HLA-B44 supertype showed prolonged survival, and patients with HLA-B62 supertype or somatic loss of heterozygosity at HLA-I showed reduced survival^[48]. Chowell *et al.*^[48] analyzed the expression of MHC class I and II in tumor tissues in malignant melanoma treated with ipilimumab, nivolumab, or their combination. They found that 78 of 181 cases (43%) showed disappearance of MHC class I, which was correlated with initial tolerance of ipilimumab. In addition, MHC class II expression was observed in 55 of 181 cases (30%), and a correlation with the therapeutic effect of nivolumab was demonstrated^[48].

As described above, several pharmacogenomic factors on the tumor side and host side are attracting attention as ICI efficacy biomarkers. It is difficult to establish a single biomarker for ICIs because there are multiple factors, such as blocking efficiency of the signal pathway and immune environment, on the host side. In particular, the host immune system is considered to be a large factor, and identification of a pharmacogenomic factor that is an index of host immune responsiveness is required.

Antibody-drug conjugate

Currently, antibody-antibody drugs (ADCs), which are obtained by linking a cytotoxic anticancer drug (called “payload”) to the antibody with a linker, have rapidly developed as a new antibody treatment strategy against cancer. The ADC is an innovative drug design approach that increases the local concentration of payload only around the target due to the high target selectivity of antibody drugs (called “bystander effect”). Drugs such as KS1/4-methotrexate and BR96-doxorubicin were developed as the first-generation ADCs in the 1980s, but their efficacy was not satisfactory^[49,50]. This may be due to insufficient titer of the drug itself, wrong target antigen selection, poor internalization efficiency of the antibody, poor tumor accumulation, linker stability too high/low, and immune response to mouse antibodies. Gemtuzumab ozogamicin, an anti-CD33 ADC, received FDA approval for the first time as an ADC product in 2000^[51]. However, subsequent clinical trials found no clinical effect and increased fatal adverse events, and approval was withdrawn^[52,53].

In order to overcome the challenges of first-generation ADCs, appropriate target search and appropriate payload development are underway, and brentuximab vedotin (anti-CD30 ADC), ado-trastuzumab emtansine (anti-HER2 ADC), and inotuzumab ozogamicin (anti-CD22 ADC) were approved by the FDA as second-generation ADCs^[54]. However, the second-generation ADCs also have problems such as the presence of a few unbound types due to the instability of the linker, early clearance by becoming a free drug, and causing off-target toxicities. The development of these first- and second-generation ADCs showed that selections of appropriate tumor cell targets, payloads, antibodies, linkers, and payload binding sites were important points in drug discovery. In other words, if the appropriate target and an antibody with high binding power cannot be selected, the accumulation of ADC in the tumor will be reduced; if effective payload selection cannot be performed, sufficient cell killing effects cannot be achieved; if the stability of the linker is low, it will dissociate in the body and cause an off-target effect; and if the stability of the linker is too high, an effective bystander effect cannot be attained.

Based on the above, many third-generation ADC products are currently being developed [Table 4]. In particular, in June 2019, the FDA approved Genentech’s anti-CD79b ADC, polatuzumab vedotin (Polivy),

Table 4. Current status of antibody-drug conjugates

Generic name	Brand name/ investigational name	Company	Target	Payload	DAR	Major indication	Current status
Brentuximab vedotin	Adcetris	Seattle Genetics/ Takeda	CD30	MMAE	4	Hodgkin lymphoma	Approved
Gemtuzumab ozogamicin	Mylotarg	Pfizer	CD33	Calicheamicins	3	Acute myeloid leukemia	Approved
Trastuzumab emtansine	Kadcyla	Roche	HER2	DM1	3.5	Breast cancer	Approved
Inotuzumab ozogamicin	Besponsa	Pfizer	CD22	Calicheamicins	NR	Acute B-cell lymphoblastic leukemia	Approved
Polatuzumab vedotin	Polivy	Genentech	CD79b	MMAE	3.5	DLBCL	Approved
Telisotuzumab vedotin	ABBV-399	AbbVie	c-Met	MMAE	3.1	NSCLC, solid tumor	Phase 2
Samrotamab vedotin	ABBV-085	AbbVie	LRR15	MMAE	2	Sarcoma, HNSCC, Breast	Phase 1
Trastuzumab deruxtecan	DS-8201a	Daiichi Sankyo	HER2	DXd	8	Breast, Lung, Colon	Phase 3
-	DS-1062a	Daiichi Sankyo	Trop2	DXd	4	Solid tumor	Phase 1
-	U3-1402	Daiichi Sankyo	HER3	DXd	8	Breast, Lung	Phase 1
-	MORAB-202	Eisai	FOLR1	Eribulin	4	Solid tumor	Phase 1
Enfortumab vedotin	ASG-22CE	Astellas pharma/ Seattle genetics	Nectin-4	MMAE	NR	Urothelial	Phase 3
Tisotumab vedotin	HuMax-TF	Genmab/Seattle Genetics	TF	MMAE	NR	Solid tumor, Cervical	Phase 2

MMAE: monomethyl auristatin E; AF-HPA: austatin F-HPA; DXd: exatecan derivative; NR: not reported

for relapsed/refractory DLBCL. This drug showed the surprising result that complete remission was obtained in 40% (16/40) in the polatuzumab vedotin and bendamustine plus rituzimab therapy group in the Phase 1b/2 trial (GO29365 study)^[55]. Currently, clinical trials are ongoing with hematological tumors such as follicular lymphoma and in combination with other drugs^[56]. Moreover, Daiichi Sankyo's novel anti-HER2 ADC, Ds8201a (Trastuzumab Deruxtecan), is under development. In breast cancer, multiple phase 3 studies for patients with HER2-positive cancer (DESTINY-Breast01: NCT03248492, DESTINY-Breast02: NCT03523585, DESTINY-Breast03: NCT03529110), a phase 3 study for HER2-low cancer (DESTINY-Breast04: NCT03734029), a phase 2 study for HER2-positive gastric (DESTINY-Gastric01: NCT03329690), lung (NCT03505710), and colon cancers (NCT03384940), and combined use with ICIs (NCT04042701, NCT03523572) are in progress. A recently reported Phase 1 trial for HER2-positive advanced breast cancer showed a surprising response rate of 59.5% despite a previous heavy treatment history with trastuzumab or T-DM1^[57]. On the other hand, as an adverse event, pneumonitis was reported in 20 cases, and 2 fatal cases also occurred. Currently, the FDA has granted Fast Track and Breakthrough Therapy designations, and early approval is expected.

As shown in Table 4, there are currently 14 ADCs showing relatively good progress. Each drug targets not only HER2, but also HER3, Trop2, FOLR1, c-Met, AXL, and other molecules that are specifically expressed in tumors. Of 14 ADCs, 10 drugs used tubulin inhibitors (including 6 MMAE, 2 Maytansinoid DM4, 1 Eribulin, and 1 AF-HPA), and 4 drugs used a DNA topoisomerase I inhibitor (3 DXd, 1 SN38). In previous generations of ADCs, tubulin inhibitors were used in about 60% or more of payloads, but ADCs using a topoisomerase I inhibitor are increasing. In addition to improving the payload, each company is improving

the drug-antibody ratio, the stability of the linker, and the cancer cell specificity, which have been issues with ADCs. In addition to the development of ADCs alone, their combination with ICIs is being actively developed.

Although it is expected that there will be a wider range of options for antibody therapy, the pharmacogenomic factors in ADCs are not clear so far. Since the antibody part is IgG1 in many ADCs, the above-mentioned FcγR polymorphism may have an effect. There is also concern about the effects of metabolic and excretory enzymes in the payload. For example, there are reports that ABCC1 overexpression is involved in drug resistance to trastuzumab emtansine, and that ABCB1 is associated with the efficacy of gemtuzumab ozogamicin^[58,59]. In addition, MMAE, frequently used as a payload in many ADCs, is a CYP3A4 substrate, and eribulin is also a CYP3A4 substrate and an ABCB1 substrate. In other words, classical pharmacogenomic factors such as ABC transporter and CYP may affect metabolism and excretion of payloads and thus drug efficacy even in ADCs.

Moreover, recent ADC adverse events in clinical trials raise new concerns about immunogenicity. It has been reported that Ds8201a has a high incidence of pneumonitis, and this was the same case with Morab-202, which showed pneumonitis in 3 of 19 cases (15.8%)^[60]. Since the frequency of pneumonitis is not high with antibody drugs alone, pneumonitis may be a characteristic adverse event of ADCs. It is desirable to examine the pharmacogenomic factors of ADCs that are expected to be used more frequently in the future, including the enhancement of immunogenicity due to the linkage between linker and payload, and the possibility of affecting the responsiveness of host immunity.

As described above, ADCs have developed rapidly in recent years, but pharmacogenomic factors have not been fully studied. In addition to analyzing classical ABC transporters and CYP polymorphisms, pharmacogenomic analyses including host factors for characteristic adverse events such as lung injury are greatly needed.

FUTURE DIRECTION OF RESEARCH

There are still many black boxes in the pharmacokinetics of antibody drugs. Despite confirming doses several tens of times for the target occupancy in preclinical research, antibody blood concentrations in clinical practice may vary widely. Until now, it has been said that the pharmacokinetics of antibody drugs are not related to renal function, liver function or metabolic pathway, however, increased catabolism associated with organ dysfunction may affect the pharmacokinetics of antibody drugs. Furthermore, it is not clear whether the blood concentration of antibody drugs is correlated with the intratumoral concentration. It is necessary to identify the detailed pharmacokinetics of antibody drugs and the factors that affect the pharmacokinetics.

Another issue that must be considered is biosimilars. Unlike generic drugs, biosimilars cannot prove the identity of active ingredients. Therefore, at the time of approval, structural similarity is shown in a comparative quality study, PD and toxicity are shown in a comparative preclinical study, and PK, safety and efficacy are confirmed in a comparative clinical study. However, comparative clinical trials are only specifically designed to rule out clinically relevant differences in safety or efficacy between the biosimilar and the reference medicine, and to confirm biosimilarity. Differences in sugar chain modification and activity between lots have also been pointed out in the previous products, and it is still unclear whether biosimilars can exhibit sufficient pharmacokinetics and antitumor effects in clinical practice^[61]. In addition, it will be necessary to verify immunogenicity and pharmacogenomic differences.

CONCLUSION

The pharmacogenomics of antibody drugs is a complex area with more relevant factors than small molecule compounds. It is expected that pharmacogenomic factors related to drug efficacy and adverse events will be identified by comprehensively analyzing not only PK and PD, but also multiple factors such as host immune environment and genetic factors.

Abstract

Unresectable recurrent or metastatic head and neck cancer is an incurable disease with survival of approximately 12 months. Head and neck tumors exhibit numerous derangements in the tumor microenvironment that aid in immune evasion and may serve as targets for future therapies. Pembrolizumab is now approved as a first line therapy. Despite the promise of currently approved immunotherapies there continues to be low response rates and additional strategies are needed. Here, alterations in the immune microenvironment and current therapeutic strategies are reviewed with a focus on novel immunologic approaches.

Keywords: Immunotherapy, head and neck, immune evasion, immune derangement, checkpoint inhibitors, recurrent/metastatic

INTRODUCTION

Head and neck squamous cell carcinoma (HNSCC) represents the 6th most common malignancy globally and accounts for 1%-2% of all cancer related deaths^[1]. HNSCC is comprised of a heterogenous group of tumors including those arising from the oral cavity, oropharynx, hypopharynx and larynx. Traditional risk

factors include tobacco, alcohol, and more recently human papillomavirus (HPV). High risk strains of HPV (HPV 16, 18) now are responsible for 70%-80% of oropharyngeal squamous cell carcinoma^[2,3].

Treatment of HNSCC varies by tumor site and stage, however the mainstays of treatment include surgery, radiation, and cytotoxic chemotherapy. Despite advancements in surgical and radiation techniques, treatment failures occur in up to 50% of patients with HNSCC^[4,5]. In the unresectable recurrent or metastatic (R/M) setting, chemotherapy has previously been the main therapeutic option, with dismal outcomes and median survival times ranging from 6-10 months^[6]. Immunotherapy, particularly checkpoint inhibitors, have shown promising results in R/M HNSCC^[7,8]. In June of 2019, the United States Food and Drug Administration approved pembrolizumab as a 1st line treatment for patients based on PD-L1 expression in the tumor immune microenvironment^[9]. Despite these recent reports, overall response rates remain low with underwhelming improvements in long term survival. Hence there continues to be a need for novel therapeutic options.

Head and neck tumors display various derangements in anti-tumor immunity and detailed understanding of these changes has led to development of currently approved immunotherapies. Here, we discuss alterations in the tumor immune microenvironment, review the mechanism of current treatments and focus on approaches for development of novel immunologic therapies.

DERANGEMENT OF HEAD AND NECK TUMOR IMMUNE MICROENVIRONMENT

Tumor immunity cycle

Anti-tumor immunity requires a complex set of interactions between the tumor and host immune system. This process has been termed the cancer immunity cycle^[10,11]. Initial tumor cell lysis results in release of tumor specific antigens (TAs) and priming of antigen presenting cells (APCs). APCs then interact with host immune cells resulting in activation and trafficking of cytotoxic T cells (CTLs) into the tumor. Once in the tumor, CTLs identify malignant cells displaying the specified tumor antigen and target them for cell death. Tumor antigens also referred to as neoantigens have become an area of intense research. These can be derived from either driver or passenger mutations and generation of TAs is thought to be closely linked to mutational burden, with a higher mutational load correlating to increased TAs^[12,13]. HNSCC has been found to have 1 of highest mutational burdens of all malignancies, likely due to their relationship with carcinogen exposure (i.e., tobacco smoke) which results in significant mutagenesis^[13,14]. As sequencing techniques have advanced, more sophisticated modeling has allowed for identification of specific mutational profiles including smoking and APOBEC signatures as well as prediction of neoantigen load^[15]. Detailed review of neoantigen prediction modeling has previously been published and is outside the scope of this review^[16-19]. Finally, with targeted tumor cell death by CTLs there is further release of tumor antigens resulting in perpetuation of the cycle. Head and neck tumors have evolved multiple mechanisms of immune escape which will be reviewed below in context of the cancer-immunity cycle.

Inhibition of antigen processing and presentation and immune cell activation

While HNSCC is thought to be highly antigenic, further steps are required for activation of a TA-specific adaptive immune response. After being released from tumor cells, TAs are degraded, processed, and presented by professional APCs including dendritic cells. Normal processes allow for extracellular protein presentation through major histocompatibility complex (MHC) class II and CD4 interaction, however, for TA to activate a CD8 response, cross presentation occurs, requiring an additional set of processing machinery^[20]. Large scale sequencing studies as well as analysis of TCGA data have revealed that up to 20% of HNSCCs contain alterations in antigen processing machinery (APM) or downregulation of MHC class I^[20,21]. In HPV positive tumors, the latter is thought to be mediated through viral oncoproteins, E5 and E7, which have been shown to downregulate both MHC class I and class II^[22-24]. Additional studies show that patients with

alterations in these pathways had both decreased CD8 T cell infiltration and worse survival outcomes^[25,26], indicating inhibition of antigen presentation may play a key role in head and neck tumor immune escape.

Once primed, APCs interact with and activate CTLs. Activation of CTLs occurs through contact between the T cell receptors and MHC class I bound to TA. This process requires a co-stimulatory signal between CD80 (present on the surface of the APC) and CD28 (a surface receptor on the CTL). Conversely, CD80 may instead bind CTL associated antigen 4 (CTLA-4) leading to CTL inhibition^[11,27,28]. While in normal physiologic conditions, the CTLA-4 immune checkpoint prevents an exaggerated immune response, in the setting of malignancies, it is thought to be a major mechanism of immune escape^[27,28].

Immune cell trafficking and infiltration

After priming and activation, CTLs infiltrate the tumor where they identify malignant cells displaying the specific TAs. In order for successful immune cell trafficking to occur, there must be appropriate cytokine signaling as well as an optimized physical environment. Physical blockade of immune cell infiltration has been suggested to play a role in immune escape and is thought to be mediated through elevated vascular endothelial growth factor (VEGF) signaling. This results in increased angiogenesis and increased oncotic pressure within the tumor creating a physical barrier to infiltration^[29]. *In vivo* studies evaluating anti-angiogenic tyrosine kinase inhibitors have shown an increase in tumor infiltrating lymphocytes correlating with reduced angiogenesis^[30,31]. Tumors may also promote an immune deplete environment through recruitment of suppressive and regulatory immune cells. This is achieved through direct secretion of suppressive cytokines such as tumor growth factor beta (TGF- β), or through secretion of CCL, CXCL, or VEGF which recruit myeloid derived suppressor cells (MDSC)^[32-34]. MDSCs are able to directly induce T cell tolerance through arginase, nitric oxide synthase^[35] and indoleamine 2,3-dioxygenase (IDO)^[36] dependent mechanisms^[32,37,38]. In HNSCC, increased tumor lymphocyte infiltration is linked to improved prognosis^[39-41], while elevated levels of MDSCs have been linked worse prognosis^[38,42].

PD-1/PD-L1 axis inhibition

Once in the tumor, CTLs induce tumor cell death. However, tumor cells may inhibit cell killing via co-stimulatory signals through the PD-1/PD-L1 axis. PD-1 is a member of the CD28 superfamily and is expressed on dendritic cells, regulatory T cells (Treg), CD8 and CD4 T cells, MDSCs, and natural killer cells (NK)^[43]. PD-L1 is expressed on APCs and causes T cell anergy and apoptosis upon binding with PD-1 receptors, thereby serving as a check to prevent an overactive immune response^[44,45]. However, upregulation of PD-L1 or additional PD-1 ligands such as PD-L2 can also be seen on tumor cells and acts as a mechanism of immune escape in various malignancies^[46]. The interaction between PD-L1 and PD-1 is complex and has been previously explored in multiple reviews^[47,48]. In HNSCC, PD-1/PD-L1 expression has been reported in 46%-100% of tumors and with higher expression in HPV-positive tumors compared to HPV negative tumors^[46,49-51]. Multiple currently approved therapeutics have been developed to target the PD-1/PD-L1 axis, including Pembrolizumab and Nivolumab as well as additional therapeutics that are currently undergoing clinical investigation such as Atezolizumab, and Durvalumab among others [Figure 1]. Both Pembrolizumab and Nivolumab inhibit PD-1, while the latter 2 (Atezolizumab and Durvalumab) target PD-L1. As PD-1 can be activated by additional ligands such as PD-L2 there is a theoretical advantage to targeting PD-1 over PD-L1, however anti-PD-1 and anti-PD-L1 therapies have demonstrated similar response rates and toxicity profiles in clinical trials as discussed below.

IMMUNOMODULATORY MECHANISMS OF TRADITION THERAPIES

Prior to review of current immunotherapeutics, it is prudent to discuss the immunomodulatory role of traditional therapies. Both platinum based chemotherapy and radiation have been shown to alter the tumor immune microenvironment. *In vivo* studies revealed that cisplatin treatment increases expression of MHC class I and antigen presentation machinery in patient derived HNSCC cell lines^[52]. While these

Mechanism of Action of Checkpoint Inhibitors

Figure 1. Mechanism of action of checkpoint inhibitors. APC: antigen presenting cell; MHC: major histocompatibility complex

changes may improve the anti-tumor immune response, this same study also demonstrated increased PD-L1 expression, decreased IFN- γ release by Tregs, and increased antigen specific T cell death with cisplatin treatment^[52,53]. These alterations in the tumor immune microenvironment suggest potential for dual treatment with cisplatin and anti-PD-1/PD-L1 immunotherapeutics, and *in vivo* studies have shown benefit of combination therapy^[52]. While cisplatin leads to increased Treg populations in HNSCC, similar studies performed in other types of malignancies have found that cisplatin treatment can actually lead to decreased Treg function and CTL activation by dendritic cells^[53,54]. These contradicting results suggest a complex mechanism by which cisplatin may affect the tumor microenvironment.

Radiation therapy (RT) is commonly used in the treatment of head and neck cancer and has also been shown to play a regulatory role in the tumor immune microenvironment. The specific mechanism by which radiation enhances the immune system is multifactorial. RT has been shown to increase production of TA^[55], increase expression of MHC class I and APM components^[56-58], and increase the number of tumor infiltrating lymphocytes^[59]. Similar to chemotherapy, RT can also suppress the immune response through recruitment of MDSCs and other suppressive immune cells^[60]. Further indication of the immunoregulatory effect of radiation is evident by the fact that radiation has been reported to induce tumor cell death in tumor deposits outside of the irradiated field. This is termed the abscopal effect and is thought to be an immune mediated response^[61,62].

MECHANISMS OF CURRENTLY APPROVED IMMUNOTHERAPEUTICS

In addition to traditional therapies, there are 3 currently approved biologics for HNSCC including Cetuximab, Pembrolizumab, and Nivolumab, which have also been shown to have immunomodulatory mechanisms.

Cetuximab, a monoclonal antibody against epidermal growth factor receptor (EGFR), was designed as a targeted therapy. However, recent studies have suggested that it may be tumoricidal via immune modulation^[63]. Accumulating evidence suggests that cetuximab increases antibody dependent cellular cytotoxicity (ADCC) of NKs^[63-65]. As Tregs inhibit NK mediated ADCC, through a TGF- β dependent pathway, it is postulated Cetuximab's mechanism of action may be through reduction or inhibition of Tregs. A recent study demonstrated a decrease in the number of Treg in peripheral blood samples in HNSCC patients treated with Cetuximab. This observed decrease in Treg population also correlated with improved overall survival in this cohort^[63]. Additional mechanisms of cetuximab have also been suggested, including increased crosstalk between dendritic cells and NK cells with further activation of the adaptive immune response, specifically targeting EGFR expressing cells^[66,67] and activation of the complement system^[68]. More recent studies have also indicated that cetuximab may increase CTLA-4 and PD-1/PD-L1 expression and suggest a need for combination therapies^[64,69].

Both Pembrolizumab and Nivolumab which target PD-1 have proven to have clinical benefit in patients with progressive disease after platinum based therapy^[7,70]. Initial approval for these drugs occurred in 2016 after the published results from multiple clinical trials were released. The phase III clinical trial, CHECKMATE-141, evaluated nivolumab *vs.* standard of care (SOC) chemotherapy in patients with platinum refractory R/M HNSCC. The overall response rate (ORR) for the nivolumab group was 13.3% compared to 5.5% in the SOC arm. Furthermore, nivolumab demonstrated an improved survival [7.5 months *vs.* 5.1 months (HR = 0.7, 97.7%CI: 0.51-0.96)] which was the 1st time a 2nd line agent demonstrated survival benefit^[7]. Similar results were seen in the KEYNOTE 040 trial, comparing Pembrolizumab to SOC in patients with R/M HNSCC who had failed platinum therapy. In this trial there was an ORR of 14.6% in the pembrolizumab group compared to 10.1% in the SOC group and a median OS of 8.4 months *vs.* 6.9 months (95%CI: 0.65-0.98)^[70]. Both studies had secondary endpoints evaluating survival outcomes stratified by PD-L1 status and revealed a greater benefit in patients with positive PD-L1 expression although not statistically significant. These results supported the use of nivolumab or pembrolizumab as a standard of care treatment for patients with platinum refractor R/M HNSCC.

Until recently, there has been no data supporting use of PD-1 inhibitors as a first line treatment option for R/M HNSCC. The results of the KEYNOTE 048 trial were presented at the 2019 American Society of Clinical Oncology meeting^[71]. This study evaluated the use of pembrolizumab alone, pembrolizumab with platinum and fluorouracil, *vs.* the EXTREME regimen in patients with R/M HNSCC. Results revealed an improvement in OS in all patients treated with pembrolizumab with a PD-L1 combined positive score $\geq 1\%$ by the 22C3 assay^[9].

While there are no mature data evaluating the effect of anti-PD-L1 therapeutics, such as Atezolizumab or Durvalumab, ongoing phase I and II trials have demonstrated excellent safety profiles with promising responses. A phase I trial published by Colevas *et al.*^[72] in 2018 enrolled 32 patients with advanced unresectable or incurable HNSCC who underwent treatment with Atezolizumab. The overall response rate in this cohort was 22% with a median progression free survival of 2.6 months and median overall survival of 6 months. Responses were found to be independent of PD-L1 expression level or HPV status. While 66% of patients experienced treatment related adverse events, only 4 patients (13%) had grade 3 or 4 toxicity. Given these results, a phase III randomized control trial is currently underway investigating the use of Atezolizumab in HNSCC (NCT03452137). Durvalumab has also been evaluated in Phase I/II trials in HNSCC. A study by Segal *et al.*^[73] published in 2019 examined 62 patients with unresectable and previously treated HNSCC treated with Durvalumab and found an ORR of 6.5% with a median overall survival of 8.4 months. Unfortunately, the results of the phase III EAGLE trial evaluating Durvalumab as single modality therapy in patients with progressive disease after platinum therapy was did not reveal any survival benefit alone or in combination with CTLA-4 inhibitor, Tremelimumab^[74]. An ongoing trial (NCT02551159)

Table 1. Checkpoint inhibitors in HNSCC

Immunotherapeutic	Target	Select ongoing trials
Pembrolizumab (Pembro)	PD-1	NCT03546582 (KEYSTROKE) - SBRT +/- Pembro in recurrent or secondary primary HNSCC NCT02641093 - Pembro + adjuvant RT or CRT (cisplatin) after surgery in HNSCC NCT02296684 - Neoadjuvant Pembro + SOC (surgery or RT) in high risk HNSCC NCT03765918 - Pembro before surgery and Pembro +/- Cisplatin and RT post-operatively in stage III-IV LA HNSCC
Nivolumab (Nivo)	PD-1	NCT03521570 - IMRT + Nivo for recurrent or second primary HNSCC after prior RT (resectable or eligible for curative re-irradiation) NCT03576417 - SOC (C/RT) +/- Nivo in HNSCC NCT03247712 - Nivo + RT prior to surgical resection of HNSCC
Atezolizumab	PD-L1	NCT03452137 - Atezolizumab or placebo as adjuvant therapy after definitive local therapy in high-risk LA HNSCC NCT03708224 - Effect of neoadjuvant Atezolizumab prior to surgical resection in HNSCC NCT03818061 - Atezolizumab + Bevacizumab in recurrent/metastatic previously treated HNSCC
Durvalumab	PD-L1	NCT03212469 - Durvalumab + RT or Durvalumab + Tremelimumab and SBRT in metastatic HNSCC (also includes lung and esophageal tumors) NCT02997332 (MEDINDUCTION) - Durvalumab + Docetaxel, Cisplatin and 5-FU for LA HNSCC NCT03635164 - Radiotherapy + Durvalumab before surgical resection for HPV negative HNSCC
Avelumab	PD-L1	NCT03498378 - Avelumab, Cetuximab, and Palbociclib in recurrent/metastatic HNSCC NCT02999087 - Avelumab-cetuximab-radiotherapy vs. SOC in LA HNSCC NCT03260023 - TG4001 and avelumab in patients with HPV-16 positive recurrent or metastatic malignancies (including OPSCC)
Ipilimumab	CTLA-4	NCT02812524 - Intratumoral injections of ipilimumab prior to surgical resection in HNSCC NCT03799445 - Ipilimumab, nivolumab, and RT for HPV positive OPSCC
Tremelimumab	CTLA-4	NCT03522584 - Tremelimumab + Durvalumab + hypofractionated RT in recurrent/metastatic HNSCC NCT03212469 - Durvalumab + RT or Durvalumab + Tremelimumab and SBRT in metastatic HNSCC (also includes lung and esophageal tumors) NCT02551159 (KESTREL) - MEDI 4736 +/- Tremelimumab vs. SOC in recurrent/metastatic HNSCC (active, not recruiting)
Relatlimab	Lag-3	NCT04080804 - Nivolumab +/- Relatlimab or Ipilimumab in head and neck cancer

HNSCC: head and neck squamous cell carcinoma; OPSCC: oropharynx squamous cell carcinoma; RT: radiation therapy; CRT: chemoradiation therapy; LA: locally advanced; SBRT: stereotactic body radiation therapy; SOC: standard of care; HPV: human papillomavirus

is evaluating Durvalumab with and without Tremelimumab in patients with R/M disease who have not received previous treatment for recurrent disease. A summary of select ongoing clinical trials investigating these therapies in addition to other checkpoint inhibitors is shown in [Table 1](#).

