Abstract

Potassium-ion batteries (PIBs) are considered as promising alternatives to lithium-ion batteries (LIBs) due to their abundant potassium resources, cost-effectiveness, and comparable electrochemical performance to LIBs. However, the practical application of PIBs is hindered by the slow dynamics and large volume expansion of anode materials. Owing to their unique morphology, rich pores, abundant active sites, and tunable composition, metal-organic framework (MOF)-derived carbon and its composites have been widely studied and developed as PIB anodes. In this review, the basic configuration, performance evaluation indicators, and energy storage mechanisms of PIBs were first introduced, followed by a comprehensive summary of the research progress in MOF-derived carbon and its composites, especially the design strategies and different types of composites. Moreover, the advances of *in situ* characterization techniques to understand the electrochemical mechanism during potassiation/depotassiation were also highlighted, which is crucial for the directional optimization of the electrochemical performance of PIBs. Finally, the challenges and development prospects of MOF-derived carbon and its composites for PIBs are prospected. It is envisioned that this review will guide and inspire more research efforts toward advanced MOF-derived PIB anode materials in the future.

Keywords: Metal-organic framework-derived carbon, carbon composites, *in situ* characterization, potassium-ion batteries

INTRODUCTION

The massive consumption of limited fossil fuels over the past decades, accompanied by excessive carbon emissions, has led to environmental pollution and a potential energy crisis, endangering the sustainable development and survival of mankind[1-3]. The international focus on reducing carbon emissions to achieve carbon neutrality has prompted researchers to harvest clean and renewable energies in nature, such as wind, solar, and tidal energy[4-7]. However, wide utilization of these intermittent energies is restricted due to their dependence on climate and region. Therefore, it is extremely urgent to develop efficient and economical energy conversion and storage devices. Lithium-ion batteries (LIBs) have been successfully commercialized in portable charging devices and electric vehicles due to their high energy density, fast charging/discharging, and long cycle life[8-12]. Unfortunately, the deficiency and uneven geographical distribution of lithium (Li) resources have caused the rising cost of LIBs, which compromised their competitiveness in the large-scale economic energy storage market[13-15]. Sodium (Na), a neighboring element of Li, has received plentiful attention because the content of Na (2.3%) is much higher than that of Li (0.0017%) in the earth's crust[16,17]. In addition, the similar physicochemical properties of Na with Li drive the research of sodium-ion batteries (SIBs)[18,19]. Regrettably, the energy density of SIBs is relatively lower than that of LIBs due to the higher standard reduction potential of Na compared to Li[20]. Potassium-ion batteries (PIBs) are considered as another alternative to LIBs due to their abundant potassium (K) resources (1.5%) and lower costs[21-23]. Figure 1A shows the physicochemical parameters of Li, Na, and K. Compared to SIBs, PIBs possess the following merits: (i) The standard reduction potential of K (-2.93 V *vs.* standard hydrogen electrodes (SHE)) is lower than Na (-2.71 V *vs.* SHE) and closer to Li (-3.04 V *vs.* SHE), endowing PIBs with relatively wide operating voltage and high energy density[24]; (ii) The Stokes radius of K ions (3.6 Å) in propylene carbonate (PC) is smaller than that of Na and Li ions (4.6 Å and 4.8 Å), ensuring their good ionic conductivity and fast kinetics[20]; and (iii) Aluminum (Al) foil can be employed as the current collector of PIBs because K will not react with Al, and the cost of PIB electrolyte salts is lower than that of SIBs, thus greatly reducing the cost of PIBs[25]. Based on the above advantages, PIBs have been considered as the most competitive candidates for next-generation large-scale energy storage devices.

Similar to LIBs, PIBs are typical rocking chair batteries and are mainly constituted of cathodes, electrolytes, and anodes. Owing to the large K ion radius, advanced anode materials play a key role in improving the electrochemical performance of PIBs. Since it was verified that the K ion can be inserted into and extracted from the graphitic layer ($KC_{36} \leftrightarrow KC_{24} \leftrightarrow KC_8$), and commercial graphite anodes can achieve a capacity of 273 mAh g^{-1}[26], the number of publications involving anode materials and PIBs has rapidly increased in recent years [Figure 1B]. At present, various anode materials, such as carbon, metal compounds, alloying materials, and their composites, have been synthesized and applied to improve the electrochemical performance of PIBs[27-29]. Generally, carbon materials are ideal anode materials for PIBs owing to their low cost and excellent physicochemical properties. Rational structure design and doping engineering can effectively enhance their potassium storage performance[30-32]. In addition, conversion-type materials (such as metal compounds) and alloying-type materials (such as Bi and P) have been investigated as anodes for PIBs due to their high theoretical capacity. Unfortunately, these materials have inferior cyclic performance due to tremendous volume expansion during potassiation. Therefore, composite materials combining carbon materials and conversion/alloying-type materials have been investigated[33-35]. Although progress has been achieved, it is still an enormous challenge to synchronously harvest the merits of both carbon and conversion/alloying-type materials through structural design, doping engineering, and the formation of composites.
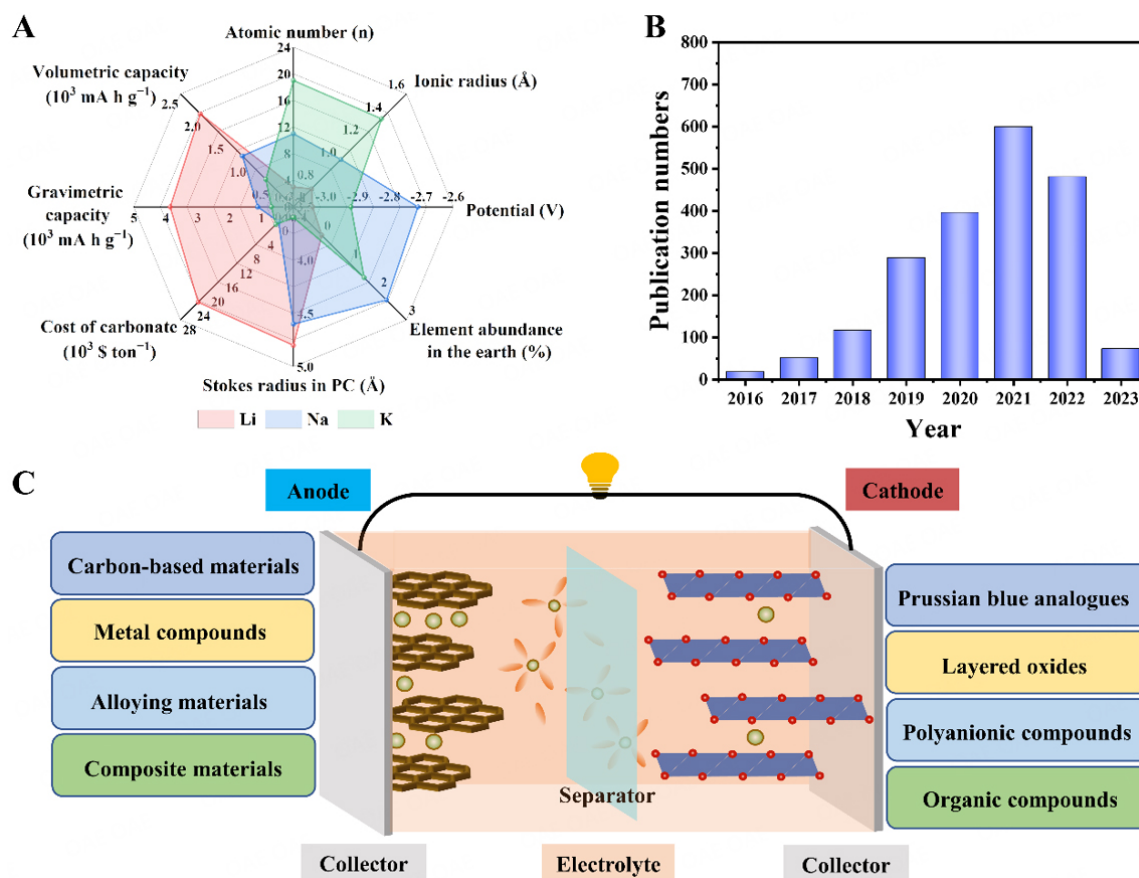

Figure 1. (A) Comparison of physicochemical parameters of Li, Na, and K. (B) Publication numbers related to anode materials of PIBs. The data come from the Web of Science with the keywords including "anode materials" and "potassium-ion batteries" (accessed on 1 March 2023). (C) Illustration of the configuration of PIBs.

Metal-organic frameworks (MOFs), composed of metal ions and organic ligands through covalent coordination, have harvested extensive attention as a new kind of porous material due to their different morphologies, adjustable pore structures, and abundant active sites[36-40]. Owing to their controllable structure and tunable composition, MOFs have been employed to derive carbon materials with large specific surface area, well-developed pores, and high levels of heteroatom doping by carbonization and acid etching[41,42]. Moreover, MOF-derived carbon composites can be obtained through facile synthesis strategies. Recently, Cao *et al.* reported a novel space-confined method that successfully confined different metal ions (Mg^{2+}, Al^{3+}, Ca^{2+}, Ti^{4+}, Mn^{2+}, Fe^{3+}, Ni^{2+}, Zn^{2+}, Pb^{2+}, Ba^{2+}, and Ce^{4+}) in quasi-microcube shaped cobalt (Co) benzimidazole frameworks (CoZIF9)[43]. The original framework of CoZIF9 will not be destroyed by metal ion addition when the ratio of Co to metal ions is optimized to 10/1. Excitingly, a series of MOF-derived carbon prepared through high-temperature carbonization exhibited excellent electrochemical performance. Based on the above advantages, MOF-derived carbon and its composites have been comprehensively applied in LIBs and SIBs and are gradually adopted in PIBs in recent years[44-46]. For example, Jiang *et al.* confined $Sn_3(PO_4)_2$ nanocrystals in an interconnected carbon framework through a controllable particle attachment crystallization growing process of Sn-based phosphate MOFs and high-temperature calcination strategies[47]. The as-fabricated composite exhibited appreciable electrochemical performance as both SIB and PIB anodes. Therefore, it is necessary to summarize the recent progress of MOF-derived carbon and its composites in PIBs. To our knowledge, most of the previous reviews on PIB anodes focused on the classification and optimization of carbon materials[21,22,48] or the type and regulation of metal compounds[5,28],

but few reviews on MOF-derived carbon and its composites[37,49]. In this review, we first briefly introduce the configuration, performance evaluation indicators, and energy storage mechanisms of PIBs. Then, we comprehensively summarize the research progress of MOF-derived carbon and its composites as PIB anodes, especially the design strategies and composite types. Furthermore, the importance and necessity of advanced characterization techniques are highlighted for understanding potassium storage mechanisms. Finally, we put forward the challenges and development prospects of MOF-derived carbon and its composites for PIBs. We aspire that this review will guide and inspire more research efforts toward advanced MOF-derived PIB anode materials in the future.

A BRIEF INTRODUCTION OF PIBS

Basic configuration

As shown in Figure 1C, PIBs are mainly composed of cathodes, anodes, electrolytes, and separators. Generally, the cathode determines the maximum operating voltage of PIBs, but it provides a lower capacity than the anode. Considering the intercalation-dominated reaction of large radius K ion, cathode materials with rigid structures and large channels are favorable for reversible K ion intercalation/deintercalation. At present, PIB cathodes mainly include Prussian blue analogs, layered oxides, polyanionic compounds, and organic compounds[50,51]. As the counterpart of a cathode, an anode is another important component of PIBs. Due to the low standard reduction potential and high theoretical capacity, potassium metal is the ultimate anode for PIBs. Notwithstanding, the practical application of potassium metal is difficult, as its high reactivity with electrolytes and water will cause poor cycle efficiency and serious safety hazards. Therefore, other advanced anode materials, including carbon-based materials, metal compounds, alloying materials, and their composites, are to be developed[52,53]. Electrolytes also play a crucial role in PIBs because the utilization of inappropriate electrolytes will not only deteriorate the performance of PIBs but also may promote the dendrite growth and formation of uneven solid electrolyte interface (SEI) layers, causing safety problems. Generally, an excellent electrolyte should have wide working potential window, high ionic conductivity, and so on. To date, commonly used PIB electrolytes are organic electrolytes composed of ethylene carbonate (EC), diethyl carbonate (DEC), dimethyl carbonate (DMC), ethyl methyl carbonate (EMC), ethylene glycol dimethyl ether (DME) or diethylene glycol dimethyl ether (DEGDME) solvents, and potassium hexafluorophosphate (KPF_6) or potassium bis(fluorosulfonyl)imide (KFSI) salts[54-58]. Finally, the separator should ensure the free shuttle of electrolyte ions between cathodes and anodes and prevent the battery short circuit caused by the growing potassium dendrites penetrating the separator. A thick Whatman glass fiber filter is usually applied as the PIB separator[59,60].

Performance evaluation indicators

The electrochemical performance of energy storage devices should be comprehensively evaluated before commercialization. Generally, PIBs can be evaluated by specific capacity, working voltage, rate capability, energy density, power density, cycle stability, and Coulombic efficiency (CE), *etc.*[22,48] Among them, the specific capacity is the most intuitive indicator to reflect the potassium storage capability of electrodes, which also determines the energy density of PIBs. Working voltage is another decisive factor affecting the energy density of PIBs, which can be enhanced through electrolyte optimization. Therefore, to achieve PIBs with high energy density, high-potential cathodes with high capacity are to be coupled with low-potential anodes. Power density determines the speed at which PIBs store/release energy, which is related to rate capability. Considering the fast kinetics of a capacitive process, rational design of anode materials with higher contributions of capacitive behavior is an effective strategy to improve rate capability and power density[61]. In addition, cycle stability is another key indicator determining the commercialization process of PIBs, which is mainly related to the structural stability of electrodes and electrolytes and the electrode-electrolyte interface. CE refers to the ratio of released to stored potassium ions, which is calculated from the ratio of charge to discharge capacity in the same cycle[62,63]. When CE is less than 100%, it means that the

anode is constantly trapping limited K ions, which is not conducive to the commercial application of PIBs. The first discharge will form a stable SEI and lead to poor initial CE (ICE), which is also an important indicator for evaluating PIBs.

Energy storage mechanisms

Similar to LIBs and SIBs, PIBs are also typical rocking chair batteries[64,65]. Generally, the main K ion storage mechanism in the cathode is intercalation. On the contrary, the storage mechanisms of K ion at the anode mainly include intercalation, adsorption, conversion, and alloying reactions[22]. The intercalation reaction is often observed in layered materials (such as graphite), which usually deliver a capacity of less than 300 mAh g^{-1}[26,66]. The capacity of carbon nanomaterials with high specific surface area and rich active sites can be improved by enhanced adsorption reaction[67-69]. The conversion reaction usually occurs in metal compounds[70,71]. Compared with intercalation reaction and adsorption reaction, conversion reaction-based anodes usually have higher K ion storage capacity but are often accompanied by large volume change, leading to poor cycle performance. Additionally, Some Bi-, Sn-, and P-based materials that can form alloys upon potassiation often exhibit superior K ion storage capacity through alloying reaction[72-74]. Generally, composites with mixed K ion storage mechanisms have been designed and synthesized to improve the overall performance of PIBs. In addition to the above reaction mechanisms, there are two K ion storage behaviors in anodes: surface-induced capacitive behavior (SCB) and diffusion-controlled intercalation behavior (DIB)[75,76]. The SCB refers to reversible physical/chemical adsorption of K ion in nanopores, defects, and functional groups, while the DIB is related to a Faradaic reaction of potassiation. The SCB and DIB can be qualitatively analyzed by the formula $i = av^b$, in which i and v represent peak current and scanning rate, respectively, and the b-value determines the storage behavior of K ion. The b-value close to 1 (SCB-dominated K ion storage) rather than 0.5 (DIB-dominated K ion storage) indicates fast kinetics and higher SCB contributions to K ion storage capacity. Besides, the SCB contribution can be further quantified by the formula $i = k_1v + k_2v^{1/2}$, in which k_1v and $k_2v^{1/2}$ represent the SCB and DIB contribution, respectively.

MOF-DERIVED CARBON AND ITS COMPOSITES FOR PIB ANODES

Based on the above discussion, PIBs are expected to implement LIBs due to the abundant and evenly distributed potassium resources and low prices of potassium carbonate and aluminum current collectors. In order to overcome the rapid electrochemical performance degradation of PIBs caused by large K ions during cycling, a series of anode materials have been designed and synthesized. It has been proved that rational design of carbon materials can observably improve the potassium storage performance. By intelligently adjusting the pore structure of carbon materials, ions/electrons transmission can be promoted, and volume change can be mitigated, thus improving potassium storage performance. Heteroatom doping is another method to significantly improve potassium storage performance via adjusting the electronic structure to increase the conductivity and wettability and expand the layer spacing. In addition, the construction of carbon-based composite materials with conversion/alloy-based materials is also a significant strategy through synergistic effects. Thanks to the diversified selection of metal sources (such as Zn and Co), organic ligands (such as 2-methylimidazole and terephthalic acid), and solvents (such as deionized water and methanol), the prepared MOF-derived carbon possesses the advantages of controlled structure and abundant heteroatoms[77,78]. Furthermore, the composite materials can be facilely prepared from pristine MOFs with abundant carbon/heteroatom/metal ions. Therefore, MOF-derived carbon and its composites have received increasing attention as PIB anodes. In this section, we summarize the rational design strategies of MOF-derived carbon and the progress in different types of MOF-derived carbon composites [Figure 2].
Figure 2. Schematic of the rational design strategies of MOF-derived carbon and typical types of MOF-derived carbon composites.