DEVELOPMENT OF NOVEL IMMUNOTHERAPEUTICS

Despite these encouraging results and updated treatment guidelines, it should be noted that overall response rates to these immunotherapies remains low for HNSCC and ongoing clinical trials are evaluating novel immunotherapeutic strategies [[Table 2](#)].

Oncolytic viruses provide potential for direct tumor cell lysis with further activation of an immune specific response. One of the most promising trials involving oncolytic vaccines in HNSCC to date evaluates the use of pembrolizumab in combination with Talimogene laherparepvec in patients with R/M disease. Final study results are pending, however initial updates suggest at least partial response in some patients (NCT02626000). Additional oncolytic viruses are also under early phase studies (NCT00625456, NCT03740256, NCT01584284).

Vaccinations represent a promising novel therapeutic strategy for various malignancies including HNSCC. Vaccines currently under investigation in HNSCC target patient specific TA (NCT03633110, NCT03548467), or TAs that are expressed in the majority of HNSCC such as mutant p53 (NCT02432963, NCT02955290, NCT02544880, NCT03946358). Additional vaccines are designed to enhance a general immune response such as those using the fowlpox-TRICOM vaccine (NCT00021424). For patients with HPV-mediated disease, the potential for vaccines targeting HPV specific peptides has gained enthusiasm

Table 2. Ongoing clinical trials

Category of therapy	Trial number (clinicaltrials.gov) - name/description
Oncolytic viruses	NCT02626000 (MASTERKEY232/KEYNOTE-137) - Talimogene Laherparepvec + Pembro in recurrent/metastatic HNSCC NCT00625456 - Safety study of recombinant vaccinia virus to treat refractory solid tumors NCT03740256 - Attenuated vaccinia virus (GL-ONC1) in combination with cisplatin and radiation therapy in locoregionally advanced HNSCC
Cancer vaccines	NCT03633110 - Safety, tolerability, immunogenicity, and antitumor activity of GEN-009 adjuvanted vaccine NCT03548467 - Safety, feasibility, efficacy of multiple dosing with VB10.NEO immunotherapy in patients with LA or metastatic solid tumors NCT02432963 - p53MVA vaccine (modified vaccinia virus ankara vaccine expressing p53) + Pembro in solid tumors after failed prior therapy NCT02955290 - Human EGF-rP64K/montanide ISA 51 vaccine (CIMAavax) + nivolumab in advanced HNSCC and non-small cell lung cancer NCT02544880 - PDE5 inhibition via Tadalafil to enhance anti-tumor mucin 1 (MUC1) vaccine efficacy in patients with HNSCC NCT03946358 - Combination of UCPVax vaccine and Atezolizumab for the treatment of human papillomavirus positive cancers (VolATIL) NCT00021424 - Recombinant fowlpox-TRICOM vaccine therapy in stage IV HNSCC NCT03418480 - Phase I/II vaccine dose escalation study with intradermal injections of HPV anti-CD40 RNA vaccine (HARE-40) in patients with advanced HPV 16 + cancers NCT03260023 - TG4001 and Avelumab in patients with HPV-16 positive recurrent or metastatic malignancies (including OPSCC) NCT00257738 - 0804 GCC: MAGE-A3/HPV 16 vaccine for squamous cell carcinoma of the head and neck NCT02002182 - DXS 11-001 vaccination prior to robotic surgery, HPV-positive OPSCC
Immunomodulatory	NCT03689192 - Arginase-1 peptide vaccine in patients with metastatic solid tumors NCT02752074 (Keynote-252/ECHO-301) - A phase 3 study of pembrolizumab + epacadostat or placebo in subjects with unresectable or metastatic melanoma NCT02740270 - Phase I/Ib study of GWN323 alone and in combination with PDR001 in patients with advanced malignancies and lymphomas NCT02274155 - Anti-OX40 antibody in head and neck cancer patients
T-cell therapy	NCT03578406 - HPV-E6-specific anti-PD1 TCR-T cells in the treatment of HPV-positive HNSCC or cervical cancer

HNSCC: head and neck squamous cell carcinoma; OPSCC: oropharynx squamous cell carcinoma; LA: locally advanced; HPV: human papillomavirus

and there are multiple ongoing trials investigating vaccines in this subset (NCT03418480, NCT03260023, NCT00257738, NCT02002182).

Both oncolytic viruses and vaccine therapy aim to promote a tumor specific adaptive immune response. Additional novel therapeutics have also been developed to try to remove the inhibitory signals that suppress an already active immune response.

One example of this strategy is the targeting of MDSCs, as multiple studies have shown these cells to be present in high abundance in HNSCC^[38,75]. *In vivo* studies have shown that elimination of MDSCs from the tumor microenvironment results in decreased Tregs and increased activity of CTLs^[76]. As discussed above, Arg, NOS, and IDO are thought to play a role in MDSC mediated Treg function; thus, drugs targeting these pathways are of particular interest. Phosphodiesterase-5 inhibitors are known to reduce both NOS and Arg production and a recent clinical trial leveraged the already FDA approved drug Tadalafil for use in HNSCC. In this randomized, double blinded, placebo controlled trial, patients with previously untreated (primary or recurrent) HNSCC received either tadalafil or placebo for 10 or more days prior to definite treatment. This study revealed decreased MDSC and Treg populations in the tadalafil treated cohort compared to placebo controls as well as increased CTL activity. Subgroup analysis of patients with available tumor specimens ($n = 6$) demonstrated increased tumor specific immunity in the Tadalafil treated group^[37]. No measures of survival outcomes were reported for this study. An additional clinical trial (NCT03689192) evaluating a vaccine targeting arginase is also currently underway.

Inhibition of IDO in combination with Pembrolizumab has also been under intense study in various malignancies^[77]. In HNSCC, a phase III clinical trial evaluating IDO inhibitor, Epacadostat in combination

with Pembrolizumab (NCT02752074), was unfortunately halted after a similar trial in melanoma revealed no improvement in overall or progression free survival with the addition of Epacadostat to pembrolizumab compared to the control arm^[36].

Additional therapies targeting immunosuppressive cytokines have also been developed^[78]. Current trials investigating antagonists of TNF receptor aims to inhibit Treg activity and are being tested both as monotherapy and in combination with anti-PD-1 therapies in HNSCC (NCT02740270, NCT02274155).

The final step in the cancer immunity cycle involves tumor cell death induced by activated CTLs. The ideal immunotherapy would bypass the preceding steps and provide T cells already primed to patient specific antigens. This has been successful in hematologic malignancies with therapies such as CAR-T and multiple ongoing clinical trials are investigating the use of T-cell therapies in solid malignancies as well^[79]. A clinical trial investigating the use of adoptive T cell transfer in HPV mediated disease in currently ongoing (NCT03578406). A previous study has shown some promise in seven patients with head and neck cancer (5 with SCC, 1 with melanoma and 1 with spindle cell sarcoma)^[80].

There are also ongoing trials assessing unique approaches that target multiple aspects of the immune cycle. MVX-ONCO-1 is a treatment that involves subcutaneous injection of capsules containing immune-modulatory granulocyte-macrophage colony stimulating factor and irradiated tumor cells with the aim of stimulating a tumor specific immune response (NCT02999646).

CONCLUSION

HNSCC represents a diverse group of diseases and exhibits varying degrees of immune dysregulation. Traditional therapeutic approaches are curative in 50% of patients and have proven to have immunomodulatory effects. Currently approved immunotherapies have shown some promise but unfortunately only a small fraction of patients benefit. This review summarizes the most common immune disruptions identified in head and neck cancer and discusses ongoing approaches aimed at targeting the tumor immune microenvironment.

Abstract

Aim: Colorectal cancer (CRC) is the third leading cancer-related cause of death due to its propensity to metastasize. Epithelial-mesenchymal transition (EMT) is a multistep process important for invasion and metastasis of CRC. Krüppel-like factor 4 (KLF4) is a zinc finger transcription factor highly expressed in differentiated cells of the intestinal epithelium. KLF4 has been shown to play a tumor suppressor role during CRC tumorigenesis - its loss accelerates development and progression of cancer. The present study examined the relationship between KLF4 and markers of EMT in CRC.

Methods: Immunofluorescence staining for KLF4 and EMT markers was performed on archived patient samples after colorectal cancer resection and on colonic tissues of mice with colitis-associated cancer.

Results: We found that KLF4 expression is lost in tumor sections obtained from CRC patients and in those of mouse colon following azoxymethane and dextran sodium sulfate (AOM/DSS) treatment when compared to their respective normal appearing mucosa. Importantly, in CRC patient tumor sections, we observed a negative correlation between KLF4 levels and mesenchymal markers including TWIST, β -catenin, claudin-1, N-cadherin, and

vimentin. Similarly, in tumor tissues from AOM/DSS-treated mice, KLF4 levels were negatively correlated with mesenchymal markers including SNAI2, β -catenin, and vimentin and positively correlated with the epithelial marker E-cadherin.

Conclusion: These findings suggest that the loss of KLF4 expression is a potentially significant indicator of EMT in CRC.

Keywords: Krüppel-like factor 4, colorectal cancer, epithelial-mesenchymal transition

INTRODUCTION

Colorectal cancer (CRC) is the third leading cause of the cancer-related deaths often with metastasis to the liver, lung, and bone^[1,2]. Epithelial-mesenchymal transition (EMT) is a transdifferentiation process that allows a polarized epithelial cell to assume a mesenchymal cell phenotype, characterized by enhanced migratory and invasiveness capacity, elevated resistance to apoptosis, and increased synthesis of extracellular matrix (ECM) components^[3]. During the EMT process, epithelial cells lose apical-basal polarity that is accompanied by reorganization of cytoskeleton and reprogramming of the signaling pathways that allow for an increase in motility and the development of an invasive phenotype. This multistep complex process is characterized by modifications in the expression of a host of transcription factors and specific cell-surface proteins, as well as reorganization and expression of cytoskeletal proteins, and production of enzymes that degrade the ECM^[3]. A change in some of these factors, such as upregulation of TWIST, SNAI1, SNAI2, ZEB1, vimentin, and N-cadherin, and downregulation of E-cadherin and tight junction proteins such as ZO-1 is indicative of progression of EMT^[4,5]. In CRC, EMT has been strongly associated with the invasive and metastatic phenotype, thereby generating the life-threatening manifestations of metastatic disease cancer. The activation of the EMT program has been suggested to be the critical mechanism for the acquisition of malignant phenotypes by epithelial cancer cells^[3].

Krüppel-like factor 4 (KLF4) belongs to the family of zinc-finger transcriptions factors that play critical roles during development, proliferation, differentiation, and homeostasis, as well as development and progression of many diseases including inflammation and carcinogenesis^[6-8]. In the digestive tract, KLF4 is predominantly expressed in differentiated cells of the villus and surface epithelium of the small intestine and colon, respectively^[9-13]. Importantly, evidence indicates that KLF4 functions as a tumor suppressor that inhibits progression of CRC^[12]. It has been shown that loss of KLF4 expression is associated with the early stage of CRC development and that KLF4 is a prognostic indicator for CRC survival and recurrence^[14,15]. Recently, we demonstrated that KLF4 also plays a protective role against tumor formation during inflammation-induced colorectal tumorigenesis^[16-18]. The biochemical mechanisms triggering the acquisition of the invasive phenotype and the subsequent systemic spread of the cancer cell have been areas of intensive research. Here, we demonstrate that KLF4's role in colorectal tumorigenesis extends to its ability to regulate EMT.

METHODS

Samples from patients

Surgical specimens of resected colorectal cancer specimen obtained from Stony Brook University and State University of New York Downstate were used in this study. In total, 12 specimens were processed for immunofluorescence. All samples were of Caucasian origin, with 2 female and 10 male. One sample was qualified as stage I, one as stage 2, two as stage 3, and eight as stage IV [Table 1]. The protocol for the sample collection was originally approved by the Institutional Review Board by the State University of

Mice

All animal studies were approved by the Stony Brook University Institutional Animal Care and Use Committee and performed in accordance with institutional policies and NIH guidelines. Mice with the floxed *Klf4* gene (*Klf4^{fl/fl}*) were described previously^[12]. These mice were derived from a C57BL/6 background and are indistinguishable from the wild-type mice.

Azoxymethane and dextran sodium sulfate treatment

Azoxymethane (AOM) and dextran sodium sulfate (DSS) treatment was performed as described previously^[18]. Briefly, adult gender- and age-matched *Klf4^{fl/fl}* mice ($n = 16$) were injected intraperitoneally with 10 mg/kg of AOM working solution. After seven days, normal water was replaced with 2.5% DSS in the drinking water for five days, followed by two weeks of recovery (with normal water). This was followed by a second cycle of 2.5% DSS for five days, with two weeks of recovery (with normal water). The mice were euthanized at the end of the last recovery treatment, and samples were collected for pathologic analysis.

Tissue harvesting and tumor assessment, preparation, and immunostaining

Tissues were collected and prepared for immunofluorescence as described previously^[18]. Briefly, tissue sections were baked in a 65 °C oven overnight, deparaffinized in xylene, and rehydrated by incubation in a decreasing ethanol bath series (100%, 95%, and 70%), followed by antigen retrieval in citrate buffer solution (10 mM sodium citrate and 0.05% Tween-20, pH 6.0) at 120 °C for 10 min using a decloaking chamber (Biocare Medical) and 30 min incubation at 4 °C. The histological sections were incubated with blocking buffer (5% bovine serum albumin and 0.01% Tween 20 in 1 × Tris-buffered phosphate-buffered saline) for 1 h at 37 °C. The primary antibodies goat anti-KLF4 (1:200 for human sections and 1:300 for mice sections; R&D: AF3158), mouse anti-PanCK (1:200 for human sections; Biocare Medical: AE1/AE3), rabbit anti-β-catenin (1:500 for human sections and 1:150 for mice sections; Cell Signaling: 8480), rabbit anti-TWIST (1:500; Abcam: ab49254), rabbit anti-Claudin-1 (1:500; Cell Signaling: 13255), rabbit anti-N-cadherin (1:500; Cell Signaling: 13116), rabbit anti-E-cadherin (1:300 for mice sections, Cell Signaling: 3195), rabbit anti-Vimentin (1:500 for human sections and 1:100 for mice sections; Cell Signaling: 5741), and rabbit anti-SNAI2 (1:500 for human sections and 1:400 for mice sections, Cell Signaling: 9585) were added and incubated at 4 °C overnight. For KLF4, secondary unconjugated bovine anti-goat antibody was added at 1:500 dilution in blocking buffer for 30 min at 37 °C. For human sections to stain for PanCK, secondary unconjugated chicken anti-mouse antibody was added at 1:500 dilution in blocking buffer for 30 min at 37

°C. Appropriate Alexa Fluor-labeled antibodies (Molecular Probes) were added at 1:500 dilution in blocking buffer for 30 min at 37 °C. For mice sections, mouse anti-PanCK antibodies conjugated with Alexa 488 (1:100; ThermoFisher Scientific: 53-9003-82) were used. All slides were counterstained with Hoechst 33258 (ThermoFisher Scientific: H3569) and mounted with Fluoromount Aqueous Mounting Medium (Sigma-Aldrich: F4680). Slides were analyzed using a Nikon eclipse 90i microscope (Nikon Instruments Inc.) equipped with DS-Qi1Mc and DS-Fi1 CCD cameras (Nikon Instruments Inc.).

Immunofluorescence quantification

For each EMT/KLF4 co-stain, we quantified slides of 4-6 human specimen. For normal adjacent mucosa and tumor sections, we quantified four separate fields and counted 250-400 cells per each field. Each cell was labeled as positive or negative for KLF4 and positive or negative for each of the specific EMT markers. The statistical analysis was performed using a two-tailed Student *t* test.

Cell culture

SW480 colorectal cancer cell line (ATCC® CCL-228) was maintained in RPMI640 medium supplemented with 10% FBS and 1% penicillin/streptomycin at 37 °C in atmosphere containing 5% CO₂. To overexpress Klf4-GFP and GFP-control in SW480 cell line, cells were transiently transfected with 3 µg plasmid DNA (per well in a six-well plate) using Lipofectamine 2000 reagent (ThermoFisher Scientific) according to manufacturer's instructions. The cell lysates were collected using Laemmli buffer and subjected to Western blot analysis with the following antibodies: rabbit anti-KLF4 (MBL: PM057), rabbit anti-ZEB1 (Cell Signaling: 3396), rabbit anti-SNAI1 (Cell Signaling: 3879), rabbit anti-SNAI2 (Cell Signaling: 9585), and mouse anti-actin (SigmaAldrich: A1978). Then, they were developed using secondary antibodies goat anti-rabbit HRP-conjugated (JacksonImmuno Research: 111-035-144) and goat anti-mouse HRP conjugated (SigmaAldrich: AP200P), respectively.

Statistical analysis

Student's paired or unpaired *t* test was used for statistical analyses. Differences between values were considered significant when $P < 0.05$. This analysis was performed using GraphPad Prism version 5.00 for Windows (GraphPad Software, San Diego, CA).

RESULTS

Expression of KLF4 in human colorectal cancer is negatively correlated with markers of EMT

EMT is a precisely orchestrated multistep process regulated by several transcriptional factors including TWIST, SNAI1, SNAI2, and ZEB1^[3]. To determine the correlation between KLF4 expression and EMT in CRC, we performed immunofluorescence analysis of matched pairs of archived samples from patients after tumor resections. Firstly, we analyzed the expression pattern of KLF4 and TWIST. As shown in [Figure 1A](#) (SB396N), KLF4 is expressed in the nucleus of epithelial cells in the normal-appearing mucosa adjacent to the cancer tissues. These cells are positive for PanCK, an epithelial marker, and negative for the nuclear expression of the biomarker of EMT, TWIST. In contrast, in the tumor samples from the same patient [[Figure 1A](#), SB396T], the expression of KLF4 is downregulated in the epithelial cells, which is accompanied by a significant increase in the expression of TWIST. Our statistical analysis showed that there is a negative correlation between KLF4 and TWIST expression in normal-appearing mucosa and tumor tissues ($P < 0.001$). Several common signaling pathways regulate factors involved in EMT including HH, WNT, NOTCH, and TGF-β^[19]. WNT signaling plays an important role in the homeostasis of the intestinal epithelium and its deregulation leads to cancer formation which is accompanied by modification of the pattern and level of expression of its major effector, β-catenin^[20-22]. In the normal-appearing mucosa, β-catenin is predominantly localized to the membrane of the epithelial cells with a modest nuclear staining [[Figure 1B](#), SB474N]. Upon loss of KLF4 in the colorectal tumor [[Figure 1B](#), SB474T], the levels of the cytoplasmic and

Figure 1. Immunofluorescence staining for PanCK, KLF4, TWIST, and β -catenin in human colonic tissues. Representative images of normal adjacent mucosa and tumor sections from two different human specimens: (A) TWIST (SB396N and SB396T); and (B) β -catenin (SB474N and SB474T). White arrowheads indicate KLF4 stain in stromal tissue. White boxes mark insets. Scale bar: 50 μ m

nuclear β -catenin are significantly increased while its membranous expression is decreased ($P < 0.001$). Loss of cell polarity and cell-cell junctions is another hallmark of EMT and is characterized by increased expression of claudin-1 and N-cadherin^[23-27]. Immunofluorescence staining of claudin-1 [Figure 2A, SB474N] and N-cadherin [Figure 2B, SB378N] within the normal-appearing mucosa shows little or no staining while there is pronounced nuclear KLF4 staining. In matching colorectal cancer tumor tissues with lack of KLF4 expression, both claudin-1 and N-cadherin levels are significantly increased [Figure 2A, SB474T and Figure 2B, SB378T, respectively]. Our analysis showed that there is a significant negative correlation between expression of KLF4 and claudin-1 and N-cadherin between the normal-appearing mucosa and tumor tissues ($P < 0.001$). Furthermore, staining for vimentin, another mesenchymal marker, showed a lack of expression within the epithelial component of the normal-appearing mucosa [Figure 3, SB474N], but a slight increase within the epithelial compartment upon loss of KLF4 in the tumor tissues [Figure 3, SB474T, white arrowheads]. Statistical analysis showed that the expression levels of KLF4 and vimentin are negatively correlated in normal mucosa ($P < 0.05$) and in tumor sections ($P < 0.001$).

KLF4 expression is negatively correlated with markers of EMT in a mouse model of colitis-associated cancer

Recently, in a mouse model, we demonstrated that KLF4 plays a protective role against progression of colitis-associated cancer and that decrease in KLF4 levels is associated with increased aggressiveness of the disease^[18]. To test if KLF4 expression levels correlate with the expression pattern of EMT markers, we performed immunofluorescence staining of KLF4 and select EMT markers on the mouse tissues (*Klf4*^{fl/fl} mice) after treatment with AOM/DSS, as described in the Material and Methods Section.

Figure 2. Immunofluorescence staining for PanCK, KLF4, claudin-1, and N-cadherin in human colonic tissues. Representative images of normal adjacent mucosa and tumor sections from two different human specimens: (A) claudin-1 (SB474N and SB474T); and (B) N-cadherin (SB378N and SB378T). White boxes mark insets. Scale bar: 50 μ m

Figure 3. Immunofluorescence staining for PanCK, KLF4, and vimentin in human colonic tissues. Representative images of normal adjacent mucosa (SB474N) show that KLF4 and vimentin do not co-localize (top inset) and tumor sections (SB474T) that show loss of KLF4 and stain of vimentin in epithelial cells. White boxes mark insets. White arrowheads indicate vimentin stain within epithelial cells (bottom inset). Scale bar: 50 μ m

Immunofluorescence staining showed that in normal mucosa KLF4 is expressed in the nuclei of epithelial cells defined by staining for PanCK. Co-staining for SNAI2 showed that SNAI2 was predominantly expressed in the stromal section of the normal-appearing mucosa and tumor section of mice after AOM/DSS treatment [Figure 4A] and was absent from epithelial compartment. However, in the tumor section

Figure 4. Immunofluorescence staining for PanCK, KLF4, SNAI2 and, β -catenin in mouse colonic tissues after AOM/DSS treatment. (A) Representative images of PanCK, KLF4, and SNAI2 in normal adjacent mucosa (top panel) and tumor sections (bottom panel). (B) Representative images of PanCK, KLF4, and β -catenin in normal adjacent mucosa (top panel) and tumor sections (bottom panel). Scale bar: 50 μ m. AOM/DSS: azoxymethane and dextran sodium sulfate

where KLF4 loss was observed, we noticed increased levels of SNAI2 in the nuclei of the epithelial cells that were defined by positive staining for PanCK [Figure 4A]. As in human specimens, we performed immunostaining analysis for β -catenin. However, we did not observe an increase in nuclear β -catenin staining in the tumor sections in comparison to the normal adjacent mucosa [Figure 4B]. With respect to adherens junction complexes, we observed a reduction in the expression levels of E-cadherin in the tumor section as compared to the normal adjacent mucosa [Figure 5A]. Expression of the mesenchymal marker vimentin in normal adjacent mucosa of mice after AOM/DSS treatment is confined to the stroma [Figure 5B] and does not correlate with KLF4 expression. However, in the tumor of mice after AOM/DSS treatment, we observed a slight increase in the staining of vimentin within the epithelial section, which suggests a change in the characteristics of these cells from epithelial toward mesenchymal phenotype [Figure 5B]. Furthermore, overexpression of KLF4 in SW480 CRC cell line resulted in decreased levels of the mesenchymal markers of EMT, namely ZEB1, SNAI1, and SNAI2 [Figure 6], confirming a suppressive role in the regulation of the epithelial-to-mesenchymal transition.

DISCUSSION

In this study, we investigated the correlation in expression between KLF4 and EMT markers in tissues obtained from patients with CRC and from a mouse model of colitis-associated cancer. The results from studies of epidermal cancer, hepatocellular carcinoma, breast cancer, pancreatic cancer, and prostate cancer with data predominantly originating from *in vitro* experiments show that KLF4 negatively regulates EMT^[28-33]. On the other hand, KLF4's ability to regulate the stemness of cancer cells has been shown as an important factor in stimulating EMT in pancreatic, ovarian, endometrial, nasopharyngeal, prostate, and non-small cell lung cancers^[34-40]. We demonstrated that KLF4 expression is positively correlated with

Figure 5. Immunofluorescence staining for PanCK, KLF4, E-cadherin, and vimentin in mouse colonic tissues after AOM/DSS treatment. (A) Representative images of PanCK, KLF4, and E-cadherin in normal adjacent mucosa (top panel) and tumor sections (bottom panel). (B) Representative images of PanCK, KLF4, and vimentin in normal adjacent mucosa (top panel) and tumor sections (bottom panel). Dotted area shows transition from epithelial (PanCK staining) to mesenchymal characteristic (vimentin staining). Scale bar: 50 μ m. AOM/DSS: azoxymethane and dextran sodium sulfate

Figure 6. Overexpression of KLF4 in CRC cell line decreases the levels of mesenchymal EMT markers. Western blot analysis of KLF4 and EMT markers ZEB1, SNAI1, and SNAI2 in SW480 colon cancer cell line with EGFP or KLF4-EGFP overexpression. Actin is a loading control. EMT: epithelial-mesenchymal transition

epithelial markers of EMT in normal mucosa and negatively with mesenchymal markers in CRC. These results are in agreement with previous observations that KLF4 is a suppressor of EMT^[28-31,41]. This could be accredited to the role of KLF4 in the regulation of differentiation along the crypt-luminal axis in the intestinal epithelium^[40]. Importantly, KLF4's suppressive role in EMT regulation is not limited to the colonic epithelium but has been shown to play a crucial role in corneal epithelial cell fate. It was shown that downregulation of KLF4 promotes expression of mesenchymal markers and decreases the expression of epithelial markers^[42-45]. Furthermore, studies using conditional ablation of KLF4 from the intestinal epithelium showed a deficiency in goblet cell differentiation, thereby demonstrating that KLF4 plays a role in maintaining intestinal epithelial morphology and homeostasis^[9,12]. Additionally, KLF4 has been

shown to regulate apical-basolateral polarity in intestinal epithelial cells and to enhance their polarity by transcriptional regulation^[13]. Thus, loss of KLF4 expression during development and progression of CRC may lead to loss of cell polarity with progression toward EMT. Furthermore, it has been previously demonstrated that E-cadherin (*Cdh1*), N-cadherin (*Cdh2*), vimentin (*Vim*), and β -catenin (*Ctnnb1*) genes are direct transcriptional targets of KLF4^[30]. Yori et al.^[29,41] demonstrated that KLF4 is necessary for the maintenance of E-cadherin expression, repression of SNAIL1, and prevention of EMT in mammary epithelial cells. These results are consistent with our observations. We demonstrated a positive correlation between KLF4 and E-cadherin and a negative one between KLF4 and N-cadherin and vimentin in human and mouse tissues. However, we were not able to show increased nuclear levels of β -catenin in mouse tissues after AOM/DSS treatment^[18]. This could be due to technical differences, as we previously used immunohistochemical staining and the current analysis was based on immunofluorescence studies. In addition, we showed that KLF4 expression is negatively correlated to the expression of TWIST, SNAIL2, and claudin-1. Taken together, these results suggest that KLF4 may regulate EMT at several different stages of CRC progression, including suppression of expression of transcription factors (TWIST and SNAIL2), transcriptional co-activator (β -catenin), and regulation of cell polarity (E-cadherin, N-cadherin, and claudin-1). In conclusion, we showed a negative association between KLF4 and mesenchymal EMT markers in both human and mouse CRC tissues. Future studies are necessary to identify the mechanism by which KLF4 regulates EMT progression in CRC.