Rational design of MOF-derived carbon

The structure of MOF-derived carbon is a key factor affecting the potassium storage performance. The structural characteristics, such as morphology, pore size/volume, interlayer spacing, and specific surface area, greatly affect electron transmission, ion diffusion, volume expansion, and effective contact area with electrolyte, which further determines the capacity, CE, rate capability, and cycle ability of PIBs. In addition, the introduction of heteroatoms can adjust the electronic structure, number of defects, layer spacing, and wettability of MOF-derived carbon anodes so as to achieve good potassium storage performance. Herein, we mainly discuss the influence of structural engineering (morphology/pore design) and doping engineering (mono-/co-doping) of MOF-derived carbon anodes.

Structural engineering (morphology design)

The morphology of MOF-derived carbon can generally be divided into one-, two- and three-dimensional (1, 2, and 3D) nanostructures. 1D nanostructures refer to structures, such as nanofibers, nanowires, nanotubes, and nanorods, which can rapidly transfer electrons. A zeolitic imidazolate framework (ZIF), as a typical MOF, has been used to synthesize carbon with unique structures. For example, Xiong *et al.* prepared 1D N-doped carbon nanotubes (NCNTs) with an average outer diameter of approximately 20 nm through simple and high-yield high-temperature calcination of ZIF-67, which delivered a high capacity of 300.7 mAh g^{-1} as PIB anodes[79]. 2D nanostructures have directional layered carbon sheets, which not only ensure the full contact between electrolyte/electrode but also effectively mitigate the volume change during potassiation. Li *et al.* prepared 2D amorphous carbon/graphitic carbon nanoplates from Zn-MOF@Co-MOF[80]. In addition, other 2D MOF-derived carbon materials, including carbon-onion-constructed nanosheets[81], Mn-MOF-derived carbon microsheets[82], and 2D Cu-MOF-derived carbon sheets[83], have been prepared and deliver excellent potassium storage properties.

Apart from 1D and 2D nanostructures, MOF-derived carbon with 3D networks usually shows increased layer spacing for K ion storage and interconnected highways for electron conduction, thus improving the rate performance. Zhang *et al.* synthesized ZIF-67-derived 3D graphitic carbon networks, exhibiting excellent potassium storage properties with good rate capability and long cycle life[84]. Li *et al.* synthesized S-doped ZIF-67-derived carbon microboxes with an expanded interlayer distance, which is conducive to K

ion insertion/extraction[85]. Thus, the as-prepared carbon anode delivered good cycle life. In addition, MOF-derived carbon with core-shell nanostructures has been widely studied due to its unique merits[86]. For PIBs, core-shell nanostructures can not only increase more active sites but also speed up reaction kinetics. Yu *et al.* successfully synthesized ten different Ni/Co-MOF@ZIF core-shell materials by helical chains and 2,5-dihydroxybenzenedicarboxylate (DHBDC), including 3D nanoparticles, 2D nanosheets, and 1D nanowires, as shown in transmission electron microscope (TEM) images [Figure 3A][87]. After high-temperature carbonization and etching, the prepared carbon materials retained the core-shell structure of the pristine MOFs, as displayed in scanning electron microscopy (SEM) images [Figure 3B]. Electrochemical tests had verified the improved potassium storage performance of all core-shell MOF-derived carbon than that of single MOF-derived carbon.

Structural engineering (pore design)
MOF-derived carbon often contains abundant nanopores, either open or closed. Open pores can increase the specific surface area, while closed pores can provide active sites. According to the pore size (d), the pores in carbon materials can be divided into macropores ($d > 50$ nm), mesopores (2 nm $< d < 50$ nm), and micropores ($d < 2$ nm)[22,48]. Macropores can be used as buffer reservoirs for electrolytes, mesopores can be used as diffusion channels for electrolyte ions, and micropores can be used for capacitive storage of K ions. Therefore, rational pore structure design of MOF-derived carbon is important to improve its potassium storage performance.

Thanks to the unique porous properties of MOFs, MOF-derived carbon also has rich pore structures. For instance, Liang *et al.* synthesized 3D Al-MOF with a nanorod-assembly structure by precisely adjusting the nucleation and growth process of MOFs [Figure 3C][88]. The N-doped carbon nanorod-assembled superstructures (NCS) obtained after pyrolysis and etching possessed rich micropores, with micropore area of up to 915.1 m^2 g^{-1}, which is 63% of the total surface area. Compared with the potassiation of a graphite anode, abundant micropores in NCS can capture a large number of K ions at a voltage above 0.4 V [Figure 3D]. As a result, the NCS anode displayed a high capacity [Figure 3E]. However, excess micropores will prolong the time for electrolyte infiltration, thus forming a thicker SEI layer, resulting in active K ions loss. Thus, the properly controlled formation of micropores can increase the CE of PIBs. Yuan *et al.* successfully prepared superstructure carbon materials (SCNSs) through pyrolysis of mixed ZIF-8 and polyvinylpyrrolidone (PVP)[89]. Due to the preferential decomposition of external PVP, the as-prepared SCNSs presented a mesopores-dominated pore structure, which greatly shortened the ion diffusion distance and inhibited the loss of active K ions. Accordingly, the SCNS anode achieved an outstanding rate capacity and cycling life.

In addition to single dominant pores, carbon anodes with hierarchical pore structures of macropore, mesopore, and micropore often show excellent potassium storage performance. Zhou *et al.* synthesized interconnected N-doped hierarchical porous carbon (N-HPC) by carbonizing the well-designed ZIF-8[90]. The interconnected structure and hierarchical pores promoted the transfer of electrons and ions, respectively. Thus, the N-HPC anode delivered an excellent reversible capacity and superior rate performance. Ruan *et al.* constructed N-doped microporous carbon polyhedrons (NMCP), which were further wrapped by reduced graphene oxide (NMCP@rGO)[91]. Figure 3F illustrated that the NMCP@rGO possessed 3D NMCP with rich micropores as the interior carbon and 2D rGO with mesopores and macropores as the outer carbon. Therefore, the NMCP@rGO exhibited a multi-dimensional double carbon structure with hierarchical pores [Figure 3G], which delivered excellent potassium storage performance.

Doping engineering (mono-doping)

N is one of the most commonly used doping elements to enhance potassium storage performance in carbon materials. Generally, N species are divided into pyridine N (N-6), pyrrolic N (N-5), and quaternary N (N-Q)[92]. N-6 and N-5 can function as electrochemical sites to enhance the SCB of K ions, which is conducive to capacity improvement. N-Q bonds with three sp^2 carbon atoms, which is beneficial for improving conductivity[93]. Encouragingly, 2-methylimidazole of ZIF-67 and ZIF-8 contain abundant and various N chemical bonds, which can be decomposed under different calcination temperatures and *in situ* produce different N species. Therefore, ZIF-67 and ZIF-8 are often used to prepare N-doped MOF-derived carbon. Li *et al.* prepared N-doped porous carbon (NPC) with controllable N-6 content by optimizing the carbonization temperature [Figure 4A][94]. The as-prepared NPC retained the polyhedron morphology of the precursor with abundant pores. When the calcination temperature was 600 °C, the as-prepared NPC-600 had the highest level of N-6 among all samples [Figure 4B]. MET-6, a MOF composed of Zn^{2+} and N-rich 1H-1,2,3-triazole ligands (60 wt.% N), was used as C and N precursors to synthesize the NPC framework with the N level of up to 13.57%[95]. The as-prepared sample achieved an excellent potassium storage performance. Moreover, the density functional theory (DFT) was used to further understand the advantages of N doping in enhancing the potassium storage properties. The K ion adsorption energies of

pristine carbon, N-Q-doped carbon, N-5-doped carbon, and N-6-doped carbon were -0.38, 0.08, -1.62, and -3.26 eV, respectively, which indicated that N-5 and N-6 can improve the K ion adsorption ability. As the number of N-6 increased from 1 to 3, the adsorption energy was increased to -3.48 and -3.67 eV, respectively, indicating that a higher level of N-6 was conducive to improving potassium storage capacity.

Besides the N element, S is also often doped in carbon skeleton to enhance the potassium storage properties[96,97]. S doping can also increase the conductivity and active sites. Moreover, the larger atomic radius of S can extend layer spacing and reduce K ion diffusion barriers, thus forming more active sites. Zuo *et al.* adopted a Fe-based MOF (MIL-88A) as C and S precursor to prepare S-doped PC (S-MPC) through a multi-step synthesis strategy[98]. The as-synthesized S-MPC had a unique 3D flower-like nanostructure with abundant mesopores, which can promote K ion transport. Furthermore, S doping expanded the interlayer spacing and introduced rich electrochemical sites, which can enhance the storage capacity of K ions. First-principles calculations were used to corroborate the enhanced potassium storage enabled by S doping. The results indicated that the adsorption energies of K atoms on the S side and H side of S-doped carbon (-2.54 eV and -2.22 eV) were greater than that of pure carbon (-1.98 eV). Furthermore,

The K atom diffusion barriers of S-doped carbon on the S side and H side (0.62 eV and 0.49 eV) were lower than that of pure carbon (0.81 eV). Therefore, S doping can effectively enhance the adsorption and reduce the diffusion barrier of K ions.