DECLARATIONS

Acknowledgments

We thank the Department of Pathology at Stony Brook University for technical assistance in histopathological analysis.

Authors' contributions

Made substantial contributions to conception and design of the study and performed data analysis and interpretation: Yang VW, Ghaleb AM, Bialkowska AB

Performed data acquisition and analyzed data: Agbo KC, Huang JZ, Ghaleb AM

Provided tissues samples: Williams JL

Provided assistance with histopathological analysis: Shroyer KR

Abstract

The histone chaperone facilitates chromatin transcription (FACT) plays important roles in essentially every chromatin-associated process and is an important indirect target of the curaxin class of anti-cancer drugs. Curaxins are aromatic compounds that intercalate into DNA and can trap FACT in bulk chromatin, thus interfering with its distribution and its functions in cancer cells. Recent studies have provided mechanistic insight into how FACT and curaxins cooperate to promote unfolding of nucleosomes and chromatin fibers, resulting in genome-wide disruption of contact chromatin domain boundaries, perturbation of higher-order chromatin organization, and global dysregulation of gene expression. Here, we discuss the implications of these insights for cancer biology.

Keywords: Genomics, transcription, nucleosomes, chromatin structure

INTRODUCTION

Facilitates chromatin transcription (FACT) is a highly conserved histone chaperone that participates in multiple physiological processes^[1] including transcription^[2-8], DNA replication^[9-13], DNA repair^[14-17],

and centromere function^[18,19]. FACT is a heterodimer of the suppressor of Ty 16 (Spt16) protein and the structure-specific recognition protein 1 (SSRP1) in mammals or the polymerase one binding protein 3 (Pob3) in yeast^[1,8,9,20,21]. Unlike human SSRP1, the yeast Pob3 lacks the high mobility group B1 (HMGB1) DNA-binding domain; however, yeast FACT functionally interacts with the non-histone protein 6 (Nhp6) that consists of a single HMG box^[22-24]. Both Spt16 and SSRP1 are able to interact with H2A/H2B dimers and H3/H4 tetramers^[20,25-29]. FACT is involved in both assembly and disassembly of nucleosomes, as well as in nucleosome unfolding that is dependent on its interactions with other factors. Single-particle Förster resonance energy transfer (spFRET) microscopy studies demonstrated that in the presence of Nhp6 protein yeast FACT can induce large-scale, reversible, and ATP-independent unfolding (reorganization) of individual nucleosomes that involves uncoiling of nucleosomal DNA^[30,31]. In contrast, in the absence of Nhp6 protein, FACT can stabilize nucleosomes lacking the unstructured histone tails^[32]. The Spt16 and SSRP1 subunits of FACT also contain additional intrinsic DNA-binding sites^[33,34]. SSRP1 can bind the left-handed Z-form of DNA^[35]. Notably, SSRP1 is usually phosphorylated by casein kinase 2, which inhibits its DNA binding activity^[36,37]; the phosphorylated FACT can only bind destabilized nucleosomes or hexasomes^[22,38].

Curaxins are carbazole-based compounds that intercalate into DNA and alter the physical properties of both DNA and chromatin without causing structural damage (i.e., phosphodiester bond breaks or chemical modifications)^[34,39,40]. These drugs inhibit the activities of FACT, which has particularly severe consequences in cancer cells^[35]. The curaxins CBL0137 and CBL0100 have been demonstrated to have broad anticancer activity in many different models^[35,41-45]. Clinical candidate CBL0137 has higher metabolic stability and water solubility, and efficiently inhibits growth of various cancers in preclinical models^[35]. CBL0100 is more biologically active but is rarely used in animal studies due to its lower solubility and higher toxicity. Curaxins were first identified in a screen for small molecule compounds capable of simultaneously inhibiting NF- κ B, activating p53, and preferentially killing tumor cells^[35]. Curaxins induce chromatin trapping (c-trapping) of FACT in less than 1 min after addition to cells, and strongly inhibit normal human FACT activities *in vivo*^[35]. This c-trapping of FACT involves rapid formation of Z-DNA and binding of the SSRP1 subunit (z-trapping)^[34], as well as curaxin-dependent nucleosome unfolding resulting in binding of FACT to the disrupted nucleosomes (n-trapping)^[31]. The anticancer activity of curaxins is highly dependent on c-trapping of FACT^[31,34,35]. However, in addition to the c-trapping and activation of p53, curaxins also induce dramatic changes in chromatin structure (e.g., disruption of long-range chromatin interactions^[46], see below) and dysregulation of multiple cellular responses, including changes in transcription profiles^[31,40] and induction of transcription of repeats activates interferon (TRAIN)^[47].

This review focuses on recent studies of the roles of FACT and curaxins in gene expression and genome structure; other topics have been extensively covered in several excellent recent reviews^[3,39,48].

ROLES OF FACT IN TRANSCRIPTION, REPLICATION, AND DNA DAMAGE REPAIR

FACT is detected at transcribed regions of genes in multiple eukaryotes^[40,49-51]. FACT is associated with both promoters and coding regions of transcribed genes^[31,49,52,53]. Insertion of transposons (Ty elements) often interferes with the expression of nearby genes in *Saccharomyces cerevisiae*^[54]. Depletion of yeast *SPT16* causes cell cycle arrest in early G1 phase due to failure to transcribe cyclin genes, and less severe mutations cause the Spt- (suppressor of Ty) phenotype due to inappropriate activation of a cryptic promoter in Ty1^[54]. Yeast FACT and Nhp6 are also involved in maintaining nucleosome-depleted regions near many yeast promoters^[52]. The nucleosome unfolding activity of yeast FACT working together with Nhp6 protein that has been detected *in vitro* likely plays a role in nucleosome destabilization and/or histone removal at promoter regions^[2,30]. The *in vitro* studies of chromatin transcription by yeast RNA polymerase II (Pol II) have determined that FACT can facilitate Pol II transcript elongation through chromatin and nucleosome survival during this process by transiently interacting with the DNA binding surface of the H2A/H2B

dimers^[9]. However, depletion of FACT only minimally affects transcript elongation rates *in vivo*, while numerous studies have shown that FACT is critically involved in maintaining the nucleosomal structure of the genome^[6,9,55-59]. Thus, depletion of FACT in yeast causes accumulation of short transcripts from normal transcription start sites and cryptic transcripts initiated intragenically^[56-59]. Yeast FACT also plays important roles in facilitating efficient replication and nucleosome assembly/disassembly during this process^[14,15]. FACT occupancy is increased at DNA damage sites after different stresses, including UV-induced damage^[17,60,61], oxidative damage^[19], and single- and double-strand breaks^[62,63]. FACT also plays roles in recovery from transcription arrest^[61], replication fork stalling^[64], and R-loop formation^[65]. The FACT subunit SSRP1 is able to detect non-B form DNA structures, and this activity might be important for inducing cell signaling cascades in response to these perturbations^[34].

FACT is essential for normal embryonic development. *Ssrp1* knockout mice demonstrated early embryonic lethality at the blastocyst stage (3.5 dpc), and ES cells derived from the *Ssrp1*-null blastocysts could not be propagated *in vitro*^[66]. Defects in development were also observed in zebrafish with a mutant *Ssrp1*^[67] and in plants with reduced levels of SSRP1 and SPT16 proteins^[68,69]. Several studies also revealed that FACT subunits play specific roles in mammalian cell differentiation and considerably modify gene expression profiles during muscle cell differentiation^[70] and *in vitro* differentiation of human mesenchymal stem cells^[71]. Although FACT can be involved in gene transcription, it is not ubiquitously expressed and therefore is not a required core component of the transcription machinery. The levels of FACT expression are higher in undifferentiated and proliferating cells, but are very low in most differentiated mammalian cells^[72-75]. Importantly, both curaxin treatment and (CRISPR)-mediated deletion of the FACT subunit Spt16 block induction of pluripotency without affecting the viability or proliferation of fibroblasts^[76]. In tumor cells, both FACT subunits are highly expressed, and their higher levels correlate with poor prognosis in several tumor types^[35,74,77-80]. Thus, FACT plays a more important role in cancer cells than in normal cells, making it a target for cancer therapy. The FACT complex is also involved in HIV integration into the host genome^[81] and viral gene transcription^[82,83], suggesting that FACT could serve as a target for HIV therapy as well. The mechanistic studies of FACT activity described below therefore provide insights that could have clinical significance.

FACT-NUCLEOSOME INTERACTIONS

FACT does not bind stably to intact nucleosomes and does not affect nucleosome structure unless it is assisted by additional factors. The HMGB1-domain protein Nhp6 provides this nucleosome-destabilizing activity *in vitro* and *in vivo* for yeast FACT, and also supports nucleosome reorganization by human FACT *in vitro*^[2]. The HMGB1 domain of SSRP1 does not appear to be adequate to promote uncoiling of the DNA from intact nucleosomes, suggesting that it may function primarily during nucleosome assembly^[29,31,55]. Curaxins can distort DNA shape and this distortion promotes trapping of FACT in chromatin and changes chromatin compaction^[31,46]. We propose that either HMGB proteins or curaxins weaken the histone-DNA contacts near the entry/exit sites of nucleosomal DNA and thus initiate a series of binding events by FACT domains that can lead to full reorganization of the nucleosome [Figure 1]. In this model, DNA distortion exposes the initial set of binding sites for the CTDs of each subunit of FACT, resulting in similar reorganization of the nucleosome independent of the initiating factor (curaxin or HMGB binding). In the reverse reaction leading to nucleosome assembly, Nhp6 or the intrinsic HMGB domain of SSRP1 can assist in stabilizing bent forms of the DNA to promote formation of the canonical nucleosome, resulting in release of FACT. Curaxins do not provide this assistance, instead leading to persistent binding of FACT and trapping it in chromatin (see below).

CURAXIN-INDUCED TRAPPING OF FACT ON CHROMATIN

Computational modeling and circular dichroism studies suggest that curaxins intercalate between DNA base pairs and the side chains of the molecule bind to both major and minor grooves of DNA^[34,39]. Intercalation of curaxins in DNA causes an increase in the distance between the DNA base pairs, resulting

Figure 1. Nhp6 or curaxins can initiate uncoiling of nucleosomal DNA to promote reorganization by FACT. Either Nhp6/HMGB or curaxins can weaken the histone: DNA contacts near the entry/exit points of the nucleosomal DNA, exposing the binding site in H2A-H2B dimers for the acidic/hydrophobic anchor sequences found in the C-terminal domains of both subunits of FACT^[1]. The DNA distortion initiates a stepwise series of binding events by different domains of FACT that ultimately leads to uncoiling of the DNA to make the reorganized form of the nucleosome. Each step is reversible, providing a pathway for assembly of nucleosomes. Structures of the domains of FACT are shown, with the HMGB domain of SSRP1 represented by Nhp6 (modified from Figure 8^[2]). FACT: facilitates chromatin transcription; Nhp6: non-histone protein 6; HMGB: high mobility group B; Spt16: suppressor of ty 16; Pob3: polymerase one binding protein 3

in unwinding of the DNA helix and a change in the DNA topology^[34]. In the presence of curaxins, the nucleosome structure is destabilized in a dose- and time-dependent manner^[31,34,39,40]. In cells, CBL0137 does not cause histone loss or nucleosome disassembly at concentrations lower than 3 $\mu\text{mol/L}$ during a short time period (< 20 min in cancer cells). However, histone loss is detectable in cells treated with ≥ 3 $\mu\text{mol/L}$ CBL0137, and chromatin structure is destabilized when the concentration is > 5 $\mu\text{mol/L}$ ^[34]. Similarly, CBL0137 and CBL0100 cause only minimal disruption of nucleosomes in cell free conditions at concentrations ≤ 2.5 $\mu\text{mol/L}$ after incubation for several minutes^[31,34], while nucleosomes become unstable and are partially disassembled after incubation for a longer time period (> 1 h)^[31].

Although at concentrations ≤ 2.5 $\mu\text{mol/L}$ curaxins only minimally affect nucleosome structure, they significantly alter the structure of the internucleosomal linker DNA, increasing the average distance between the DNA regions entering and exiting a nucleosome^[46]. On defined nucleosomal arrays the change in the structure of linker DNA is translated into a considerable decrease in the probability of long-range interactions, impacting enhancer-promoter communication (EPC) *in vitro*. As a result, enhancer-dependent transcription is strongly inhibited by curaxins; no direct effect on the activity of the transcriptional machinery itself was observed^[46]. In agreement with the *in vitro* data, enhancer-dependent transcription is preferentially inhibited by curaxins in cells^[46].

Curaxin treatment has been shown to cause FACT (detected by fluorescence microscopy and chromatin immunoprecipitation) in cancer cells to disperse from transcribed regions and become trapped in other regions within 1 min^[31,34]. This FACT redistribution results in genome-wide changes in FACT-dependent transcription profiles^[31]. This phenomenon was recapitulated using a highly purified Pol II transcription system and positioned mononucleosomes *in vitro*^[31]. Curaxins inhibit human (hFACT) action during chromatin transcription *in vitro* by trapping FACT complexes on competitor nucleosomes. Under conditions where hFACT and curaxins alone had minimal effects on nucleosomes in spFRET assay, they induced extensive, reversible uncoiling of nucleosomal DNA (nucleosome unfolding or reorganization) when combined, demonstrating highly synergistic action^[31]. The non-transcribed regions of the genome are in excess over transcribed regions in a human cell, so FACT trapping by unfolded nucleosomes (n-trapping) causes depletion of hFACT from active regions of chromatin^[31]. Thus, FACT n-trapping is an important mechanism behind the short-term curaxin action in cancer cells.

Although hFACT induces extensive, reversible nucleosome unfolding in the presence of either Nhp6 protein or curaxins [Figure 1], the properties of these FACT-unfolded nucleosomes are different^[2,31]. The hFACT-γNhp6-nucleosome forms a reversible complex that is stable during electrophoresis, while the hFACT-nucleosome complex formed in the presence of curaxins is stable in solution, but falls apart during PAGE^[2,31]. Since Nhp6 and curaxins are expected to bind to similar, end-proximal regions of the nucleosomal DNA and produce similar unfolding of nucleosomes together with FACT^[2,31], the differences in stability of the complexes may be explained by the different structures/stabilities of Nhp6-nucleosome and curaxin-nucleosome complexes, or possibly by a direct effect of Nhp6 protein on the properties of hFACT.

Many DNA binding molecules other than curaxins also cause trapping of FACT on chromatin in cell-free systems^[40]. However, to be potent in chromatin destabilization, small molecules need to be able to get to the nuclei and compete with histones and other chromatin components for DNA binding. The curaxins that were selected and optimized in a cell-based assay for p53 activation^[84,85] easily enter into cell nuclei and are strong DNA binders. They were also selected in cells which were not responsive to DNA damage after p53 activation; thus, compounds capable of causing DNA damage were eliminated from the analysis. Curaxins can cause DNA damage in some systems; e.g., they cause frame shift mutations in some strains of *E. coli* in the Ames test. However, the much higher proofreading efficiency of mammalian DNA polymerases probably mitigates this effect at low concentrations of curaxins and blocks replication at high concentrations of the drug. Curaxins are also potent inhibitors of topoisomerases^[34], but, in contrast to many known drugs that inhibit resolution of topoisomerase cleavage complexes, do not prevent cleavage itself: curaxins inhibit initiation of topoisomerase action, preventing the induction of DNA breaks. Most importantly, the toxicity of curaxins for cells does not depend on DNA damage, since DNA damage is undetectable in many types of tumor cells as they are being killed by curaxin treatment^[35].

In addition to the c-trapping of FACT, curaxins globally affect the three-dimensional organization of the genome in living cells^[46]. Studies employing nucleosome arrays show that curaxins induce changes in the structure of internucleosomal linker DNA and unfolding of the chromatin fiber^[46]. Hi-C analysis demonstrated that addition of curaxins to cancer cells partially disrupted the boundaries of topologically associated domains (TADs), inhibited spatial interactions within the TADs (over distances less than 600 Kb), and enhanced spatial interactions over longer distances^[46]. These alterations of the three-dimensional genome organization strongly affected enhancer-promoter interactions: only 30% of the intradomain chromatin interactions annotated in control cells were maintained in CBL0137-treated cells. As a result, numerous new alternative, long-range interdomain interactions were detected^[46]. Furthermore, genomic studies demonstrated that curaxins caused partial depletion of CCCTC-binding factor (CTCF) from its binding sites^[46]. Since CTCF contributes to maintaining the spatial organization of the mammalian genome^[86], depletion of CTCF from domain boundaries by curaxins likely contributed to the drastic changes observed in genome topology. The changes in chromatin structure, in turn, are expected to dramatically change gene regulation and the pattern of gene expression. Indeed, after CBL0137 treatment, gene expression profiles were drastically changed. These changes included downregulation of essential genes necessary for cell survival, including both normal and translocated versions of MYC family genes, which could explain the observed drop in cancer cell viability^[46]. Thus, curaxins can be classified as epigenetic drugs that globally affect gene regulation and cause cancer cell death by targeting the three-dimensional organization of the genome within living cell nuclei.

THE MECHANISM OF CURAXIN ACTION

Taken together, the current studies suggest the following scenario for curaxin action in cancer cells [Figure 2]. In untreated cancer cells, FACT is present mostly in the nucleoplasm; only a small fraction of the complexes are transiently associated with nucleosomes perturbed by transcribing RNA polymerase.

Figure 2. Curaxins affect different levels of chromatin structure. A proposed sequence of events during incubation of cancer cells with curaxins. Upper part: initially, curaxins induce time- and concentration-dependent FACT trapping on the unfolded nucleosomes. As curaxins intercalate into DNA, they induce progressive, FACT-dependent unfolding of nucleosomes that could eventually lead to eviction of core histones. Lower part: in parallel with the changes in the nucleosome structure, the higher-order chromatin structure is dramatically disturbed. Curaxins induce changes in the structure of internucleosomal linker DNA, releasing linker histones, unfolding the chromatin fiber, causing displacement of CTCF factor from DNA, and disrupting existing chromatin domain boundaries. Taken together, these changes in the structure of nucleosomes, chromatin fibers, and global three-dimensional chromatin organization lead to a large-scale loss of chromatin integrity and cancer cell death. Components are modeled as in Figure 1, with the addition of PDB 1Y1V (RNA polymerase II elongation complex structure). FACT: facilitates chromatin transcription; CTCF: CCCTC-binding factor

Curaxins rapidly induce changes in the structure of internucleosomal linker DNA and eviction of histone H1 from chromatin. The speed of this process is probably explained by the dynamic interaction of linker histones with chromatin^[13]. FACT trapping in bulk chromatin is initiated at the same concentrations of curaxins (0.5-1 $\mu\text{mol/L}$ of CBL0137) that induce displacement of H1, and both processes occur at about the same time (a few seconds after addition of CBL0137). It is therefore possible that FACT participates in H1 eviction or prevents reassociation of H1 with linker DNA. Higher curaxin concentrations also displace core histones from chromatin.

Binding of FACT to bulk chromatin occurs at multiple genomic locations, but there is some preference for regions enriched for tandem dinucleotide AC/TG repeats known as mini- and microsatellites. These occur mostly at non-coding regions, which are dispersed throughout the human genome^[87]. FACT binding and

displacement of histone H1 contribute to unfolding of the chromatin fibers and also to largely reversible uncoiling of nucleosomal DNA (nucleosome unfolding). Since FACT is tightly bound to (trapped by) and unfolds nucleosomes genome-wide, FACT-dependent gene expression is globally affected, preferentially decreasing the viability of cancer cells that have a higher requirement for FACT. After a longer curaxin treatment, FACT-bound unfolded/destabilized nucleosomes are prone to disruption, possibly evicting core histones from the DNA. Nucleosome unfolding and histone eviction are likely to result in the release of negative DNA supercoiling that was constrained in intact nucleosomes and in formation of alternative DNA structures, such as Z-DNA, resulting in further FACT trapping.

In addition to affecting the structures of nucleosomes and chromatin fibers, curaxins globally alter genome topology in cells. Curaxins induce eviction of CTCF from DNA, thus disrupting domain boundaries and dramatically decreasing the number and type of chromatin loops that are characteristic of cancer cells. The latter effect is likely explained by the global unfolding of the chromatin fiber due to the altered geometry and topology caused by curaxin treatment. In turn, the changes in chromatin topology result in less efficient EPC, and in preferentially reduced expression levels of enhancer-dependent genes (e.g., *Myc*) and global alteration of the profiles of gene expression. The suppression of enhancer-dependent oncogenes strongly decreases the efficiency of cancer cell survival. This combined mechanism of curaxin action explains the high efficiency of the compounds and suggests novel therapeutic strategies targeting chromatin structure and spatial organization of the genome to alter gene expression profiles, thereby suppressing cancer cell growth.

PERSPECTIVES

Mutations in enzymes that “write”, “read”, or “erase” chromatin marks have emerged as a recurring theme in multiple types of cancer^[88]. However, the mechanisms through which epigenetic changes benefit cancer cells remain poorly understood. Existing theories tend to focus on specific genes or pathways; that is, the effects of altering global properties of chromatin are usually attributed to altered expression of individual genes or groups of genes. However, discoveries such as “oncohistones”, where mutations in core histones are associated with cancer^[89], raise the possibility that carcinogenesis results from a broad combination of defects occurring genome-wide.

The role of FACT in cancer, and the use of curaxins to combat cancers, face similar questions. Neither FACT nor curaxins have clear gene-specific effects, and yet the former preferentially supports the viability of aggressive cancer cells and the latter has clear anti-cancer activity. In one scenario, FACT and curaxins could function through a common mechanism by destabilizing nucleosomes. In this model, FACT might enhance global expression of genes, including a set that is important for maintaining excessive proliferation, and curaxins extend this activity past the point where it is advantageous. However, recent results suggest instead that FACT and curaxins might have opposing effects on nucleosomes, with curaxins promoting unwrapping of DNA from the core^[34], while FACT promotes survival of nucleosomes by tethering the components together and promoting reassembly^[29]. As FACT is capable of both destabilizing and stabilizing nucleosomes, understanding how it promotes survival of cancer cells and how curaxins oppose this activity will ultimately require better understanding of how global nucleosome stability contributes to cancer cell progression and viability.

Pervasive cryptic transcription has been detected in multiple types of cancer^[90-92], suggesting that the DNA is more accessible to transcription machinery in tumor cells than it is in normal cells, as expected if the nucleosomal barrier is globally weakened. In this case, the role of FACT in stabilizing and restoring nucleosomes would be critical to allowing tumor cells to maintain chromatin. Curaxins would then interfere with this process, creating an excessive burden of disrupted chromatin, eventually leading to cell death. Then, the next questions to answer are: Why are nucleosomes less stable in tumors, thereby

creating greater need for FACT activity? Do elevated transcription and replication decrease the stability of nucleosomes, or do tumor cells promote destabilization through an unknown mechanism to provide advantages such as easier reorganization of the three-dimensional structure of the genome or easier transitions among gene expression profiles? What is the relationship between nucleosome stability and three-dimensional chromatin structure? While it might seem obvious that loss of chromatin structure is disadvantageous, is this because of toxicity of the free histones that are produced by chromatin disassembly or is it the result of inappropriate exposure of DNA? Cancer cells survive by unleashing the beasts of excessive proliferation and metastasis that are normally constrained within chromatin; how do FACT and curaxins alter the balance between taking advantage of these dangerous forces to become cancerous and being overtaken by them?

DECLARATIONS

Authors' contributions

Wrote the initial draft of the manuscript and finalized it: Chang HW

Wrote parts of the manuscript: Nizovtseva EV, Razin SV

Wrote parts of the manuscript and prepared the final figures: Formosa T

Wrote parts of the manuscript: Gurova KV

Designed the review and the figures, wrote parts of the manuscript and finalized it: Studitsky VM

Abstract

Electrolyte disorders are very common complications in cancer patients. They might be associated to a worsening outcome, influencing quality of life, possibility to receive anticancer drugs, and conditioning survival. In fact, they might provoke important morbidity, with dysfunction of multiple organs and rarely causing life-threatening conditions. Moreover, recent studies showed that they might worsen cancer patients' outcome, while a prompt correction seems to have a positive impact. Furthermore, there is evidence of a correlation between electrolyte alterations and poorer performance status, delays in therapy commencement and continuation, and negative treatment outcomes. These alterations usually involve sodium, potassium, calcium, and magnesium serum levels. Several causes might contribute to electrolyte disorders in cancer patients: cancer effects, such as paraneoplastic syndrome of inappropriate antidiuresis and tumor lysis syndrome; anti-cancer therapies; and other concomitant clinical conditions or treatments. However, the origin of the electrolyte disorder is often multifactorial, thus identifying and correcting the causes is not always feasible. Furthermore, they are often not recognized or not considered in clinical practice, worsening these alterations and patient condition. An improvement of knowledge about the physiological mechanisms underlying electrolyte disorders is necessary to strengthen their identification and set up a prompt, adequate, and effective treatment. The aim of this systematic review is to provide an analysis of the pathophysiological mechanisms of electrolyte abnormalities in cancer patients to facilitate their identification, management, and therapy to improve patient outcome.

Keywords: Cancer, electrolyte disorders, hyponatremia, syndrome of inappropriate antidiuresis, hyperkalemia, hypocalcemia, hypomagnesemia

INTRODUCTION

Electrolyte disorders are very common conditions in cancer patients. They mainly concern changes in serum sodium, potassium, calcium, and magnesium levels. In most cases, these alterations are asymptomatic and therefore not always taken into consideration in clinical practice. However, they can sometimes be associated with clinical manifestations that can worsen patient's clinical condition up to more serious life-threatening events. Furthermore, several clinical studies showed an important impact of electrolyte disorders on cancer patients' journey. Firstly, they seem to correlate with a worsening quality of life and performance status, reduced probability of tumor response to anti-cancer treatment and treatment delays, and cause poorer outcomes and reduced survival^[1]. Electrolyte disorders in cancer patients might depend on several causes: cancer physiopathology, anti-tumor treatments, concomitant clinical conditions, or therapies. However, they often have a multifactorial origin and they might be both secondary and responsible for multiple organ systems' dysfunction. A prompt correction of electrolyte disorders is commonly associated with a better prognosis. Therefore, increasing attention towards electrolyte disturbances is emerging in the literature and clinical trials^[2]. Ingles Garces *et al.*^[3] published a review on phase I trials performed between 2011 and 2015. They showed elevated rates of hyponatremia (62%), hypokalemia (40%), hypomagnesemia (17%), and hypocalcemia (12%) in cancer patients treated with new anticancer-agents and that patients who developed adverse events in terms of electrolyte disturbances during follow-up had a poorer median overall survival (26 weeks *vs.* 37 weeks, hazard ratio = 1.61; $P < 0.001$). These data suggest the importance of monitoring and correcting electrolyte disorders in cancer patients. The relationship between electrolyte disorders and poor prognostic impact on cancer patients might depend on the fact that several ion channels and transporters are over- or under-expressed in cancer cells and implicated in phenomena of cell proliferation, apoptosis, migration, and invasiveness^[4]. Recently, it has been demonstrated that several channel genes are expressed in several cancer types, suggesting an important role in tumor development and progression. For example, a recent study proposed an ion channel gene signature for breast cancer as a prognostic and diagnostic biomarker, showing an association between different ion gene expression and p53 mutation status, estrogen receptor status, and grading^[5].

Our review aims to focus on electrolyte disorders in cancer patients, providing information for correct and prompt diagnosis, therapy, and monitoring, in order to improve the outcome of the patients.

SODIUM

Sodium is the major cation of extracellular fluid (ECF) and the main constituent of serum osmolality. Its concentration in ECF is essential for maintaining the circulating blood volume and it is strictly interdependent of water presence. Normal serum sodium level is 135-145 mmol/L and its imbalance may be caused by alteration of both solute and water intake, depletion, and dilution^[6].

Several integrated systems are involved in maintaining normal serum sodium concentration, such as regulation of water intake by thirst, control of free water renal excretion by antidiuretic hormone secretion, renal sodium excretion by glomerular filtration, peritubular conditions, and adrenal aldosterone secretion.

In particular, the angiotensin II arginine vasopressin (AVP) - atrial natriuretic peptide pathway is the most important mechanism of sodium balance^[7], and it is strictly associated to serum osmolality^[8].

Alterations in serum sodium concentration include hyponatremia and hypernatremia. Sodium channels have been described in cancer cells and associated with a more aggressive behavior^[4]. Voltage-gated sodium channels (VGSC) are a large group of trans-membrane proteins that allow the flow of sodium ions down the electrochemical gradient through cell membranes. In particular, overexpression of Nav 1.5, a VGSC, seems to promote cell proliferation, migration, invasion, and metastasis of oral squamous cell

carcinoma^[9], breast cancer^[10], and cervical carcinoma^[11]. The expression of a particular VGSC, SCN9A, in prostate cancer is associated with higher risk of metastasis due to its activity promoting cell migration. Furthermore, it is overexpressed in prostate cancer cells, compared to normal cells, representing a potential diagnostic biomarker^[12]. VGSCs are overexpressed in non-small-cell lung cancer cells and involved in cell invasiveness. Recent data show that the upregulation of SCN9A in non small cell lung cancer is regulated by EGFR signaling and it is crucial for the invasive behavior of cancer cells, suggesting a potential new biomarker and therapeutic target^[13]. Nav 1.5 (SCN5A) was found overexpressed also in colorectal cancer (CRC) cells compared to normal colon tissues. SCNA5 was demonstrated to regulate CRC invasion process. In fact, it is involved in activation of several pathways: Wnt signaling, steroid metabolic process, favoring cell migration, ectoderm development, and influencing cell cycle control^[14]. Finally, a recent multicenter study identified two single nucleotide polymorphisms of VGSC genes (the intron SNP SCN4A-rs2302237 and the SCN10A-rs12632942 SNP) that were associated with oxaliplatin-induced peripheral neuropathy development, which is interesting as the majority of patients with CRC are given oxaliplatin^[15].

Serum sodium concentration is also regulated by aquaporins (AQP), or water channels, a large family of membrane proteins involved in water transportation between cells. AQP1 might be expressed in breast cancer cells and it is associated with aggressive behavior. In fact, it correlates with higher grading, CK14 expression, smooth muscle actin expression, basal-like group, and poor prognosis^[16]. Aquaporin's expression has also been investigated in CRC. In particular, AQP1, AQP3, and AQP5 are expressed in CRC cell lines and in primary CRC. They have been described during CRC progression and in liver metastases^[17]. AQP5 over-expression was demonstrated to be associated with worse TNM stage, grading, and lymph node involvement^[18]. AQP3 expression is positively regulated by endothelial growth factor pathway and it is associated with lymph node involvement, metastasis, and tumor differentiation^[19]. Furthermore, a recent study showed that reduced AQP9 gene expression is associated with a lack of response to adjuvant chemotherapy^[20]. AQP3 and AQP5 are also over-expressed in esophageal cancer cells compared to normal tissue and their co-expression seems to have a negative prognostic role^[21]. The co-expression of AQP3 and AQP5, also described in gastric cancer, is associated with lymph node involvement and intestinal type^[22].

Although the effect of serum sodium concentrations' alterations on the functionality of VGSCs and AQP in tumor cells is still unknown, many data are emerging on the effect of dysnatremic conditions in neurons. In particular, a hyponatremic condition induces a modification of the axonal Na⁺ channels kinetics, resulting in a decreased Na⁺ current. Moreover, the damage is proportional to the severity of hyponatremia and concerns the recovery phase of VGSC. On the other hand, hypernatremia increases the excitability of the membrane, reducing the response time of the channel. However, the effect of hyponatremic condition seems to be less destructive compared to situation of hyponatremia on the activity of Na ion channel^[23]. Syndrome of inappropriate antidiuresis (SIAD) is a rare cancer paraneoplastic syndrome causing hyponatremia. It is associated with overexpression of AQP in renal cells. Even though no data are available on AQP expression in cancer cells, secondary to SIAD, dysnatremia could also play a role in AQP expression in cancer cells^[1]. These data suggest that alterations in serum sodium concentration might play an important role on the functionality of tumor cells that overexpress sodium channels and AQPs.

Finally, the importance of sodium in oncology is also underlined by another potential development field, sodium magnetic resonance imaging (²³NaMRI). ²³NaMRI seems to be able to provide information on cells' metabolism and their physiology, exploiting the different total tissue sodium concentration between healthy tissue and neoplastic cells. ²³NaMRI takes advantage of the abnormally high sodium concentration of proliferating cells, due to altered pH and Na⁺/H⁺ transport kinetics. Currently, the most promising application areas of ²³NaMRI are the early diagnosis of brain tumors and breast cancer^[24].

Hyponatremia

Definition and clinical implications

Hyponatremia is defined as a serum/plasma sodium concentration lower than 135 mmol/L. It can arise rapidly within 48 h (acute hyponatremia) or, more frequently, slowly (chronic hyponatremia). According to its serum level, it can be classified into three severity grades: mild (130-134 mEq/L), moderate (125-129 mEq/L), and severe (< 125 mEq/L)^[25].

It represents the most common tumor-related electrolyte disorder. Even though its accurate incidence is still unknown because different serum sodium cut-off levels were considered in several studies, a variable incidence of 4%-44% was reported, depending on cancer type and clinical setting^[26]. Higher incidences are associated with thoracic neoplasms, and, in particular, it occurs more frequently in patients with small-cell lung cancer, with a median estimated rate of 15%^[26].

Several studies evaluated the impact of hyponatremia on cancer patients, showing that, independently of causes, it negatively correlates with patients' outcome^[27]. In particular, hyponatremia seems associated to poorer performance status^[28] and reduced survival in patients with lung cancer^[29], renal cell carcinoma^[30], malignant pleural mesothelioma^[31], gastric cancer^[32], colon-rectal cancer^[33], and lymphoma^[34]. Recent evidence shows an important negative predictive role of hyponatremia, for patients receiving both chemotherapy and target therapy^[35], while a prompt correction of this electrolyte disorder improves patients' outcome, which takes into account the correct timing to avoid neurological damage^[36]. Furthermore, hyponatremia seems to also have a negative role in hospitalized patients, as it was demonstrated to be associated with a longer length of hospital stay, inducing a negative impact on quality of life and prognosis and an increase in hospitalization costs^[37].

Causes

In cancer patients, several causes might induce hyponatremia^[1]:

- (1) Cancer: paraneoplastic syndromes such as SIAD, brain metastasis, adrenal metastasis, and kidney metastasis can cause hyponatremia.
- (2) Cancer-treatment: it can cause hyponatremia as a direct effect of their mechanism of action (vinca alkaloids might induce SIAD; platinum derivatives are frequently associated to hyponatremia; and target therapies, in particular antiangiogenic agents, seem to induce hyponatremia, despite the underlying mechanism being unknown) or as a result of side effects such as gastrointestinal losses (vomiting and diarrhea caused by most of chemotherapeutic agents, target therapies, and immunotherapy), kidney loss, and heart failure (cardiotoxic drugs such as anthracyclines and target therapies such as anti HER-2, anti-ALK, and anti-MEK). Immunotherapeutic agents might cause direct damage to adrenal or pituitary gland, favoring hyponatremia development.
- (3) Concomitant drugs: diuretics, antibiotics, non-steroidal anti-inflammatory drugs (NSAIDs), opioids, antidepressants, and neuroleptics can induce hyponatremia.
- (4) Concomitant diseases: heart failure, kidney failure, thyroiditis, hypercortisolism, liver cirrhosis, pneumonia, and inflammatory lung or brain diseases can induce hyponatremia.

However, in most cases, more than one of the aforementioned factors might induce hyponatremia in cancer patients.

These causes can be traced back to two different basic mechanisms: excessive free water (for increased intake or reduced elimination) or, rarely, sodium loss (reduced intake or increased loss). The knowledge

Table 1. Causes of hyponatremia

Extracellular volume	Causes of hyponatremia
Hypovolemic: increased water loss	Gastrointestinal losses (vomiting, diarrhea) Renal losses (nephropathies, M. Addison, Diuretics) Cerebral salt wasting syndrome
Euvolemic: salt loss	Syndrome of inappropriate antidiuresis Endocrine dysfunctions (hypercortisolism, hypothyroidism)
Hypervolemic: water retention	Edematogenic syndromes (cirrhosis, heart failure, kidney failure, nephrotic syndrome)

of these two different mechanisms is fundamental for the differential diagnosis between the potential causes in order to set a correct therapeutic approach. Extracellular volume (ECV) status is fundamental to distinguishing the mechanism underlying hyponatremia.

According to ECV status, hyponatremia can be classified in [Table 1]:

- Hypovolemic, with reduced ECV.
- Euvolemic, with normal ECV.
- Hypervolemic, with increased ECV.

Hypovolemic hyponatremia is often due to water loss, namely gastrointestinal loss (vomiting, diarrhea), renal losses, bleeding, and cerebral salt wasting, caused by a dysfunction of hypothalamic-renal axis.

Euvolemic hyponatremia, despite being rare, is an important and frequent condition in cancer patients. Several mechanisms induce euvolemic hyponatremia such as adrenal insufficiency, hypothyroidism, and SIAD. SIAD is the principal cause of hyponatremia in oncological and hospitalized patients, occurring in 1%-2% of all subjects and in 30% of cancer patients^[26]. It is characterized by a deregulated AVP activity, which induces a lower free water excretion. The relative free water surplus leads to serum euvolemic hypo-osmolar hyponatremia. It is often due to a paraneoplastic syndrome, related to several kinds of tumors. It is most frequently reported in patients with small-cell lung cancer, but it is also described in patients with non-small-cell lung cancer, head and neck cancer, and, rarely, other malignancies^[26].

SIAD may be caused by^[38]:

- Inappropriate secretion of antidiuretic hormone (ADH) from cancer cells (paraneoplastic syndrome).
- Activating mutation of ADH receptor V2.
- Inappropriate or persistent release of AVP.

Although paraneoplastic syndrome is the most frequent cause of SIAD, it should be considered that many conditions might lead to an inappropriate release of AVP in cancer patients^[39,40]:

- Concomitant drugs: diuretics, analgesics, chemotherapies, anticancer target agents, antidepressants, antipsychotics, antiepileptics, and antiemetics.
- Central nervous system disease: expansive lesions such as neoplasms or hematomas, inflammatory diseases (e.g., encephalitis, meningitis, *etc.*), degenerative diseases (e.g., Guillain-Barré syndrome), and other rare conditions (e.g., hemorrhage, delirium tremens, hypophyseal peduncle section, transphenoidal adenectomy^[41], and hydrocephalus).
- Pulmonary disorders: infections, respiratory failure, chronic obstructive pulmonary disease, and active pressure ventilation^[1].
- Others: AIDS, senile atrophy, and idiopathic.

Hypervolemic hyponatremia is characterized by an excess of both total body sodium and water. It occurs in edematous conditions such as cirrhosis, chronic kidney disease, nephrotic syndrome, and congestive heart failure^[42].

According to serum osmolality status, hyponatremia can be divided into^[43,44]:

- Hypotonic is characterized by reduced serum osmolality, due to an excess of free water compared to the sodium. This condition might be induced by an excessive water intake (e.g., primary polydipsia) or by a compromised renal water excretory capacity (SIAD).
- Hypertonic is characterized by increased serum osmolality (e.g., in glycemic decompensation).
- Isotonic is characterized by normal serum osmolality, often secondary to an artificially hyponatremia (pseudohyponatremia) due to elevated serum solutes concentrations (e.g., hyperlipidemia).

Management

A correct and timely diagnosis of hyponatremia is essential to setting up a rapid therapy and improving the prognosis of cancer patients. Diagnosis can occur from clinical suspicion, but it is essential for clinicians monitoring serum/plasma sodium level in all cancer patients, in order to promptly correct this electrolyte disturbance, when present, even in the case of symptoms' absence. Hyponatremia symptoms are often absent or generic and closely related to hyponatremia grade and onset speed^[1].

Patients with mild and/or chronic hyponatremia are often asymptomatic or present blurred symptoms that can be misunderstood or imputed to other causes (e.g., dizziness, postural instability, and asthenia).

Patients with severe and/or acute hyponatremia can present different symptoms (from gastrointestinal symptoms such as lack of appetite, nausea, and vomiting to neurological disorders such as headache, irritability, attention deficit, confusion, gait disturbances, and muscle cramps), including life-threatening conditions (bulbar paralysis, lethargy, convulsions, encephalic brain herniation, coma, and cardio-respiratory arrest).

Diagnosis of hyponatremia requires routine laboratory tests. For a correct therapeutic approach, it is crucial to identify the underlying causes, thus lab assessment should also include plasma and urine osmolality, ECV status evaluation, and urinary sodium concentration to obtain a correct differential diagnosis [Figure 1].

In particular, due to different therapeutic options, it is fundamental to exclude SIAD. SIAD diagnosis is diagnosis of exclusion, for which the main criteria are:

- Presence of hyponatremia (< 135 mEq/L).
- Normal ECV.
- Lower serum osmolality (< 275 mOsm/kg).
- Altered urine osmolality (> 100 mOsm/kg).
- Elevated urine sodium concentration (> 30 mmol/L).
- Normal renal function.
- Normal adrenal and thyroid function.
- No use of diuretics.

The therapeutic approach depends on etiology, presence of symptoms, and grade of hyponatremia [Figure 1]. Regardless of hyponatremia's cause, it is important to remember that an effective and prompt correction of serum sodium concentration improves the outcome of cancer patients^[45].

Treatment options include fluid restriction, diuretics, saline solution administration, and vaptans (selective vasopressin receptor antagonists).

Fluid restriction is a difficult therapeutic choice since it is associated with poor compliance because cancer patients often need abundant hydration for oncological therapies. Furthermore, several days are required to correct serum sodium concentrations. In the case of ECV, isotonic saline infusion should be preferred.

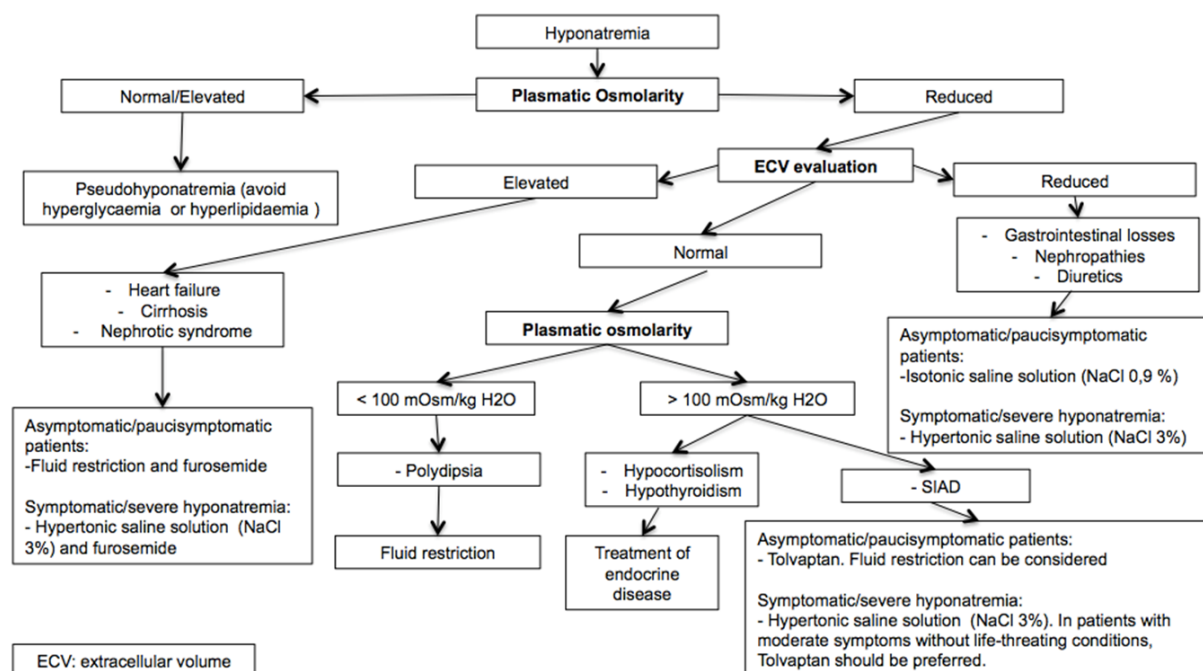

Figure 1. Hyponatremia management algorithm^[38,44-48]. The correct management of hyponatremia and its treatment require the detection of its cause. Plasmatic osmolarity and ECV evaluation are necessary to recognize the origin of hyponatremia. Symptomatic hyponatremia should be treated with hypertonic saline solution. Tolvaptan should be considered in hyponatremia due to SIAD. ECV: extracellular volume; SIAD: syndrome of inappropriate antidiuresis

In the case of hyponatremia secondary to SIAD, the use of Tolvaptan, a selective V2 receptor antagonist, should be considered^[46]. In fact, has shown an important efficacy to correct and stabilize serum sodium concentration, favoring the beginning and prosecution of anticancer treatments without delay. Furthermore, it seems to reduce the risk of hyponatremia development as chemotherapy adverse event^[47]. Tolvaptan schedule requires starting dose of 15 mg once daily and it should be administrated first in a hospital department to monitor the therapeutic response and any adverse event. It could be increased at 24-h intervals, when serum/plasma sodium levels are not improved, to a maximum of 60 mg once a day^[46].

Other approved therapeutic agents are urea and Demeclocycline. However, due to their toxicity and poor patient compliance, they are no longer employed in clinical practice.

In the case of presence of severe neurological symptoms or life-threatening conditions, serum sodium levels should be corrected rapidly and the appropriate therapy is the administration of 3% hypertonic saline^[48].

It is important to monitor the rate of correction of hyponatremia since an excessive speed of rising sodium levels might cause the development of central pontine myelinolysis, an irreversible condition that leads to death. The correction rate should not exceed 12 mmol/L/24 h. Therefore, it is recommended to monitor plasma sodium levels in the first 24 h at regular intervals of 4-6 h, in order to control the correction speed^[49].

Hypernatremia

Definition and clinical implication

Hypernatremia is defined as an elevated serum sodium level over 145 mmol/L. It is a frequent electrolyte disturbance occurring in 1%-5% of hospitalized patients. It represents a negative prognostic factor, related to an elevated mortality rate (40%-75%) compared to eunatremic patients^[50].

Table 2. Causes of hypernatremia

Causes of hypernatremia	
Euvoletic: loss of free water	Losses through skin and breath Reduced thirst stimulation Neurogenic or nephrogenic diabetes insipidus
Hypovolemic: loss of free water	Renal disorders (diuretics, tubular necrosis) Gastro-intestinal disorders (e.g., vomiting, nasogastric drainage, entero-cutaneous fistulae, diarrhea) Cutaneous diseases (burns, excessive sweating)
Hypervolemic: sodium accumulation	Hypertonic sodium bicarbonate or hypertonic saline infusion Excessive ingestion of NaCl Use of emetics rich in NaCl Enteral nutrition Urogenital injection of hypertonic saline Hypertonic dialysis Primitive hyperaldosteronism Cushing Syndrome

Causes

In cancer patients, several causes might induce hypernatremia [Table 2]^[51,52]:

- (1) Cancer: anorexia and cancer cachexia, kidney damage, brain metastasis inducing diabetes insipidus, and gastrointestinal disorders due to cancer infiltration (e.g., fistulae and nasogastric drainage due to bowel obstruction) can induce hypernatremia.
- (2) Cancer treatment: adverse events such as vomiting and diarrhea common to most anti-cancer agents (chemotherapy, TKIs, and immunotherapies) associated with reduced thirst stimulation might cause hypernatremia. Elevated serum sodium concentration might be induced also by bowel direct damage due to antiangiogenetic agents or immunotherapy. Furthermore, some chemotherapeutic agents such as ifosfamide might induce an iatrogenic diabetes insipidus.
- (3) Concomitant drugs: osmotic diuretics, corticosteroids, enteral or parenteral nutrition, and hypertonic saline infusion can induce hypernatremia.
- (4) Concomitant diseases: cushing syndrome might induce hypernatremia.

Two different basic mechanisms might be involved in hypernatremia development: water loss (for reduced introduction (euvoletic hypernatremia) or increased elimination (hypovolemic hypernatremia), or, rarely, accumulation of sodium (often on iatrogenic basis, hypervolemic hypernatremia). Understanding these mechanisms is crucial for a correct differential diagnosis among potential causes of hypernatremia.

The most frequent mechanism underlying hypernatremia is total body water loss due to impaired thirst stimulation. It is often associated with altered mental status conditions, such as older age, brain tumors, damage, or surgery, causing a deficit in thirst and osmoregulation^[51]. Water loss can also be due to renal or extra renal disorders^[52].

Renal water loss usually is caused by osmotic diuresis (e.g., hyperglycemia, increased serum urea concentration, or administration of mannitol or hypertonic solutions) and by a treatment with diuretics^[53].

Rarely, renal water loss can be induced by insipidus diabetes, a deficit of the vasopressin-ADH-receptor system, which can have a central or a nephrogenic origin. Central insipidus diabetes is characterized by a reduced secretion of AVP, often related to a central nervous system damage (e.g., pituitary or hypothalamus neoplasms, brain surgery, or irradiation)^[54]. Nephrogenic insipidus diabetes instead depends on renal resistance to the action of AVP. It is a rarely congenic condition, more frequently related to iatrogenic effect of amphotericin B, lithium, ifosfamide, foscarnet, and streptozocin on tubular reabsorption of water^[53].

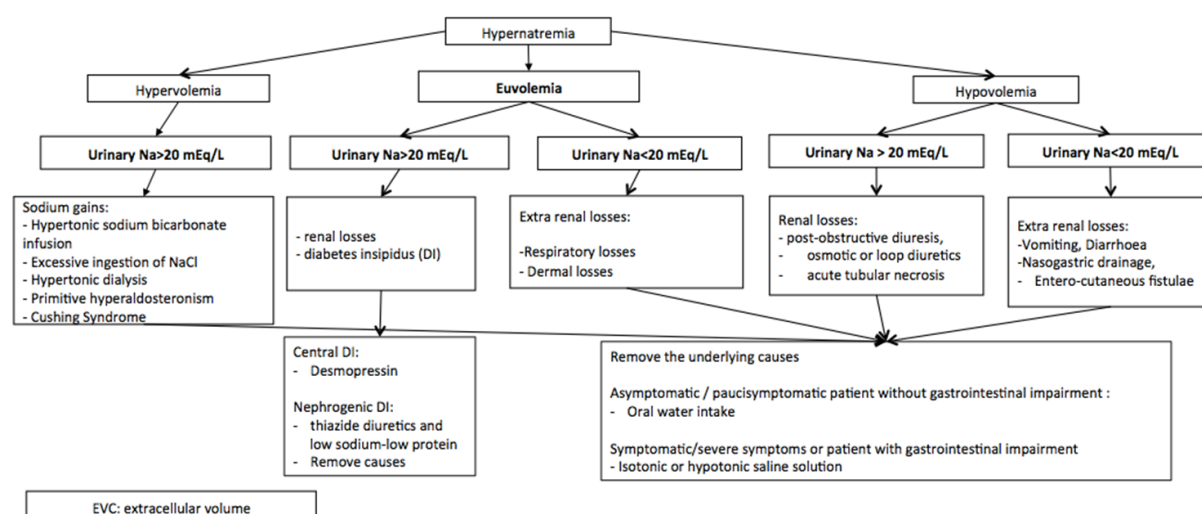

Figure 2. Algorithm of hypernatremia's management^[48,51-60]. The treatment of hypernatremia in cancer patients is based on the correction of the cause. For the differential diagnosis, the evaluation of volume and urinary sodium are fundamental. DI: diabetes insipidus; EVC: extracellular volume

Extra-renal water loss is often related to gastrointestinal diseases (vomiting, nasogastric drainage, and diarrhea).

Rarely, hypernatremia can be caused by excessive salt intake. This condition is often iatrogenic and induced by parenteral administering of hypertonic solutions or chronic nutrition support with hyperosmolar or high protein feeds^[55].

Management

Hypernatremia causes neurological symptoms, for which severity is correlated with both grade and onset speed. In most cases, patients refer non-specific symptoms such as thirst, anorexia, restlessness, nausea, muscle weakness, and confusion. In the case of rapid onset or severe hypernatremia, patients might present lethargy, hyperreflexia, until convulsions, and coma^[56].

Clinical suspicion of hypernatremia should be confirmed by laboratory exam. The correct diagnosis and the detection of specific causes or predisposing factors are crucial for a correct management [Figure 2].

For a correct differential diagnosis between hyponatremia caused by excess of sodium intake and hyponatremia caused by loss of free water, the assessment of urine osmolality, urine sodium concentration, and urine volume should be obtained^[57]. Concentrated urine is usually related to insufficient water intake or extra-renal losses.

Conversely, hypernatremia is associated to elevated serum osmolality and low urine osmolality renal damage with deficient capacity of urinary concentration^[56].

Hypernatremia associated to polyuria (e.g., 24 h urine volume exceeding 2.5 L), low urine osmolality, and urinary sodium are criteria for central insipidus diabetes diagnosis^[58].

Once hypernatremia diagnosis is confirmed, the optimal management requires the removal of the cause and the correction of the electrolyte disorder based on the total ECV, restoring intravascular volume and free water.

In collaborating and asymptomatic patients without gastrointestinal dysfunction, oral hydration is effective, and should be preferred. In patients with severe hypernatremia or unable to intake fluid orally (due to vomiting or neurological changes), intravenous hydration should be considered.

The infusion of free water (5% dextrose solution) should be considered in the case of loss of free water alone. Loop diuretics should be considered in the case of pure sodium gain natriuresis.

In patients with acute hypernatremia (within 24 h) or severe symptoms, treatment with isotonic or hypotonic solutions should be started immediately, since it was demonstrated that a prompt correction (up to 8-12 mmol/L per day) improves patients' prognosis without risk of convulsions or cerebral edema. A correction of 1 mEq/L/h should be considered safe^[59].

In patients with chronic hypernatremia or when time of onset is unknown, the correction should be obtained within 48 h, with a reduction of serum osmolality of no more than 0.5 mOsm/L/h to avoid cerebral edema onset. A reduction of serum sodium concentration of 8-10 mmol/L per day should be considered safe. Monitoring serum sodium levels at regular intervals of 4 h is highly recommended to control the correction speed^[59].

Patients experiencing central insipidus diabetes should receive nasal or oral desmopressin. Nephrogenic insipidus diabetes should be treated with a combination of thiazide diuretics and low sodium-low protein, removing potential precipitation factors^[60].

CALCIUM

Calcium is an extracellular cation and the normal serum calcium concentration range is 2.1-2.5 mmol/L (8.5-10.5 mg/dL) or ionized calcium of 1.1-1.4 mmol/L (4.5-5.6 mg/dL)^[61]. Most of the calcium content is deposited in the organic matrix by hydroxyapatite crystals of bones. Calcium appears in three different forms: free ion (50%), bound to plasma proteins, and in diffusible complexes. Acid-base status influences the binding between calcium and serum proteins. In particular, alkalosis favors the binding while acidosis induces the ionized calcium form. Calcium derives from diet and it is excreted by kidney.

Calcium reabsorption in kidney occurs mainly in the proximal tubules, and a small share in the ascending loop of Henle, thus loop diuretics decrease tubular calcium resorption, whereas thiazide diuretics improve its resorption^[62]. Calcium metabolism requires a steady interaction between bone and ECF. Several hormones are involved in calcium homeostasis. Parathyroid hormone (PTH), whose secretion is mediated by reduced serum calcium levels, acts on bone, favoring osteoclastic-mediated bone resorption and promoting calcium leakage and it induces the synthesis of active vitamin D and calcium intestinal absorption. Calcitonin instead, whose secretion is mediated by increased serum calcium levels, reduces the transfer of calcium from bone calcium pool to the ECF, and it decreases bone resorption inhibiting osteoclasts' activity and increases calcium renal excretion^[63].