Doping engineering (co-doping)

Compared with mono-doping, heteroatom co-doping can not only harvest the merits of respective heteroatoms but also incur interactions between different atoms, allowing for enhanced potassium storage performance. Moreover, the doping of one heteroatom can affect the content and species of another heteroatom dopant, which allows directional optimization of heteroatom co-doping. Therefore, the number of electrochemical sites and electronic structure of MOF-derived carbon can be adjusted through a co-doping strategy.

N/P co-doping is the most used strategy for MOF-derived carbon. Hu *et al.* prepared P/N co-doped carbon (named as PN-HPCNFs) from a mixed solution of ZIF-8, urea, polyacrylonitrile (PAN), and triphenylphosphine through electrospinning and subsequent high-temperature calcination[99]. The content of N-6 increased from 46.1% of N-HPCNFs to 55.2% of PN-HPCNFs, proving that additional P atoms can optimize the electronic structure and create more active sites, thus obtaining higher K ion storage capacity. P/N co-doping expanded the layer spacing to 0.41 nm, which is beneficial to alleviate the structural damage caused by K ion insertion/extraction, thus achieving an ultralong cycle life. In addition, the DFT calculation results showed that P/N co-doped carbon exhibited increased K ion adsorption energy and reduced diffusion barriers [Figure 4C-F], which further demonstrated the advantage of P/N co-doping in achieving elevated potassium storage. Similarly, Wu *et al.* prepared PNCNFs with ultrahigh N content (19.52 wt.%) and more N-6 active sites by calcining MET-6@PPh$_3$-PAN[100]. The DFT results revealed that the K ion was more easily adsorbed on N-6-P active sites [Figure 4G-J]. Moreover, the density of states (DOS) of the Fermi level at the N/P co-doped site was higher than that at the N-doped site, indicating that the introduction of additional P atoms increased the electronic conductivity [Figure 4K]. The comparable DOS values of the N-6-P site before and after K ion adsorption indicated the maintained high electronic conductivity during potassiation/depotassiation [Figure 4L]. Therefore, the introduction of P into the N-rich system can improve the K ion adsorption ability, facilitate electron transport, and render excellent reversible capacity and rate performance.

Zhu *et al.* prepared N/S co-doped carbon microspheres (NSCMs) through high-temperature calcination and acid washing of Zn-MOF-74 and rationalized the improved potassium storage performance of undoped carbon microspheres (CMs) by N/S co-doping through material characterization, kinetic analysis, and DFT calculations[101]. It was found that the intensity ratio of D-band to G-band (I_D/I_G), specific surface area (m^2 g^{-1}), interlayer spacing (nm), and conductivity (S cm^{-1}) of NSCMs were 1.10, 1347.4, 0.408, and 8.74, respectively, all higher than those of CMs (1.05, 1014.8, 0.400, and 5.83), which can be attributed to N/S co-doping. The improved I_D/I_G and specific surface area can effectively create more defects for K ions adsorption, increasing potassium storage capacity. The expanded interlayer spacing and conductivity accelerate the K ions insertion/extraction and electrons transport, respectively, thereby improving the rate performance. The kinetics analysis showed that N/S co-doping can reduce the charge transfer resistance and increase the capacitive contribution, which promoted rapid mass transfer and led to enhanced rate performance. Moreover, the DFT calculations revealed that N/S co-doping can improve the adsorption capacity of CMs for K ions, which is beneficial for capturing and storing K ions. Therefore, N/S co-doping can optimize the physicochemical properties of carbon materials, thereby exhibiting enhanced potassium storage performance.

Besides N/P and N/S co-doping, N/O and O/F co-doped MOF-derived carbon was also explored. Yang *et al.* synthesized N/O co-doped PC with high N (7.06%) and O (7.90%) content by calcining and etching an Al-based MOF[93]. The additional O element can enhance wettability and increase effective contact area. Lu *et al.* prepared O/F dual-doped PC nanopolyhedra (OFPCN) as an anode for PIBs[102]. Through experimental results and DFT calculations, it was demonstrated that O/F co-doping can strengthen K ion adsorption without structural damage, which accounted for the excellent potassium storage properties.

Typical types of MOF-derived carbon composites

Differing from intercalation and adsorption reactions of carbon materials, metal compounds/alloying materials with conversion/alloying reactions show higher K ion storage capacity. Owing to inferior conductivity and huge volume change during charging/discharging, the practical application of metal compounds/alloying materials is limited by terrible rate and cycling performance. The combination of metal compounds/alloying materials and carbon can effectively improve conductivity and cycling stability. Moreover, rational structure design can relieve the volume expansion during cycling. Thanks to the abundant metal/heteroatom/carbon resources and controllable morphology, MOFs can be facilely converted into metal compound/carbon and alloying material/carbon composites. In addition, metal ions in pristine MOFs are evenly distributed, while the MOF-derived carbons prepared by high-temperature carbonization can well maintain the morphology of pristine MOFs, which ensures the uniform dispersion of generated metal compounds/alloying materials in the carbon matrix. Based on these advantages, abundant MOF-derived carbon composites, including metal oxide/carbon, metal phosphide/carbon, metal sulfide/carbon, and metal selenide/carbon composites, have been widely studied. Herein, we mainly discuss the application of these MOF-derived carbon composites in PIB anodes.

Metal oxide/carbon

Metal oxides have attracted extensive attention as PIB anodes on account of their excellent theoretical capacity and eco-friendliness[5]. The organic ligand of MOFs can not only anchor active metal oxides into the carbon skeleton but also alleviate the agglomeration of metal oxides during calcination, which is conducive to improving the cycle stability. For example, Hu *et al.* successfully prepared MoO_2@N-doped carbon nano-octahedron (MoO_2@NPC) from the MOF-based polyoxometalate (NENU-5)[103]. The MoO_2 nanoparticles (~10 nm) were evenly embedded in the carbon skeleton, which ensured the rapid K ion transfer between MoO_2 nanoparticles and carbon materials and reduced volume expansion during cycling. Moreover, DFT calculations showed the higher K ion adsorption energy of MoO_2@NPC than that of bare MoO_2 and NPC, suggesting the higher potassium storage capacity in MoO_2@NPC. Dubal *et al.* used Ti-based MOFs as a self-sacrificial template to synthesize a composite of ultrafine TiO_2 nanoparticles (1-3 nm) embedded in N-rich graphitic carbon (TiO_2@NGC) with hierarchical pores[104]. *Ex situ* characterization techniques revealed that the bare TiO_2 phase was converted into a mixed phase of Ti_7O_{13} and $K_2Ti_4O_9$ after the first potassiation/depotassiation, which further demonstrated the conversion-based potassium storage mechanism. As discussed earlier, the well-designed core-shell structure can shorten the K ion transport path and withstand the volume change during charging/discharging, thus facilitating K ion storage capacity. Wang *et al.* synthesized $ZnO/ZnFe_2O_4$/carbon with a core-double shell nanostructure, achieving excellent potassium storage properties[105]. Embedding metal oxides into the porous carbon skeleton of core-shell structures can promote K ions transfer and endure the volume expansion caused by the conversion reaction of metal oxides during cycling. As displayed in Figure 5A, a TiO_2/carbon composite wrapped by N/P/S co-doped carbon (TiO_2/C@NPSC) with a well-designed core-shell structure was synthesized by pyrolyzing a modified Ti-based MOF[106]. Consequently, the TiO_2/C@NPSC delivered excellent cycle stability (122.9 mAh g^{-1} at 1.0 A g^{-1} after 5,000 cycles) as a PIB anode [Figure 5B].

Metal phosphide/carbon

Metal phosphides are also widely used in PIBs owing to their high theoretical capacity and cost-effectiveness[5]. There are usually two strategies for synthesizing MOF-derived metal phosphide/carbon composites. One is that MOF precursors and P sources are calcined at high temperatures at the same time, and another is that MOF precursors are carbonized and then phosphatized by P sources. Following the first strategy, Zhang *et al.* successfully prepared a 3D graphene skeleton (3DG) and FeP hollow nanospheres (3DG/FeP) composite through a simple one-step thermal conversion[107]. The as-prepared 3DG/FeP possessed discrete FeP hollow nanospheres encapsulated by 3DG, resulting in excellent potassium storage properties. *Ex situ* high-resolution TEM (HRTEM) and X-ray diffraction (XRD) characterizations further revealed the intercalation and conversion-based potassium storage mechanism of 3DG/FeP, producing K$_3$P after the conversion reaction between FeP and K [Figure 5C-H]. Similarly, Das *et al.* prepared Co$_2$P nanoparticle encapsulated N-doped carbon (Co$_2$P@NCCs) via one-step carbonization-phosphorization of ZIF-67, which delivered a stable cycling performance as PIB anodes[108]. For another synthesis strategy, Jiang *et al.* synthesized N-doped carbon-limited CoP polyhedrons wrapped by rGO sheets (CoP/NC@rGO) for PIBs[109]. First, ZIF-67 and graphene oxide (GO) were mixed and carbonized to prepare intermediate Co/NC@rGO, which was then phosphatized to obtain CoP/NC@rGO. The as-synthesized composite possessed a ZIF-67-derived carbon matrix, encapsulating discrete CoP nanoparticles as the internal structure and highly conductive rGO as the external structure, which significantly improved conductivity and effectively

avoided CoP nanoparticle agglomeration. Thus, the CoP/NC@rGO anode achieved a satisfactory cycle performance.