Vitamin D also plays a crucial role in serum calcium homeostasis, favoring increased intestinal calcium absorption and bone calcium storage^[64].

Several studies demonstrated a crucial role of calcium-mediated signaling pathways in carcinogenesis, dedifferentiated into cancer stem cells, cellular motility favoring tumor invasion and metastasis, and the regulation of apoptosis^[65].

Several calcium channels are involved and expressed in cancer cells. Ca^{2+} ATPase I isoforms (SPCA1 and ATP2C1) are described in basal-like breast cancer, favoring cell proliferation, while calcium efflux pump

Table 3. Causes of hypocalcemia

Causes of hypocalcemia	
Reduction of serum calcium	Not ionized calcium: hypoalbuminemia, nephrotic syndrome, liver disease, malnutrition Ionized calcium: hyperlipidemia, parenteral nutrition enriched of free fatty acid Extravascular deposition: osteoblastic metastases, pancreatitis
Renal failure	Iatrogenic, post-renal obstruction, compression and infiltration by malignancy, tumor lysis syndrome, hyperuricemia, sepsis, contrast agent nephropathy
Endocrine disorders	Vitamin D deficiency or resistance: inadequate dietary intake, reduced absorption due to hepatobiliary or intestinal malabsorption, liver disease PTH deficiency or resistance: parathyroidectomy, autoimmune disorders, hungry bone syndrome
Concomitant electrolyte disorders	Hypomagnesemia Hyperphosphatemia
Drugs	Antiepileptics: phenytoin, phenobarbital Anticancer agents: fluorouracil, leucovorin, nab-paclitaxel, estramustine, octreotide, imatinib, axitinib, panitumumab, cetuximab, cisplatin Others: bisphosphonates, denosumab, rifampicin, calcium chelators, radiographic contrast agent, furosemide, foscarnet, EDTA, cinacalcet

PTH: parathyroid hormone

PMCA2 (ATP2B2) is most frequently overexpressed in HER2-receptor-positive breast cancer^[66]. Calcium channels are also described in androgen-responsive prostate cancer. In fact, they mediate androgen-induced effects^[67]. Transient receptor potential cation channel (TRPC), subfamily C, is a group of channels expressed in cancer cells. In breast cancer, TRPC1 correlates with low proliferation and TRPM8 overexpression correlates with ER-positive and well-differentiated lower-grade breast cancer^[68]. In prostate cancer, TRPM8 expression is regulated by androgens. Decreased expressions of TRPM8 and TRCP1 are associated with the progression to androgen-independent phase and poor prognosis^[67]. Contrariwise, TRPV6 ion channel's expression seems to be controlled by androgen receptors and it is highly expressed in cancer prostate cells, regardless of androgen dependence, representing a potential biomarker of cancer. In fact, it is not expressed in the healthy prostate cells and benign prostatic hyperplasia. Furthermore, its expression correlates with Gleason score and presence of metastases^[69].

Hypocalcemia

Definition

Hypocalcemia is defined as a lower serum calcium concentration (total serum calcium of < 2.1 mmol/L or < 8.5 mg/dL or ionized form of < 1.1 mmol/L or > 4.5 mg/dL)^[70].

Causes

Several causes can induce hypocalcemia in cancer patients [Table 3]:

(1) Cancer: malnutrition due to anorexia, cancer cachexia or bowel obstruction, malabsorption related to bowel tumor infiltration or previous intestinal surgery, abnormal liver function due to liver metastasis might promote the development of hypoalbuminemia and subsequent hypocalcemia^[70]. Furthermore, malabsorption and malnutrition might frequently cause vitamin D deficiency and then hypocalcemia in cancer patients^[70]. Another condition leading to hypocalcemia is PTH deficiency. It is a common condition of patients undergoing total thyroidectomy with subtotal or total parathyroidectomy for cancer^[71]. Paraneoplastic disorders are also involved in hypocalcemia in cancer syndrome. Such as tumor lysis syndrome or the hungry bone syndrome. The “hungry bone syndrome” is frequent in metastatic parathyroid and prostate cancer and it is characterized by osteoblastic metastases causing an increased deposition of calcium and phosphate in bone and decreased serum calcium and phosphate concentrations^[72].

(2) Cancer treatment: hypocalcemia is also reported in cancer patients receiving bisphosphonates or denosumab, an anti-RANKL (receptor activator of nuclear factor kappa B ligand) monoclonal antibody, employed in cancer patients with bone metastasis in order to delay or prevent skeletal-related events. In

fact, they promote calcium deposition in the bones, reducing blood calcium concentration^[73]. Therefore, checking calcium serum level before these treatments and implementation of calcium and vitamin D oral intake are recommended^[74]. Furthermore, several drugs, such as chemotherapeutic agents, target therapies, immunotherapies can induce hypocalcemia in cancer patients, through different mechanisms: kidney injuries, iatrogenic magnesium-deficiency, gastrointestinal damage, pancreatitis^[75]. In particular, monoclonal anti EGFR antibodies can cause hypomagnesemia with consequent hypocalcemia^[75].

(3) Concomitant drugs: diuretics and parenteral nutrition can induce hypocalcemia^[70].

(4) Concomitant diseases: kidney failure, autoimmune disorders causing PTH deficiency, sepsis, and pancreatitis can induce hypocalcemia^[70].

Management

Clinical manifestations of hypocalcemia are closely related to severity and time of onset. Symptoms and signs are influenced by other factors such as acid-base status, hypomagnesemia, and over-activity of sympathetic system^[76].

Clinical disorders due to hypocalcemia depend on altered electrical potential of cell membrane, and it appears as an imbalanced neuromuscular excitability. Chronic and mild hypocalcemia are often asymptomatic or they can present with muscle cramps, ectopic calcifications, parkinsonism, dementia, depression, psychosis, dry skin, and cataract.

Severe or acute hypocalcemia might cause tetanic spasms, laryngospasm until generalized convulsions, and coma^[76].

Severe hypocalcemia might also provoke cardiac alteration such as arrhythmias or heart block. ECG shows typical alteration such as prolongation of the QTc and ST interval, altered repolarization, T-wave pointed shape, or inversion^[77].

Diagnosis of hypocalcemia is based on symptoms' presence and it needs to be confirmed through laboratory exam. Since serum calcium is partially bound to proteins, it is suggested to correct total serum calcium concentrations with albumin levels [e.g., serum calcium (mg/dL) + 0.8 × (4-patient's albumin)]. Alternatively, ionized calcium can be evaluated. For a correct differential diagnosis, serum albumin, total protein, urinary calcium, phosphate, vitamin D, plasma PTH, and parathyroid, renal, and liver function should be evaluated [Figure 3]^[78].

Treatment of hypocalcemia depends on severity, clinical manifestation, and underlying causes. When possible, it is always advisable to correct the cause of hypocalcemia^[78].

In the case of acute and/or symptomatic hypocalcemia, patients should receive intravenous calcium. To avoid adverse events, calcium gluconate should be infused slowly (e.g., 10 mL of a formulations of 10% calcium gluconate should be diluted in 50-100 mL of 5% dextrose and infused over 5-10 min), and administered via a central venous catheter to prevent extravasation's complications^[79]. In fact, a rapid correction of hypocalcemia might increase the risk of cardiac arrhythmias, especially in patients receiving digoxin, thus cardiac activity should be monitored with ECG and correction rate of hypocalcemia should be checked every 1-2 h during intravenous calcium gluconate infusion^[79].

In the case of tetanic signs due to severe and/or acute hypocalcemia, the treatment initially requires a 10-min bolus of calcium gluconate intravenous infusion (10 mL of 10% solution) followed by the aforementioned formulation. Moreover, concomitant hypomagnesemia or alkalosis should be corrected^[80].

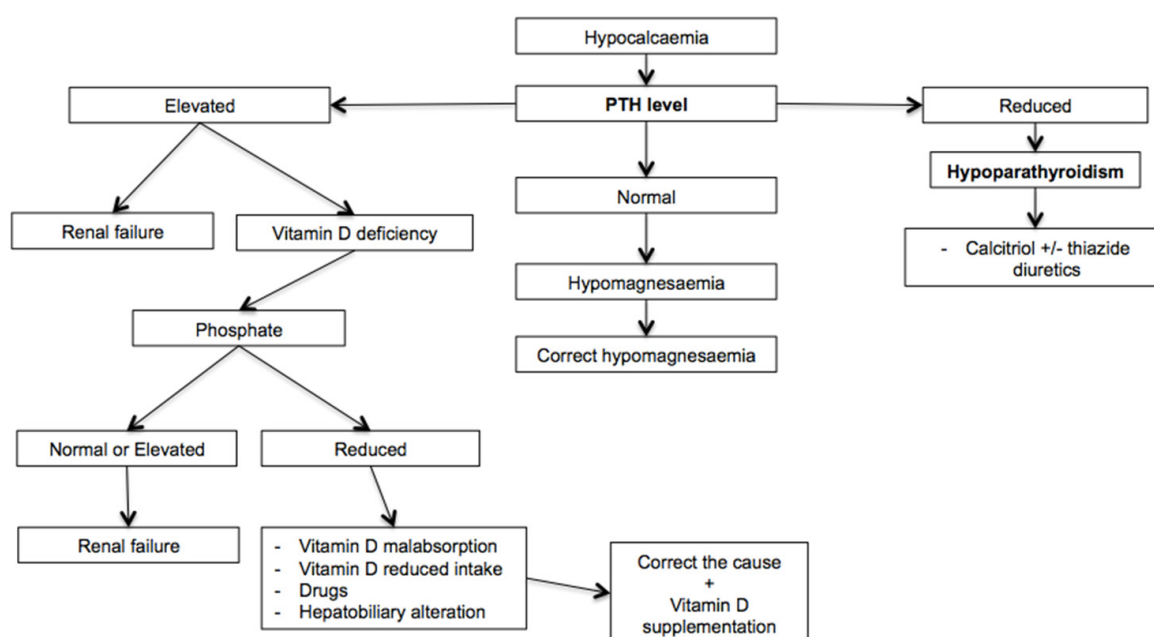

Figure 3. Algorithm of hypocalcemia management^[48,78-86]. For a correct diagnostic classification of hypocalcemia, it is essential to distinguish between hypoparathyroidism and other causes through the dosage of blood parathyroid hormone. In the case of high parathormone concentrations, dosage of vitamin D is useful to exclude deficiency. PTH: parathyroid hormone

In the case of hypoparathyroidism, the treatment aims to control symptoms, maintaining adequate serum calcium levels (2.00-2.12 mmol/L), and a calcium-phosphate ratio below 4.4 mmol/L, in order to prevent hypercalciuria and precipitation of calcium salts in soft tissues^[81]. Calcitriol, a vitamin D analog, is usually used with a starting dose of 0.5 mcg/day, which might be increased until adequate serum calcium concentrations are reached. Thiazide diuretics associated with a low phosphate diet could be considered^[82].

It is recommended to monitor weekly serum calcium, phosphorus concentration, and creatinine during initial administration to obtain a correct stabilization of the dose^[83].

In the case of chronic hypocalcemia, oral supplementation of calcium (calcium carbonate or calcium citrate) and vitamin D is recommended. In the case of hypomagnesemia, it should be corrected^[84].

Vitamin D insufficiency requires supplementation with oral or intramuscular ergocalciferol (vitamin D2) or oral cholecalciferol (vitamin D3). When hypocalcemia is secondary to vitamin D malabsorption, it is important to correct the underlying cause (e.g., celiac patients should receive a gluten-free diet)^[85].

Patients receiving bisphosphonates or anti-RANKL should receive oral calcium and vitamin D supplementation to prevent hypocalcemia^[86].

Hypercalcemia

Definition and clinical implication

Hypercalcemia is defined as a higher serum calcium concentration (total serum calcium over than 10.5 mg/dL)^[87]. It is a common electrolyte disorder in patients with advanced malignancies and it correlates with poor prognosis^[88].

Causes

Several causes might contribute to the development of hypercalcemia in cancer patients [Table 4]:

(1) Cancer: the main cause of hypercalcemia in cancer patients is hyperparathyroidism. It can be divided

Table 4. Causes of hypercalcemia

Causes of hypercalcemia	
Primary hyperparathyroidism	Parathyroid adenoma (MEN1 and 2a), parathyroid carcinoma, familial hypocalciuric hypercalcemia, isolated familial hyperparathyroidism
Secondary hyperparathyroidism	Renal failure, lithium, tumors, bone metastasis
Drugs	Lithium, thiazide diuretics, calcium containing antacids, vitamin A, estrogens, growth hormone, vitamin D intoxication, theophylline
Immobilization	Spinal cord injury, neurological diseases, pathological fracture, orthopedic surgery
Miscellanea	Chronic granulomatous disorders, hyperthyroidism, acromegaly, pheochromocytoma, adrenal insufficiency, parenteral nutrition

into primary and secondary hyperparathyroidism. Primary hyperparathyroidism, the most common cause of hypercalcemia in the general population, is characterized by inappropriate secretion of PTH provoking elevated serum calcium concentrations. Single parathyroid carcinoma is a frequent cause of primary hyperparathyroidism, sometimes inducing a rare but life-threatening condition, hyperparathyroidism-induced hypercalcemic crisis characterized by elevated PTH concentrations (3-10 times higher than normal values) and serum calcium-levels^[89]. Secondary hyperparathyroidism, instead, is characterized by elevated quantities of PTH, secreted by parathyroids. Several causes might contribute to this mechanism^[90], in particular malnutrition and cancer anorexia are the most common cancer related causes. Malignancies are an important cause of hypercalcemia. It was described as occurring in 20%-30% of cancer patients, especially those hospitalized, and it represents one of the most common life-threatening metabolic disorders^[91]. Even though several mechanisms underlay hypercalcemia in cancer patients, it seems to be correlated, especially in some kinds of tumors (head and neck, lung, renal cell, ovarian, thyroid, endometrial, colorectal, breast cancer, hepatocarcinoma, cholangiocarcinoma, thymomas, neuroendocrine tumors, gastrointestinal stromal tumor, and leukemias), with the ectopic production of PTH or parathormone-related peptide (PTHrP). These factors seem responsible for osteoclastic activation, through an increased synthesis of RANKL, provoking bone destruction and calcium release. Furthermore, they determine an increased renal calcium reabsorption, favoring the development of metastatic calcification involving multiple organs, especially lungs, potentially resulting in pulmonary edema^[92]. Moreover, bone metastases, in particular osteolytic ones, are often associated to hypercalcemia due to calcium release from bone. It represents a common cause of hypercalcemia, occurring in approximately 20% of patients with malignancy-related hypercalcemia. Bone metastasis releases several local factors, e.g., transforming growth factor β , RANKL, lymphotoxin, interleukin-1, interleukin-6, hepatocyte growth factor, and macrophage inflammatory protein (MIP-1 α), that favor the release of PTHrP and bone remodeling resulting in hypercalcemia^[93]. Rarely, hypercalcemia might be due to ectopic activity of 1- α -hydroxylase resulting in calcitriol production that promotes increased bone resorption with calcium release and intestinal calcium absorption. This mechanism is described in some kinds of tumors such as lymphomas (lymphoma-associated calcitriol production) and ovarian germ cell tumors^[88]. Finally, immobilization due to bedridden patients, a common condition of advanced cancer, can favor an acceleration of bone resorption resulting in hypercalcemia^[94].

(2) Cancer treatment: antineoplastic drugs can indirectly cause hypercalcemia, for example through kidney damage^[88].

(3) Concomitant drugs: several drugs might cause hypercalcemia. Thiazide diuretics, vitamin D intoxication, and parenteral nutrition are the most common agents involved in this electrolyte disorder in cancer patients.

(4) Concomitant diseases: several pathological conditions might cause hypercalcemia. It may depend on excess of PTH (primary hyperparathyroidism due to parathyroid adenoma, familial hypocalciuric hypercalcemia, isolated familial hyperparathyroidism, or most commonly secondary hyperparathyroidism

due to renal failure or drugs such as lithium) or arise due to mechanisms independent of PTH (chronic granulomatous disorders, hyperthyroidism, acromegaly, pheochromocytoma, and adrenal insufficiency)^[88-90].

Management

To improve patients' outcome, a periodic monitoring of calcium serum levels and prompt correction of potential hypercalcemia should be performed. To define an effective hypercalcemia, it is important to avoid the presence of concomitant factors that can influence the share of bound and free calcium (e.g., hyperglobulinemia might increase total calcium levels without modifying ionized concentrations; acidemia and reducing albumin-calcium affinity might increase the level of the ionized form, without altering total calcium levels)^[87]. Diagnosis is often incidentally during routine laboratory investigations, as most patients with mild hypercalcemia are asymptomatic^[88]. Chronic hypercalcemia, due to hyperparathyroidism, is often asymptomatic; however, in some cases, this long-lasting electrolyte disorder might cause nephrolithiasis. Instead, chronic hyperparathyroidism secondary to renal failure and dialysis might cause bone pain related to bone remodeling process, fibrous degeneration, and formation of cysts and nodules of fibrosis.

Clinical presentation depends on grade and time of onset. Most common symptoms are general malaise, thirst, lethargy, and constipation often associated with abdominal pain. Renal symptoms and signs such as polyuria, polydipsia, nycturia, nephrolithiasis, and rarely renal failure and nephrocalcinosis should be also considered.

Neuromuscular disorders, starting from muscles weakness, emotional instability, and confusion, until development of delirium, psychosis, stupor, and coma, could be observed in acute or severe hypercalcemia (serum calcium levels > 12 mg/dL). Furthermore, hypercalcemia might cause cardiac arrhythmias. The most common electrocardiographic changes are absent or shortened ST segment, shortened QT interval, widened QRS complex, enlarged T wave, and prolonged PR interval. Rarely, it might cause branch block and arrhythmias until to cardiac arrest in the case of serum calcium levels over 15 mg/dL^[88].

Renal function and immunoreactive parathyroid hormone analysis are recommended for a complete diagnostic classification that allows making differential diagnosis and to consider potential serious conditions (cardiac arrhythmias).

Electrocardiography should also be performed in order to avoid presence of cardiac alterations^[95].

Generally, primary hyperparathyroidism is usually characterized by hypercalcemia (with high ionized free serum calcium levels), hypophosphatemia, PTH being inappropriately high (e.g., no hypocalcemia), and excessive bone turnover.

Differential diagnosis between primary and secondary hyperparathyroidism could be difficult in the case of renal failure, although hyperphosphatemia is often linked to secondary hyperparathyroidism and normal or low phosphorus levels are indicative of primary hyperparathyroidism^[96].

Furthermore, in the presence of secondary hyperparathyroidism, radiographic examination should be useful to detect bone cysts presence and bone reabsorption.

When hyperparathyroidism has been excluded, a serum calcium level above 12 mg/dL is suspicious of malignancies, mostly when associated with hypophosphatemia, hypoalbuminemia, and lower or undetectable PTH level. PTHrP is a peptide that shows homology with the N-terminal portion of PTH, mimicking the action. It can be produced from breast, lung, and kidney cancer cells. When possible, the individuation of PTHrP is useful for reach diagnosis of paraneoplastic hypercalcemia^[88].

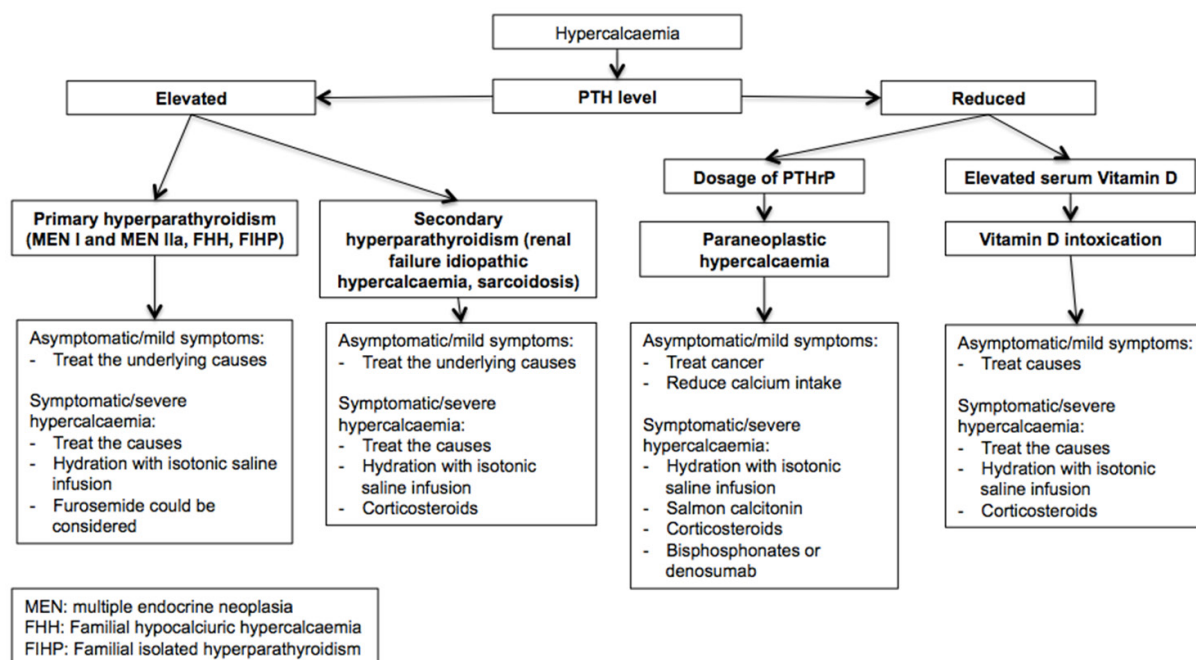

Figure 4. Algorithm of hypercalcaemia management^[48,88,94-104]. To treat hypercalcaemia, a correct diagnostic framework is essential, which is based on the parathyroid dosage to distinguish between hyperparathyroidism and other causes. In the case of low blood PTH concentrations, the dosage of PTHrP is useful to exclude paraneoplastic hypercalcaemia and vitamin D intoxication. PTH: parathyroid hormone; PTHrP: parathyroid hormone-related protein; MEN: multiple endocrine neoplasia; FHH: familial hypocalciuric hypercalcaemia; FIHP: familial isolated hyperparathyroidism

Treatment depends on clinical manifestation, grade of hypercalcaemia, and underlying cause, which should be correct whenever possible [Figure 4]. In the case of mild symptoms, serum calcium levels are below 11.5 mg/dL, which could sufficiently remove the cause of hypercalcaemia.

In the case of severe hypercalcaemia (total serum calcium over 15 mg/dL) or severe symptoms or signs, a treatment aimed to reduce serum calcium levels is recommended, in order to restore adequate intravascular volume and to improve glomerular filtration rate^[96]. Since hypercalcaemia induces polyuria, most patients are dehydrated. Therefore, intravenous isotonic saline solution (NaCl 0.9%) should be administered with an infusion rate of 100/120 mL/h, in order to obtain a urine output of 100-150 mL/h and a reduction of serum calcium concentration^[97]. Two to three liters of isotonic saline solution/day with a close monitoring of serum electrolyte levels and urinary volume is recommended^[98]. In patients with edematogenic syndromes (e.g., congestive heart failure) or anuria isotonic solution should be administered with caution in order to avoid fluid overload. However, only 30% of patients reach normocalcemia with fluids alone. Loop diuretics (e.g., furosemide) might be considered mostly in patients with edematogenic syndromes, in whom it is required to improve diuresis. The use of furosemide should be limited in dehydrated patients or in patients presenting other electrolyte abnormalities (magnesium and, potassium)^[99].

In patients with malignant hypercalcaemia, salmon calcitonin administration (4-8 IU/kg s.c. or i.m. every 12 h) was demonstrated to control serum calcium levels (estimated a maximal serum calcium drop of 2 mg/dL in 4 h after administration), and it can be used also in patents with renal injuries, in which intravenous saline is not recommended^[100]. Furthermore, calcitonin is more efficacious and quicker than bisphosphonates in normalizing calcemia and it can be used with bisphosphonates or in the case of bisphosphonates' resistance. However, due to the risk of tachyphylaxis, the duration of treatment with calcitonin should not exceed 48 h^[101].

The addition of corticosteroids (e.g., 20-40 mg of prednisone/day) is useful to control malignant hypercalcemia especially due to hematological tumors, through an increased renal calcium excretion and inhibition of bone reabsorption. However, since fewer than 50% of patients with malignant hypercalcemia respond to glucocorticoids after several days, in clinical practice, an alternative treatment is usually preferred. Corticosteroids are also used for the treatment of vitamin D intoxication, idiopathic hypercalcemia, and sarcoidosis^[102].

Finally, bisphosphonates, such as ibandronate, pamidronate, and mostly zoledronic acid, have been shown to be effective in reducing serum calcium in approximately 12 h^[103].

Recent evidence demonstrates the activity of denosumab in control malignant hypercalcemia, especially in patients with persistent hypercalcemia despite bisphosphonates. Furthermore, it could also be used in patients with reduced renal function^[104].

POTASSIUM

Potassium is the second most abundant cation in the human organism. It is the main intracellular cation; in fact, only 2%-5% of total body potassium is restrained in extracellular fluids, including blood. Normal serum potassium concentration ranges between 3.5 and 5.0 mEq/L^[105]. The maintenance of this concentration is crucial for several physiological processes (maintenance of cellular membrane potential, cellular volume, and action potentials' transmission in nerve cells)^[105]. Many mechanisms act for preserving potassium homeostasis: oral intake, renal elimination, and balance between intracellular and extracellular concentration.

Renal active excretion of potassium in cortical collecting ducts is regulated by aldosterone, through the modification of the epithelial sodium channel into the open configuration and the increase of the number of epithelial sodium channel. This modification favors sodium reabsorption and increases potassium secretion^[106].

Potassium transit among intracellular and extracellular fluid compartments depends on Na⁺-K⁺-ATPase, a membrane pump ubiquitous in all cells^[107]. This ionic channel creates a concentration gradient across cell membrane, maintaining the potential of cell membrane. Several factors influence the transit of potassium through cell membrane: blood pH, in particular, alkalosis induces the potassium's input from extracellular to intracellular fluid compartments, while acidosis causes the leak of potassium from cells. Furthermore, insulin and β -adrenergic catecholamines favor potassium's input into cells^[108].

Several potassium channels are involved in cancer proliferation. Potassium channels (KCN) are a large group of proteins involved in potassium transfer. In breast cancer, KCNMA1, KCNJ3, KCNN4, and KCNK9 are associated with estrogen receptor's expression and brain and lymph-node metastasis^[109]. In prostate cancer, several potassium channels are involved. In particular, KCNMA1 represents a promising diagnostic biomarker of prostate cancer. In fact, it is over-expressed in cancer cells with Gleason score of 5-6, and in hormone sensitive phase. KCNK2 seems to be involved in the regulation of cell proliferation^[110]. KCNQ1, a pore K⁺ channels, is over-expressed in more than 35% of lung tumors and it favors tumor development, cell proliferation and migration, and resistance to hypoxia^[111]. Voltage-gated K⁺ channels seem to have an important role in colorectal cancer. In particular, over-expression of KCNH2 regulates cell invasion, giving an invasive phenotype to the tumor, and it represents a negative prognostic factor in early stages when associated with the absence of Glut-1. It also seems to confer different chemosensitivity to different drugs; in particular, cells with over-expression of KCNH2 are inhibited by paclitaxel, vincristine, and hydroxy-camptothecin, while they seem to have resistance to doxorubicin. The clinical implication is due to

the influence of KCNH2 in modulating VEGF-A secretion^[112]. Overexpression of KCNH2 has been also demonstrated to be associated with poorer prognosis in squamous-cell carcinoma of esophagus^[113]. Overexpression of KCNH2 seems to also have a role in pancreatic cancer. In particular, it is involved in EGFR pathway, conferring an aggressive behavior and poorer prognosis^[114]. KCNH2 has also been investigated in gastric cancer. In particular, it has been demonstrated to be negatively correlated with grading, stage of disease, venous invasion, and shorter survival^[115]. Otherwise, it has been investigated in surgical samples of patients undergoing radical tumor resection and it seem to correlate with Lauren's intestinal type, fundus localization, low grading, and early stages (TNM I and II)^[116]. Furthermore, it has been demonstrated to modulate VEGF-A secretion and cisplatin-induced apoptosis^[117].

Hypokalemia

Definition and clinical implications

Hypokalemia is defined as a low serum potassium concentration (< 3.5 mEq/L). Severe hypokalemia is defined as a potassium level lower than 2.5 mEq/L, representing a potential life-threatening disorder^[118].

Causes

Hypokalemia is a common electrolyte disorder in cancer patients. Several causes might induce hypokalemia in cancer patients^[108]:

- (1) Cancer: several conditions related to cancer might induce a reduced potassium intake (malnutrition, anorexia, and malabsorption due to cancer bowel infiltration or bowel obstruction). Some neuroendocrine tumors might cause hypokalemia through secretive diarrhea, favoring potassium losses. Other tumors induce renal potassium losses through the production of hormones such as adrenocorticotrophic hormone (ACTH), cortisol, and mineralocorticoids, or through kidney damage, such as multiple myeloma.
- (2) Cancer treatment: chemotherapeutic agents, target therapies and immunotherapies might cause hypokalemia secondary to diarrhea or vomiting.
- (3) Concomitant drugs: thiazide diuretics, insulin, granulocyte growth factors, beta-2 agonists, and glucocorticoids might cause hypokalemia.
- (4) Concomitant diseases: endocrine dysfunctions causing excess glucocorticoids or mineralocorticoids, toxic epidermal necrolysis, and inflammatory bowel diseases might cause hypokalemia.

Causes of hypokalemia might be resumed substantially in three mechanisms: an inadequate potassium intake, redistribution of potassium among intra- and extracellular compartments, and potassium losses [Table 5].

In cancer patients, inadequate intake is often related to malnutrition and anorexia due to drugs and/or tumor condition.

The passage of potassium into the intracellular compartment might depend on many mechanisms: uptake of potassium by tumor cells, alkalosis, hypothermia, and drugs. For example, granulocyte growth factors, often employed in cancer patients, provoke an acute hematopoietic cell formation, favoring rapid potassium intake by the new cells^[119]. Hypokalemia is similarly induced by rapid cell proliferation in acute leukemia^[120].

Potassium losses can be classified into renal and non-renal losses. The most common extra-renal losses are gastrointestinal losses due to drugs or cancer-induced diarrhea and vomiting, infections, radiation enteritis, and type of tumors (villous adenoma and neuroendocrine neoplasms)^[121]. In particular, neuroendocrine neoplasms, although rare, are represented with the carcinoid syndrome characterized by serotonin and

Table 5. Causes of hypokalemia

Causes of hypokalemia	
Reduced potassium intake	Malnutrition, anorexia, refeeding syndrome Gastrointestinal injuries Vomit (caused by anticancer therapies, intestinal obstruction, etc.) Diarrhea (caused by anticancer therapies, cancer, surgery)
Redistribution of the potassium into intracellular compartment	Drugs (catecholamine, nasal decongestants, insulin, granulocyte growth factors, beta-2 agonists, barium intoxication, theophylline, bicarbonate, verapamil) Alkalosis Hypothermia
Increased potassium losses	Non-renal losses: Losses (diarrhea, vomiting, fistula, laxative abuse, villous adenoma) Profuse sweating Extended burns Toxic epidermal necrolysis Renal losses: Metabolic alkalosis Use of diuretics Osmotic diuresis Renal tubular diseases (tubular acidosis, Liddle syndrome) Endocrine dysfunctions (excess of glucocorticoids or mineralocorticoids, primary hyperaldosteronism due to adenoma or adrenal carcinoma, renin-secreting neoplasms, ectopic secretion of ACTH) Concomitant electrolyte disorders (hypercalcemia, hypomagnesemia) Drugs (amphotericin B, cisplatin, ifosfamide, glucocorticoids, anti-EGFR agents, mTOR inhibitors, eribulin, abiraterone)

ACTH: adrenocorticotrophic hormone; EGFR: endothelial growth factor receptor

kallikrein hypersecretion inducing flushing, severe secretory diarrhea with cramps and hypokalemia, tachycardia, hypotension until heart failure, and bronchial constriction^[122]. Another rare syndrome due to tumor hypersecretion of vasoactive intestinal polypeptide induces important watery diarrhea with hypokalemia and achlorhydria^[123].

Renal losses have several potential causes. Endocrine disorders should be considered in cancer patients. For example, Cushing syndrome can be due in rare cases to ACTH-producing tumors, especially in patients with small-cell lung cancer, medullary thyroid carcinoma, islet cell adenoma or carcinoma, pheochromocytoma, and ganglioneuroma, inducing an excessive production of cortisol able to blind mineralocorticoid receptors inducing hypokalemia^[124]. Another rare cause is primary aldosteronism, due to the excessive and autonomous secretion of aldosterone by adrenal adenomas or carcinoma. This syndrome is characterized by polydipsia, polyuria, resistant hypertension, and severe hypokalemia^[125].

Furthermore, a common cause of potassium renal losses in cancer patients is drug-related tubular toxicity. Several chemotherapeutic agents, target therapies, and immunotherapeutic drugs [Table 5] might induce renal injury associated to hypokalemia. Renal function should be evaluated before drug administration to avoid further renal damage^[126]. Concomitant therapies such as thiazide diuretics and glucocorticoids can favor potassium renal losses.

Finally, some kinds of tumor induce renal damage. For example, patients with multiple myeloma producing Bence-Jones proteins develop a progressive renal injury leading to hypomagnesemia and hypokalemia. Acute myeloid leukemia, through secretion of lysozyme, induces renal tubular damage^[127].

In hematological patients, especially in those with marked leukocytosis (e.g., in acute myeloid leukemia), hypokalemia can be confused with pseudo-hypokalemia, due to potassium intake in the stored blood sample before the laboratory analysis^[128].

Management

Clinical presentation depends on severity of hypokalemia. Patients are often asymptomatic, especially those with mild hypokalemia^[129]. Symptoms and sign of hypokalemia are non-specific and due to

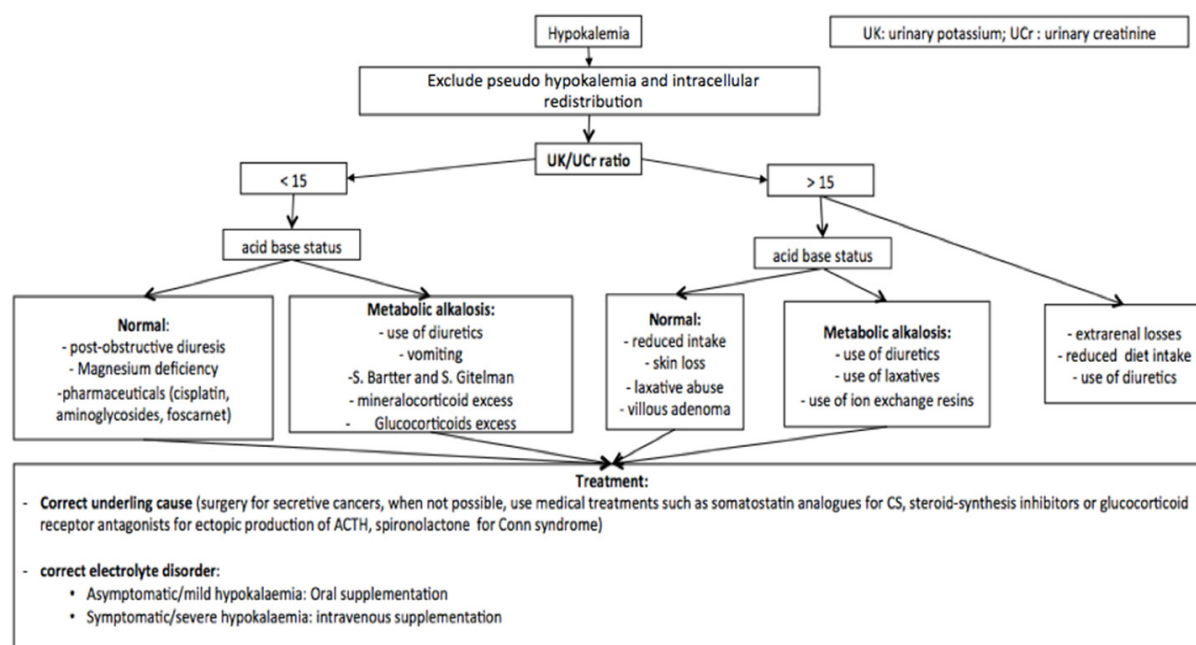

Figure 5. Algorithm of hypokalemia management^[48,129-139]. In the case of hypokalemia, it is useful to consider oral or intravenous supplementation based on the degree and symptoms. It is always useful to associate the identification and correction of the underlying cause. For a correct differential diagnosis, it is essential to evaluate UK and UCr. UK: urinary potassium; UCr: urinary creatinine

muscular, neurological, or cardiac dysfunction. The most common clinical manifestation is characterized by weakness, fatigue, myalgia, muscle cramps, and constipation. In the case of moderate or severe hypokalemia, neurological and psychiatric symptoms (e.g., psychosis, delirium, hallucinations, and depression), or cardiac signs (bradycardia) until acute respiratory failure with cardiovascular collapse, secondary to muscle paralysis, might occur. In particular, cardiac arrhythmias represent life-threatening complications requiring immediate diagnosis and adequate treatment. Therefore, ECG monitoring should be performed in patients with hypokalemia (typical alterations are inverted T waves, appearance of U wave, ST depression, and enlarged PR interval)^[130].

Diagnosis of hypokalemia is based on detection of low serum potassium levels. For a correct management of hypokalemia, it is important to understand the underlying causes. For a correct differential diagnosis, it is important investigate the patient's medical history, evaluating the concomitant therapies and clinical conditions that might cause potassium losses or intracellular redistribution (insulin, diuretics, nephrotoxic agents, anticancer agents, diarrhea, and vomiting). Presence of pseudo-hypokalemia should be excluded in patients with marked leukocytosis.

Furthermore, other laboratory exams should be performed for a correct differential diagnosis. Blood sugar, acid-base balance, creatinine, magnesium levels, and urine electrolytes concentration should be evaluated [Figure 5]^[131]. In particular, 24-h renal potassium concentration is useful to establish renal or extra-renal potassium losses.

When urinary potassium is > 30 mEq/L there is a renal potassium loss, while a urinary potassium concentration of < 25 mEq/L might be related to an extra-renal potassium loss. Another useful evaluation to distinguish between renal and extra-renal potassium losses is the urinary potassium concentration and urinary creatinine concentration ratio. Values > 15 are suggestive for renal potassium losses^[131].

The treatment of hypokalemia depends on symptoms and their severity. It is focused on preventing life-threatening complications and removing the underlying cause [Figure 5].

In patients with mild or moderate hypokalemia (serum potassium levels of 3.0-3.5 mEq/L), potassium oral supplementation should be preferred to intravenous, in order to avoid an iatrogenic hyperkalemia. A daily dose of 60-80 mEq of potassium chloride is recommended. However, it is important to monitor serum potassium concentration in order to adjust treatment doses accordingly. In the case of chronic hypokalemia refractory to oral supplementation, the addition of potassium-sparing diuretics (amiloride and spironolactone) should be considered^[132].

In asymptomatic patients with severe hypokalemia (serum potassium level of < 3.0 mEq/L), an oral potassium supplementation with potassium chloride 40 mEq every 3-4 h should be considered^[133]. Otherwise, in symptomatic patients with a life-threatening complication, or in patients unable to take oral drugs, intravenous potassium (10-20 mEq/h, able to increase serum potassium level an average of 0.25 mEq/h) is recommended^[134]. Continuous ECG monitoring is recommended in patients with arrhythmias, digitalis toxicity, and history of cardiac ischemia. In patients with renal failure, the doses should be reduced and serum potassium level monitored frequently. Refractory hypokalemia might depend on the presence of concomitant electrolyte disorders, such as hypomagnesemia, which should be investigated and treated when present^[135].

When hypokalemia is secondary to tumor activity, treating the cancer is necessary, in addition to symptomatic therapy for hypokalemia, in order to prevent the recurrence of symptoms.

Patients with carcinoid syndrome should receive somatostatin analog in order to inhibiting hormonal hyper-secretion and improve symptoms^[136]. When hypokalemia depends on primary aldosteronism, unilateral adrenalectomy is preferred to mineralocorticoid receptor antagonists^[137].

In the case of ectopic ACTH secretion, a complete resection of the tumor should be preferred, when possible. Other treatment options, such as steroid-synthesis inhibitors (metyrapone, mitotane, trilostane, ketoconazole, and aminoglutethimide) and glucocorticoid receptor antagonists (mifepristone), are available to control severe hypercortisolemia^[138]. In patients with severe (Grades 2-3) diarrhea due to anticancer drugs or radiotherapy, a symptomatic treatment with probiotics, loperamide, and in refractory cases octreotide should be administered in order to prevent hypokalemia^[139].

Hyperkalemia

Definition and clinical implications

Hyperkalemia is defined as an increased serum potassium concentration (> 5.5 mEq/L). According to potassium level, three different grades of severity are described: mild hyperkalemia (5.1-6.0 mEq/L), moderate hyperkalemia (6.1-7.0 mEq/L), and severe hyperkalemia (> 7.0 mEq/L), which represents a life-threatening condition^[140].

Causes

Several causes might induce hypokalemia in cancer patients^[108]:

(1) Cancer: several conditions related to cancer might induce hyperkalemia. Tumors with high proliferative index such as leukemia and small-cell lung carcinomas can result in lysis syndrome after specific anticancer treatment, inducing hyperkalemia.

(2) Cancer treatment: chemotherapeutic agents, such as platinum derivatives, might cause renal injury, which can lead to hyperkalemia.

Table 6. Causes of hyperkalemia

Causes of hyperkalemia	
Increased intake	Iatrogenic (excessive potassium infusion, parenteral nutrition, <i>etc.</i>)
Redistribution into extracellular compartment	Massive tissue catabolism (hemolysis, sepsis, diffuse trauma, rhabdomyolysis, chemotherapies, lysis syndrome) Drugs (beta-blockers, arginine, digital) Metabolic acidosis Insulin deficiency and hyperglycemia Severe muscular exercise Pseudo-hyperkalemia (<i>in vitro</i> hemolysis, leukocytosis, thrombocytosis)
Reduction of renal excretion of potassium	Renal injuries: Acute or chronic renal failure Depletion of effective circulating volume Tubulopathies Selective alteration of potassium excretion (acute transplant rejection, lupus nephritis, cyclosporine, analgesic nephropathy, lead poisoning) Nephrotoxic drugs (cisplatin, ifosfamide, mitomycin C, gemcitabine, methotrexate, bisphosphonates, interferon, somatostatin analogs) Corticosteroid insufficiency: Iopreninemic hypoaldosteronism (diabetic nephropathy, chronic interstitial nephritis, drug nephropathy) Primitive hypoaldosteronism (M. Addison) Use of potassium-sparing diuretics

(3) Concomitant drugs: diuretics, potassium-sparing diuretics, angiotensin-converting enzyme, inhibitors, and NSAIDs might induce hypokalemia.

(4) Concomitant diseases: renal failure, diabetes mellitus, sepsis, and parenteral nutrition might induce hypokalemia.

However, causes of hyperkalemia might be resumed in different mechanisms, such as excessive intake, redistribution into extracellular compartment, or abnormal renal elimination, that might depend on aldosterone deficiency or on renal parenchyma damage [Table 6].

Rarely, hyperkalemia depends only on increased potassium intake, and it is often associated with other risk factors: renal failure, diabetes mellitus, and concomitant medications that inhibit potassium excretion (e.g., potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, and NSAIDs). Furthermore, in cancer patients, parenteral nutrition rich in potassium might induce to life-threatening hyperkalemia^[141].

Tumor lysis syndrome (TLS) represents an important cause of acute hyperkalemia in cancer patients. It is a rare but serious oncological emergency characterized by hyperuricemia, hyperkalemia, hyperphosphatemia, hypocalcemia, and azotemia. It usually appears 48-72 h after the commencement of anticancer-therapy (chemotherapy, radiotherapy, and radiofrequency ablation) as a consequence of massive cell necrosis and acute release of intracellular factors into the systemic circulation^[142]. In particular, elevated uric acid and calcium phosphate release tend to precipitate into renal tubules, causing local damage with glomerular filtration rate reduction until acute kidney injury (AKI). AKI worsens metabolic disorders and hyperkalemia, which might induce severe cardiac arrhythmias until death; low serum calcium levels and acidosis may exacerbate this risk^[143]. In high-grade hematologic malignancies and childhood cancers, it might also occur spontaneously^[144].

Several predisposing factors to tumor lysis syndrome were detected, such as elevated tumor burden, rapidly-growing neoplasms, high tumor sensibility to anti-cancer treatment, concomitant renal failure, elevated lactate dehydrogenase serum level, hyperuricemia, and hyperazotemia. These factors should be investigated before starting treatment, in order to set up a preventive therapy^[145].

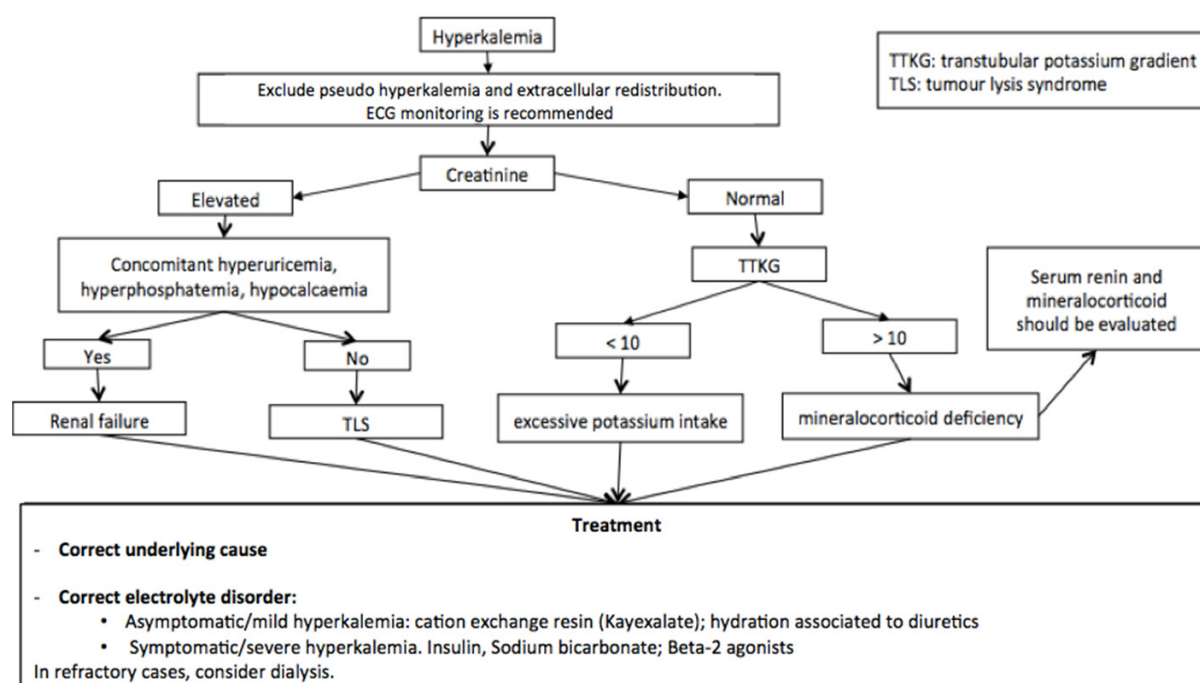

Figure 6. Algorithm of hyperkalemia management^[48,149-154]. In the case of hyperkalemia, the treatment is based on the degree and reported symptoms. When patients are symptomatic for hyperkalemia, insulin, beta-2 agonist, and sodium bicarbonate should be considered. It is always useful to associate the identification and correction of the underlying cause. For a correct differential diagnosis, it is necessary to evaluate renal function through blood creatinine level. If elevated, evaluate uricemia, calcemia, and phosphatemia to distinguish between renal failure and tumor lysis syndrome; TTKG: transtubular potassium gradient

Adrenal insufficiency secondary to metastasis involving both adrenal glands might cause hyperkalemia in cancer patients, especially with advanced lung and breast cancer or lymphomas. However, despite the high frequency of adrenal metastasis (40%-60% of patients), adrenal insufficiency is rarely described, thanks to concomitant administration of corticosteroids^[146]. Finally, in the case of elevated leukocytosis or thrombocytosis, hyperkalemia should be distinguished from pseudo-hyperkalemia, due cellular potassium escape after the blood sample is taken^[147].

Management

Diagnosis of hyperkalemia occurs with the detection of elevated serum potassium concentration. The diagnosis is often an incidental laboratory finding, as patients are often asymptomatic, especially in the case of plasma potassium concentration of < 5.5 mEq/L. When present, symptoms and signs are related to altered cellular resting membrane potential, causing muscle, neurological and cardiac dysfunctions, until life-threatening cardiac arrhythmias. Patients might experience, according to hyperkalemia grade, fatigue and weakness, fasciculation, cramps, and paresthesia, as well as muscular paralysis and palpitations in serious cases. Sometimes, the only signs of hyperkalemia are electrocardiographic specific alterations or cardiac arrhythmias such as pointed T-waves, decrease or absence of P waves, prolonged PR interval, enlarged QRS complex, reduced QT interval, ventricular fibrillation, or asystole^[148].

For a correct differential diagnosis, clinical history evaluating potassium intake and concomitant medications should be collected [Figure 6]. Furthermore, other laboratory exams should be performed: complete blood count, urinary potassium, sodium and osmolality, transtubular potassium gradient (TTKG), renal function, lactate dehydrogenase, and uricemia. Elevated serum creatinine and urea associated with hyperkalemia are suspicious for renal failure. Hyperkalemia, concomitant to the presence of hyperuricemia, hyperphosphatemia, and hypocalcemia, might be suggestive of TLS. In the case of $TTKG > 10$, hyperkalemia might depend on excessive potassium intake. Instead, a $TTKG < 10$ is generally due to a mineralocorticoid

insufficiency and serum concentrations of renin and mineralocorticoid should be evaluated to confirm the diagnosis^[149].

For a correct management of cancer patients with hyperkalemia, it is important to consider presence of ECG alteration, symptoms, and degree of hyperkalemia.

Hyperkalemia treatment requires first to eliminate all potassium exogenous sources and, when possible, discontinue treatment with drugs favoring hyperkalemia [Figure 6].

Furthermore, it is important to counteract cardiac effects of hyperkalemia. In the case of enlargement of QRS complex, intravenous infusion of calcium (e.g., 1fl calcium gluconate 10 mL) and electrocardiographic monitoring are required.

In the case of severe hyperkalemia and electrocardiographic alterations, immediate treatment should be set up. To obtain a rapid reduction of serum potassium level, the administration of medications able to bring potassium in intracellular compartment should be performed^[150]. Several treatment options can be considered:

- Insulin (e.g., 10 units of fast insulin associated to 500 mL of glucose solution at 10% or 250 mL of glucose solution infused in 30-60 min).
- Sodium bicarbonate (e.g., Sodium bicarbonate 1 mEq/kg in 10-20 min), which should be avoided in patients with heart or renal failure, because it might worsen fluid retention.
- Beta-2 agonists (e.g., 10-20 mg salbutamol to inhale in 10 min), which should be avoided in patients with ischemic cardiomyopathy or cardiac arrhythmias.

Although these treatment options are effective in rapidly correcting hyperkalemia, the redistribution of potassium into the intracellular compartment is temporary. Furthermore, sodium bicarbonate and beta-2 agonists should be used as adjuvant treatments, in combination with other therapies^[150].

Patients with moderate and asymptomatic hyperkalemia do not require an immediate serum potassium reduction and can be treated with medications that remove potassium excess but require several hours^[151]. Several treatment options can be considered. Cation exchange resins (Kayexalate) should be preferred. However, due to high sodium content, they have to be used with caution in presence of heart or renal failure, to avoid fluid retention.

Abundant intravenous hydration associated with diuretics (furosemide 40-80 mg) can be considered a valid treatment option; however, it should be avoided in patients with heart failure for fluid overload risk. Furthermore, diuretics have been demonstrated to control serum potassium level only in chronic hyperkalemia, and they should be reserved only for the management of these forms. Dialysis can be considered in the case of renal failure when resins and diuretics fail^[152].

In patients with severe hyperkalemia, plasma potassium levels and ECG should be frequently monitored during treatment (every 1-6 h) until symptoms' resolution, followed by monitoring every 4-12 h until normokalemia achievement^[153].

MAGNESIUM

Magnesium is an important intracellular cation, second to potassium for prevalence. It acts as an essential cofactor for several intracellular enzymes involved in cells replication and energy metabolism processes, including phosphate transfer. Furthermore, it has a crucial role in muscular contractility and neuronal transmission^[154].

Almost the complete amount (about 99%) of magnesium is placed in the intracellular compartment: about 50%-60% is in bone and 38% in soft tissues, while only 1% of total body magnesium is extracellular. Normal serum magnesium concentration is between 1.5 and 1.9 mEq/L (1.7-2.2 mg/dL). Dietary magnesium absorption takes place in intestinal tract, and it is negatively influenced by high protein, phosphate, and fat. Magnesium elimination is mainly controlled by kidney. Several factors (hormonal: PTH, calcitonin, glucagon, and vasopressin; and non-hormonal: acid-base balance, potassium reduction, and magnesium plasma concentration) are involved in renal elimination^[155].

Hypomagnesemia

Definition and clinical implications

Hypomagnesemia is an electrolyte disorder characterized by reduced magnesium serum level (< 1.5 mEq/L). Serum magnesium concentration lower than 1 mg/dL is defined as severe hypomagnesemia. It occurs frequently (7%-12%) in hospitalized patients, and it is correlated to increased risk of death^[156].

Causes

Hypomagnesemia in cancer patients might result from different causes:

(1) Cancer: several conditions related to cancer might induce hypomagnesemia. Anorexia, malnutrition, vomiting, intestinal injury, intestinal drainage/fistulae, diarrhea, and malabsorption syndrome are frequent conditions in cancer patients inducing reduced magnesium intake.

(2) Cancer treatment: several drugs commonly used in cancer patients induce kidney damage and secondary hypomagnesemia. Cisplatin might induce hypomagnesemia through distal renal tubular damage, and it persists after treatment discontinuation. Therefore, intravenous supplementation of magnesium is indicated to prevent hypomagnesemia and decrease risk of nephrotoxicity^[157]. Hypomagnesemia was also described in patients receiving EGFR inhibitors with an incidence of 34% in patients treated with monoclonal anti-EGFR antibodies. In fact, EGFR activation is crucial for magnesium renal reabsorption through TRPM-6 channel^[158].

(3) Concomitant drugs: diuretics, antibiotics beta-adrenergic agonists, foscarnet, and amphotericin B might induce hypomagnesemia.

(4) Concomitant diseases: hyperparathyroidism, hyperthyroidism, diabetes mellitus, dialysis, renal failure, and hereditary disorders (e.g., Bartter's syndrome and Gitelman's syndrome) might induce hypomagnesemia.

Three main mechanisms are involved: reduced intake, redistribution into intracellular compartment, and increased renal losses [Table 7].

The most common mechanism inducing hypomagnesemia is renal losses. However, reduced magnesium intake is also frequent in cancer patients, mainly due to altered absorption secondary to diarrhea, malabsorption syndromes, and extensive bowel resection, while rarely due to severe malnutrition.

Management

Treatment of hypomagnesemia depends on clinical manifestation and severity, and it should be focused on hypomagnesemia correction and causes removal.

Patients with hypomagnesemia are usually asymptomatic, until magnesium concentration falls below 1.2 mg/dL, although symptoms usually do not correlate with serum magnesium levels^[159].