Similar to metal oxides, embedding metal phosphides into the porous carbon skeleton of a well-designed core-shell structure can further enhance the potassium storage performance. Miao *et al.* electrospun a MOF (ZIF-8/ZIF-67) precursor and then synthesized a novel MOF-derived CoP/carbon composite with a 3D core-shell structure by a carbonization-oxidation-phosphorization strategy, showing excellent potassium storage properties[110]. Yi *et al.* synthesized ZIF-8@ZIF-67-derived NPC with confined CoP polyhedrons via a carbonization-phosphorization strategy[111]. First-principles calculations suggested that K ion was more likely to be located at the hollow site encompassed by three P atoms, with adsorption energy and diffusion barriers of about 0.79 eV and less than 0.06 eV, which was conducive to K ion diffusion on the CoP surface, enhancing the reaction kinetics. The DOS results showed that CoP/NC and CoP had no bandgap at the Fermi level, indicating good conductivity. These excellent characteristics ensured the good rate capability and cyclic stability of NC@CoP/NC.

Metal sulfide/carbon

Metal sulfides have become burgeoning candidate PIB anodes owing to their rich active sites, large interlayer spacing, and high theoretical capacity[5,112]. The non-etched MOF-derived carbon contains rich metal nanoparticles, which can form metal sulfide/carbon composites after further sulfidation. Miao *et al.* electrospun ZIF-8/ZIF-67 and then synthesized a novel MOF-derived CoS/carbon composite with 3D hierarchical structure units by a carbonization-oxidation-vulcanization strategy, showing excellent potassium storage performance[113]. In order to alleviate the agglomeration and collapse of MOFs, Zhou *et al.* introduced GO into the solution for the synthesis of Fe-MOF, which not only improved the dispersion of Fe-MOF but also increased the conductivity of the as-prepared FeS_2@C-rGO composites[114]. Similarly, Choi *et al.* used acid-treated carbon nanotube networks (ACNT) to provide a conductive framework and nucleation site for the *in-situ* growth of MOF-5[115]. The as-obtained ZnS nanoparticles with a size of ~15 nm were uniformly dispersed in MOF-5@ACNT-derived 3D-interconnected carbon networks after carbonization-vulcanization treatment, displaying ultradurable K ion storage.

MoS_2, a typical metal sulfide, has been widely studied in PIBs because its large interlayer spacing (0.62 nm) is conducive to the insertion/extraction of large-radius K ions[116-118]. Moreover, well-structured MoS_2/carbon composites can effectively overcome the drawbacks of poor conductivity and volume change of MoS_2 during cycling. Generally, MoS_2 can be coated on a carbon material surface via a hydrothermal method. Rui *et al.* used ZIF-67 as the polyhedron template and C/N sources to prepare ultrathin MoS_2 ornamented Co nanoparticle/carbon composite (ZIF-67-C@MoS_2)[116]. *In situ* growth of NCNTs and Co nanoparticles formed a cross-linking conductive network, which improved the conductivity and reduced the volume expansion of MoS_2 during cycling. Thus, the ZIF-67-C@MoS_2 anode delivered good potassium storage performance. Analogously, Jiang *et al.* coated MoS_2 nanosheets on ZIF-8-derived carbon, showing excellent potassium storage performance[117]. Different from coating MoS_2 on the carbon material surface, Hu *et al.* confined few-layer MoS_2 nanosheets (< 10 nm) to the interior of MOF-derived carbon ($MoS_2 \subset C$) [Figure 5][118]. The strong confinement effect of outer porous carbon inhibited the growth and aggregation of MoS_2, producing abundant edges and active sites for promoted K ions reaction kinetics.

Recently, emerging electrode materials with heterostructures have attracted considerable attention due to their stronger stability and higher capacity compared to the single component[119]. Furthermore, hetero-structured electrodes can combine the advantages of building blocks while offsetting the drawbacks of individual modules through synergistic effects. Li *et al.* successfully synthesized hetero-structured bimetallic

sulfides with VS_4 nanodots ornamented on CoS_2/N-doped carbon (CoS_2/NC@VS_4) and employed as PIB anodes[120]. The heterogeneous structure composed of CoS_2 and VS_4 was conducive to ensuring full contact with the electrolyte and shortening the diffusion length of K ions. Moreover, the N-doped carbon skeleton promoted electron transport and alleviated volume expansion during discharging/charging. Therefore, the CoS_2/NC@VS_4 anode achieved admirable ICE of 84.59% and high reversible capacity. Zhang *et al.* designed a Cu_9S_5/MoS_2 heterostructure wrapped in a GO matrix by a MOF-assisted strategy[121]. The *in-situ* thiophilic Cu^0 mesophase was evenly distributed in Mo^0/K_xS_y compounds, which is conducive to rapid charge transfer and anchoring of K_xS_y, thus improving the reversibility of the phase transition process. Additionally, the internal hollow structure and the external 3D conductive framework guarantee long cycling stability. As expected, the as-prepared composite delivered outstanding capacity and a long cycle lifespan.

Metal selenide/carbon

Compared with the metal-P and metal-S bonds, the metal-Se bond is easy to break due to the larger radius of Se than that of P and S, which is conducive to facilitated kinetics of conversion reaction. Thus, MOF-derived metal selenide/carbon composites are receiving increasing attention. Ma *et al.* implanted $Co_{0.85}$Se particles in ZIF-67-derived N-doped carbon ($Co_{0.85}$Se@NC), which maintained the morphological characteristics of ZIF-67 with abundant small nanoparticles (20-38 nm)[122]. The $Co_{0.85}$Se@NC anode delivered excellent potassium storage performance. Since then, researchers prepared a variety of CoSe/carbon or ZnSe/carbon composites by calcining the ZIF-67 or ZIF-8 precursors with subsequent selenization, all of which delivered good potassium storage properties[123-125]. Different from the gasification selenization process of selenium powder, Kim *et al.* reported a simple solution-phase selenization method in which Co-Se bonds were formed by ion exchange between Se^{2-} in NaHSe solution and organic anions in ZIF-67[126]. Through crystallization and carbonization treatment, ultrafine $Co_{0.85}$Se and N-doped carbon composite were successfully prepared. In order to improve the potassium storage performance of CoSe, Wang *et al. in situ* constructed ZIF-67-derived Co/CoSe Schottky heterojunction on the surface of hollow carbon nanospheres[127]. The close contact and strong electron coupling between Co and CoSe promoted the spontaneous electron flow from Co to CoSe at the contact interface, leading to charge redistribution. As a result, the enhanced lattice defects provide active sites for K^+ migration, thus improving the potassium storage performance. Similar to MoS_2, $MoSe_2$, with a unique 2D structure and broad interlayer spacing, is conducive to promoting the insertion/extraction of K ions but suffers from a huge volume change during cycling. Jiang *et al.* synthesized $MoSe_2$ nanosheets on the NPC polyhedron through annealing ZIF-8 and a subsequent solvothermal strategy[128]. Thanks to the synergistic effects between $MoSe_2$ and carbon, the composite delivered high capacity and excellent rate performance.

Rational structural design of MOF-derived metal selenide/carbon composites is conducive to further improving K ion storage performance. Na *et al.* synthesized ultrasmall ZnSe nanocrystals embedded in carbon nanofibers (ZnSe@PCNF) by electrospinning ZIF-8 and a subsequent carbonization-selenization strategy, which delivered good potassium storage properties[129]. Wang *et al.* synthesized ZIF-8@ZIF-67-derived carbon nanotubes confining metal Se (Co-Se@CNNCP) with a 3D core-shell structure by a carbonization-selenization strategy[130]. In addition, wrapping metal selenides in the interior of the hollow porous carbon is an effective strategy to improve electronic conductivity and alleviate volume changes during cycling. Liu *et al.* adopted the unique microporous openings and mesoporous cages of a Fe-based MOF to well constrain metal selenide and prepare FeSe@C with a mesoporous structure, which exhibited outstanding potassium storage properties[131]. Yang *et al.* reported a vacuum-assisted method to prepare carbon-coated $CoSe_2$ nanoparticles confined in the interior of hollow mesoporous carbon nanospheres ($CoSe_2$@NC/HMCS)[132]. Owing to the "double confinement" of the carbon skeleton derived from ZIF-67 and HMCS, the $CoSe_2$ nanoparticles were confined in the interior of HMCS, ensuring ultrahigh reversible

capacity and outstanding rate capability in $CoSe_2$@NC/HMCS anode. Ruan *et al.* also constructed a "double-carbon-confined" framework (ZnSe@i-NMC@o-rGO), and ZnSe was confined by internal ZIF-8-derived microporous carbon and further wrapped in external rGO sheets [Figure 6A][133]. The stress distribution of ZnSe structures in three models (ZnSe, ZnSe@i-NMC, and ZnSe@i-NMC@o-rGO) during potassiation was studied via a finite element method [Figure 6B], revealing the smallest axial stress and maximum stress of ZnSe particle in ZnSe@i-NMC@o-rGO and indicating the superior mechanical stability of the double-carbon constrained structure and outstanding cyclic stability for PIB anode.