The earliest manifestations of magnesium deficiency are usually non-specific neuromuscular and neuropsychiatric alterations such as weakness and muscle cramps. Severe hypomagnesemia might cause

Table 7. Causes of hypomagnesemia

Causes of hypomagnesemia	
Reduced intake	Insufficient introit (anorexia, malnutrition, vomiting) Altered intestinal absorption (intestinal injury, intestinal drainage/fistulae, diarrhea, malabsorption syndrome) Alcoholism
Redistribution from extracellular into intracellular compartment	Acidosis correction Re-feeding syndrome Catecholamine Accelerated ontogenesis Endocrine disorders (hyperparathyroidism, malignant hypercalcemia, hyperthyroidism, aldosteronism, diabetes mellitus)
Renal losses	Reduced sodium reabsorption, SIADH Infusion of saline diuretics Post-obstructive nephropathy Renal transplantation Dialysis Diuretic phase of acute renal failure Hereditary disorders (e.g., Bartter's syndrome, Gitelman's syndrome)
Other	Pancreatitis, burns, excessive sweating Drugs [diuretics, cytotoxic chemotherapy (cisplatin), EGFR inhibitors, antibiotics beta-adrenergic agonists, foscarnet, amphotericin B]

SIADH: syndrome of inappropriate secretion of antidiuretic hormone

cardiac arrhythmia, disorientation, irritability, tremors, tetany, athetosis, jerking, and confusion, as well as eventually hallucinations, depression, and epileptic crisis. Furthermore, hypomagnesemia is often associated with multiple biochemical alterations, such as hypokalemia, hypocalcemia, and metabolic acidosis that might confuse clinical manifestations^[160].

Hypomagnesemia might manifest with electrocardiographic alterations such as prolonged PR and QT intervals, T wave inversion, and ST elevation^[161].

The diagnosis is based on the detection of lower serum magnesium levels. For a correct differential diagnosis, data on potential gastrointestinal or renal losses and concomitant drugs should be collected. To distinguish between renal and extra-renal losses, magnesium fractional excretion, and urinary calcium and creatinine should be assessed [Figure 7]. Urine magnesium concentration > 2 mmol/day is due to renal wasting.

Treatment for hypomagnesemia depends on severity and clinical presentations. Underlying disorders causing hypomagnesemia should be corrected^[162]. Patients with anamnestic risk magnesium deficiency; laboratory tests and clinical symptoms should be monitored and, when indicated, a prophylactic treatment should be considered. For example, in patients receiving cisplatin-based chemotherapy, intravenous supplementation of magnesium on the day of cisplatin administration and 2-3 days after therapy is indicated.

In asymptomatic patients, oral supplementation of magnesium salts should be preferred (40-60 mEq/day); however, diarrhea might represent a dose-limiting adverse event.

In symptomatic patients, infusion of intravenous magnesium sulfate should be preferred. A total of 1-4 g should be administered with low infusion in 12-24 h (1 g/h), until magnesium levels rise to 1.2 mg/dL.

In the case of severe hypomagnesemia, patients should receive a prompt replacement therapy, in order to prevent cardiac arrhythmias and death^[161]. A total dose of 4-6 g of magnesium sulfate is usually required in these cases.

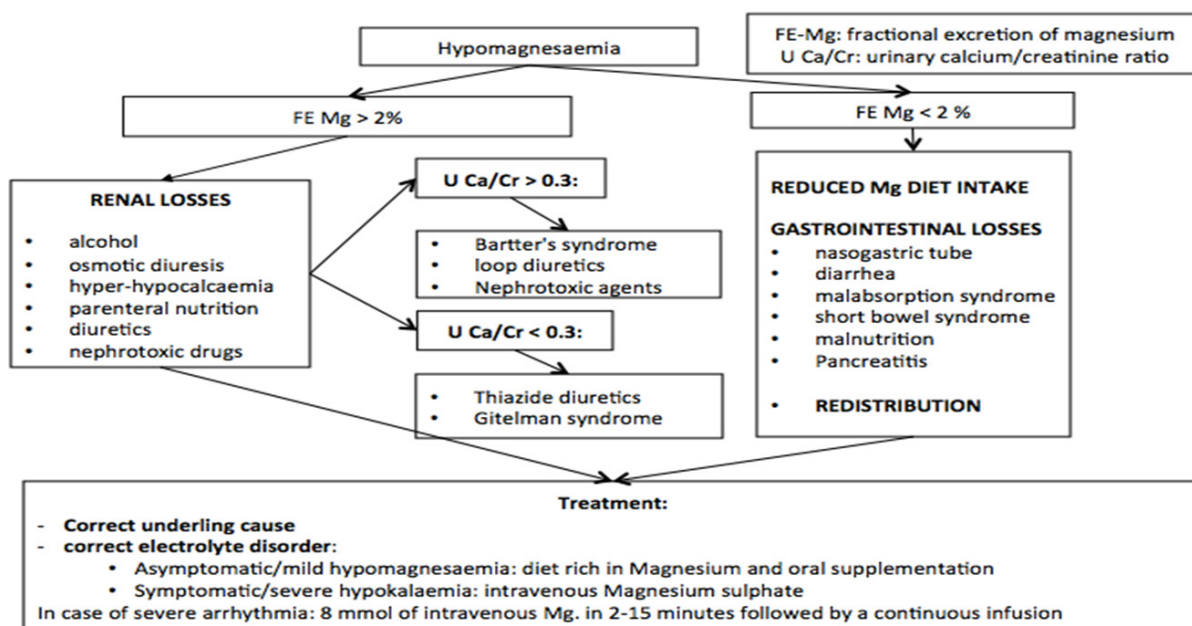

Figure 7. Algorithm of hypomagnesaemia management^[48,159-162]. The treatment of hypomagnesaemia is based on the correction of the underlying cause and the integration of magnesium, which can be oral or intravenous based on the degree and symptoms reported. The differential diagnosis of hypomagnesaemia is based on fractional excretion of magnesium: if it is > 2%, it might indicate renal loss, while, if it is < 2%, hypomagnesaemia might depend on gastrointestinal losses or reduced intake. FE-Mg: fractional excretion of magnesium; U Ca/Cr: urinary calcium/creatinine ratio

The maximum infusion rate should be 8 mEq/h in asymptomatic patients, since rapid intravenous administration of magnesium sulfate induces elevated serum magnesium levels, which favor magnesium renal excretion. Therefore, a slow infusion is crucial to obtain an adequate correction of hypomagnesaemia^[163]. Concomitant electrolyte disorder and vitamin D deficiency should be corrected^[164].

Hypermagnesaemia

Hypermagnesaemia is defined as a magnesium plasma level > 2.2 mEq/L. It is a rare electrolyte disorder and is usually iatrogenic (intravenous magnesium, magnesium-containing laxatives, or anti-acids).

Patient with hypomagnesaemia might complain of hypotension, respiratory depression, confusion, and ECG alterations such as bradycardia and complete AV-block until asystole. Treatment requires discontinuation of magnesium intake. In symptomatic patients presenting cardiac arrhythmias, respiratory depression, and hypotension, intravenous infusion of calcium gluconate 10% is suggested. In severe cases, hemodialysis may be necessary^[164].

CONCLUSION

Electrolyte alterations are common disorders in cancer patients and they are demonstrated to worsen prognosis. Altered electrolyte blood balance might depend on the presence of concomitant diseases and treatments, antineoplastic therapies, or paraneoplastic syndrome. Moreover, electrolytic alterations often cause important morbidity, negatively influencing quality of life and possibility of administration and response to the antineoplastic therapies. Furthermore, recent evidence shows the potential role of electrolyte channels in carcinogenesis, suggesting an important role of electrolyte balance in cancer patients. An improvement of knowledge about these conditions is necessary to monitor patients at risk for a prompt diagnosis and effective treatment, in order to improve patient outcome. Considering the lack of data in the literature supported by clinical trials enrolling cancer patients, the treatment recommendations

are based on retrospective or non-randomized studies such as case reports and case series, and based on clinical recommendations obtained by an Italian group of experts. A recent review analyzed dysnatremia, hypocalcemia, and hypercalcemia in cancer patients^[165]. Our manuscript deepens understanding of the consequences of electrolytic disturbances on the outcome of cancer patients as well as the roles of ion channels in carcinogenesis. In addition, in this review, the electrolytic disturbances of four cations are analyzed, namely Na, K, Ca, and Mg, to try to offer diagnostic and therapeutic algorithms useful for patient management in clinical practice. Prospective studies are needed to improve the management of electrolyte disorders in cancer patients.

DECLARATIONS

Authors' contributions

Made substantial contributions to conception and design of the work: Berardi R

Performed acquisition and analysis of data and have drafted the manuscript: Torniai M, Lenci E, Pecci F, Morgese F, Rinaldi S

Revised the manuscript: Berardi R

Abstract

Breast and prostate cancer are the leading causes of death in females and males, respectively. Triple negative breast cancer (TNBC) does not express the estrogen receptor, progesterone receptor, or human epidermal growth factor receptor 2, resulting in limited treatment options. Androgen deprivation therapy is the standard care for prostate cancer patients; however, metastasis and recurrence are seen in androgen-independent prostate cancer. Both prostate and breast cancer show higher resistance after recurrence and metastasis, which increases the difficulty of treatment. Natural killer (NK) cells play a critical role during innate immunity and tumor recognition and elimination. NK cell function is determined by a delicate balance of inhibitory signals and activation signals received through cell surface receptors. Lectin-like transcript 1 (LLT1, CLEC2D, OCIL) is a ligand of NK cell inhibitory receptor NKR1A (CD161). Several studies have reported higher expression of LLT1 is associated with the development of various tumors. Our studies revealed that TNBC and prostate cancer cells express higher levels of LLT1. In the presence of a monoclonal antibody against LLT1, NK cell-mediated killing of TNBC and prostate cancer cells were greatly enhanced. This review highlights the potential that using monoclonal antibodies to block LLT1 - NKR1A interactions could be an effective immunotherapeutic approach to treat triple negative breast cancer and prostate cancer.

INTRODUCTION

Breast cancer is one of the most serious diseases influencing the health of women, whereas prostate cancer threatens the health of men^[1]. In the 2019 Cancer Statistics report by Siegel *et al.*^[2], it was estimated that more than 170,000 men will be diagnosed with prostate cancer in the United States in 2019. Triple negative breast cancer (TNBC), a subtype of breast cancer, has the poorest prognosis and highest rate of recurrence and metastasis^[3]. Cancer recurrence and metastasis is the primary cause of cancer-related deaths and resistance to previous treatments is commonly seen. The critical functions of the immune system in cancer have been known for decades, but the transition to immunotherapy as a major method of cancer treatment has only occurred within the past few years. After the immunoediting hypothesis was suggested, the role of immune cells in cancer cell elimination, tolerance, and escape has been recognized^[4]. Although our immune system utilizes both innate and adaptive immune cells to recognize and eliminate abnormal cells, in many situations, cancer cells are still able to avoid immune surveillance. Cancer cells can adopt several mechanisms to evade immune surveillance; one mechanism is the upregulation of inhibitory signal pathways of immune cells to inhibit the immune response, such as upregulation of PD-L1 in TNBC^[5]. Lectin-like transcript 1 (LLT1) is a natural killer (NK) cell inhibitory ligand that has been described to contribute to the immunosuppressive properties of glioblastoma, prostate cancer, and triple negative breast cancer^[6-9]. This review highlights breast and prostate cancer, the function of NK cells, and NK cell-based immunotherapy. Additionally, this review explores LLT1 as a potential immunotherapeutic target for breast and prostate cancer elimination by NK cells.

BREAST CANCER AND PROSTATE CANCER

In 2019, there will be approximately 270,000 women diagnosed with breast cancer and 170,000 men diagnosed with prostate cancer in the United States^[2]. Unlike other cancers, breast cancer and prostate cancer are primarily gender specific in females and males, respectively. According to the expression level of estrogen receptor, progesterone receptor, and human epidermal growth factor receptor 2 (HER2), breast cancer is classified into the subtypes luminal A, luminal B, HER2 positive, and TNBC^[10,11]. Compared with the other subtypes of breast cancer, TNBC has a relatively worse prognosis owing to lack of recognizable molecular targets and high level of heterogeneity^[10,12-14]. Conventional treatments, including chemotherapy and radiotherapy, are still the primary way to treat TNBC patients. Beneficial results are observed when patients first begin chemotherapy; however, resistance to the chemotherapy and recurrence have been shown after later treatments^[15]. *BRCA1*, *BRCA2*, *ATM*, and *TP53* are essential genes in the DNA damage response signal pathways^[16]. Studies suggest mutations in these genes are found in TNBC^[16,17]. In TNBC, critical DNA damage response gene mutations lead to genomic instability, and a higher probability to produce neoantigens, which are termed “non-self” to differentiate from “self”^[18]. These neoantigens offer promising targets for immunotherapy.

In the United States, prostate cancer is the second leading cause of cancer-related death in males. Due to the vital role of the androgen receptor in the development of prostate cancer, androgen deprivation therapy has become the standard treatment for prostate cancer^[19-22]. Prostate cancer recurrence is usually androgen independent, which is termed castration-resistant prostate cancer^[23,24]. Therefore, new treatments are required for castration-resistant prostate cancer.

NK CELL FUNCTION

NK cells are an indispensable component of immune cells, but their role in immunotherapy has only been considered in recent years. NK cells were first suggested in tumor immunosurveillance due to studies

that showed people with higher incidence of cancers have defective NK cell functions caused by gene deficiency^[25,26]. Additionally, tumor growth and metastasis were also observed in NK mutant mice or after blocking NK cell activity by antibodies^[27,28]. Two types of receptors are expressed on NK cells: inhibitory receptors and activation receptors. Natural cytotoxicity receptor family, killer cell lectin-like receptor, and CD16 comprise the majority of activation receptors expressed on NK cells^[29,30]. The common characteristic of these NK cell activation receptors is having a cytoplasmic immunoreceptor tyrosine-based activation motif to mediate the activation signals. Unlike NK cell activation receptors, inhibitory receptors such as killer cell immunoglobulin-like receptors and the heterodimer CD94-NK group 2A recognize and bind to self MHC class I molecules and the inhibitory signals are mediated via cytoplasmic immunoreceptor tyrosine-based inhibition motifs^[31]. In contrast with CD8⁺ T cells, activation of NK cells does not require antigen presenting cell priming or MHC restriction^[32]. NK cell activation is regulated by the balance from activation and inhibitory receptor mediated signaling^[33]. Therefore, through multiple, simultaneous complex signaling pathways, NK cells recognize and kill a broad range of tumor cells. For example, tumor specific antigen interaction with activation receptors on NK cells, accompanied with lack of co-engagement of inhibitory receptors, will lead to secretion of perforin and granzyme from NK cells to target tumor cells^[34]. Additionally, it has been reported that some tumor cells have spontaneous loss of MHC class I expression as a mechanism for CD8⁺ T cell escape. NK cells, which do not require antigen presentation, are able to recognize and kill MHC class I low tumor cells^[35].

NK CELLS AND IMMUNOTHERAPY

Antibody dependent cell-mediated cytotoxicity (ADCC) is another primary function of NK cells and is currently being investigated to be used in NK cell-mediated immunotherapy. NK cells use the CD16 (FcγRIII) receptor to bind with the Fc portion of antibodies bound to specific antigens on target cells and induce NK cell cytotoxicity^[36]. Monoclonal antibodies (mAb) can also be used to block the interaction between ligands and receptors on NK cells. We have shown that activating NK cells via surface receptor CS1 (CD319, SLAMF7) enhanced the ability of NK cells to kill various tumor cells^[37,38]. Several other studies showed that CS1 is overexpressed on multiple myeloma (MM) and a humanized anti-CS1 mAb (Elotuzumab/Empliciti) was approved as a break through drug for treatment for MM patients^[39,40]. Our lab has found overexpression of LLT1 ligand on TNBC and prostate cancer, which interacts with the NK receptor NKR1A (CD161) and inhibits NK cell cytotoxicity^[9,41]. Thus, blocking inhibitory signals to NK cells using monoclonal antibodies to LLT1 could enhance the lysis of prostate cancer and TNBC cells by NK cells^[9,41].

Checkpoint inhibitors, which are traditionally used to promote CD8⁺ T cell function, have also been demonstrated to effect NK cell function. More specifically, NK cells express PD-1 and binding to PDL-1 on target cells results in inhibition of NK cell function and more aggressive tumors. Blockade of PD-1 and PDL-1 with mAb results in the strong NK cell responses required for full immunotherapeutic effect^[42].

In addition to checkpoint inhibitors, CARs (chimeric antigen receptor) can be engineered in NK cells or NK cell lines. Binding of a CAR to a tumor associated antigen leads to a strong activating signal, which triggers NK cell cytotoxicity^[43]. Currently, there are many clinical trials taking advantage of CAR NK cells. One such trial (NCT03056339) utilizes a CAR specific for the tumor associated antigen CD19 coupled to the costimulatory domains of CD28 and the zeta chain of the TCR/CD3 complex. Additionally, the retroviral vector expresses IL-15 for optimal NK cell activation and the inducible caspase 9 (iC9; iCasp9) suicide gene.

LLT1 AND NKR1A

LLT1, also known as CLEC2D (C-type lectin domain family 2 member D), OCIL (Osteoclast inhibitory lectin), and CLAX (Lectin-like NK cell receptor), belongs to the C-type lectin-like receptor superfamily and

was first described and cloned by our lab in human NK cells^[44]. Cross-linking of the LLT1 receptor on NK cells induces the production of IFN- γ without activation of the cytolytic pathway^[45]. Our lab, confirmed by others, also identified the NK cell inhibitory receptor NKR1A (CD161) as the ligand for LLT1 and implicated that LLT1 expressed on other cells could inhibit NK cell function^[46,47]. LLT1 is encoded by the *CLEC2D* gene, which produces five different isoforms through alternative splicing. Isoform 1 of LLT1 interacts with the NKR1A (CD161) receptor. Isoforms 2 and 4 stay in the endoplasmic reticulum and associate with LLT1 to form homodimers or heterodimers. Unlike LLT1 expressed on the cell surface, Isoforms 5 and 6 are soluble forms of LLT1^[48,49]. As a C-type lectin-like receptor, LLT1 is composed of three domains: a transmembrane domain, a stalk region, and the extracellular carbohydrate recognition domain, which is responsible for recognition^[7]. B cells, NK cells, T cells, and activated dendritic cells also express LLT1 on the cell surface^[48,49]. The crystal structure of LLT1 demonstrated it is highly glycosylated and when it forms a homodimer at the cell surface it serves as a ligand for the NKR1A receptor on NK cells^[46,47,50,51]. NKR1A is encoded by *KLRB1* and CD4⁺ T cells, invariant NKT cells, and $\gamma\delta$ -T cells have also been shown to express NKR1A^[49]. In mice, *CLEC2D* encodes the protein Oc1/Clr-b, which interacts with NKR-P1B/D^[52-54].

LLT1 AS AN IMMUNOTHERAPEUTIC TARGET FOR BREAST CANCER AND PROSTATE CANCER

NK cells, B cells, T cells, and activated dendritic cells express LLT1^[46,48]. Monoclonal antibody blocking of LLT1 could enhance the IFN- γ production of NK cells, but no differences in cytotoxicity have been seen^[45]. Increased expression of LLT1 was observed after Toll-like receptor induced activation of B cells and dendritic cells, which led to NK cell inhibition via LLT1 - NKR1A interaction^[49]. Inhibition of NK cell function through LLT1 has been observed on human malignant glioma cells, and immune crosstalk with B cells and monocyte-derived dendritic cells^[8,49,55]. Identification of a specific marker to enhance the ability of NK cells to recognize TNBC cells and prostate cancer cells provides a promising way for clearance of cancer cells. Previously, our lab studied the expression of LLT1 on TNBC and prostate cancer, and the results showed higher expression of LLT1 on TNBC cells compared to normal cells. Monoclonal antibody blocking of LLT1 enhanced NK cell cytotoxicity and TNBC cells lysis^[9]. In addition to higher surface expression of LLT1 on TNBC cells, our studies also demonstrated higher intracellular and surface expression of LLT1 in the prostate cancer cells compared with normal prostate cells. Blocking the interaction between LLT1 and NKR1A increased NK cell cytotoxicity against prostate cancer cells^[41]. In addition to blocking the inhibitory signal, anti-LLT1 mAb may activate ADCC (antibody dependent cell mediated cytotoxicity) function of NK cell against breast cancer and prostate cancer [Figure 1]. Pasero *et al.*^[56] showed that highly effective NK cells are associated with better prognosis in metastatic prostate cancer patients. Collectively, we demonstrate that monoclonal antibodies to enhance NK cell activation may provide a promising treatment to target and potentially prevent breast and prostate cancer metastasis. Santos-Juanes' newest study showed higher LLT1 expression was contributed to the risk of neck cutaneous squamous cell carcinoma (cSCC) nodal metastasis, which implicates LLT1 may also be a potential target to block cSCC nodal metastasis^[57]. Similar results have also been seen in mice; inhibition of NKR1B: Clr-b axis could enhance the NK cell-mediated immune surveillance to oncogenic transformation^[52]. Due to the important role of LLT1 in tumor progression and metastasis, monoclonal antibody blocking of LLT1 to enhance NK cell cytotoxicity may provide a novel treatment to prevent tumor metastasis.

CONCLUSION

Tumor recurrence and metastasis is associated with chemotherapy resistance, which greatly enhances the mortality in breast and prostate cancer^[3,58]. NK cell-mediated immunotherapy could provide specific recognition of tumor cells and overcome the resistance from chemotherapeutic drugs. LLT1, an inhibitory ligand, is widely expressed on several cancer cell lines. Our lab has demonstrated higher expression of LLT1 on TNBC and prostate cancer cells and increased lysis of cancer cells after blocking LLT1 with monoclonal antibodies. These results suggest LLT1 may offer a potential target for breast and prostate cancer treatment.

Figure 1. Activation of NK cell using anti-LLT1 monoclonal antibody. (Left) Prostate and triple-negative breast cancer cells express LLT1 which can bind to NCRP1A on NK cells leading to inhibition of NK cell function. (Right) However, in the presence of anti-LLT1 antibodies, NK cells can be activated via two mechanisms: (1) blocking of LLT1 prevents inhibitory signal transmission; and (2) activation when NK cell receptor CD16 binds to anti-LLT1 antibody bound to LLT1 on cancer cells. Image created using BioRender (www.BioRender.com). NK: natural killer; LLT1: lectin-like transcript 1; mAb: monoclonal antibody

Abstract

The most widely used chemotherapeutic combinations in locally advanced (LA) or metastatic pancreatic ductal adenocarcinoma (PDAC) are Nab-Paclitaxel-Gemcitabine (Nab-PCT-GEM) and Fluorouracil, Folinic acid, Oxaliplatin, and irinotecan (FOLFIRINOX). Chemo-resistance, typical of PDAC, appears to be due to the negative influence of stroma population cells, namely regulatory T cells (Treg) and myeloid-derived suppressor cells, macrophages with inhibitory effects on the antitumor activity of the innate and adaptive immune systems, and resistance to cancer treatment. Among other factors that may influence immune surveillance, constant physical activity appears to reduce the risk of cancer-related mortality and cardiovascular risk. However, this does not seem to increase the survival of patients with PDAC. The exception is our young inoperable patient. For LA head PDAC, he was treated with seven cycles of Nab-PCT-GEM and RT 50 Gy/15 fractions combined to biweekly GEM and salvage FOLFIRINOX. The five-year surviving patient travelled 15,000 km on foot and continues inexorably his “walking therapy”.

INTRODUCTION

The severity of pancreatic ductal adenocarcinoma (PDAC) is often linked to a late diagnosis with evidence of a locally advanced or metastatic disease, and the prognosis is poor. PDAC is one of the most chemoresistant tumors, which seems related to derived tumor-associated macrophages (TAMs) cells in the tumor's desmoplastic reaction^[1]. They are distinguished in M1 macrophages, which express inducible nitric oxide synthase, major histocompatibility complex class II (MHC-II) proteins, and CD80, CD86, and tumor necrosis factor α proteins, and they have immunostimulatory activity. In contrast, M2 macrophages expressing Th2 cytokines, arginase 1, CD206, and low amounts of MHC-II have immunosuppressive functions that allow tumor progression^[2]. Furthermore, the tumor microenvironment (TME), through Treg^[3] and myeloid-derived suppressor cells (MDSC)^[4] cells, has negative immunosuppressive effects.

Current treatments for advanced PDAC that improve prognosis and survival are Nab-Paclitaxel-Gemcitabine (Nab-PCT-GEM)^[5] and FOLFIRINOX^[6]. Furthermore, Nab-PCT-GEM regimen, in addition to its direct antitumor activity, seems to have immunoregulatory function. In fact, nab-PCT polarizes M1 macrophages by toll-like receptor 4 signaling^[2,7], whereas GEM has a dual action on MDSC and Treg^[8].

However, a cancer patient's immune system is affected by other factors, such as depression and impairment of physical activity. Depression due to a cancer diagnosis, as well as chronic stress and social isolation, suppresses immune function by the adrenergic and glucocorticoid pathways^[9]. The effects are especially strong on the lymphocytic stromal TME^[10], and are determinants in response to therapy.

Regarding physical activity, which could modify the depressive state, there are no conclusive data on the real impact on the immune system. Finally, although there is experience that correlates the amplitude of physical activity with the reduction of the risk of cancer-related and cardiovascular mortality^[11], this has not been reported on PDAC^[12].

The aim of this report is to analyze the characteristics of this long-term PDAC patient and the possible positive influence of long and constant physical activity on the global control of the disease.

CASE REPORT

A male 40-year-old patient has been recognized to have a locally advanced neoplasm of the pancreas head. After the appearance of obstructive jaundice, he was subjected to endoscopic retrograde cholangiopancreatography and positioning of biliary stenting with resolution of jaundice. Subsequently, he was subjected to exploratory laparotomy, which showed a locally advanced head pancreatic tumor that was judged inoperable. The intraoperative biopsy provided the diagnosis of PDAC. From December 2013 to July 2014, the patient underwent chemotherapy with Nab-PCT-GEM combination [Figure 1A and B] for seven cycles with radiological stability (not shown). Taking into consideration the persistence of non-operability, he performed RT 50 Gy/15 fractions combined to biweekly GEM with stabilization of the disease [Figure 1C and D].

After subsequent local progression, he was treated from April to October 2015 with FOLFIRINOX for six months with stabilization of the disease (not shown). This treatment resulted in bone marrow and peripheral neurological toxicity with negative repercussions on general conditions. After a slow and progressive clinical improvement, from February 2017, the patient undertook a constant course of physical exercise until he reached 15,000 km of walking. The reported daily route, carried out exclusively on foot, was on average 20 km and the total distance traveled was performed in 750 days.

During the five-year follow-up period, the stability status of the disease was confirmed [Figure 1E and F]. Furthermore, blood samples were taken the morning following a walk, periodically about every three months. The blood data are reported corresponding to the km traveled.

Figure 1. A: Computed tomography (CT) scan before Nab-paclitaxel-Gemcitabine therapy: hypodense lesion of 30 mm maximum transverse diameter, infiltrating the posterior lamina and presenting contact with the superior mesenteric artery; B: Wirsung duct dilatation of 8.42 mm; C: CT scan after Nab-paclitaxel-Gemcitabine therapy and consolidation radiotherapy: volumetric stability of the pancreatic lesion (29.76 mm); D: the Wirsung duct caliber (7.99 mm); E: 63 months from start therapy (after Nab-paclitaxel-Gemcitabine, radiotherapy and FOLFIRINOX salvage therapy) presence of slight reduction of the pancreatic lesion (25.38 mm maximum transverse diameter); and F: increase of the Wirsung caliber (10.67 mm) with atrophy of the pancreas body and tail

The hematological study has documented a count reduction of lymphocytes and platelets during chemo-radiotherapy followed by stabilization [Figure 2A]. Regarding the immune profile of lymphocyte subpopulations, a progressive reduction of CD3, CD4, and CD8 followed by an increase; a wave trend of CD16; and stability of HLA-DR and Treg were reported.