To enhance the potassium storage performance, bimetallic selenides were prepared as PIB anode materials. Oh *et al.* successfully synthesized novel MC-Se@NC with 1D hybrid nanostructures by carbonization-selenization of ZIF-67-coated MoO_3 nanorods, which contained a $MoSe_2$ core and a $CoSe_2$/N-doped carbon shell[134]. Owing to the abundant active sites provided by the synergistic $MoSe_2$ and $CoSe_2$, enhanced electronic conductivity, and alleviated volume expansion during cycling ensured by N-doped carbon coatings, the MC-Se@NC delivered great potassium storage properties. Zhou *et al.* synthesized carbon anchoring Zn-Mn binary selenides (ZMS@FC) as PIB anodes[135]. With the aid of structural control reagents, Zn and Mn ions were cross-linked with trimesic acid and self-assembled into flower-like MOFs (Zn-Mn-BTC) by a solvothermal method. Subsequently, the flower-like ZMS@FC was obtained by calcining Zn-Mn-BTC mixed with selenium powder. The 2D porous petal layered structure not only improved the electrode surface wettability and electron transfer efficiency but also effectively limited the volume change, which played a key role in enhancing rate performance and stabilizing long cycle life. Through *ex situ* XRD and TEM characterization, a highly reversible conversion-based potassium storage mechanism was confirmed in ZMS@FC.

Alloying material/carbon
The emerging alloying-type materials, including Sn, Sb, Bi, and P, have been considered as promising PIB anode materials due to their high theoretical capacity, appropriate working potential, and attractive safety. Notwithstanding, serious volume damage during potassiation/depotassiation is still a key challenge, resulting in inferior cycle lifespan and severe capacity attenuation. The strategies of nanostructure engineering and carbon decoration could effectively reduce the volume dilation of alloying-type anodes. Nanoparticles can significantly reduce the mechanical stress during potassiation, thereby alleviating the pulverization. In addition, the introduction of carbon materials with strong mechanical elasticity, high conductivity, and stable structure into metal nanoparticles can improve conductivity and buffer volume dilation or agglomeration. Therefore, MOF-derived alloying-based electrodes show great application prospects in PIBs. Yan *et al.* synthesized highly dispersed zinc particles in carbon networks (ZNP/C) via calcining ZIF-8 precursors[136]. The as-prepared ZNP/C delivered a satisfactory capacity due to the unique structure composed of highly dispersed zinc nanoparticles and conductive carbon networks, which inhibited the volume change in the alloying/dealloying (Zn↔KxZn) process.

Metal Bi has been widely used in PIBs owing to its relatively high theoretical capacity (385.0 mAh g^{-1}; Bi↔KxBi), large lattice spacing, high electronic conductivity, and low cost[137]. Su *et al.* synthesized ultrathin carbon film@carbon nanorods@Bi nanoparticle (UCF@CNs@BiNs) composites for PIB anodes [Figure 6C][138]. The UCF@CNs@BiNs possessed a rod-shaped structure, which was completely wrapped by a 6 nm thick carbon film and abundant Bi nanoparticles evenly distributed in a carbon nanorod framework. The UCF@CN matrix enabled the SEI formation on carbon film instead of Bi nanoparticles, thus mitigating the decomposition of active materials and achieving stable cycling performance [Figure 6D and E]. Sun *et al.* successfully encapsulated Bi nanoparticles into a 3D foam-like carbon nanocage framework (Bi@N-CNCs) by annealing 2D Bi-based MOFs[139]. Thanks to the unique structure and composition, the as-

prepared sample achieved excellent K ions storage properties. In addition, Tong *et al.* prepared metastable Bi:Co or Bi:Fe alloying materials and carbon composites (Bi:Co@C or Bi:Fe@C) by annealing Bi-Co-MOF or Bi-Fe-MOF precursors, all of which exhibited excellent potassium storage performance[140].

Metal Sb is another promising alloying-type anode material for PIBs because of its high theoretical capacity (660.0 mAh g^{-1}; Sb$\leftrightarrow$K$_x$Sb), low alloying reaction potential, and great conductivity[137]. Cheng *et al.* successfully embedded uniform Sb nanoparticles (~19 nm) into porous carbon (Sb-NPs@PC) by simple annealing treatment of Sb-MOF precursors, which delivered ultrahigh reversible capacity and excellent rate performance[141]. Huang *et al.* successfully designed a hybrid yolk-shell structure constituted of Sb nanoparticles as yolk and carbon nanofibers as shell (Sb@CNFs) through a MOF electrospinning coupled with confined ion-exchange strategy followed by subsequent thermal reduction [Figure 6F][142]. Consequently, the Sb@CNFs maintained an excellent capacity of 227 mAh g^{-1} after 1,000 cycles at 1.0 A g^{-1} with CE of approximately 100% [Figure 6G].

In addition to metal-based alloying materials, P-based materials have attracted extensive attention in PIBs because of their safety, environmentally friendly, low cost, and ultrahigh theoretical capacity (2,956.0 mAh g^{-1}; P$\leftrightarrow$K$_3$P)[143]. Sui *et al.* embedded red P into carbon nanorods derived from Zn-MOF (P@ZCRods)[144]. By adjusting the size and P content, the optimized P@ZCRods achieved superior ICE of 78.5% and a remarkable reversible capacity of 595.8 mAh g^{-1}. Similarly, Liang *et al.* prepared carbon superstructure by calcining Al-based MOFs, which were further used as a substrate to confine red P

effectively[145]. As a result, the as-prepared sample exhibited satisfactory potassium storage properties.

Recently, electrode materials with conversion-alloying reactions have received attention as they exhibit higher capacity than single alloying materials through dual storage mechanisms[146]. Chen *et al.* utilized the excellent structure of Bi-based MOFs and a carbonization-selenization technique to uniformly embed Bi/Bi_3Se_4 hybrid nanoparticles into hollow porous carbon nanorods[147]. The external hollow porous carbon framework derived from Bi-MOF manifested structural integrity, which not only prevented the aggregation of Bi-based active nanoparticles but also provided rich ion/electron transfer channels. In addition, the composite possessed rich C-O-Bi bonds, indicating a close connection between Bi/Bi_3Se_4 nanoparticles and the carbon matrix, which further enhanced the stability of Bi-based active particles. As a result, the assembled half-cell showed an ultrahigh rate capacity of 307.5 mAh g^{-1} at 20.0 A g^{-1}. Zhang *et al.* embedded Bi_2O_3 nanomaterials in a carbon framework by carbonization and further oxidation of Bi-MOF precursors[148]. The Bi_2O_3@C anode achieved a high reversible capacity via a conversion-alloying reaction ($Bi_2O_3\leftrightarrow Bi\leftrightarrow K_3Bi$). Tong *et al.* designed Bi/Bi_2O_3-C with heterostructure for PIB anodes via annealing an accordion-like structure of Bi-based MOFs[149].

Summary

We summarized the electrochemical performance of MOF-derived carbon and its composites as PIB anode materials, as shown in Table 1. Through rational structural design and doping engineering, MOF-derived carbon exhibit enhanced reversible capacity, favorable rate capability, and cyclic stability. However, the ICE values are usually less than 50% because of their large specific surface area. In general, K ions in PIB full cells come from commercial cathodes, but exorbitant consumption of K ions will restrain the industry application of these anode materials. Therefore, many efforts are still needed to improve the ICE without sacrificing the merits of MOF-derived carbon anodes. Encouragingly, MOF-derived carbon composites possess higher ICE values (mainly > 50%) than MOF-derived carbon; meanwhile, their rate performance and cycle life are better than those of bare metal compounds and alloying materials. However, the cyclic stability of MOF-derived carbon composites (mainly < 1,000 cycles) is inferior to that of MOF-derived carbon. At present, the design of MOF-derived carbon composites mainly focuses on structural optimization and composition diversification but ignores the carbon content tuning, which also affects the cycle performance. Therefore, there are still great challenges in improving the overall electrochemical properties of MOF-derived carbon and its composites.

ADVANCED CHARACTERIZATION FOR PIB ANODES

As mentioned above, the application of MOF-derived carbon and its composites in PIBs is still at its early stage, and the performance needs to be further enhanced. Therefore, a more in-depth exploration of working mechanisms is needed to better optimize potassium storage performance. Although plentiful *ex situ* characterization methods have been widely used in the study of potassium storage mechanisms and some achievements have been made, these technologies cannot avoid exposure of electrodes to air during battery disassembly, electrode cleaning, and transfer[48]. Therefore, it is necessary to develop advanced characterization techniques to monitor the electrode material during charging/discharging in real time to ensure the accuracy of the results. *In situ* characterization technologies, including *in situ* Raman, *in situ* XRD, *in situ* TEM, and so on, have been widely employed in the mechanism research of alkaline ion batteries and supercapacitors[150,151]. For PIBs, these advanced techniques can continuously monitor the SEI film formation, ion transport process, and electrode structure evolution of PIBs during the cycle, which is conducive to a deeper understanding of the reaction process and potassium storage mechanism under actual operating conditions. In this section, we mainly summarized the application of *in situ* characterization technologies in PIB anodes.