Moreover, after initial reduction of platelet/lymphocyte ratio followed by stabilization during therapy, an initial temporary increase tending to a fair final reduction after start of physical exercise was reported [Figure 2B and C]. Furthermore, after a decrease of Ca19.9 [Figure 2E] and C-reactive protein (CRP) and increase of albumin [Figure 2D], the stability over time of its level, as well as those of the other indexes of illness such as albumin [Figure 2D], CEA, and Ca19.9 [Figure 2E], was observed.

DISCUSSION

Current treatments for advanced PDAC represented by Nab-PCT-GEM and FOLFIRINOX combinations have improved prognosis and survival, which remain poor.

In addition to the aforementioned factors of a local nature, other factors of an immunological nature contribute to resistance to cytoreductive drugs and ultimately to neoplastic progression.

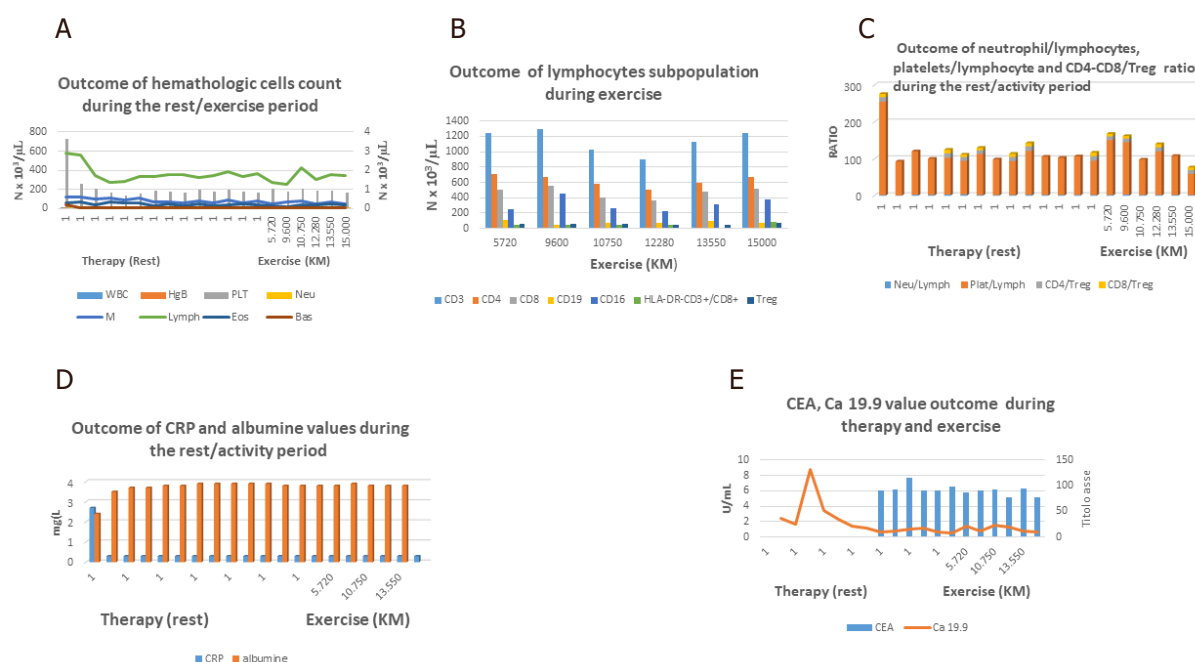

Figure 2. A: Hematologic outcome of population cells: decrease of platelets and lymphocytes count after therapy followed by stability of count cells during physical activity. Stability over time of hemoglobin level and white blood cells types; B: lymphocyte subpopulation during physical activity: progressive reduction of CD3, CD4 and CD8 followed by an increase, a wave trend of CD16 and stability of HLA-DR and Treg cells; C: initial reduction of Platelet/lymphocyte ratio followed by stabilization during therapy; it is followed by initial slight increase followed by stability and therefore slight reduction during exercise. Furthermore is shown a relative stability of neutrophil/lymphocyte, CD4/Treg, CD8/Treg ratios; D: recovery of albumin levels and decrease of CRP after therapy followed by stability during physical activity; E: decrease of Ca 19.9 after therapy followed by the stability over time together of CEA levels during exercise

It is known how the magnitude of the tumor mutation burden correlates with the probability of response to the new checkpoint inhibitory agents that have recently entered clinical practice in the treatment of tumors.

PDAC is also negatively influenced by the low tumor mutation burden, characterized by low prevalence of somatic mutations and of neo-antigens expression with consequent resistance to new immunotherapeutic agents, such as anti-PD1^[13]. One of the key points of immunosuppression also present in PDAC is represented by the CXCR4/CXCL12 axis. In fact, from its block derives the promotion of intratumoral lymphocyte infiltration and the synergism of action with anti-PD-1 agent^[14].

Among the external factors, physical activity is very important in the homeostasis of the organism. It exercises antitumor activity in animal models and high levels of post-diagnosis exercise reduce the risk of recurrence and cancer-specific mortality in common solid tumors^[15]. Such exercise must be undertaken gradually until a constant level is reached and maintained (inverted-J hypothesis), whereby regular moderate exercise improves immune system function while acute, intermittent efforts correlate with immunosuppression and increased susceptibility to cancer^[16].

Regarding the repercussions of physical activity and immune surveillance, the cells that are most stimulated are the natural killer (NK) cells, influenced by neuroendocrine^[17,18] and immunological mechanism such as IL-6 secretion resulting from muscle stress^[19].

However, discordant results have been reported in animal and clinical studies and were reiterated in a systematic literature review on the repercussions of physical exercise on NK cell counts and cytotoxicity. Indeed, definitive conclusions cannot yet be drawn because of the diversity in the intensity and duration of the exercise and in the time of blood sampling^[20].

The emerging difficulties derive from the possible hormonal role on the total NK count, which does not include the tissue one, and from the correlations with performance status, age, and disease status in acute and chronic exercise^[20].

Regarding innate immunity, immunological differences between healthy persons and cancer patients have been demonstrated^[21,22]. In healthy persons, exercise can positively influence the pro-inflammatory polarization of M1 macrophages following immune escape^[21], and neutrophil counts^[22], while, in a tumor animal model, exercise caused vascular normalization and hypoxia reduction with improvement of response to chemotherapy^[23] and reduction of TAMs and neutrophils infiltrating their tumors determining tumor volume reduction^[24].

In the adaptive immune response, Th1-polarized T cells and Tregs, influenced by adhesion molecules, are involved in maintaining peripheral tolerance and appear to have a prognostic role^[25-27]. Moderate-intensity exercise produced in healthy 65-year-old subjects a greater increase in lymphocyte response to immunogenic stimulation than in those who performed flexibility and toning exercises^[28]. In fact, a single bout of physical exercise also seems to determine in the healthy an increase of differentiated NK-cells, CD8+, and $\alpha\delta$ T-cells, with marked sensitivity to external stimulation. This could have an implication in hematopoietic stem cell transplantation and represent a valid aid in the conventional treatment of tumors^[29].

Reduction of leukocyte count, improvement of depressive symptoms, and increase in diurnal salivary cortisol rhythm can be obtained in patients with a six-month exercise program differently from in sedentary patients but without the lymphocyte functional finding^[18].

Finally, in low immunogenic tumors, such as pancreatic adenocarcinoma, chemotherapy with drugs such as anthracyclines can trigger an immune response through dendritic cells (DC)^[30].

Similar to chemotherapy, marathon running increases myeloid DC counts and the production of pro- and anti-inflammatory cytokines^[31]. This finding supports the role of immunomodulatory mechanisms in the response and adaptation to acute, excessive exercise. The possible clinical application of these results has found a clinical finding in pretreated, unresponsive patients and in progression of disease, obtaining a disease control rate of 41%, improvement of physical status, reduced risk of progression, and impact on increase of cytotoxic CD8+ CD28+ and decrease of suppressive CD8+ CD28- T cell^[32].

Regarding long-term survivors, the increased risk of developing second cancers and cardiovascular complications is known.

In this case, it also seems that the amplitude of physical activity reduced the risk of both cancer-related mortality and cardiovascular disease^[11]. However, this was not found in PDAC^[12].

Nevertheless, there is some evidence for correlations among antitlastic treatment, moderate but constant physical exercise, and immune response in the neoplastic patients, although knowledge about the impact of physical activity on the immune system is not conclusive.

Cell death by chemotherapy might not be the single modality of antitumor action; there may be other immunomodulation mechanisms, regulated and controlled by immunosuppressive cells, that can condition the therapeutic response. They could act as an additive to chemotherapy and could improve the therapeutic index if “physical conditioning exercise” has been administered in selected patients before starting chemotherapy or new innovative therapy with checkpoint inhibitors.

Therefore, if physical activity were recognized as a determining factor in the induction and maintenance of antitumor immune function, it could be used as adjuvant and maintenance therapies in the on and off phases of the active antineoplastic therapy, respectively.

Physical activity may have surprising positive results, especially in patients with a life-threatening disease, such as PDAC, who have undergone systemic treatments that cause long-term sequelae such as neurotoxicity with a negative impact on their quality of life. After a slow and progressive clinical improvement, our patient undertook a constant course of physical exercise until he reached more than 15,000 km of walking. These results are described in his book^[33], which deals with his manifold experiences, feelings, and personal reflections, as well as the clinical approach to his neoplastic disease. During the five-year follow-up period and walking activity, the stability of the disease was confirmed. Therefore, this could be linked to the contribution of the physical exercise as maintenance of response obtained after FOLFIRINOX. It is also worth noting the stability of the hematological and immunological profile, with a reduction trend of PLT/Lymph ratio, the normalization of CRP after treatment, and its maintenance over time during physical activity, which are indirect indices of immune surveillance. However, no statistical considerations can be made due to the lack of comparative data during an actual rest phase for the relative constant physical activity of the patient.

His unique experience should make us profoundly reflect on the effects of reactive depression to a cancer diagnosis, and to further study the relationships between physical activity and both treatment efficacy and immunosuppression. Prospective studies involving medical oncologists, immunologists, biologists, neurologists, and physiotherapists are needed to confirm these results.

DECLARATIONS

Authors' contributions

Conceptualization, data curation, formal analysis, investigation, methodology, project administration, software, supervision, validation, visualization, writing - original draft, writing - review & editing, and used in attributes: Lo Re G, Magnaldi S, Doretto P, Innocente R, Lo Re F

Availability of data and materials

We declare that the patient's data derive from personal treatment and clinical-instrumental follow-up. The scientific data reported derive from the international literature and it is listed in the references.

Financial support and sponsorship

None.

Conflicts of interest

All authors declared that there are no conflicts of interest.

Ethical approval and consent to participate

Not applicable.

Consent for publication

Not applicable.

AUTHOR INSTRUCTIONS

1. Submission Overview

Before you decide to publish with us, please read the following items carefully and make sure that you are well aware of Editorial Policies and the following requirements.

1.1 Topic Suitability

The topic of the manuscript must fit the scope of the journal. Please refer to Aims and Scope for more information.

1.2 Open Access and Copyright

The journal adopts Gold Open Access publishing model since its establishment and has been distributing contents under Attribution 4.0 International License since October 2017, whereas Attribution-NonCommercial-ShareAlike 3.0 Unported had been adopted by then. Please make sure that you are well aware of these policies.

1.3 Publication Fees

Authors are required to pay Article Processing Charges of 299 US Dollars after the manuscript is officially accepted. For more details, please refer to Article Processing Charges.

1.4 Language Editing

All submissions are required to be presented clearly and cohesively in good English. Authors whose first language is not English are advised to have their manuscripts checked or edited by a native English speaker before submission to ensure the high quality of expression. A well-organized manuscript in good English would make the peer review even the whole editorial handling more smooth and efficient.

If needed, authors are recommended to consider the language editing services provided by Charlesworth to ensure that the manuscript is written in correct scientific English before submission. Authors who publish with OAE journals enjoy a special discount for the services of Charlesworth via the following two ways.

Submit your manuscripts directly at <http://www.charlesworthauthorservices.com/~OAE>;

Open the link <http://www.charlesworthauthorservices.com/>, and enter Promotion Code “OAE” when you submit.

1.5 Work Funded by the National Institutes of Health

If an accepted manuscript was funded by National Institutes of Health (NIH), the author may inform editors of the NIH funding number. The editors are able to deposit the paper to the NIH Manuscript Submission System on behalf of the author.

2. Submission Preparation

2.1 Cover Letter

A cover letter is required to be submitted accompanying each manuscript. It should be concise and explain why the study is significant, why it fits the scope of the journal, and why it would be attractive to readers, *etc.*

Here is a guideline of a cover letter for authors' consideration:

In the first paragraph: include the title and type (e.g., Original Article, Review, Case Report, *etc.*) of the manuscript, a brief on the background of the study, the question the author sought out to answer and why;

In the second paragraph: concisely explain what was done, the main findings and why they are significant;

In the third paragraph: indicate why the manuscript fits the Aims and Scope of the journal, and why it would be attractive to readers;

In the fourth paragraph: confirm that the manuscript has not been published elsewhere and not under consideration of any other journal. All authors have approved the manuscript and agreed on its submission to the journal. Journal's specific requirements have been met if any.

If the manuscript is contributed to a special issue, please also mention it in the cover letter.

If the manuscript was presented partly or entirely in a conference, the author should clearly state the background information of the event, including the conference name, time and place in the cover letter.

2.2 Types of Manuscripts

There is no restriction on the length of manuscripts, number of figures, tables and references, provided that the manuscript is concise and comprehensive. The journal publishes Original Article, Review, Meta-Analysis, Case Report, Commentary, *etc.* For more details about paper type, please refer to the following table.

Manuscript Type	Definition	Abstract	Keywords	Main Text Structure
Original Article	An Original Article describes detailed results from novel research. All findings are extensively discussed.	Structured abstract including Aim, Methods, Results and Conclusion. No more than 250 words.	3-8 keywords	The main content should include four sections: Introduction, Methods, Results and Discussion.
Review	A Review paper summarizes the literature on previous studies. It usually does not present any new information on a subject.	Unstructured abstract. No more than 250 words.	3-8 keywords	The main text may consist of several sections with unfixed section titles. We suggest that the author includes an "Introduction" section at the beginning, several sections with unfixed titles in the middle part, and a "Conclusion" section in the end.
Case Report	A Case Report details symptoms, signs, diagnosis, treatment, and follows up an individual patient. The goal of a Case Report is to make other researchers aware of the possibility that a specific phenomenon might occur.	Unstructured abstract. No more than 150 words.	3-8 keywords	The main text consists of three sections with fixed section titles: Introduction, Case Report, and Discussion.
Meta-Analysis	A Meta-Analysis is a statistical analysis combining the results of multiple scientific studies. It is often an overview of clinical trials.	Structured abstract including Aim, Methods, Results and Conclusion. No more than 250 words.	3-8 keywords	The main content should include four sections: Introduction, Methods, Results and Discussion.
Systematic Review	A Systematic Review collects and critically analyzes multiple research studies, using methods selected before one or more research questions are formulated, and then finding and analyzing related studies and answering those questions in a structured methodology.	Structured abstract including Aim, Methods, Results and Conclusion. No more than 250 words.	3-8 keywords	The main content should include four sections: Introduction, Methods, Results and Discussion.
Technical Note	A Technical Note is a short article giving a brief description of a specific development, technique or procedure, or it may describe a modification of an existing technique, procedure or device applied in research.	Unstructured abstract. No more than 250 words.	3-8 keywords	/
Commentary	A Commentary is to provide comments on a newly published article or an alternative viewpoint on a certain topic.	Unstructured abstract. No more than 250 words.	3-8 keywords	/
Editorial	An Editorial is a short article describing news about the journal or opinions of senior editors or the publisher.	None required	None required	/
Letter to Editor	A Letter to Editor is usually an open post-publication review of a paper from its readers, often critical of some aspect of a published paper. Controversial papers often attract numerous Letters to Editor	Unstructured abstract (optional). No more than 250 words.	3-8 keywords (optional)	/
Opinion	An Opinion usually presents personal thoughts, beliefs, or feelings on a topic.	Unstructured abstract (optional). No more than 250 words.	3-8 keywords	/
Perspective	A Perspective provides personal points of view on the state-of-the-art of a specific area of knowledge and its future prospects. Links to areas of intense current research focus can also be made. The emphasis should be on a personal assessment rather than a comprehensive, critical review. However, comments should be put into the context of existing literature. Perspectives are usually invited by the Editors.	Unstructured abstract. No more than 150 words.	3-8 keywords	/

2.3 Manuscript Structure

2.3.1 Front Matter

2.3.1.1 Title

The title of the manuscript should be concise, specific and relevant, with no more than 16 words if possible. When gene or protein names are included, the abbreviated name rather than full name should be used.

2.3.1.2 Authors and Affiliations

Authors' full names should be listed. The initials of middle names can be provided. Institutional addresses and email addresses for all authors should be listed. At least one author should be designated as corresponding author. In addition, corresponding authors are suggested to provide their Open Researcher and Contributor ID upon submission. Please note that any change to authorship is not allowed after manuscript acceptance.

2.3.1.3 Abstract

The abstract should be a single paragraph with word limitation and specific structure requirements (for more details please refer to Types of Manuscripts). It usually describes the main objective(s) of the study, explains how the study was done, including any model organisms used, without methodological detail, and summarizes the most important results and their significance. The abstract must be an objective representation of the study: it is not allowed to contain results which are not presented and substantiated in the manuscript, or exaggerate the main conclusions. Citations should not be included in the abstract.

2.3.1.4 Keywords

Three to eight keywords should be provided, which are specific to the article, yet reasonably common within the subject discipline.

2.3.2 Main Text

Manuscripts of different types are structured with different sections of content. Please refer to Types of Manuscripts to make sure which sections should be included in the manuscripts.

2.3.2.1 Introduction

The introduction should contain background that puts the manuscript into context, allow readers to understand why the study is important, include a brief review of key literature, and conclude with a brief statement of the overall aim of the work and a comment about whether that aim was achieved. Relevant controversies or disagreements in the field should be introduced as well.

2.3.2.2 Methods

Methods should contain sufficient details to allow others to fully replicate the study. New methods and protocols should be described in detail while well-established methods can be briefly described or appropriately cited. Experimental participants selected, the drugs and chemicals used, the statistical methods taken, and the computer software used should be identified precisely. Statistical terms, abbreviations, and all symbols used should be defined clearly. Protocol documents for clinical trials, observational studies, and other non-laboratory investigations may be uploaded as supplementary materials.

2.3.2.3 Results

This section contains the findings of the study. Results of statistical analysis should also be included either as text or as tables or figures if appropriate. Authors should emphasize and summarize only the most important observations. Data on all primary and secondary outcomes identified in the section Methods should also be provided. Extra or supplementary materials and technical details can be placed in supplementary documents.

2.3.2.4 Discussion

This section should discuss the implications of the findings in context of existing research and highlight limitations of the study. Future research directions may also be mentioned.

2.3.2.5 Conclusion

It should state clearly the main conclusions and include the explanation of their relevance or importance to the field.

2.3.3 Back Matter

2.3.3.1 Acknowledgments

Anyone who contributed towards the article but does not meet the criteria for authorship, including those who provided professional writing services or materials, should be acknowledged. Authors should obtain permission to acknowledge from all those mentioned in the Acknowledgments section. This section is not added if the author does not have anyone to acknowledge.

2.3.3.2 Authors' Contributions

Each author is expected to have made substantial contributions to the conception or design of the work, or the acquisition, analysis, or interpretation of data, or the creation of new software used in the work, or have drafted the work or substantively revised it.

Please use Surname and Initial of Forename to refer to an author's contribution. For example: made substantial contributions to conception and design of the study and performed data analysis and interpretation: Salas H, Castaneda WV; performed data acquisition, as well as provided administrative, technical, and material support: Castillo N, Young V.

If an article is single-authored, please include "The author contributed solely to the article." in this section.

2.3.3.3 Availability of Data and Materials

In order to maintain the integrity, transparency and reproducibility of research records, authors should include this section in their manuscripts, detailing where the data supporting their findings can be found. Data can be deposited into data repositories or published as supplementary information in the journal. Authors who cannot share their data should state that the data will not be shared and explain it. If a manuscript does not involve such issue, please state "Not applicable." in this section.

2.3.3.4 Financial Support and Sponsorship

All sources of funding for the study reported should be declared. The role of the funding body in the experiment design, collection, analysis and interpretation of data, and writing of the manuscript should be declared. Any relevant grant numbers and the link of funder's website should be provided if any. If the study is not involved with this issue, state "None." in this section.

2.3.3.5 Conflicts of Interest

Authors must declare any potential conflicts of interest that may be perceived as inappropriately influencing the representation or interpretation of reported research results. If there are no conflicts of interest, please state "All authors declared that there are no conflicts of interest." in this section. Some authors may be bound by confidentiality agreements. In such cases, in place of itemized disclosures, we will require authors to state "All authors declare that they are bound by confidentiality agreements that prevent them from disclosing their conflicts of interest in this work." If authors are unsure whether conflicts of interest exist, please refer to the "Conflicts of Interest" of OAE Editorial Policies for a full explanation.

2.3.3.6 Ethical Approval and Consent to Participate

Research involving human subjects, human material or human data must be performed in accordance with the Declaration of Helsinki and approved by an appropriate ethics committee. An informed consent to participate in the study should also be obtained from participants, or their parents or legal guardians for children under 16. A statement detailing the name of the ethics committee (including the reference number where appropriate) and the informed consent obtained must appear in the manuscripts reporting such research.

Studies involving animals and cell lines must include a statement on ethical approval. More information is available at Editorial Policies.

If the manuscript does not involve such issue, please state "Not applicable." in this section.

2.3.3.7 Consent for Publication

Manuscripts containing individual details, images or videos, must obtain consent for publication from that person, or in the case of children, their parents or legal guardians. If the person has died, consent for publication must be obtained from the next of kin of the participant. Manuscripts must include a statement that a written informed consent for publication was obtained. Authors do not have to submit such content accompanying the manuscript. However, these documents must be available if requested. If the manuscript does not involve this issue, state "Not applicable." in this section.

2.3.3.8 Copyright

Authors retain copyright of their works through a Creative Commons Attribution 4.0 International License that clearly states how readers can copy, distribute, and use their attributed research, free of charge. A declaration "© The Author(s) 2019." will be added to each article. Authors are required to sign License to Publish before formal publication.

2.3.3.9 References

References should be numbered in order of appearance at the end of manuscripts. In the text, reference numbers should be placed in square brackets and the corresponding references are cited thereafter. Only the first five authors' names are required to be listed in the references, other authors' names should be omitted and replaced with "et al.". Abbreviations of the journals should be provided on the basis of Index Medicus. Information from manuscripts accepted but not published should be cited in the text as "Unpublished material" with written permission from the source.

References should be described as follows, depending on the types of works:

Types	Examples
Journal articles by individual authors	Weaver DL, Ashikaga T, Krag DN, Skelly JM, Anderson SJ, et al. Effect of occult metastases on survival in node-negative breast cancer. <i>N Engl J Med</i> 2011;364:412-21. [PMID: 21247310 DOI: 10.1056/NEJMoal008108]

For other types of references, please refer to U.S. National Library of Medicine.

The journal also recommends that authors prepare references with a bibliography software package, such as EndNote to avoid typing mistakes and duplicated references.

2.3.3.10 Supplementary Materials

Additional data and information can be uploaded as Supplementary Material to accompany the manuscripts. The supplementary materials will also be available to the referees as part of the peer-review process. Any file format is acceptable, such as data sheet (word, excel, csv, cdx, fasta, pdf or zip files), presentation (powerpoint, pdf or zip files), image (cdx, eps, jpeg, pdf, png or tiff), table (word, excel, csv or pdf), audio (mp3, wav or wma) or video (avi, divx, flv, mov, mp4, mpeg, mpg or wmv). All information should be clearly presented. Supplementary materials should be cited in the main text in numeric order (e.g., Supplementary Figure 1, Supplementary Figure 2, Supplementary Table 1, Supplementary Table 2, *etc.*). The style of supplementary figures or tables complies with the same requirements on figures or tables in main text. Videos and audios should be prepared in English, and limited to a size of 500 MB or a duration of 3 minutes.

2.4 Manuscript Format

2.4.1 File Format

Manuscript files can be in DOC and DOCX formats and should not be locked or protected.

2.4.2 Length

There are no restrictions on paper length, number of figures, or amount of supporting documents. Authors are encouraged to present and discuss their findings concisely.

2.4.3 Language

Manuscripts must be written in English.

2.4.4 Multimedia Files

The journal supports manuscripts with multimedia files. The requirements are listed as follows:

Videos or audio files are only acceptable in English. The presentation and introduction should be easy to understand. The frames should be clear, and the speech speed should be moderate.

A brief overview of the video or audio files should be given in the manuscript text.

The video or audio files should be limited to a duration of 3 min and a size of up to 500 MB.

Please use professional software to produce high-quality video files, to facilitate acceptance and publication along with the submitted article. Upload the videos in mp4, wmv, or rm format (preferably mp4) and audio files in mp3 or wav format.

2.4.5 Figures

Figures should be cited in numeric order (e.g., Figure 1, Figure 2) and placed after the paragraph where it is first cited;

Figures can be submitted in format of tiff, psd, AI or jpeg, with resolution of 300-600 dpi;

Figure caption is placed under the Figure;

Diagrams with describing words (including, flow chart, coordinate diagram, bar chart, line chart, and scatter diagram, *etc.*) should be editable in word, excel or powerpoint format. Non-English information should be avoided;

Labels, numbers, letters, arrows, and symbols in figure should be clear, of uniform size, and contrast with the background; Symbols, arrows, numbers, or letters used to identify parts of the illustrations must be identified and explained in the legend;

Internal scale (magnification) should be explained and the staining method in photomicrographs should be identified;

All non-standard abbreviations should be explained in the legend;

Permission for use of copyrighted materials from other sources, including re-published, adapted, modified, or partial figures and images from the internet, must be obtained. It is authors' responsibility to acquire the licenses, to follow any citation instruction requested by third-party rights holders, and cover any supplementary charges.

2.4.6 Tables

Tables should be cited in numeric order and placed after the paragraph where it is first cited;

The table caption should be placed above the table and labeled sequentially (e.g., Table 1, Table 2);

Tables should be provided in editable form like DOC or DOCX format (picture is not allowed);

Abbreviations and symbols used in table should be explained in footnote;

Explanatory matter should also be placed in footnotes;

Permission for use of copyrighted materials from other sources, including re-published, adapted, modified, or partial tables from the internet, must be obtained. It is authors' responsibility to acquire the licenses, to follow any citation instruction requested by third-party rights holders, and cover any supplementary charges.

2.4.7 Abbreviations

Abbreviations should be defined upon first appearance in the abstract, main text, and in figure or table captions and used consistently thereafter. Non-standard abbreviations are not allowed unless they appear at least three times in the text. Commonly-used abbreviations, such as DNA, RNA, ATP, *etc.*, can be used directly without definition. Abbreviations in titles and keywords should be avoided, except for the ones which are widely used.

2.4.8 Italics

General italic words like *vs.*, *et al.*, *etc.*, *in vivo*, *in vitro*; *t* test, *F* test, *U* test; related coefficient as *r*, sample number as *n*, and probability as *P*; names of genes; names of bacteria and biology species in Latin.

2.4.9 Units

SI Units should be used. Imperial, US customary and other units should be converted to SI units whenever possible. There is a space between the number and the unit (i.e., 23 mL). Hour, minute, second should be written as h, min, s.

2.4.10 Numbers

Numbers appearing at the beginning of sentences should be expressed in English. When there are two or more numbers in a paragraph, they should be expressed as Arabic numerals; when there is only one number in a paragraph, number < 10 should be expressed in English and number > 10 should be expressed as Arabic numerals. 12345678 should be written as 12,345,678.

2.4.11 Equations

Equations should be editable and not appear in a picture format. Authors are advised to use either the Microsoft Equation Editor or the MathType for display and inline equations.