Table 1. The electrochemical performance of MOF-derived carbon and its composites for PIBs

Anode materials	MOF precursors (Organic ligands)	Electrolyte	ICE (%)	Rate capability (mAh g^{-1})	Cycling stability (mAh g^{-1})	Ref.
NCNTs	ZIF-67 (2-methylimidazole)	0.8 M KPF$_6$ in EC/DEC (v/v = 1:1)	24.5	293.1 at 0.05 A g^{-1} 131.0 at 2.0 A g^{-1}	102.0 at 2.0 A g^{-1} after 500 cycles	[79]

In situ Raman

Raman spectroscopy is a non-destructive analysis method applied to solids, solutions, pure substances, and mixtures, which effectively provides detailed information, including phase, morphology, chemical structure, crystallinity, and graphitization degree. Therefore, *in situ* Raman can realize dynamic monitoring of electrode materials during discharging/charging. Zhou *et al.* investigated the potassiation/depotassiation mechanism during cyclic voltammetry scans of N-HPC by *in situ* Raman[90]. Figure 7A shows the schematic of *in situ* Raman testing. There are three obvious phenomena during the potassiation process [Figure 7B]. First, the G peak gradually shifted from 1,595 to 1,558 cm^{-1} when discharged from 3.01 to 0.30 V, which can be attributed to the increased steric hindrance and electron density with K ion insertion, resulting in the stretching of C-C bonds in the plane. This expansion produces biaxial strain, causing the red shift of the G peak. Second, no obvious symmetrical G peaks can be observed at 0.01 V, which can be attributed to the interference between the metal-like behavior of the intercalation compound and the resonance phonon scattering process, leading to decreased intensity of the G peak. Third, the value of I_D/I_G gradually decreased, indicating that K ions filled the defects of the material and increased graphitization. During the subsequent depotassiation process [Figure 7C], *in situ* Raman spectroscopy displayed the opposite changes. The G peak was blue-shifted when charged from 0.01 V to 3.00 V. The I_D/I_G value and G peak intensity were also restored to the initial state, indicating high reversibility. Thus, the working mechanism in N-HPC was speculated to be K ions adsorption on surface-active sites and filling in nanopores. Liang *et al.* also explored the working mechanism of NCS by *in situ* Raman testing [Figure 7D-F][88]. The G peak shifted from 1,572 to 1,524 cm^{-1} when discharged to 0.01 V, which might be due to the expansion of the C-C bond in the plane caused by the increased steric hindrance and electron density. After charging to 2.8 V, the G peak shifted back to 1,572 cm^{-1}, demonstrating a highly reversible discharging/ charging process. In addition, the value of I_D/I_G decreased during potassiation, which might be due to the filling of K ions into the defective N-doped micropores of NCS.

In addition to MOF-derived carbon materials, the *in situ* Raman technique has also played an important role in revealing the potassium storage mechanism of MOF-derived composite materials. Recently, Jiang *et al.* confined $Sn_3(PO_4)_2$ nanocrystal in an interconnect carbon framework [$Sn_3(PO_4)_2$@PC] through a controllable particle attachment crystallization growing process of Sn-based phosphate MOFs and high-temperature calcination strategies[47]. As displayed in Figure 7G, the peaks at 986 cm^{-1} shifted to 936 cm^{-1} during potassiation, indicating that $Sn_3(PO_4)_2$ reacted with K to form K_3PO_4. Moreover, the peak of $Sn_3(PO_4)_2$ reappears when recharged to 3.0 V, indicating that the conversion reaction is reversible.

In situ XRD

In situ XRD techniques can monitor the structural evolution and phase transition of electrodes in real-time during potassiation/depotassiation, which is conducive to a deeper understanding of the potassium storage mechanism, thus providing clear guidance for the optimization of potassium storage performance. Wu *et al.* used *in situ* XRD techniques to explore the structural evolution of PNCNFs during discharge/charge[100]. Figure 8A exhibited a broad peak (23.27°) at the pristine stage. During discharging, the peak continuously shifted to smaller angles, indicating that K ion intercalation led to the expansion of interlayer spacing. When charged to 2.80 V, the peak recovered to 22.28°, indicating the partially restored interlayer spacing after potassium ion extraction. The incomplete recovery can be attributed to the irreversible capture of K ions. Sun *et al.* also studied the potassium storage mechanism of Bi/carbon composite (Bi@N-CNCs)[139]. Figure 8B exhibited three typical peaks of metal Bi (27.2°, 37.9°, and 39.6°) at the pristine stage. During the first discharging, the peaks of metal Bi gradually decreased. When discharged to 0.40 V, two new peaks appeared at 31.1° and 32.5°, indicating the formation of KBi_2. When the electrode was further discharged to below 0.20 V, two new peaks assigned to K_3Bi appeared at 28.9° and 29.5°, while Bi and KBi_2 diffraction peaks completely disappeared. Therefore, the phase evolution of active Bi in Bi@N-CNCs involved a two-step alloying reaction during the first discharging, which can be described as $Bi{\rightarrow}KBi_2{\rightarrow}K_3Bi$ [Figure 8C]. During the subsequent charging process, the three recognizable stages indicated a three-step dealloying reaction from K_3Bi to metal Bi. The extraction of K ions in K_3Bi first occurred at 0.55 V with the formation of K_3Bi_2. When charged to about 0.70 V, K_3Bi_2 gradually evolved to KBi_2. Finally, metal Bi was recovered with the disappearance of KBi_2 at about 1.10 V.

In situ TEM

With the development of aberration correction instruments, monochromators, and other instruments, TEM has achieved unprecedented spatial and temporal resolution and multifunctional external field and has
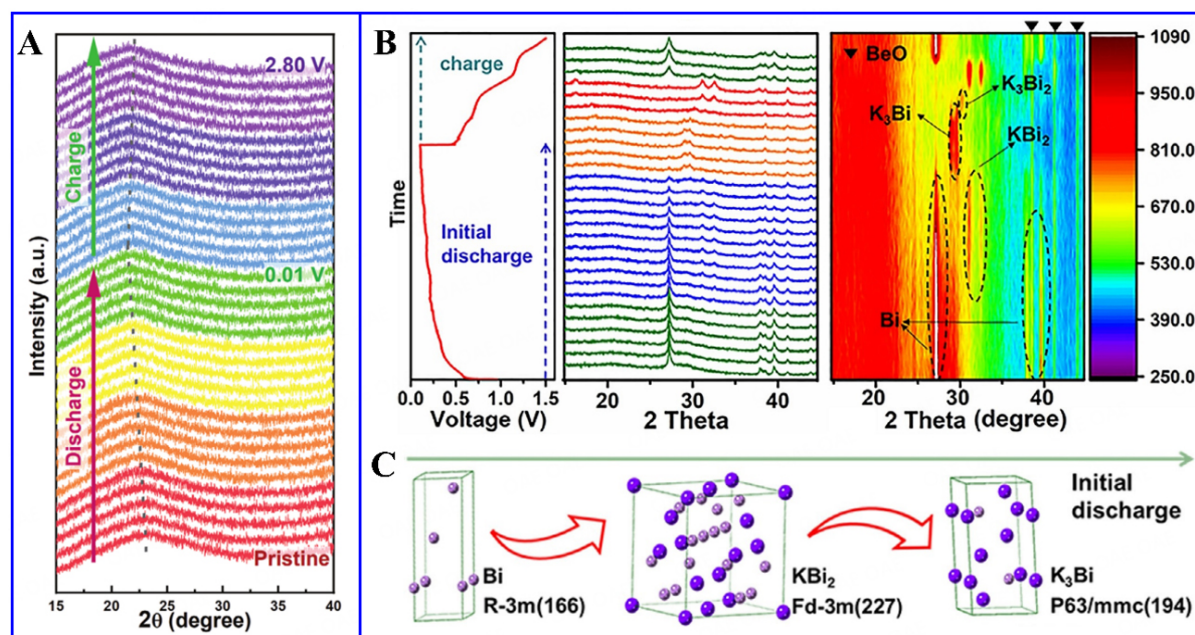

Figure 8. (A) *In situ* XRD patterns of PNCNFs during the discharge/charge process. This figure is quoted with permission from Wang *et al.*[92]. This figure is quoted with permission from Hu *et al.*[124].

become one of the most commonly used and powerful tools in the static characterization and dynamic manipulation of materials[152,153]. In order to carry out the charge/discharge reaction and monitor the dynamic morphology and phase evolution in real time to explore the reaction mechanism of electrode materials, the *in situ* TEM technique was developed to supplement the *in situ* Raman and XRD techniques. For example, Sun *et al.* explored the microstructure/morphology changes of Bi/carbon composite (Bi@N-CNCs) during discharging/charging[139]. As shown in Figure 9A, Bi@N-CNCs, metal K, and K_2O grown on the surface of metal potassium were used as the working electrode, counter electrode, and solid electrolyte of *in situ* TEM battery devices. During potassiation [Figure 9B-D], K ions first entered the N-CNC skeleton and then reacted with Bi nanoparticles through alloying reaction, along with increased Bi nanoparticle sizes from about 26 nm to about 39 nm. The expanded Bi nanoparticles filled the internal space of N-CNCs, increasing the length of the carbon skeleton from 195 nm to 201 nm, proving the excellent structural stability of carbon frameworks. During depotassiation [Figure 9E-G], the dealloying reaction occurred with the size of Bi nanoparticles and carbon skeleton returning to 22 nm and 191 nm, respectively. The phase evolution of Bi@N-CNCs during the first potassiation was further studied by *in situ* selected area electron diffraction (SAED). Figure 9H-J exhibited that the phase evolution of active Bi in Bi@N-CNCs involved a two-step alloying reaction, which can be described as $Bi \rightarrow KBi_2 \rightarrow K_3Bi$. Huang *et al.* employed *in situ* TEM to reveal morphological changes of Sb/carbon composite (Sb@CNFs) during potassiation/depotassiation[142]. The internal Sb nanoparticles have significant volume expansion during the alloying reaction. Fortunately, the internal space effectively mitigated the overall volume expansion, while the outer carbon shell avoided the framework collapse, which fully demonstrated the advantages of nanostructure engineering and carbon modification strategies in the alloying-type PIB anodes.

Summary

The working mechanism of MOF-derived carbon is mainly attributed to K ions adsorption on surface-active sites and filling into nanopores due to their high specific surface area and abundant pores, while
Figure 9. (A) Schematics of *in situ* TEM battery devices; (B-G) *In situ* TEM images of Bi@N-CNCs during potassiation/depotassiation; (H-J) *In situ* SAED images of Bi@N-CNCs during first potassiation. This figure is quoted with permission from Hu *et al.*[124].

MOF-derived carbon composites undergo corresponding chemical reactions. Here, we summarized the reaction mechanisms of common MOF-derived carbon composites in Table 2. Therefore, *in situ* characterization techniques play a crucial role in revealing the potassium storage mechanism of MOF-derived carbon and its composites. *In situ* Raman, *in situ* XRD, and *in situ* TEM have strong tracking capabilities for the evolution of the chemical structure, crystal structure, and morphology in anode materials. Therefore, it is necessary to combine various *in situ* characterization techniques to fully explore the mechanism. Moreover, other *in situ* characterization techniques, such as *in situ* X-ray scattering, *in situ* atomic force microscopy, *in situ* nuclear magnetic resonance, *in situ* SEM, *etc.*, can obtain information on ion transportation dynamics, mechanical properties variation, local chemical environment, and heterogeneous charge transfer rate constants, respectively, but are rarely applied to PIBs[151]. These *in situ* characterization techniques still need to be further explored in PIBs, which is conducive to revealing the mechanism of improved electrochemical performance and guiding the fabrication of advanced MOF-based PIB anodes.

CONCLUSION AND OUTLOOK

To promote the substitution of sustainable and renewable energy sources for harmful fossil fuels and achieve carbon neutrality, developing low-cost, safe, and high-performance energy storage and conversion devices is highly urgent. Although LIBs have been mature and successfully commercialized, the shortage of lithium resources and increasing costs make it difficult to maintain their dominance in research and commercialization. The cost advantage of PIBs makes it possible to implement and even replace LIBs for large-scale applications. However, the electrochemical properties of PIBs are still to be further enhanced to satisfy the requirements of commercial applications. As such, it is urgent to prepare high-performance PIB anode materials through novel processes suitable for industrialization and commercialization. Recently, MOFs have been considered as promising self-sacrificial templates and precursors for preparing advanced

anode materials with controllable composition, morphology, performance, *etc*. In this review, we comprehensively summarize the research progress of MOF-derived carbon and its composites, especially the design strategies and composite types. Furthermore, advanced characterization techniques are highlighted for understanding potassium storage mechanisms.

Although significant progress has been made, there are still some challenges in employing MOF-derived carbon and its composites as PIB anodes. Firstly, MOF derivatives are usually synthesized by high-temperature pyrolysis of MOF precursors, which often leads to uncontrollable morphology collapse and pore plugging, resulting in inferior potassium storage performance. Secondly, for MOF-derived carbon, the capacity is usually less than 400 mAh g^{-1} at a low current density; meanwhile, the rate capability is rarely above 200 mAh g^{-1} at a high current density. Besides, the ICE is usually less than 50%. Thirdly, for MOF-derived carbon composites, the cycle stability is usually less than 1,000 cycles because of the huge volume expansion/contraction during conversion and alloying reaction processes. Finally, the working mechanisms of various anode materials are still unclear, and further exploration is needed to better optimize their potassium storage performance. Thus, major breakthroughs can be achieved in the following aspects:

(1) Composition engineering. Although over 20,000 MOFs have been reported, only a few have been used as precursors for PIB anode materials. Moreover, MOF-derived carbon is mostly synthesized by ZIF-8 and ZIF-67, while the active metals of MOF-derived carbon composites are mostly Zn, Co, Fe, Ni, Bi, *etc.*, which greatly limits the development of MOF-derived carbon and its composites. Given the tunable composition of MOFs, there are still plenty of possibilities for preparing MOF-derived carbon and its composites as advanced PIB anodes. For MOF-derived carbon, the selection of organic ligands can accurately synthesize carbon materials doped with different heteroatoms. For MOF-derived carbon composites, most of the current research focuses on single metal compound/carbon composites, with little attention paid to two or more metal compounds/carbon composites. The combination of two different metal compounds can form heterostructures and induce a built-in electric field, thereby improving electron transmission at the interface. In addition, there is almost no research on metal compounds/alloy materials/carbon composites. Therefore, the composition engineering of MOF derivatives deserves more exploration.

(2) Controllable synthesis. The green and controllable synthesis of MOF-derived carbon and its composites is a prerequisite for commercial large-scale production. However, the morphology of MOF precursors may be disrupted due to the high-temperature environment during the pyrolysis process, which affects their performance. Slow heating rate and staged pyrolysis are effective strategies to alleviate the morphology damage of MOF derivatives. Moreover, understanding the precise conversion mechanism of MOF derivatives and the key factors affecting their physicochemical properties is still a huge challenge because of the high-temperature environment during the synthesis. Therefore, it is necessary to conduct a detailed and accurate analysis of MOF derivatives obtained at different temperatures through advanced characterization methods. It is worth noting that simple synthesis processes need to be developed to ensure large-scale production from green and affordable raw materials.

(3) Capacity and ICE enhancement. The capacity and ICE of anode materials are important parameters for evaluating their practical applications. However, currently, the capacity and especially ICE of MOF-derived carbon and its composites are still not ideal. Several suggestions for capacity enhancement are put forward: (i) Rational design of structures and pores, such as interconnected 3D frames and hierarchical porous structures, are conducive to electron transport, ion migration and adsorption; (ii) Combined with the properties of metal sites and organic ligands, heteroatoms can be introduced from the initial synthesis process of MOFs, forming abundant and controllable doping and defects in MOF-derived carbon materials after annealing; and (iii) The combination of hard and soft carbon is expected to achieve high capacity and superior rate performance. Although ICE can be significantly improved by reducing specific surface area and surface defects, this goes against capacity enhancement. Therefore, the ICE enhancement can be alternatively attempted by these steps: (i) Appropriate pre-potassiation strategies, such as electrolyte impregnation, can effectively improve ICE; and (ii) Designing appropriate binders and electrolytes is another effective way to improve ICE.

(4) Cycle life elongation. The cycle life of anode materials is another important performance indicator. However, the cycle stability of MOF-derived carbon composites is usually less than 1,000 cycles because of the huge volume expansion/contraction during conversion and alloying reaction processes. Although external carbon materials play a protective role, it is difficult to accurately control the content and thickness of carbon materials due to the uneven distribution of internal metal compounds and alloying materials. Thus, controllable synthesis of these composite materials still needs to be further explored. In addition, the design of MOF-derived carbon composites mainly focuses on structural optimization and composition diversification but ignores the ratio tuning of carbon contents, which also plays an important role in cycle performance and deserves more attention.

(5) Mechanism understanding. The rise of advanced *in situ* characterization techniques has played a crucial role in revealing K ions storage mechanisms. It is extremely necessary and challenging to further develop *in situ* testing techniques. First, *in situ* battery device needs to be further optimized to adapt to different characterization techniques. Second, it is urgent to develop fast detection techniques with high sensitivity and resolution to provide more insights. Third, most of the current *in situ* technologies are applied to the K ion storage process of electrode materials. Consequently, the evolution of electrolytes and the formation of SEI film and potassium dendrite require further attention. Finally, combining *in situ* testing techniques and theoretical calculations is conducive to a deeper understanding of the K ions storage mechanism both experimentally and theoretically.

In summary, MOF-derived carbon and its composites have shown great potential as PIB anodes; with composition engineering, controllable and scalable synthesis, enhanced capacity and ICE, elongated cycling

stability, and well-understood electrochemical mechanism, MOF-derived carbon and its composites will serve as practical and competitive PIB anodes, implementing the commercialization of PIBs in the foreseeable future.
